PART VII Medical, Biomedical, and Health

PART VIII Environmental

PART X Displays and Recorders

Preface

Introduction

The second edition of *The Measurement, Instrumentation, and Sensors Handbook* comes in two volumes. This edition reflects the state of the art in measurement, instrumentation, and sensors. In this two-volume set, all chapters have been updated and 40 new chapters have been included to provide the finest possible reference that is both concise and useful for engineers practicing in industry, scientists and engineers involved in R&D, designers, college and university personnel and students, as well as managers together with many others who are involved in instrumentation and measurement design and applications.

The handbook covers an extensive range of topics that comprise the subject of measurement, instrumentation, and sensors. It describes the use of instruments and techniques for practical measurements required in engineering, physics, chemistry, environmental science, and the life sciences. It also explains sensors, techniques, hardware, and the associated software. The handbook includes information processing systems, automatic data acquisition, reduction and analysis, operation characteristics, accuracy, errors, calibrations, standards, and their incorporation for control purposes. Emphasis is given on modern intelligent instruments and techniques, wireless network operations, human factors, and modern display methods as well as virtual instruments.

The chapters include descriptive information for professionals, students, and workers interested in measurement. They consist of equations to assist engineers and scientists who seek to discover applications and solve problems that arise in fields not in their specialty. They also include specialized information needed by informed specialists who seek to learn advanced applications of the subject, evaluative opinions, and possible areas for future study. Thus, the handbook serves the reference needs of the broadest group of users—from the advanced high school science student to industrial and university professionals.

Organization

In this edition, the first volume has 10 parts, each consisting of several chapters, for a total of 96 chapters written by experts in their areas. It concentrates on concepts in instrumentation and measurements, spatial variable measurement, displacement measurement, mechanical variable measurement, acoustics, flow and spot velocity, thermal and temperature measurement, and radiation. It reflects recent trends in instrumentation and measurements with the addition of a new part on wireless instrumentation. Concepts in control systems and human factors are given as a separate part.

The second volume has 10 parts, each having several chapters, for a total of 98 chapters written by experts in their areas as in volume 1. It concentrates on sensors and sensor technology, electric variable measurement, electromagnetic variables, time and frequency, optical measurements, chemical variables, and medical, biomedical and health, and environmental measurement. Signal processing, and displays and recorders constitute the last two parts of this volume.

Locating Your Topic

To find out how to measure a given variable, skim the table of contents, turn to that part, and find the chapters that describe the different methods of making the measurement. Consider the alternative methods of making the measurement and each of their advantages and disadvantages. Select a method, sensor, and signal processing method. Many chapters list a number of vendors to contact for more information. You can also visit http://www.globalspec.com/ to obtain a list of vendors.

For more detailed information, consult the index, since certain principles of measurement may appear in more than one chapter.

John G. Webster and Halit Eren
Editors

Acknowledgments

We would like to thank all the authors for their valuable contribution toward this two-volume-set book. We appreciate the time and effort devoted by all our new authors and those authors who went an extra mile to revise and update their chapters. We are grateful to the CRC Press team for their encouragement to prepare this second edition. The publication of this book would not have been possible without their tireless dedication in putting it together. Last, but not least, we would like to thank all our readers for selecting this book in advancing their knowledge and technical skills.

Editors

John G. Webster received his BEE from Cornell University, Ithaca, New York, in 1953 and his MSEE and PhD from the University of Rochester, Rochester, New York, in 1965 and 1967, respectively.

He currently serves as professor emeritus of biomedical engineering at the University of Wisconsin-Madison. He serves as a highly cited researcher at King Abdulaziz University, Jeddah, Saudi Arabia. He also teaches undergraduate and graduate courses in the field of medical instrumentation and conducts research on intracranial pressure monitoring, ECG dry electrodes, and tactile vibrators.

Dr. Webster is author of *Transducers and Sensors*, an IEEE/EAB Individual Learning Program (Piscataway, NJ: IEEE, 1989). He is coauthor, with B. Jacobson, of *Medicine and Clinical Engineering* (Englewood Cliffs, NJ: Prentice-Hall, 1977); with R. Pallas-Areny, of *Sensors and Signal Conditioning, Second Edition* (New York: Wiley, 2001) and *Analog Signal Conditioning* (New York: Wiley, 1999). He is the editor of the *Encyclopedia of Medical Devices and Instrumentation, Second Edition* (New York: Wiley, 2006), *Tactile Sensors for Robotics and Medicine* (New York: Wiley, 1988), *Electrical Impedance Tomography* (Bristol, U.K.: Adam Hilger, 1990), *Teaching Design in Electrical Engineering* (Piscataway, NJ: Educational Activities Board, IEEE, 1990), *Prevention of Pressure Sores: Engineering and Clinical Aspects* (Bristol, U.K.: Adam Hilger, 1991), *Design of Cardiac Pacemakers* (Piscataway, NJ: IEEE Press, 1995), *Design of Pulse Oximeters* (Bristol, U.K.: IOP Publishing, 1997), *Medical Instrumentation: Application and Design, Fourth Edition* (Hoboken NJ: Wiley, 2010), *Encyclopedia of Electrical and Electronics Engineering* (New York, Wiley, 1999), *Minimally Invasive Medical Technology* (Bristol, U.K.: IOP Publishing, 2001), and *Bioinstrumentation* (Hoboken NJ: Wiley, 2004). He is also the coeditor, with A. M. Cook, of *Clinical Engineering: Principles and Practices* (Englewood Cliffs, NJ: Prentice-Hall, 1979) and *Therapeutic Medical Devices: Application and Design* (Englewood Cliffs, NJ: Prentice-Hall, 1982); with W. J. Tompkins, of *Design of Microcomputer-Based Medical Instrumentation* (Englewood Cliffs, NJ: Prentice-Hall, 1981) and *Interfacing Sensors to the IBM PC* (Englewood Cliffs, NJ: Prentice Hall, 1988); and with A. M. Cook, W J. Tompkins, and G. C. Vanderheiden, of *Electronic Devices for Rehabilitation* (London: Chapman & Hall, 1985).

Dr. Webster has been a member of the IEEE-EMBS Administrative Committee and the NIH Surgery and Bioengineering Study Section. He is a fellow of the Institute of Electrical and Electronics Engineers, the Instrument Society of America, the American Institute of Medical and Biological Engineering, the Biomedical Engineering Society, and the Institute of Physics. He is the recipient of the IEEE EMBS Career Achievement Award.

Halit Eren received his BEng in 1973, his MEng in 1975, and his PhD in 1978 from the University of Sheffield, United Kingdom. He obtained an MBA from Curtin University in 1999.

After his graduation, Dr. Eren worked in Etibank (a mining and metallurgy company in Turkey) as an instrumentation engineer for two years. He held the post of an assistant professor at Hacettepe University in 1980–1981 and at Middle East Technical University in 1982. He has been at Curtin University

since 1983, researching and teaching primarily in the areas of control systems, instrumentation, and engineering management.

Dr. Eren was appointed as a visiting associate professor at Polytechnic University, Hong Kong, in 2004 and served as a visiting professor at the University of Wisconsin, USA, in 2013. He is a senior member of IEEE and participates in Region 10 activities, in various committees for organizing conferences, and member of editorship in several transactions. Dr. Eren has over 180 publications in conference proceedings, books, and transactions. He is the author of *Electronic Portable Instruments—Design and Applications* (Boca Raton, FL: CRC Press, 2004) and *Wireless Sensors and Instruments—Networks, Design and Applications* (Boca Raton, FL: CRC Press, 2006). He has coedited, with Bela Liptak, *Instruments Engineers' handbook—Process Software and Digital Networks*, Vol. 3, edn.4 (Boca Raton, FL: CRC Press, 2011). He is involved in writing a number of books in the field of instrumentation and measurement. Dr. Eren researches and publishes on intelligent sensors, wireless instrumentation, wireless sensor networks, wireless biomedical devices, automation and control, and very large control systems.

Sensors and Sensor Technology

1

Soft Sensors: Software-Based Sensors

Petr Kadlec
Evonik Industries

1.1 Introduction

One of the major trends driving and driven by technological advancement is increasing use of the sensors and instruments in the world around us. Examples of sensors enabling the proliferated use of instruments around the globe are in great number presented in this chapter. A consequence of this effect is that increasing amount of digital data is available for further processing and exploitation. In fact, data are developing into a precious commodity, which is often traded at very high price. These data are the essence of soft sensors discussed in this work, and as such there is a strong pressure on the quality of the data. With some exceptions (e.g., [1]), algorithms for soft sensors development require a substantial amount of high-quality historical data in order to be able to develop useful soft sensors, and yet at the same time the quality of real-life industrial data is often very low. By analyzing the data obtained from their sources, one very often finds data impurities like outliers, missing value, and measurement noise [2]. The causes of these issues are numerous: it can be the physical limits of the hardware sensors, for example, in case of noisy data, and hardware sensor failures or maintenance, and in cases of missing data. For these reasons, the historical data often have to be manually treated to remove the impurities mentioned previously.

Once the data are pretreated, they should be ready to be processed in order to exploit their full potential by creating the useful information out of them. This process is called information extraction, and it is achieved by applying machine learning [3] and data mining [4] techniques to the raw data. These methods can either be univariate with a single variable, that is, transforming a single measurement stream (input variable) into another measurement stream (output or target variable). An example of such a technique is forecasting, where based on past values, the soft sensor is trying to forecast future values of the same variable. Other, more common, techniques are multivariate methods, which use

several input measurement streams and transform them into the output measurement stream. To name a few practical examples, soft sensors can provide predictions of the values of critical variables, which are not practical to be measured by hardware sensors or they can predict the expected trends and developments of quality variables, process states, etc.

In particular in the process industry, soft sensors have been established as useful tools, which can provide additional information about the underlying processes. One can distinguish two fundamentally different soft sensor types, namely, model-driven soft sensors and data-driven soft sensors [2]. There are several other terms that can be used for these two types of models; these include parametric vs. nonparametric models, white box vs. black box models [5], and phenomenological vs. empirical models [6]. The model-driven soft sensors use the chemical and physical principles underlying the process. In general if such knowledge is available and exploitable for the required purposes, it should be used. The problem is that, in chemical and many other industries, often this is not the case because the processes are too complex to be described by rigorous models in the form of mathematical or chemical equations. A prominent example of such process type is the biochemical processes such as penicillin production [7].

For this reason, the focus of this work is on multivariate data-driven soft sensors. These models rely on data modeling techniques and are trained on data collected during the operation of the process. The most common data-driven techniques applied for soft sensor modeling are the principal component regression (PCR), principal component analysis (PCA), and partial least squares (PLS) method, which will be explained later in the section dedicated to data-driven techniques. These techniques gained popularity due to their statistical background and ease of interpretability of the model and because they deal efficiently with data colinearity, which is common among industrial data sets. Examples of soft sensor applications based on PCA/PLS have been discussed in [8–11]. Multilayer Perceptron (MLP) [12] is another predictive technique widely applied as a soft sensor [13]. The popularity of the Layer Perceptrons (LPs) originates in their ability to model nonlinear functions. Furthermore, one can find a range of other techniques like support vector machines (SVM) [14] and neuro-fuzzy systems [15] applied for soft sensors [16,17].

While the field of application of soft sensors is broad, the most common application type is what is referred to as online prediction [2]. In the case of this application type, the soft sensor is trained using historical data before it is launched in the real-life environment where its task is to provide an online prediction on the basis of the incoming input data stream. Another frequent application type of soft sensors is their use for process monitoring and process fault detection. The systems can be either applied to describe/analyze the normal operating state or to recognize possible process faults before these states occur. Commonly, process monitoring techniques are based on multivariate statistical techniques like PCA or more precisely on Hotelling's T2 [18] and *Q*-statistics [19]. Compared to traditional univariate control charts, these measures have, on the one hand, the advantage of considering all input features and, on the other hand, providing information about the contribution of the particular features to a possible violation of the monitoring statistics [20]. Soft sensors providing a certain degree of transparency may also be very useful for the interpretation of the underlying process. Particularly useful are soft sensors based on PCA and PLS as these two methods deliver a measure of how much a given input variable contributes (1) to explaining the input data variance (in case of PCA) or (2) the output variable of interest (in case of the PLS). Soft sensors can also be developed to replicate hardware sensors. In such a case, the soft sensor predictions are used in case of failure or unavailability of the original hardware sensor, which may occur due to its maintenance, replacement, etc. [21].

A particular drawback of many of current soft sensors is their static nature [2]. Traditionally, the models are not adaptive, and once deployed into the real-life operation, the model does not change (see, e.g., [21,22]). In contrast to this, the environment, in which the soft sensors are applied, is often changing [23]. The combination of the static model and the changing data leads to performance deterioration because the model usually represents the out-of-date state of the process as it was observed during the training phase. In order to cope with this problem, one of the following two conditions has to be fulfilled: (1) the historical data have to contain all of the states, which may occur in the future, in this case the soft sensor can be trained to cope with any of the states to be expected in the future; and (2) if the

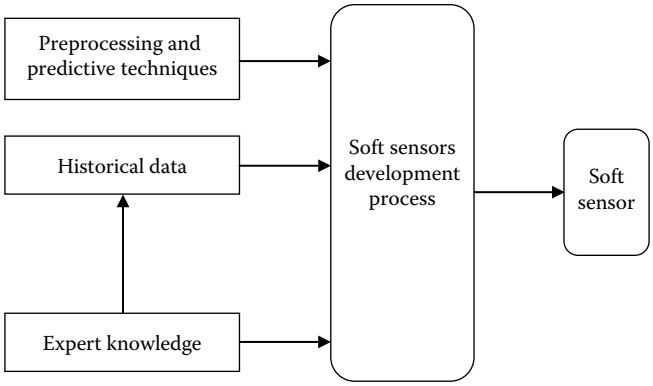

FIGURE 1.1 Soft sensor development process.

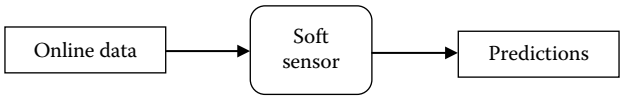

FIGURE 1.2 Soft sensor operation.

first condition cannot be met, it is necessary to equip the soft sensor with a self-adapting capability [24]. Examples of adaptive techniques and soft sensors based on these are as follows:

- Preprocessing and predictive techniques: The statistical and machine learning techniques for the data preprocessing and for the actual soft sensor. One preprocessing and two soft sensor techniques are presented in the section on data-driven technique.
- Historical data: The historical data for the training and parameterization of the preprocessing and the predictive methods. The characteristics and role of the historical data are in more detail discussed in the section on data for soft sensor development.
- Expert knowledge: The role of expert knowledge was briefly discussed in the introduction of this work. The golden rule for expert knowledge is that it has to be used for the soft sensor development when available.

All these three parts are input for the actual soft sensor development, as shown in Figure 1.1. A more detailed methodology for soft sensor development can be found in [2]. The outcome of this process is a trained predictive model—a soft sensor.

1.1.1 Soft Sensor Operations

Once developed, the soft sensor can be deployed into the real-life operation where its task is to deliver the predictions calculated measurement of the output variables as shown in Figure 1.2.

In the next section, the characteristics of the historical and online data required for the soft sensor development and operation are discussed in detail.

1.2 Data for Soft Sensor Development

1.2.1 Historical Data

Usually, when dealing with real-life industrial modeling tasks, there is a set of historical recordings available. This forms the basis for the development of the soft sensor. These data have a number of properties relevant for the soft sensor development process. The historical data consist of a number

of input variables, for example, hardware sensor measurements, and one or more target variables. Sometimes there can be a relevant delay between taking the measurement, that is, sampling the input variables, and providing the corresponding target value, that is, sampling the target variable. This is caused by the fact that the target variables may have to be obtained in a time-consuming manner (e.g., manual evaluation of quality measurement in a laboratory). Nevertheless, for the historical data, it can be assumed that the delays are compensated by entering the target values at the time point of taking the sample for the historical data.

Furthermore, although the sampling rate of the input data is usually higher than the one of the target variable, in most cases only the labeled samples (i.e., data points containing the target values) are recorded within the historical data. Therefore, the sampling rate of the input variables and the target variable can be assumed as equal.

Another relevant and possibly harming property of the data is the delays between the input variables themselves. Without prior process knowledge, these types of delays are difficult to compensate for and have to be dealt with by the application of an appropriate feature selection algorithm.

1.2.2 Online or Real-Time Data

Once the soft sensor building phase is finished, the model is applied in the online operation and needs to deal with the online data stream. In comparison to historical data, the online data have slightly different characteristics.

Data are arriving in an incremental way, that is, one sample (or a small batch of samples) after another. In general, the sampling rate between the input and the target data can differ.

The real values of the target measurement, which usually arrive at a lower sampling rate than the input samples and often with certain delays, can be used to evaluate the model performance during the online prediction phase. If there is a notable deterioration of the model performance, an adaptation of the model needs be performed using the target data. The characteristics of historical data and real-time data are summarized in Table 1.1.

1.2.3 Process Data Issues

Figure 1.3 shows examples of variables affected by common issues of industrial data that will be discussed further in this section.

1. *Missing values*: Missing data are single samples or consequent sets of them, where one or more variables (i.e., measurements) have a value that does not reflect the real state of the physical measured quantity. The affected variables usually have values like $\pm\infty$, 0.

   Missing values in industrial context have various causes. The most common ones are the failure of a hardware sensor, its maintenance or removal. As already mentioned, industrial plants are heavily instrumented for process control purposes; therefore, the recorded process data also consist of a large number of diverse variables. In such a scenario, there is a certain probability

TABLE 1.1 Characteristics of the Historical and Online Data

	Historical Data	Real-Time Data
Purpose	Model training and parameter optimization	Soft sensor operation and adaptation (if required)
Mode	Batch	Incremental
Input variable delays	Possibly present	Possibly present
Target variable delays	Compensated	Possibly present
Input vs. target sampling rate	Equal	Possibly lower

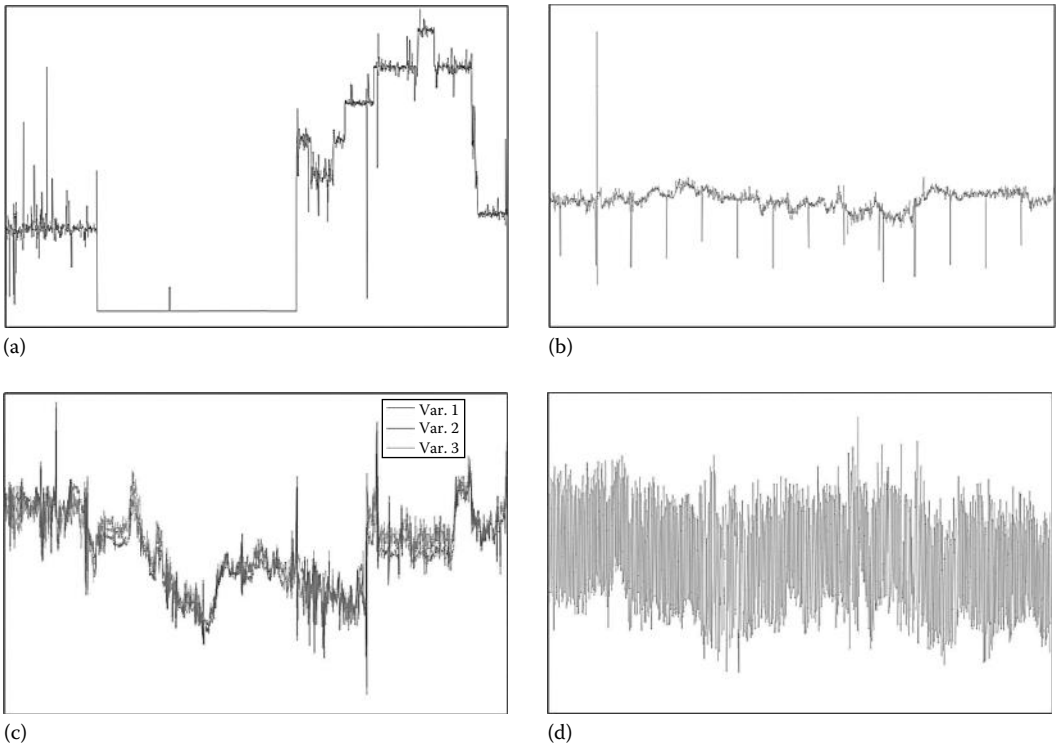

FIGURE 1.3 Common issues found in industrial data sets: (a) missing values; (b) outliers; (c) data colinearity; (d) measurement noise.

that some of the sensors occasionally will fail. A possible cause of missing data is related to the transmission of the data between the sensors and the database, errors in the database, problems in accessing the database, etc.

Since most of the techniques applied to data-driven soft sensing cannot deal with missing data, a strategy for their replacement usually has to be implemented. An approach, which is very primitive and not recommended but still commonly applied in practical scenarios, is to replace the missing values with the mean values of the affected variable. Another nonoptimal approach is to skip the data samples consisting of variable or variables with the missing values, that is, case deletion [25]. A more efficient approach to missing values handling takes into account the multivariate statistics of the data and thus makes the reconstruction of the missing values dependent on the other available variables of the affected samples (e.g., maximum-likelihood multivariate approach to missing values replacement [26]). These types of approaches are related to sensor fault detection and reconstruction. From another point of view, one can distinguish two different approaches for dealing with missing values [25]. These are (1) single imputation where the missing values are replaced in a single step (using, e.g., mean/median values) and (2) multiple imputation, which are iterative techniques where several imputation steps are performed.

In [27], an algorithm based on iteratively reweighed least squares is applied to deal with missing and noisy data. This algorithm is limited to the estimation of dynamic linear system parameters only. The authors show that the algorithm can deal with a situation where the probability of missing data is less than 50%, provided that a high number of samples are available.

Another technique for dealing with multiple imputation techniques for missing values handling was presented in [26,28].

2. *Data outliers*: Outliers are sensor values that deviate from the typical, or sometimes also meaningful, ranges of the measured values. One can distinguish between two types of outliers, namely, obvious outliers and nonobvious outliers [29]. Obvious outliers are those values that violate the physical or technological limitations. For example, the absolute pressure may not reach negative values or the flow sensor may not deliver values that exceed the technological limitations of the sensor. To be able to detect this type of outlier efficiently, the system has to be provided with the limiting values in the form of a priori information. In contrast to this, nonobvious outliers are even harder to identify because they do not violate any limitations but still do not reflect the correct variable states.

   Outlier detection as part of the data preprocessing remains very critical for soft sensor development because undetected outliers have a negative effect on the performance of the models. For example, the influence of a single outlier can be critical for the PCA [30–32]. Another problem of outlier detection is that even when applying automatic outlier handling preprocessing steps, usually the results have to be validated manually by the model developer. The goal of the manual inspection is to detect any possible outlier masking (i.e., false-negative detections, undetected outliers) and outlier swamping (i.e., false-positive detections, correct values labeled as outliers) [33].

   Typical approaches to outlier detection are based on the statistics of the historical data. The most simple approach is the 3_ outlier detection algorithm (see, e.g., [9,34]), which is based on univariate observations of the variable distributions. This method labels all data samples out of the range _(*x*) _ 3_(*x*), where _(*x*) is the mean value and _(*x*) the standard deviation of the variable *x*, as outliers. A more robust version of this approach is the Hampel identifier [35], which uses a more outlier resistant median and median absolute deviation (MAD) values [33,34] to calculate the limits.

   The influence of outliers on the identification of linear and nonlinear models is discussed in [33]. For the handled models, the Hampel identifier is found to be an effective approach for dealing with outliers. In [36], a moving window filter is combined with the Hampel identifier to obtain an outlier detection and removal system. In contrast to the univariate approaches, the multivariate methods use combinations of more features to detect the outliers. An example from this group based on the PCA is the Jolliffe parameter [37,38]. A two-stage outlier detection approach is discussed in [39]. The first stage is the application of the PCA, after this the Hotelling's T2 measure [18] can be used to detect outlier candidates that are located outside of the 99% confidence ellipse. These candidates are then further analyzed in the second step, where Scheffe's test [40] is applied to these points.
3. *Drifting data*: There are two types of drifting data, and dependent on the cause of the drifts, one can distinguish between system and sensor drifts. The causes of the system drift are the changes of the underlying system due to abrasion of equipment, aging of instruments, environmental conditions, etc. These are particularly prevalent in industries with a large number of mechanical elements that undergo steady abrasion during their operation. Another cause of system drifts can also be external influences like changing environmental conditions (e.g., weather influence), the purity of the input materials, and catalyst deactivation. These factors have not only an influence on the data but affect the process state as well. Therefore, the drifts should be recognized and reported, and appropriate actions should be taken to remove their source. This is different in the case of sensor drifts, which are caused by changes in the measuring devices and not by the process itself. The critical point is that this type of drifts, while still observed in the measured data, does not reflect any changes in the system. Therefore, in the case of sensor drifts, the action to be taken should be the recalibration of the measurement devices or the adaptation of the soft sensor.

   In terms of the effects of drifts on the data, one can observe changes in the means and variances of the single variables as well as changes of the correlation structure of the data [41].

   Distinguishing between the two different drift causes discussed is challenging and once again a lot of expert knowledge is needed in order to take appropriate action. Another challenging

aspect of dealing with drifting data is the fact that the changes may progress very slowly and may influence each other and thus leading to a nonlinearity.

The most common approach to deal with dynamics in the data is to apply the moving window technique. In this case, the model is updated on a periodic basis using only a defined number of the most recent samples. Some examples of the application of this technique in the context of soft sensor modeling were published in References [42–45].

4. *Data colinearity*: Another challenging issue for soft sensing is related to the structure of the data. Typically, the data measured in heavily instrumented industries are strongly colinear. These results from the partial redundancy in the sensor arrangement, for example, two neighboring temperature sensors, will deliver strongly correlated measurements. Such environments are often called data rich but information poor [46]. However, for soft sensing the requirements are different, in this case only informative variables are required. Anything else is unnecessarily increasing the input data dimensionality, which often has a negative effect on the model training and performance.

   There are two ways to deal with the colinearity problem. One way is by transforming the multiple input variables into a new reduced space with less colinearity as it is done in the case of the PCA and PLS. These two approaches are the most popular ones to deal with data colinearity in the process industry. Examples of applications where PCA is used are [9,43,47,48] and for the PLS [49,50,22]. Another way to handle colinearity is to select a subset of input variables that are less colinear. These approaches are summarized under the umbrella of variable (or feature) selection methods in the computational learning research. A general review of these methods is presented in [51]. Some feature selection methods in the context of soft sensing are also discussed in [38]. Among the discussed approaches are correlation- and partial correlation-based feature selection as well as Mallows' Cp statistics.
5. *Sampling rates and measurement delays*: Various sensors usually work at different sampling rates and thus one has to take care to synchronize them. The synchronization of the data is usually handled by the recording databases. The definition of such a threshold is another critical point, which influences the quality of the historical data. Soft sensors are often applied in multirate systems with several operating sampling rates. Such a scenario occurs in a system where some of the variables, usually critical for the process control, are evaluated in laboratories at a much lower sampling rate than the rest of the automatically measured data.

   Additional issues of the data are the process-related delays in the measurements. For instance, materials in the processes usually have a given run-time through the process (e.g., the dwell period within a reactor or distillation column), and thus, it is not reasonable to relate two different measurements taken at the same time at different locations within the process. Instead of this, the delays in the particular measurements should be compensated by synchronizing the variables. However, in order to perform the synchronization, an extensive knowledge about the system is required.
6. *Measurement noise*: Measurement noise is another common effect observed in industrial data. Most of the approaches to soft sensor development are trying to cope with measurement noise during the preprocessing stage of the data processing. This is achieved mainly by applying a smoothing (averaging) filter as a preprocessing step.

   The PCA is also a useful tool for dealing with measurement noise. As a least mean squares-based method, it can deal with measurement noise as long as it can be assumed as Gaussian noise, that is, randomly distributed with zero mean value [9]. In the same work the authors also highlight the application of robust statistics, that is, using the median instead of the mean operator and MAD instead of the standard deviation, for the normalization of noisy data.

   Zamprogna et al. have shown the robustness of the PLS method toward measurement noise in [22]. The authors have shown that there are only small changes of the prediction error of a PLS soft sensor with increasing noise levels. The explanation of this fact is that the noise influences mainly the higher-order latent variables that are normally skipped in practical application.

1.3 Data-Driven Techniques for Soft Sensor Development

This section describes the three most common methods for the development of soft sensors. The PCA can be either used as a data preprocessing method or in combination with a regression method as a full soft sensor, in such case the method is referred to as PCR. PLS is another popular method for soft sensing [2]. This method is in particular very useful for adaptive soft sensors. The third presented method is the artificial neural network (ANN) and in particular its popular form often used for nonlinear modeling called MLP.

1.3.1 Principal Component Regression

The PCA algorithm requires the matrix of the input data $X \in \mathbb{R}^{n \times m}$ (where n is the number of recorded time instances and m the number of input measurement streams). For the PCA, each measurement stream, that is, column of the matrix, has to be normalized to zero mean and unit variance:

$$\begin{aligned} &X' = \left(X - \mathbf{1}_n \mathbf{b}^T\right)\Sigma^{-1} \quad \text{with} \quad \mathbf{b} = \frac{1}{n} X^T \mathbf{1}_n \quad \text{and} \\ &\mathbf{1}_n = [1,1,\ldots,1]^T \in \mathbb{R}^{n \times 1}, \\ &\Sigma = diag(\sigma_1, \sigma_2, \ldots, \sigma_m) \end{aligned} \tag{1.1}$$

where σ_i is the standard deviation of the input variables. The scaling has to be done in order to assure equal influence of the input variables in the model. The normalized data X' is then transformed to 1D $l \leq m$ scores $T \in \mathbb{R}^{n \times l}$ using the following relation:

$$X' \in TP^T + E \tag{1.2}$$

where $P \in \mathbb{R}^{n \times m}$, $E \in \mathbb{R}^{n \times m}$ are the loadings and residuals matrices, respectively.

There are several ways to calculate the matrix P. In the case of the covariance approach, the correlation matrix C of the input data X has to be calculated:

$$C = \frac{1}{n-1}(X')^T X' \tag{1.3}$$

Next the eigenvalues and eigenvectors of this matrix are derived by solving

$$V^{-1} C V = eig(C) \tag{1.4}$$

where

$eig(C)$ is the diagonal eigenvalues matrix
V is the eigenvector matrix

The eigenvalues λ_i are then sorted in descending order such that $\lambda_1 > \lambda_2 > \lambda_3 > \ldots \lambda_m$. The columns of matrix P are then formed by the eigenvectors v_i corresponding to the l highest eigenvalues:

$$P = [v_1, v_2, \ldots, v_l] \quad \text{with} \quad v_i \in \mathbb{R}^{n \times l} \tag{1.5}$$

For the calculation of the eigenvalue decomposition, either the singular value decomposition (SVD) [37, p. 44], the nonlinear iterative partial least squares (NIPALS) algorithm [52] or other methods (see, e.g., [41]) can be used.

Having the matrix T, one can build a regression model using the LS algorithm:

$$\hat{y} = Ta \tag{1.6}$$

Applying the fact that the vectors in T are orthogonal, the previous equation can be simplified to

$$a = (T^T T)^{-1} T^T y = L^{-2} T^T y \quad \text{with} \quad L \in \mathbb{R}^{l \times l} \tag{1.7}$$

where L is a diagonal matrix with elements equal to $\sqrt{\lambda^i}$ (see Ref. [37, p. 168]).

1.3.2 Recursive Partial Least Squares

In this section, the most common soft sensing technique and its adaptive (recursive) version are outlined. The PLS method was originally proposed in [53]. The goal of the algorithm is to project the scaled and mean-centered input data X and output data $Y \in \mathbb{R}^{n \times p}$ (where p is the number of output variable streams that are supposed to be predicted) to separate latent variables:

$$X = TP^T + E \tag{1.8}$$

$$Y = UQ^T + F \tag{1.9}$$

where

$T \in \mathbb{R}^{n \times l}$ (with $l < m$ as the number of latent variables)
$U \in \mathbb{R}^{n \times l}$ is the score matrices
$P \in \mathbb{R}^{m \times l}$ and $Q \in \mathbb{R}^{p \times l}$ are the corresponding loading matrices
E and F are the input and output data residuals

The score matrices T and U consist of the so-called latent vectors:

$$T = [t_1, t_2, \ldots t_l] \quad \text{with} \quad u_i \in \mathbb{R}^{n \times l} \tag{1.10}$$

$$U = [u_1, u_2, \ldots u_l] \quad \text{with} \quad u_i \in \mathbb{R}^{n \times l} \tag{1.11}$$

The latent vectors, which are orthonormal to each other $\left(\text{i.e., } t_i^T t_j = 0 \ \forall_{i \neq j}\right)$, are a more compact description of the input data. The column vectors $p \in \mathbb{R}^{m \times l}$ and $q \in \mathbb{R}^{p \times l}$ of the loading matrices P and Q represent the contributions of the input and output variables to the latent vectors t and u, respectively. The previous two equations are also called the outer model of the PLS method [44].

Subsequently, the PLS method builds a regression model between the latent scores (the PLS inner model):

$$U = TB + R \tag{1.12}$$

where $B \in \mathbb{R}^{l \times l}$ is a diagonal matrix of regression weights that is calculated such as to minimize the regression residuals R. The estimates $\tilde{Y}$ of Y are consequently

$$\tilde{Y} = TBQ^T \tag{1.13}$$

There are several ways to calculate the required vectors *t*, *p*, *u*, *q*, and *b*. A particularly popular algorithm for the calculation of PLS is the NIPALS algorithm [52]. The NIPALS algorithm calculates one latent vector after the other in an iterative way. The explained covariance is removed from the data after the each iteration:

$$X_{i+1} = X_i - t_i p_i^T \tag{1.14}$$

$$Y_{i+1} = Y_i - u_i q_i^T \tag{1.15}$$

which is followed by the calculation of the next, that is, $(i + 1)th$ vectors for the PLS outer and inner models using the new data matrices X_{i+1} and Y_{i+1}. The number of calculated latent dimensions is usually established using cross-validation or some other parameter optimization techniques.

In the nonadaptive modeling scenario, the matrices *P, T, Q, U,* and *B* are calculated during the training phase based on the batch of historical data. However, as discussed in the introduction as well as in [44], this approach is often problematic because the process and its data are changing over the time. An advantage of the PLS algorithm is that it has the ability to incrementally integrate new data. The recursive partial least squares (RPLS) has been introduced in [54] and further clarified in [44]. It can be used to adapt the model in several ways: (1) on sample-by-sample basis, (2) by integrating a new batch of data, or (3) by merging two PLS models.

In the first case, which is exploited in this work, the model update is achieved by merging the old model represented by the matrices *P, B,* and *Q* with the latest data samples x_i, y_i:

$$X^{new} = \begin{bmatrix} \lambda P^T \\ x_i \end{bmatrix} \quad Y^{new} = \begin{bmatrix} \lambda B Q^T \\ y_i \end{bmatrix} \tag{1.16}$$

The forgetting factor λ defines the strength of the adaptation. The lower value this factor has, the smaller the influence of the previous model, which results in a faster adaptation to the new data. After the expansion, the PLS algorithm can be applied X^{new}, Y^{new} as usual. In order to be able to perform the previous updates, the number of latent variables has to be selected to be equal to the rank of X [44]. Practically, this condition can be assured by finding a number of latent variables $\boldsymbol{a}$, which fulfill

$$\|E_a\| \leq \varepsilon \vdots \quad \text{with} \quad \varepsilon \geq 0 \tag{1.17}$$

In general, the number of latent variables *a* required for the recursive operation can differ from the optimal number of latent variables required for the modeling.

1.3.3 Artificial Neural Networks

The original idea of ANN [12] was to build computational models motivated by the operation of biological neurons that are the basic information processing units in nervous systems. The task of both the biological and the artificial neurons is to collect signals at the inputs, to process this information, and then to output it. In case of soft sensors, the most commonly applied type of ANNs are the MLPs.

1. *MLP*: An MLP is a feed-forward ANN as shown in Figure 1.4. It consists of one input layer, one output layer, and at least one hidden layer. The role of the input layer is to collect the input data and provide it to the hidden layer for further processing. The number of units in the input layer is equivalent to the dimensionality of the input data. Each of the input units is connected to each

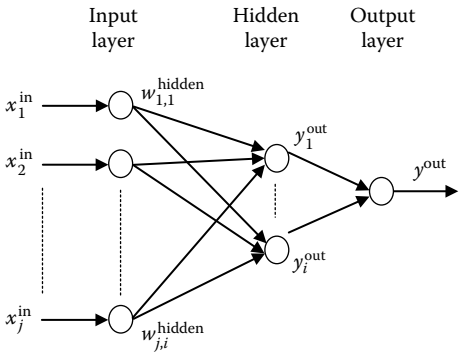

FIGURE 1.4 MLP structure.

hidden unit, and the connections between the units carry weights. The role of the hidden units is to collect the signals at their input, that is, the outputs of the preceding layer; multiply them by the connection weights; build a sum of them; and process them using the transfer function g^{hidden}:

$$x_i^{\text{hidden}} = g^{\text{hidden}}\left(\sum_j w_{j,i}^{\text{hidden}} x_j^{\text{in}}\right) \tag{1.18}$$

where

x^{out} is the output of the MLP
w_i^{out} is the weight between the ith hidden unit and the output unit
$g^{\text{out}}()$ is the transfer function of the output neuron

A remarkable theoretical property of the MLP is that they are universal function approximators, which means that provided enough training data and complex enough structure, they can be trained to approximate any function with any given accuracy [55].

Where x_j^{in} is the jth variable of the input sample, $w_{j,i}^{\text{hidden}}$ is the weight between the jth input unit and ith hidden unit and x_i^{hidden} the output of the ith hidden unit. The transfer function can be any differentiable nonlinear function. Often used are the sigmoid functions such as

$$g^{\text{hidden}}(x) = \frac{1}{1 + exp(-x)} \tag{1.19}$$

Once the signals are processed by the hidden layer, they are passed further to the next hidden layer, in the case when there is more than one hidden layer or to the output layer otherwise. The output layer can consist of one or more neurons. In the case of typical soft sensors, the output layer consists of only one unit:

$$x^{\text{out}} = g^{\text{out}}\left(\sum_i w_i^{\text{out}} x_{ij}^{\text{hidden}}\right) \tag{1.20}$$

Learning of the MLP (and ANN in general) is achieved by applying an algorithm for finding the optimal weights between the neurons. The most popular of these algorithms is the back-propagation algorithm originally proposed in [56].

1.4 Applications of Soft Sensors

The applications of soft sensors can be found across many fields of any industry. The most common application types are presented in the following sections of this work; please note that this is only short extract of the large number of applications of soft sensors. A comprehensive list of case studies can be found in [2,24,57].

1.4.1 Online Prediction

The most common application of soft sensors is the prediction of values that cannot be measured online using automated measurements. This may be for technological reasons (e.g., there is no equipment available for the required measurement), economical reasons (e.g., the necessary equipment is too expensive), etc. This often applies to critical values that are related to the final product quality. Soft sensors can in such scenarios provide useful information about the values of interest and in the case when the soft sensor prediction fulfills given standards, it can also be incorporated into the automated control loops of the process [58]. Data-driven soft sensors have been widely used in fermentation, polymerization, and refinery processes.

1.4.2 Process Monitoring and Process Fault Detection

Another application area of soft sensors is process monitoring. Process monitoring can be either an unsupervised learning or binary classification task. The systems can be either trained to describe/analyze the normal operating state or to recognize possible process faults [59–61]. Commonly, process monitoring techniques are based on multivariate statistical techniques like PCA, or more precisely on Hotelling's T2 [18] and *Q*-statistics [19]. These measures have, on the one hand, the advantage of considering all input features, that is, using multivariate statistics and, on the other hand, providing information about the contribution of the particular features to a possible violation of the monitoring statistics [20].

1.4.3 Hardware Sensor Backup

Soft sensors can also act as backup sensors for hardware sensors with a tendency to failure or with a requirement for periodic maintenance. In such a situation in order to prevent a disturbance of the whole system, soft sensors can be developed to replace the hardware sensors during their unavailability [21].

1.5 Conclusions

Undoubtedly, soft sensors will gain importance in the near future. For this reason, this work focused on the description of software-based sensors as a valuable alternative to hardware sensors. The greatest potential of soft sensors lies in situations where the application hardware sensor reaches its practical, physical, or economical limits. In such situations, soft sensors can often deliver better measurements. A prerequisite for the ability to deliver useful measurements is however the availability of high-quality and relevant data for the training of the soft sensor, which in practical applications often comes at the price of intensive manual data preprocessing only. This work described the process of soft sensor development and operation and discussed the main aspects that have to be considered during the development and application of a soft sensor. The most common techniques applied for soft sensors were also outlined in detail in this work.

Acknowledgment

Parts of the study presented in this chapter were carried out during the author's affiliation with Bournemouth University, United Kingdom.

2.1 Introduction

Nowadays, with the rapid development of bioengineering, implantable medical devices are being widely employed in treating human ailments. These devices, which are implantable in the human body, include pacemakers, smart prostheses, drug pumps, cochlear implants, implantable defibrillators, neurostimulators, bladder stimulators, nerve stimulators, and diaphragm stimulators. They perform a real-time control and/or monitoring of several physiological parameters.

Over 6 million heart patients worldwide have implanted pacemakers and about 150,000 pacemakers are being surgically implanted every year in the United States alone (Wang, 2003). These pacemakers, and defibrillators, help in treating several heart conditions including fibrillation, atrial and ventricular tachyarrhythmia, and bradycardia (Soykan, 2002).

These monitoring systems can communicate wirelessly with an external readout unit. By means of this architecture, the use of transcutaneous wires and the risk of infection can be avoided and necessary data can be collected easily. Wireless communication allows regular monitoring of several physiological parameters like the blood pressure, heart rate, and body temperature of patients during their daily activities at home (Tamura et al., 2011; Valdastri et al., 2004). These data can be collected and sent to a remote medical unit via Internet for the medical staff to access and assess and then assist the patient accordingly (Halperin et al., 2008).

As shown in Troyk et al. (2007), myoelectric sensors are another example of an implantable medical device. They are composed of several myoelectric electrodes implanted in the residual limb of patients with a prosthetic arm. These electrodes detect intramuscular myoelectric activity and provide signals that are elaborated to control the prosthesis.

Typically, implantable medical devices are powered by batteries, which is a severe limitation. In most cases, because of battery discharge, an implantable system will need battery replacement through a surgical operation. For example, although an implanted defibrillator lasts about 10 years, its battery

must be substituted after about 4 years 7 months (Wei and Liu, 2008). Hence, the patient must undergo a surgical operation that will not only cause physical and mental pain to the patient, but will also put an economic burden both on the patient and on the national health system. As stated earlier, the battery defines the lifespan of the implantable medical device. To avoid this problem, the implantable device must be powered using a telemetric technique or an energy-harvesting system that is implanted together with the device.

In the telemetric technique, an inductive powering system composed of two coils is used; the first coil is placed outside the body while the second one is implanted. The primary coil produces a magnetic field that is harvested by the secondary coil. In this way, energy is transferred through the human body. Using this technique, the circuits of the implanted medical devices are powered wirelessly, avoiding transcutaneous wires.

Examples of devices using telemetric techniques, transferring power inductively, are reported by Morais et al. (2009), Silay et al. (2011), and Riistama et al. (2007). Morais has described a smart hip prosthesis for the measurement of the joint forces and the temperature distribution in the prosthesis; the inductive link is performed through a coil placed in the stem of the insert. An inductive power system for cortical implant is reported in (Silay et al., 2011). The device mentioned is composed of a Class-E power amplifier, a matching network, and a rectifier, and two coils and is embedded in a biocompatible packaging that can be placed in a cavity of the skull. Another example of inductive power system is mentioned in Riistama et al. (2007), where an implant for the measurement of the electrocardiogram, with an operational range of approximately 16 mm, is described.

The telemetric technique requires the two coils, external and internal, to be close to each other, and that restricts the patient's movements. Furthermore, the operating frequency must be compatible with the tissue's absorption level; in particular, the power received by the implanted device, the tissue's absorption level, and the consequent warming of tissues are related to the radiation frequency. Hence, incorrect radiation frequency and energy absorption of the tissues can cause not only transmission problems, but also biocompatibility and safety issues. Table 2.1 shows maximum permissible exposure values of human tissues to magnetic, electric, and power density fields as suggested by the IEEE Standards for Safety Levels. As shown in the table, the magnetic-field strength and power density decreases as the radiation frequency increases. Ideal operating frequency for data and power transfer in telemetric systems is 125 kHz (Crescini et al., 2011).

Energy-harvesting technique, as mentioned earlier, is an alternative technique to power an implantable medical device; this technique, which is being researched and developed, will help avoid the use of a battery and, thereby, escape a battery replacement surgery, and can also allow the patient to move freely. Energy harvesting is a process by which energy is captured and stored from the ambient, in this case the human body. As reported by Starner (1996), the human body is a rich reservoir of energy, and the energy values reported are more than sufficient to supply for an implantable medical device. In Starner (1996),

TABLE 2.1 Maximum Permissible Values of Magnetic Field, Electric Field, and Power Density Field for Human Tissue

Frequency Range (MHz)	Magnetic Field Strength (H) (A/m)	Electric Field Strength (E) (V/m)	Power Density (S) E-Field, H-Field (mW/cm^2)
0.003–0.1	163	614	(100, 1,000,000)
0.1–3.0	$16.3/f$	614	$(100, 10{,}000/f^2)$
3–30	$16.3/f$	$1842/f$	$(900/f^2, 10{,}000/f^2)$
30–100	$16.3/f$	61.4	$(1, 10{,}000/f^2)$
100–300	0.163	61.4	1.0
300–3,000	—	—	$f/300$
3,000–15,000	—	—	10

the authors have calculated that energy of about 390 MJ is stored by an individual weighing 68 kg and with 15% body fat; this energy is converted into mechanical energy through muscles and is partially used up during daily activities. The paper reports the power utilized for some of the common activities; for example, the power spent for walking, upper limb motion, and breathing are approximately 67, 35, and 1 W, respectively.

The exploitable energy in the human body is classified into three different forms: thermal energy, mechanical energy, and chemical energy.

The thermal energy is harvested through a thermoelectric generator, which exploits the Seebeck effect. A thermoelectric generator is typically composed of several thermocouples, and it produces a voltage proportional to the thermal gradient across the thermoelectric generator itself. In Stark (2006), a compact thermoelectric generator composed of over 5000 thermocouples is described; this device has a volume less than 1 cm^3 and is able to produce 120 μW of power at 3 V with a thermal gradient of 5 K. Hence, an implantable medical device can be powered with one or more of these generators connected in series or in parallel. For the thermoelectric generator, obtaining a high thermal gradient in the human body is difficult; the highest thermal gradient occurs near the skin surface (Yang et al., 2007).

The chemical energy is harvested by means of microbiofuel cells, which are composed of a cathode, an anode, and an electrolyte. An example of an implantable glucose biofuel cell is described in von Stetten et al. (2006); the proposed device is composed of a hydrogel membrane that separates the electrodes realized with activated carbon. Following a series of in vitro tests, this fuel cell is able to generate a power density and a peak power of 2 μW/cm^2 and 20 μW, respectively, for a period of 7 days.

Mechanical energy is the most available and the most easily exploitable energy source in the human body; it is usually harvested with electrostatic, electromagnetic, and piezoelectric transducers. Some transducers, especially the electromagnetic and the electrostatic ones, can be modeled with a mass spring damper system working in resonance conditions with the input motion.

In a generic electromagnetic harvester, the human movement produces a displacement between a coil and a permanent magnet; this displacement generates a time-variable magnetic flux and, according to Faraday's law, an induced voltage on the coil. The permanent magnet and the coil can be placed in the resonant structure to maximize the magnet–coil relative motion, the induced voltage, and the stored energy by the harvester. An electromagnetic transducer for powering a pacemaker is presented in Goto et al. (1998); the heart muscle contractions generate a relative motion between a movable permanent magnet and a fixed coil. With a heart frequency between 0.5 and 2 Hz, the harvester is able to produce a maximum power of 200 μW, and it allows powering a pacemaker without battery. An electromagnetic harvester implanted in a hip prosthesis is reported in the work of Morais et al. (2011). The transducer is a resonant structure, composed of two external fixed coils and a Teflon tube in which a magnet swings during walking or whatever other activity, produces a hip movement. In Nasiri et al. (2011), a resonant electromagnetic transducer implantable in the diaphragm muscle is described. As the diaphragm muscle works continuously, the proposed transducer harvests energy even if the person is sleeping.

An electrostatic harvester is typically based on a variable precharged capacitor composed of a moving plate whose movement is produced by the activity of the human body. Examples of electrostatic transducers are reported in several studies (Miao et al., 2004; Tashiro et al., 2002). In Tashiro et al. (2002), the proposed transducer, composed of a honeycomb structure, exploits the heart muscle motion to power a cardiac pacemaker. In Miao et al. (2004), a MEMS electrostatic transducer is described; it produces a power of 24 μW at an input mechanical frequency of 10 Hz.

In a piezoelectric transducer, the movement of any body part can be exploited to deform a piezoelectric material in order to produce a voltage. Some piezoelectric transducers use a resonant structure to maximize the piezoelectric material deformation. In several studies (Almouahed et al., 2010, 2011a,b; Lahuec et al., 2011), a knee monitoring system embedded in a total knee prosthesis is presented. Four piezoceramics are placed in the tibial plate to measure the tibiofemoral forces and contemporaneously to harvest energy. During a single gait cycle, a total power of 7.2 mW is produced (1.8 mW for every piezoceramic). In Potkay et al. (2008), a blood pressure sensor is described.

The proposed device, composed of an arterial cuff in a thin piezoelectric film, converts the artery contraction/expansion into electric energy.

The design of energy harvesters for implantable medical devices is usually more complicated than that for industrial applications (Mitcheson, 2010). First of all, an energy harvester for an implantable medical device must have limited size. Furthermore, for mechanical transducers, the matching between the resonance frequency and the input mechanical frequency is difficult to obtain because the resonance frequency and the transducer size are, in general, inversely proportional. In particular, motion frequencies of the human body are generally less than 10 Hz (Romero et al., 2009); to lower the resonance frequency, using a linear spring-mass-damper system, a reduction in stiffness or an increase in mass is required, but, as previously stated, implantable devices must have limited dimensions; hence, it is difficult to satisfy both the requirements. In summary, from these considerations, on lowering the resonance frequency the transducer size increases, making the system unsuitable for applications in the human body. A material with nonlinear elastic characteristics can be used to solve this problem (Raman et al., 2010). Another important point is that an implantable medical device must be realized with biocompatible materials; otherwise, the different elements of the implantable medical device must be placed and fully sealed in a biocompatible material packaging. Two examples of architectures for batteryless implantable medical devices are presented in this chapter. In particular, a telemetric technique and an energy-harvesting system are described.

2.2 Architecture

Implantable systems can be defined as devices that execute their measurement functions in the human body autonomously. They are characterized by an autonomous power supply capable of measuring and transmitting data from inside the human body to a readout unit placed outside. They normally consist of a sensor module, conditioning electronics, a transmission module and a powering system. A block diagram showing the main elements of an implantable system is found in Figure 2.1. The common characteristics of each element are very low-power design, standalone configuration, minimal control and elaboration circuits resulting in less use of the microprocessor and power consumption, and minimal communication circuits, which require software with shorter and a more streamlined protocol, simple and quick to run with a low-power microprocessor.

An implantable system must be biocompatible with the tissues and cells of the environment in which it works. This requires using materials that are biocompatible to embed the sensor and electronic circuits inside a component of the prosthesis that is already biocompatible. Other requirements are the dimensions and frequency of the electromagnetic waves travelling through the human body. The antenna for the transmission must be small, for a telemetric system (Crescini et al., 2011) on the order of centimeters, and the transmission module must have frequencies that allow sending or receiving data through the human body.

Sensors and electronic blocks depend on the quantity to be measured. The supply block can be composed of a battery but, as mentioned in the introduction, a surgical operation will be required to substitute the battery. In the literature, other power sources are proposed, such as harvesting modules and inductive links. Each of these solutions determines a specific composition of the transmission and supply modules.

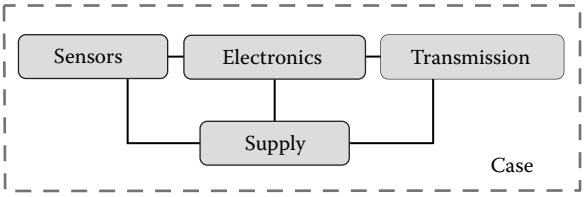

FIGURE 2.1 Block diagram of an implanted system.

The analysis of implantable systems has led to the definition of a classification according to the type of architecture; one class is "telemetric systems" and the other is "self-powered systems." "Telemetric systems" are defined as those that are powered inductively and interrogated wirelessly by a readout unit. "Self-powered systems" are those that have a power-harvesting module that scavenge energy for the functioning of the system from the environment. In the next section, the general architecture of telemetric and self-powered systems is described and discussed.

2.2.1 Telemetric Systems

The general architecture of a measurement system for telemetric systems is represented in Figure 2.2.

The telemetric system is composed of an implanted unit and a readout unit. The sensor is a block in the implanted unit inside the human body, while the readout unit is placed outside and the communication between the two units is done with telemetric techniques. A block diagram of the implanted unit and readout unit is found in Figure 2.2. It consists of different modules: a low-power sensor that measures the quantity under interest; a low-power microcontroller for the analog to digital conversion of the data, the storage in memory, and the telemetric operation; a transponder that transfers the data collected to the readout unit. The two elements are connected by wireless communication exploiting an electromagnetic field at typical frequencies of about 125 kHz (Crescini et al., 2011). The coil, connected to the transponder of the implanted module, is coupled to the external one, receiving the power

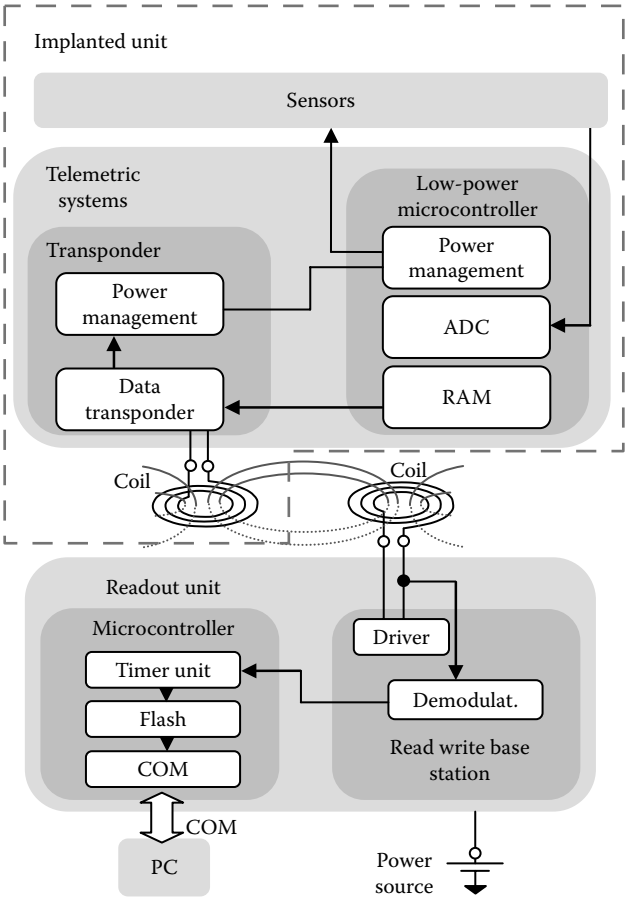

FIGURE 2.2 Block diagram of a telemetric system.

for the communication of the measurement data. Usually, the readout coil is bigger than the coil of the implanted unit. This is due, on the one hand, to the need to occupy a small space inside the human body and, on the other hand, to the difficulty of properly coupling the two windings. The readout coil therefore allows for having a greater area related to the coupling of the magnetic field, but at the expense of the efficiency of power transfer. To transmit data, the transponder of the implanted unit modulates the magnetic field using a damping stage. It modulates the coil voltage by varying the coil's load. A high level ("1") increases the current into the coil and damps the coil voltage. A low level ("0") decreases the current and increases the coil voltage. However, the current through the coil is never zero, so as to continuously provide the power supply. In particular, amplitude modulation is typical and so is the Manchester code. The transponder interface can also receive data: the readout unit modulates the emitted field with short gaps, and then a gap-detection circuit in the implanted unit reveals these gaps and decodes the signal. Furthermore, as specified earlier, the readout unit generates the power supply, which is handled via an electromagnetic field and the coil antenna of the transponder interface; then the voltage across the coil is rectified and managed by the power management module to generate a rectified voltage and current for the functioning of the electronic circuit. The power to all the internal modules of the implanted unit is supplied by the energy transmitted with the electromagnetic field generated by the read/write base station. The low-power microcontroller can include an ADC or a timer unit to measure the sensor signals. The microcontroller has a volatile memory to save the data before the transmission and timer units that permit to synchronize data transmission. To maintain low-power consumption, the bus frequency should be low, the ADC and transmitting unit have a low-power configuration, and all the unused peripherals should be switched off.

Since telemetric systems are wireless devices, transmitting not only the data but the power as well, the covered distance between the wireless device and the collecting data system must be short. The maximum transmitting distance depends on different factors; in Dalola et al. (2009) a maximum distance of about 8 cm is reported for open field transmission. For these reasons and for energy saving, point-to-point communication must be implemented. Point-to-point communication avoids the integration in the implanted system of circuits to manage the complexity of a network protocol and avoids complex communications such as those on multiple nodes that involve more complex software and therefore a longer time of execution of the same software, saving power supply and making the system compatible with the available low energy. Furthermore, the readout coil must be present and active during the measurement, conditioning, and transmitting phases; this means that the external coil, sometimes uncomfortable for the patient, must be placed close to or around the human body.

The external readout unit usually consists of a read/write base station able to supply power to the transponder driving the coil antenna and to demodulate the digital signal from the implanted unit. The readout unit is supplied by a line voltage, and no low-power characteristics are required, so the microcontroller, the bus frequency, and peripherals have no functioning limits. A timer unit is used to decode the demodulated signal, and the data collected are transferred to a personal computer (PC) using a serial communication interface (SCI).

2.2.2 Power-Harvesting Systems

A general architecture of a measurement system for passive autonomous sensors is shown in Figure 2.3.

Since the possibility of substituting batteries with the harvesting system is ecologically attractive and avoids surgical operations, our analysis shows that a self-powered system equipped with a harvesting system is a viable solution for implanted systems. These self-powered systems consist of one or more sensing elements and different modules: front-end electronics, an analog-to-digital converter, an elaboration unit to manage the internal tasks, a power management circuit, a wireless transceiver, and storage memories. In Figure 2.3, a block diagram of a typical self-powered system can be found. The power-harvesting module, usually separated from the circuit board, collects the energy present in

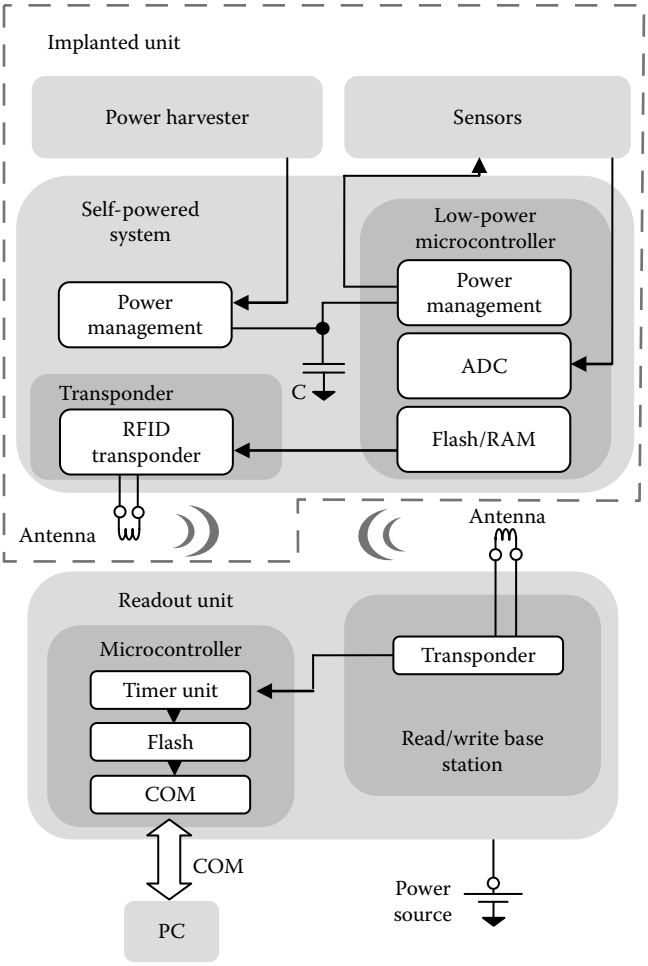

FIGURE 2.3 Block diagram of a self-powered system.

the environment of measurement in the form of mechanical energy, temperature difference, etc., and transforms it into electric energy.

The power-harvesting module must comply with very specific constraints, not only of space but also the compatibility of the materials and method of operation. For example, a system of power harvesting that uses the mechanical energy due to the movement of the human body cannot be excessively large; however, it must be able to operate with very low-frequency vibrations, of the order of a few hertz. The power harvester is connected to a power management block that is very important and essential. Since the voltage and current levels of the electronic circuits do not currently meet the possibility offered by the power harvesting system or sometimes even by batteries, management of the power supply is essential. Self-powered systems require a specific level of voltage and current obtainable by an appropriate power management block. This block commonly consists of dedicated circuits for the conditioning and/or storage of the energy harvested. First, a specific circuit can be used for matching the output electric impedance of the generator with the characteristics of the circuit load in order to have the maximum power transfer. Then, usually the power management circuit has a dedicated DC–DC converter or charge pump to provide a specific level of voltage and current at the circuit load.

The low-power microcontroller controls the sensor interface circuit, configures the front-end electronics and converts the data coming from the sensor interface circuit, and stores it in a nonvolatile

memory or directly sends the data at the transponder for communication. So, in this architecture two different strategies can be implemented. The first one, with a nonvolatile memory, saves the measurement data in the implanted unit and does not lose the data even when the device is not powered. This means that the external readout unit is not necessary during the measuring and saving phases, increasing the possible applications and the comfort for the patient, who does not need to "wear" the readout unit constantly. All the collected data can be downloaded in a second's time using different methods. The second strategy regards the possibility of measuring when enough power is scavenged and uses it to measure and transmit the data outside. In this configuration, the nonvolatile memory is not needed and the power for saving the data on the memory is not required. This means that the data, when the readout unit is not closed to the implanted unit, can be lost. Moreover, specific applications can be implemented to measure only when a specific event happens or only when requested. This leads to power savings and avoids the loss of data. In order to reduce the energy consumption for the data transmission, some smart compression algorithms on the measurement data can be implemented as well. In fact, the system deploys strategies to reduce the power consumption; the sensor module is designed to be triggered to transmission only when required, thereby consuming less power because unnecessary transmissions are avoided.

2.3 Force Measurement inside Knee Prosthesis

In this section, an example of an implantable sensor that monitors a total knee prosthesis (TKP) is described. It measures the forces applied on the knee prosthesis and exploits a telemetric technique for data communication and power supply (Crescini et al., 2011). Monitoring the prosthesis with an implantable sensor is very important in biomedical application. This provides several advantages such as the analysis of the wear conditions of the prosthesis caused by incorrect use or placement, the data collection to improve future design of the prosthesis, and a better control of the patient rehabilitation. Moreover, measurement devices for tibiofemoral contact stress give precise knowledge about articular movement behavior, and they can be used to refine surgical instrumentation, guide postoperative physical therapy, and detect human activities that can overload the implant. Therefore, monitoring the forces on the TKP it is possible to ensure the lifetime of the TKP is greater than that available with the current prosthesis.

The TKP consists of a tibial component and a femoral component, both made up of metal alloy. These components are attached to bone by using acrylic cement, and between the two components an ultra high molecular weight polyethylene (UHMWPE) insert has been embedded. The implantable sensor should be placed into the polyethylene insert avoiding biocompatibility problems.

The implantable sensor measures the forces applied on the knee insert by three magnetoresistive force transducers, which consist of magnetoresistors and permanent magnets as shown in Figure 2.4. The output resistance of each sensor depends on the distance between the permanent magnet and the magnetoresistor. Two magnetoresistors are placed in the areas where the two condyles of the femoral component transmit the forces between femur and tibia, and the third magnetoresistor is placed in the central part of the insert where the forces generated have no significant effect. The third magnetoresistor works as dummy for temperature compensation operation.

The force applied by the femoral component generates a deformation of the polyethylene insert, changing the distance between the magnet and the magnetoresistors and causing a resistance variation. The relationship between the force applied to the insert and the resistance variation of the magnetoresistors' output has been experimentally evaluated:

$$F \cong 2.15 \cdot (R - R_0) \tag{2.1}$$

Equation 2.1 shows the linear relationship between the force applied and the resistance measured, where F (N) is the force applied to the polyethylene insert, R (Ω) is the resistance value associated to the insert

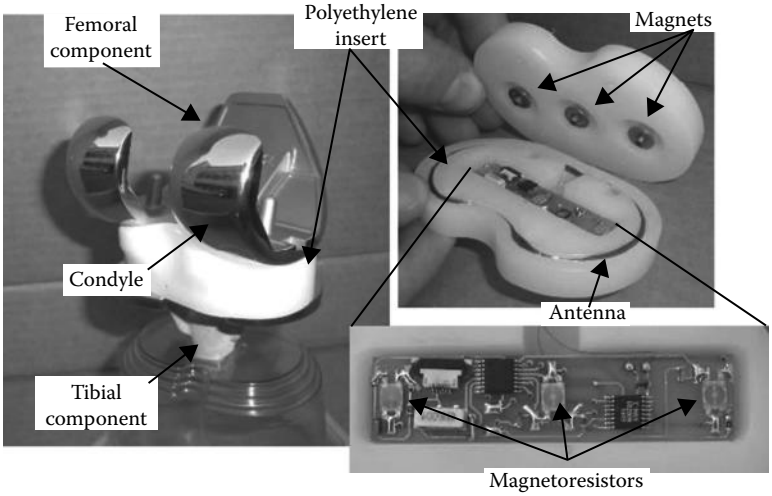

FIGURE 2.4 Example of total knee prosthesis and the implantable sensor into a polyethylene insert of the TKP.

deformation, and $R_0 = 1.25$ kΩ is the resistance value when the force applied is equal to 0 N. In this way, it has been possible to measure the forces applied to the insert by resistance measurements.

A significant issue with the implantable sensors is the relationship between the output of the sensors and the temperature. In fact, it is possible that an increase in temperature of about 3 °C, when the sensor is inside the human body, can be reached when a person walks for 45 min (Graichen et al., 1999). In this particular example, the magnetoresistors have a resistance drift equal to about 150 Ω/°C. For this reason, it is important to compensate the thermal drift so as to obtain an accurate measurement equation.

The control circuit of the implantable sensor is composed of a low-power microcontroller to acquire data with a 12 bit ADC, a 128 kB flash memory to store the force data, and a transponder working at frequency of 125 kHz. Figure 2.4 shows the antenna implanted into the insert, which communicates the data to the readout unit by RF and, at the same time, supplies the circuit coupling with another external antenna. A damping modulator is included in the implantable sensor to transmit the data in digital mode. Furthermore, a temperature sensor has been integrated in the implantable sensor so that the microcontroller is able to measure the temperature and eventually to compensate the resistance data during the measurement activity. Outside the knee, the readout unit consists of a transceiver to drive the coil antenna and to demodulate the digital signal received. The antenna is controlled by a readout unit localized around the knee as in Figure 2.5. Furthermore, the readout unit supplies the implantable system by telemetry. The readout unit is managed by a low-power microcontroller and powered by an external battery.

The readout unit contains a transponder to transmit and to receive data by modulating the magnetic field using a damping stage, in particular, with OOK (On-Off Keying) modulation and Manchester code. The RF communication between the readout unit transceiver and implantable sensor receiver is supported by a magnetic field generated applying to the antenna a sinusoidal voltage, whose magnitude is 80 Vpp at 125 kHz frequency. The capability to transfer data and energy through the human body is the main advantage of this solution.

The implantable sensor works based on three phases defined as stop, measure, and transmission modes. Figure 2.6 shows the three activities of the implantable sensor where the stop mode duration is 6 s, while the duration of the measure conversion and the transmit mode are about 6 and 7 ms, respectively. The communication protocol is composed of 6 strings of 16 bits each. The first two are synchronization strings, and, then, there are three strings that contain the resistance data of three magnetoresistors and one string that provides the temperature. Finally, the data collected are transferred to a personal computer (PC) by a serial interface so that the data can be analyzed by a qualified medical staff.

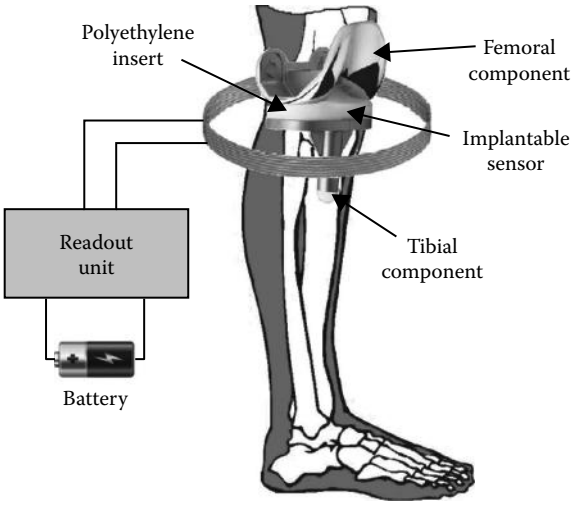

FIGURE 2.5 Prototype scheme of telemetric system to measure the forces in TKP prosthesis.

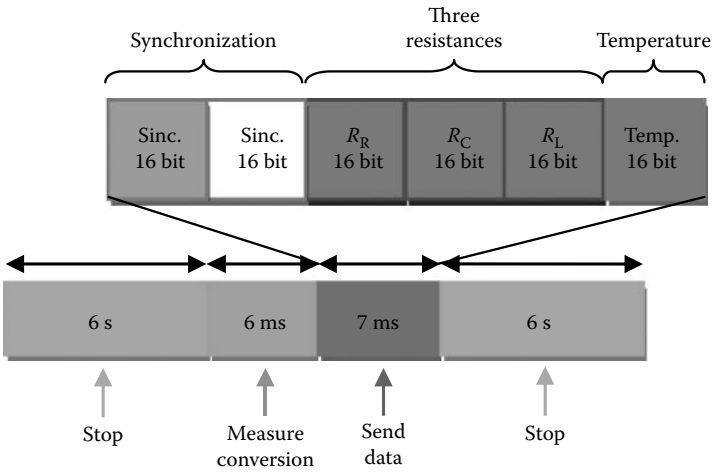

FIGURE 2.6 Functioning of implantable sensor.

2.3.1 Experimental Results

The force applied by the femoral component has been simulated using an Instron 8501 machine. This machine applies a linearly increasing force to the polyethylene insert from 0 N to 3 kN in 500 s. Figure 2.7 shows the relationship between the input orthogonal forces generated by the Instron on the TKP femoral component (solid line) and the force obtained by using Equation 2.1 considering the resistance value of the magnetoresistor output placed on the right side in the polyethylene insert (+ line). The samples were acquired every 6 s when the implantable sensor is in active mode.

The possible reasons for the difference between the two trends are mainly (1) nonlinear behavior of the magnetoresistor material, (2) no proper temperature compensation, (3) uncertainty of the experimental apparatus, and (4) the hysteresis effect due to the geometry and physical characteristics of the polyethylene insert. Figure 2.8 shows the wireless transmission signals monitored when the implantable

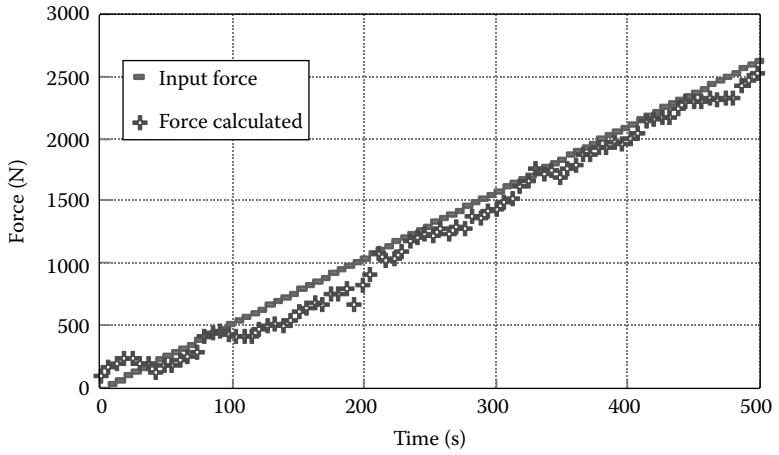

FIGURE 2.7 Comparison between the force values calculated by the resistance variation of the magnetoresistor on the right side of the insert of the implantable sensor and the input forces applied by the Instron.

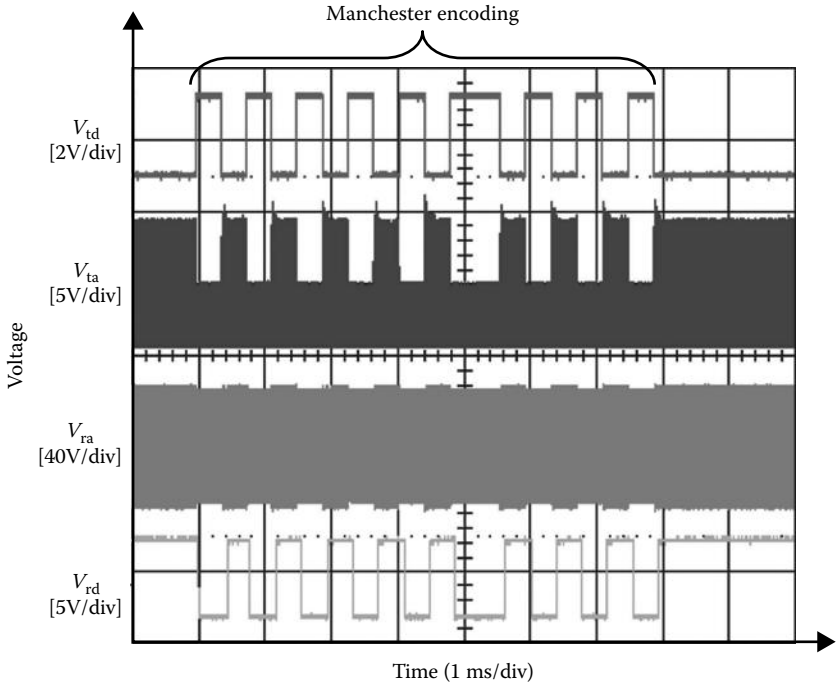

FIGURE 2.8 Wireless transmission signals of the converted data and typical implantable sensor activities.

sensor is in active mode: V_{td} is the transmitted data, V_{ta} is the transponder antenna voltage, V_{ra} is the signal of the differential voltage of the reader antenna, and V_{rd} is the received data.

Table 2.2 shows the power consumption during the different activities of the measurement system, when the external power from the readout unit is active. For example, when the implantable sensor measures and transmits the data to the readout unit, the microcontroller and the transponder require a power supply of about 1.7 mW, with a current consumption of approximately 850 μA and a voltage of 2 V.

TABLE 2.2 Power Consumption Measurements

Activity	Voltage (V)	Current (mA)	Power (mW)
Readout unit—transceiver communication	12	19.3	230.0
Implantable sensor—measurement and transmission	2	0.85	1.7
Implantable sensor—stop mode	2	0.16	0.3

2.4 Power Harvesting in Implantable Human Total Knee Prosthesis

The fundamental requirements for an implantable medical device are the capabilities of being self-powered and maintenance free. These ambitious goals excited the interest in a new and lively research field oriented toward the harvesting of energy from the human body with the aim of making the implantable (or wearable) system autonomous. Such a system, theoretically without human supervision, should provide information about the physiological parameters concerning its application. The rapid development and reduction in size, cost, and power consumption of the wireless communications devices allow for solving the important problem of the measurement of communication from the device to outside the human body. Considering the energy flow, an autonomous implantable device can be divided into two subsystems (López, 2010): the power-harvesting module and the load (power conditioning circuit, sensor, processor, and transceiver).

The first subsystem realizes the conversion of the energy from a particular domain (chemical, thermal, mechanical, etc.) to the electric domain. The second one carries out the mission of the implanted sensor, that is, the measuring and the transmission of the data.

This section shows the attempt to make autonomous a force sensor system inserted in a TKP (shown in Section 2.3), exploiting the mechanical energy produced by the human knee joint movement.

A TKP is composed of three components: the femoral component (condyles), the tibial plate, and the tibial insert constituting the contact surface of the tibia with respect to the femur. Figure 2.9 shows a 3D CAD model of the proposed solution: a copper coil is housed in a prominence of the tibial insert and six couples of block-shaped magnets are placed into each condyle. The axes of the magnets and the coil are parallel to the tibial insert.

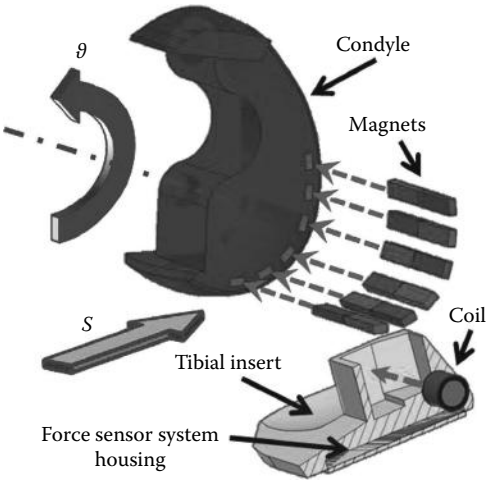

FIGURE 2.9 Cross section (in the sagittal plane) of a TKP with the energy-harvesting components. The angle ϑ and the displacement S are the degrees of freedom of the proximate relative motion of the femur (condyles) with respect to the tibial insert.

The energy conversion principle is based on the Faraday–Newmann–Lenz's law of induction: *a time-varying magnetic induction field B, linked to a conductive path c, leads to a potential difference to the extremities of c* (Woodson and Melcher, 1968). This way, when the femur moves with respect to the tibia, the magnetic induction field induces a time-varying flux and then a potential difference to the terminals of the coil.

In general, the relative motion of the condyles with respect to the tibia has six degrees of freedom and it is very difficult to reproduce. Because of this, the complex kinematics of the electromechanical system has been reduced by a reasonable simplification: only the relative rotation ϑ and translation S (Figure 2.9), in the sagittal plane, were considered in the design of the system.

A tailored motion control system allowed the reproduction of the gait conditions under the previous assumptions. In particular, the combined motion of translation and rotation of the TKP has been reproduced with the dedicated four-bar mechanism shown in Figure 2.10. An improved design of the four-bar mechanism allows for the translation S during the rotation ϑ with respect to the range of movement deduced by the literature (Masouros et al., 2010; Pinskerova et al., 2000).

During the gait cycle, in general, the angle ϑ is variable with the trend reported in Figure 2.11.

Due to the bigger amount of mechanical energy in the swing phase, with respect to the stance phase, in the following considerations and experimental tests, the analysis is limited only to the first one, that is, $\vartheta_{stance} = 0$, while ϑ_{swing} is supposed linearly variable in the time (i.e., $d\vartheta_{swing}/dt$ = constant) between $\vartheta_{swing} = 0°$ and $\vartheta_{swing} = 60°$ according to the trend reported in Figure 2.11.

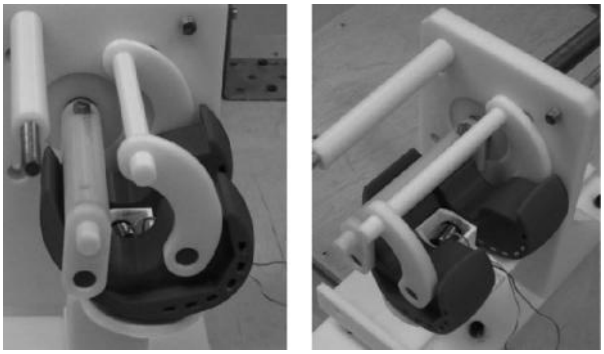

FIGURE 2.10 Prototype of the energy-harvester system implanted in the TKP.

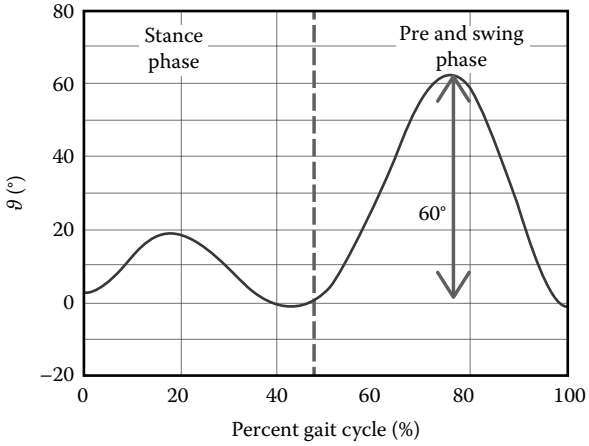

FIGURE 2.11 Knee joint angle ϑ as a function of the percent gait cycle.

The discontinuous nature of the human movement and its irregularity impose the design of a power and energy conditioning circuit for matching the power source and the energy requested by the measurement circuit. In fact, for example, depending on the technology by which the electronic circuits are realized, the voltage supply needs to respect a precise value or a proper range, while the voltage generated by the proposed energy-harvester system is very variable and discontinuous in the time domain, due to the strict dependence on the characteristics of the knee motion, as described earlier. Furthermore, the energy consumption of the system is related to the time requested to measurement and also to the techniques chosen for data processing and transmitting. Then it is necessary to establish a strategy for the functioning of the system, that is, the autonomous force sensor has a phase in which the power-harvesting module converts the mechanical energy from the knee movement, and, only when the required energy is available, a second phase in which the measurements are possible. For the proposed system, downstream of the power-harvesting module, a power conditioning circuit (*p.c.c.*) was realized with the aim to provide the energy supply to the load with the requested characteristics of voltage and duration.

Two experimental tests were performed. The first one was conducted considering the measurement of the open circuit voltage $V_{o.c.}(t)$ induced on the coil; in this test the energy-harvesting system is not connected to the *p.c.c.* and to the load. Figure 2.12 shows the oscillating nature of this voltage due to the different couples ($M1$, $M2$, …, $M6$) of magnets going near the coil (Luciano et al., 2012). In particular, the rising and falling ramps, between the broken boundary lines, delimit the complete passage, across the coil, of the generic couple Mn and the initial entrance of the following couple $M(n + 1)$.

The second test was performed, considering the complete autonomous system, that is, connecting the energy-harvesting system to the load using the realized *p.c.c.*. From Table 2.2, the mean power consumption of the force sensor system during a single cycle of data acquisition and transmission is 1.7 mW, while the time requested for the cycle is $T_{cycle} = 13$ ms, with a total energy consumption equal to $E_L = 22.1$ μJ. This load consumption was simulated using a resistive load $R_L = 2.2$ kΩ. The power conditioning circuit (Figure 2.13) is composed essentially by an impedance matching circuit, a charge pump (CP), which is turned on when the input voltage is 300 mV, and a startup capacitor. The startup capacitor is connected, by the CP, to the energy source, when the system harvests the energy, and to the load R_L, when it executes and transmits the force measures.

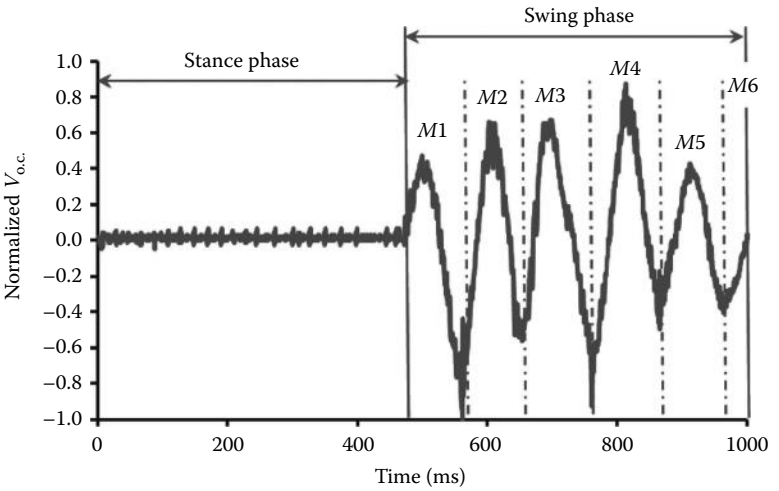

FIGURE 2.12 Normalized open circuit voltage during a gait cycle with a step frequency of 1.0 Hz.

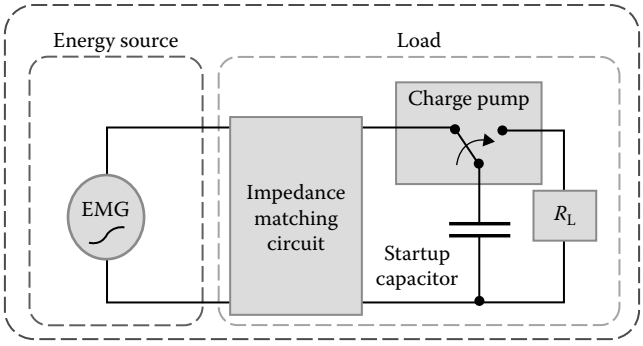

FIGURE 2.13 Block diagram of the autonomous force sensor system. EMG, electromechanical generator; R_L, resistive load equivalent to the force sensor system.

The CP has a discharge start output voltage $V_{CPout\_1} = 2.0$ V and a discharge stop voltage $V_{CPout\_2} = 1.4$ V. The charging time, T_c, requested for charging the startup capacitor is about $T_{c,zic} = 30.4$ s if the initial voltage of the startup capacitor is zero (zero initial condition), and $T_{c,ssc} = 7.6$ s when it is 1.4 V (steady state condition). The time requested of the patient, during the gait, for charging the startup capacitor, is more than acceptable. The capacitance $C_{startup}$ of the startup capacitor was deduced considering the minimum supply voltage of the processor ($V_{\mu C\_min} = 1.8$ V), the time necessary for the data acquisition ($T_{cycle} = 13$ ms), and the related energy consumption ($E_L = 22.1$ μJ). In particular, using the relation $E_L = 0.5 \cdot C_{startup}((V_{CPout\_1})^2 - (V_{\mu C\_min})^2)$, it is possible to deduce its minimum value ($C_{startup} = 58$ μF). Choosing a capacitor $C = 68$ μF, a discharge time $T_d = 16$ ms is necessary to decrease the CP output voltage from $V_{CPout\_1} = 2.0$ V to $V_{\mu C\_min} = 1.8$ V. This time is greater than the time $T_{cycle} = 13$ ms necessary for a single measurement cycle (Figure 2.14).

In conclusion, the energy-harvester system makes it possible to power supply a TKP implantable force sensor system making the system autonomous.

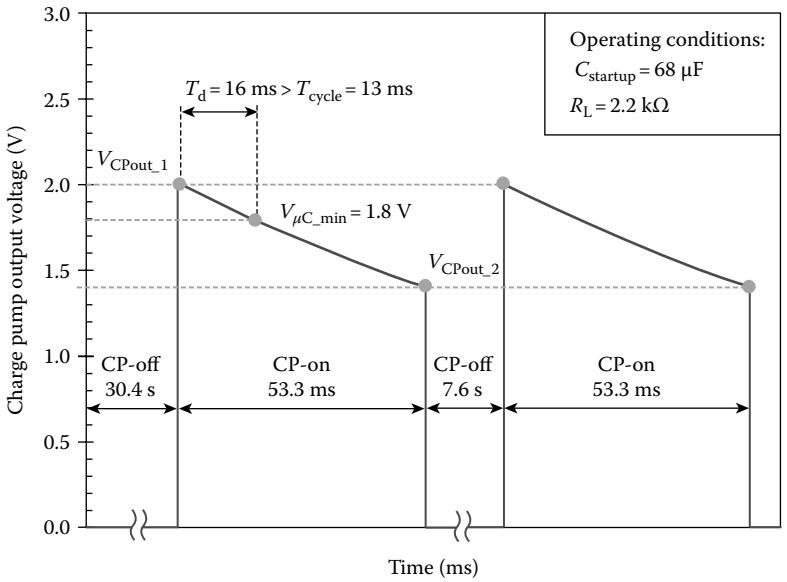

FIGURE 2.14 Operating conditions of the charge pump output voltage: CP-on, the CP connects the startup capacitor to R_L; CP-off, the CP connects the energy source to the startup capacitor.

2.5 Conclusions

Implantable medical devices are widely employed to monitor or to control different physiological parameters. Several implantable medical devices are powered by a battery, which constitutes a severe limitation because, in most cases, the battery defines the lifetime of the entire implantable medical device; in particular, because of the battery discharge, the implanted system must be surgically replaced. To obviate this problem, the implantable medical device should be powered through a telemetric technique or through an energy-harvesting system implanted together with the device. Several examples of implantable medical devices powered by telemetric or energy-harvesting technique are reported in the literature.

In this chapter, an example for each alternative to the battery is described; the first one is a force measurement system powered through the telemetric technique, while the second one is an energy-harvesting system that exploits the mechanical energy produced by the human knee joint movement.

The telemetric and the energy-harvesting systems can theoretically operate for an indefinite time, hence the implantable system must not be prematurely replaced. Furthermore, as the battery occupies significant space, batteryless implantable systems could be made smaller and more easily implanted. Otherwise, with a telemetric or an energy-harvesting system, energy is not always available and the measurement cannot be performed in a continuous way; the telemetric technique requires the presence of an external coil, while the energy-harvesting technique needs to store sufficient energy before powering the whole system.

The telemetric and the energy-harvesting techniques, especially the second one, represent two valid alternative solutions to power an implantable medical device. The energy-harvesting technique is undergoing research and development, and it could enable the patient to move in a free and autonomous way.

Bio-Inspired and Life-Inspired Sensors

Cesar Ortega-Sanchez

Halit Eren
Curtin University

3.1 Introduction

Living beings have always inspired the imagination of inventors and scientists throughout history. According to Greek mythology, Daedalus invented a pair of wings made out of waxed feathers so that he and his son Icarus could escape from the labyrinth of Crete. They succeeded, but Icarus flew so close to the sun that the wax melted and his wings dismantled, with tragic consequences. In renaissance Italy, Leonardo da Vinci invented flying machines and submarines inspired by birds and fish more than 500 years ago, but his inventions never came into real practice. These attempts failed not because they were fundamentally flawed, but mainly because technology at the time was far too immature for any realistic implementation of such projects.

What are the distinctive features of biological systems that we would like to incorporate in our man-made systems? Here is a partial list:

- *Resilience*. The ability to continue functioning even when the system has suffered damage (fault-tolerance).
- *Healing*. The ability to recover from damage and return the system to a state similar, if not identical, to the state it was before damage occurred.
- *Low power*. Living organisms are extremely efficient in transforming energy (food) into growth and behaviors.
- *Autonomy*. Plants and animals do not need external control to survive. Their behaviors are either innate, or learned from interactions with their environment.
- *Evolution, adaptation, and learning*. Biological organisms have these mechanisms that allow them to adapt, up to certain extent, to changes in their environment.
- *Intelligence*. The ability to perceive the environment and interpret it to produce behaviors in response to possible outcomes.

The remarkable increase in computational power and, more recently, advances in the architecture and size of field-programmable logic devices (FPLDs) have made it possible to build devices inspired by mechanisms found in nature. Artificial neural networks (ANN) and evolutionary algorithms (EA) are many examples of bio-inspired techniques that have been successfully developed and incorporated in commercial systems. In this chapter, we will discuss fundamentals of bio-inspired sensors and give some examples of their applications.

With today's technology it is possible to implement a complex system on a single chip with capabilities listed previously. This possibility is enhanced due to integration of the wireless communication systems and complex networking capabilities on that chip. These new types of systems are feasible and affordable for applications that require miniaturization, high performance, low-power dissipation, and distant communications. There are many advanced devices available to transmit and process measurement information from mobile objects, from inaccessible places, or remote devices and machines. This prompts stimulus for development of much rigorous and more complex niche and application-specific systems. Most of these application-specific systems contain integrated embedded microprocessor circuits that have included intelligence, augmented reality, and wearable or implanted components. It is worth mentioning that they are and must be extensively supported by a range of appropriate software.

3.2 Bio-Inspired Systems

For the purpose of studying life looking for inspiration, living organisms can be described at four fundamental structural levels, as in Figure 3.1. The features at one level of the hierarchy emerge from the interaction of elements at lower levels. Understanding life in any depth requires knowledge of all four levels shown in Figure 3.1. A fifth level can be suggested in which organisms from the same or different species interact with each other in the form of populations and ecosystems, respectively. In current research, hardware systems are used to study the organ, system, and organism levels. Cellular and population levels are studied mainly with the software systems.

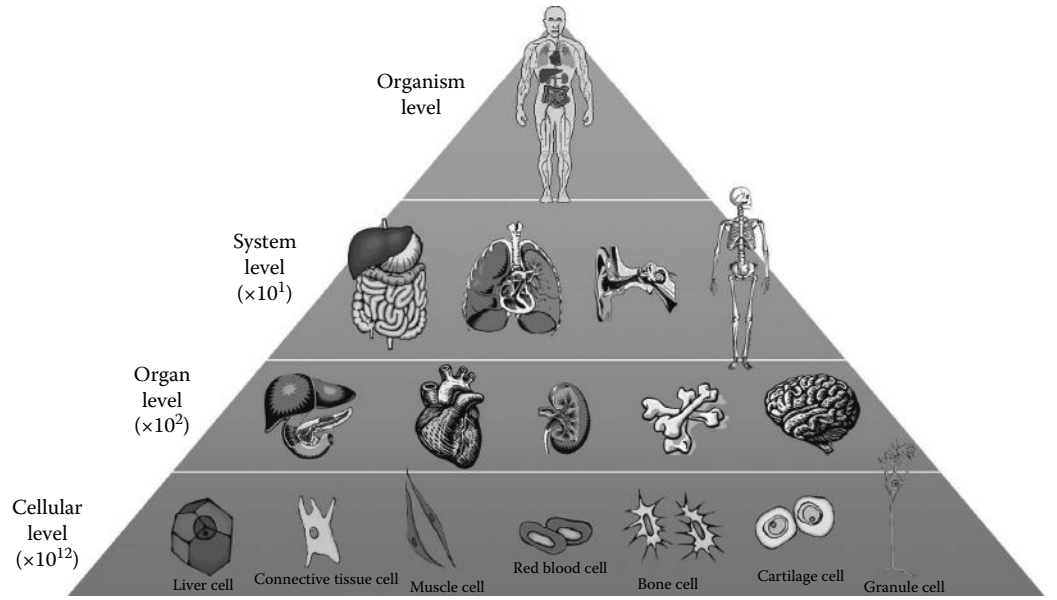

FIGURE 3.1 Hierarchical structures of multicellular organisms. (Authors' artwork incorporating Microsoft™ clip arts.)

Even though elements from every level in Figure 3.1 are very different in size and behavior, there are certain features common to all:

- Interaction of simple components that generates complex emergent behaviors
- Asynchronous interaction: As most interactions are event-driven, there is no explicit synchronization
- High level of redundancy

Current research in bio-inspired systems focuses in one, or more, of these features. In order to exploit these features, a commonly studied but very fundamental area is the bio-inspired semiconductor sensors and will be discussed in this chapter in detail.

3.3 Life-Inspired Systems

The paradigm of the life-inspired systems originates from the observations with the aim that the microelectronic-based systems should have characteristics resembling the characteristics of individual life organisms or organized populations.

Engineers and scientists aim for autonomous, self-contained, robust, self-organizing, self-adapting, self-regulating dynamic evolutionary systems that resemble real organisms. The products should be composed of autonomous systems made from diverse subsystems, but each of which has its own functionality to be integrated with the other subsystems and the central organizer just like the brain or nervous system in living organisms. The aim is to come up with systems that do not limit themselves to the basic functions of collecting, transmitting, storing, processing, and presenting information in relation to some external systems, but in addition they are able to solve complex problems, make and implement difficult decisions, learn, discover new ideas, and evolve.

To efficiently develop the new systems closely resembling intelligent life organisms, new system architecture concepts and design methods and tools are developed. Challenges in biologically and life-inspired systems created a new field termed as *bio-inspired engineering*. This new discipline applies biological principles to develop new engineering solutions for industry, medicine, environment, and many other fields that have not been previously investigated. The emergence of this discipline is the culmination of the unification of the life sciences with engineering and physical sciences. Hence, bio-inspired engineering involves deep exploration into the living cells, tissues, and organisms that can build, control, regenerate, recycle, and adapt to their environment.

A well-studied area in bio-inspired and life-inspired systems is artificial intelligence (AI). Many AI techniques have been developed and applied using computer-based technologies. Various computational models and knowledge-based systems have been applied in industrial, economic, and many other areas for the purpose of automated reasoning, learning, and problem-solving. There are thousands of publications on AI. As an example, an advanced study on AI is web intelligence (WI). Since the web is the largest network, the application of AI on this large scale is demanding and challenging. Studies such as WI brain informatics (BI) are leading to profound advances in the analysis and understanding of data, information, knowledge, and wisdom, as well as their interrelationship, organization, and creation process. Research and development in WI is making it possible to develop human-level WI [1–3].

3.4 Semiconductor Sensors

Since the early 1970s, silicon technology has been used to detect chemical changes such as hydrogen ions, pH levels, chemical substances, and odor detection. Since then many more sophisticated sensors have been developed based on complementary metal oxide semiconductor (CMOS), ion-sensitive field effect transistor (ISFET), metal oxide semiconductor field effect transistor (MOSFET), and other similar technologies. Many advanced types of semiconductor sensors are available, some of which are known as chemical field effect transistors (CHEMFETs) and enzyme field effect transistors (ENFETs)

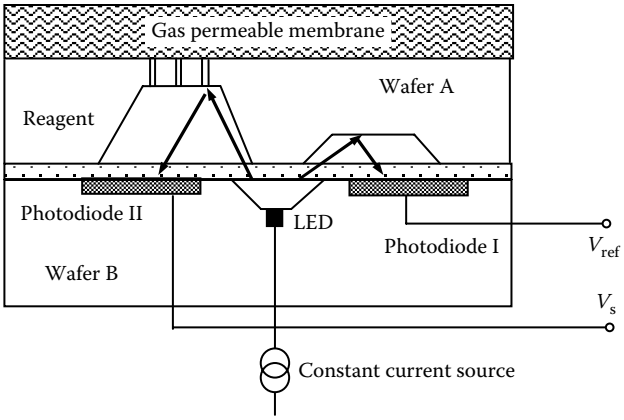

FIGURE 3.2 An optical semiconductor chemical sensor.

for sensing various analytes, elements such as potassium, sodium, and complex chemical structures such as glucose in blood and urea.

Chemical sensors have been leading to semiconductor-based devices to lead to bio-inspired sensors. Figure 3.2 illustrates an example of semiconductor-based optical chemical sensor. This sensor consists of two chambers, one acting as a reference containing a reference concentration chemical and the other as the sensor. These chambers are illuminated by a common light-emitting diode (LED). The surfaces of chambers are metalized to improve internal reflectivity, and the bottom of chambers is covered by glass. One of the chambers has slots covered with a gas-permeable membrane. The slots allow the penetration of gas to be measured (e.g., CO_2) into the chamber. Wafers A and B form optical waveguides. The chamber filled with reagent is used to monitor the optical absorbency for comparison with that obtained from the reference chamber.

Another example semiconductor-based sensor is the ISFET sensor is illustrated in Figure 3.3. In this example, the sensor is chemical based, and the signals generated by the sensor are amplified and processed in the same chip.

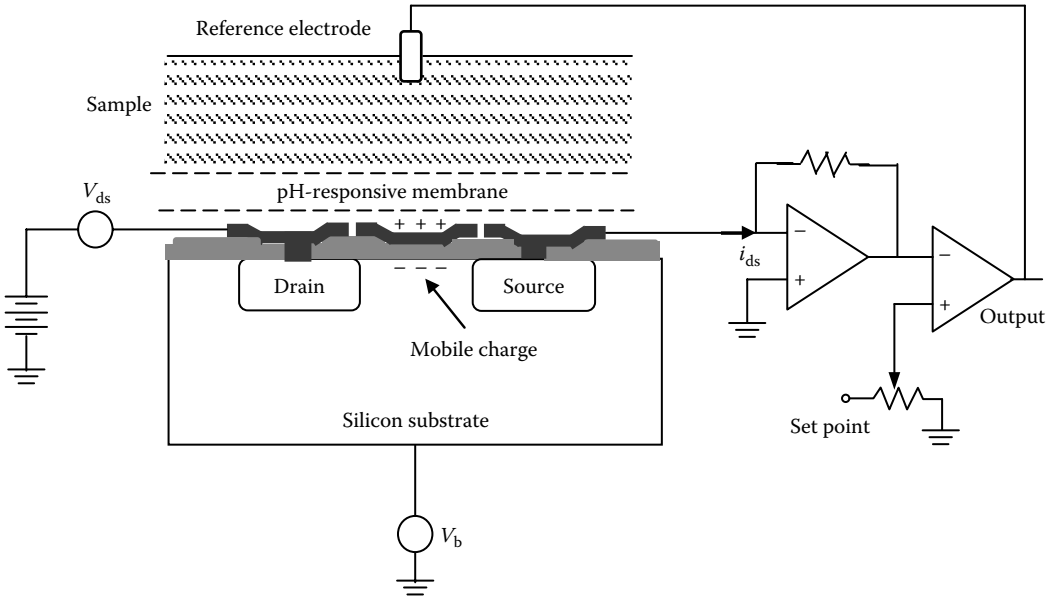

FIGURE 3.3 A pH sensor based on ISFET.

In addition to simple single-chip chemical sensors, there are many complete systems that have extensive and complex information processing features all built on a single chip or in a single package. The implementation of complete systems on a chip (SoCs) or in a system in package (SiPs) enables development of new generation sensors in a diverse range of application [4–6]. Nowadays, the use of semiconductor technology in biomedical systems is an accepted norm and very common. One of the most advanced technologies is DNA sequencing where the DNA and variations in the DNA are used to trigger sensors in microchips and go further by taking the necessary actions to be followed.

3.5 Biomedical and Biological Sensors

Semiconductor-based sensors for biomedical and biological applications have been researched and developed extensively. They find many applications, including the following:

- Biopotential and electrophysiology determination
- Blood pressure measurements
- Blood flow measurements
- Body temperature measurements
- Body weight and composition measurements

Traditionally, biological detectors require human intervention in a laboratory environment. However, in recent years, automatic devices and robots have involved biological applications, such as detection of microorganisms and their concentration levels. For example, for the detection of microorganisms in air, three different common methods are as follows:

1. *Biochemical*, which detect a DNA sequence and protein that are unique to a bio-agent through its interaction with test modules
2. *Chemical*, for example, mass spectrometry, which works by breaking down a sample into its components such as amino acids and then comparing their weights with those of known bio-agents and other molecules
3. *Biological tissue-based systems*, in which a bio-agent or biotoxin affects live mammalian cells, causing them to undergo some measurable response

Some classes of biosensors rely on comparing the DNA taken from a microorganism with the DNA of a known agent [7–9]. In other classes, there are microfluidic devices, which contain capillary channels, valves, and chambers in a single chip. Once the microorganism is in the chip, their cells are cracked open ultrasonically. Then polymerase chain reaction (PCR) is applied by means of small thin film heaters.

Some semiconductor sensors apply either optical and fluorescent methods or magnetic methods, as illustrated in Figure 3.4. These devices comprise an array of wirelike magnetic field microsensors. These sensors are coated with single-stranded DNA probes specific for a gene from a bio-agent. Once a strand of bio-agent DNA in a sample binds with a probe, the resulting double strand binds a single magnetic microbead. When there are magnetic beads in the sensor, the resistance of sensor decreases in proportion to the number of microbeads.

Among many other methods, in one application multiple array biosensors are multiplexed and electrochemical detection is realized by using an electronically active substrate, which has been constructed with a standard CMOS technology.

Another commonly used method for biosensing is by the use of live tissues. Many toxins trigger measurable or differentiable reactions in living cells. Mammalian cells, such as heart cells, are cultured in a lab and then seeded into a cartridge containing a microelectrode array. When a biotoxin is introduced, the cells create voltages detectable in millivolts at the electrodes.

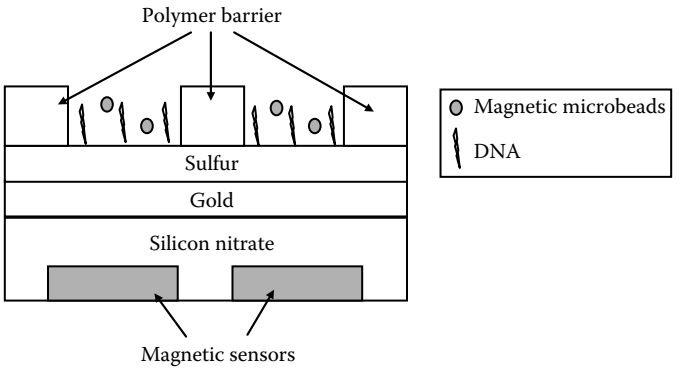

FIGURE 3.4 A magnetic biosensor.

3.5.1 Advanced Biosensors

There are many types of advanced biosensors, some of which automatically collect samples and then make multiple copies of the DNA using PCR. In this method, the samples are heated and cooled periodically to produce copies of the DNA. As the DNA is copied, the resulting strands are mixed with fluorescent DNA probes. The probe bound with the bio-agent glows under ultraviolet light. By using different probe markers several PCR reactions can run at the same time, thus enabling detection of more than one agent at a time.

In general, semiconductor sensors are extensively used in healthcare for a number of purposes. With the help of wireless systems, the CMOS-based systems are commonly implemented for physiological condition monitoring of athletes or patients (ECG, respiration, temperature, muscular conditions, etc.) They also are used for point-of-care diagnostic systems and genetic sequencing. Coupled with their potential for scalability, miniaturization, and low costs, they have applications in bio-inspired prosthetics where CMOS-based circuits are designed and implemented to replicate biology to configure implantable devices for personalized therapies such as for diabetes [10,11].

In human health, bio-inspired sensors are common in areas such as cochlear implants to restore hearing, retinas to cure blindness, glucose monitoring and control for diabetes, and vestibular feedback to restore balance.

Apart from microelectronics there are other bio-inspired technologies currently investigated and developed. For example, some polymers and polymer composites are capable of self-healing. In some applications, polymers are used for crack-mending initiated by an external thermal-, photo-, mechanical-, or chemical-induced stimulus. Successful crack healing has been demonstrated through both molecular diffusion and thermally reversible solid-state reactions. In another approach, damage in the form of a crack triggers the release of healing agents stored in the material, as also occurs for fracture events in biological systems.

3.6 Biomimetic Sensors

Bar-Cohen [12,13] explains that organisms use numerous receptors (senses) to control every aspect of their life and functions. Due to millions of years of evolution, biological sensors became very effective for providing external and internal information to warn about dangerous conditions, sense locations, control growth, and functionality of organs. These near-perfect capabilities of biological sensors prompted scientists and engineers to make efforts to understand and mimic them as closely as possible.

Scientists and engineers are studying biological sensors to copy, adapt, and inspire new capabilities and apply them in diverse ranges. These studies require interdisciplinary collaboration of researchers from the field of biology, materials science, mathematics, engineering, medicine, chemistry, and physics as well as involvement of social scientists [14–16].

The investigated biological sensors include the capabilities of self-healing, reconfigurability, replication, balancing chemical contents, and sensing of pH, temperature, pressure, and other life essentials. Armed with the observability of these sensors, studies concentrate on the understanding of the purposes, the rules, the concepts, the mechanisms, and the principles of biological sensors for developing new methods of manufacturing, processes, mechanisms, materials, and algorithms.

Biological receptors evolved for external sensing provide inputs to the central nervous system about the environment such that the muscles are commanded for action-based analysis of the received information. Some of the senses provide the equivalent of alarm conditions in the form of pain, others provide a *feel* of temperature, pressure, seeing, hearing, smelling, and tasting. However, these types of sensing have already been used extensively in human-made systems. For example, advanced robots can mimic biological models by sensing pressure and temperature. By using optical or acoustic sensors, they can determine their positions or recognize other objects, avoid collisions, interact with humans, and so on [17].

The common design requirements of engineering structures are quite similar to those of biological systems including the need to have a structure that is lightweight, consumes minimum power, and is durable over the life of the product. Mimicking biological sensors and using them help development of new technologies offer numerous benefits to human lives. Everyday improved methods and tools are emerging, finding many applications [18–20]. We can summarize the current applications of biomimetic sensors in the following areas:

- *Touch and tactile sensing*: robotics, material deposition, machining, angle sensing, pressure profiles, special resolutions, bruise sensing, and damage sensing military and commercial aircrafts
- *Sensing heat and IR*: domestic and industrial applications and forest fire detection
- *Smell and artificial nose*: odor detection, food industry, pharmaceutical, environmental monitoring, quality control, gases, chemical compounds, and space explorations
- *Taste and artificial tongue*: environmental monitoring, explosives, weapon detection, and healthcare
- *Vision and optics*: navigation systems, cameras, pattern recognition, defense systems, crime reduction, surveillance systems, endoscopes, and visual prosthetics
- *Proximity sensing*: robotics, shape identification, shape details, manufacturing, and transport industry
- *Hearing and sonar imaging*: cochlear implants, speech recognition in noisy environments, identification of localized sound sources, direction finding, submarines, oceanography, and various navigation systems
- *Flow detection*: flow and force detection and direction finding

3.7 Signal Processing

Bio-inspired sensors commonly come as microchips, and they largely generate analog signals. As in the case of all analog sensors, the signal processing requires analog-to-digital and digital-to-analog conversions, illustrated in Figure 3.5.

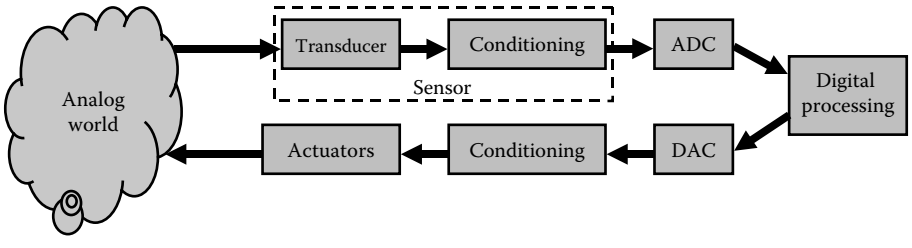

FIGURE 3.5 A bio-inspired data acquisition and control array.

The system in Figure 3.5 comprises hardware and software elements. Each one of them can potentially be biologically inspired. The number of interesting mechanisms and behaviors that could be adapted from nature into man-made systems is vast; therefore, it is possible to apply bio-inspiration to any of the blocks.

The basic principles of sensors can be temperature variations in physical (dimensions, resistivity, capacitance, etc.) or chemical (phase, color, pH, etc.). Hence, the signal processing requires appropriate selection of techniques suitable to the nature of the signals as they can be inductive, capacitive, and resistive, or they can be current source or voltage source [21,22]. In most cases the outputs of the sensors are not linear; therefore, extensive signal conditioning is required, such as the following:

- Linearization
- Impedance-matching circuitry
- Amplification
- Filtering
- Integration
- Differentiation
- Modulations

A typical example of signal processing requirements in biosensors is implantable medical devices, which require extreme low-power operation to avoid periodic replacement of batteries for long-term maintenance-free operation. For real-time monitoring of health condition, implantable medical devices also need to transmit the vital information outside of the human body for further diagnostics and processing. In an application, a data generator block takes the signal from sensors and transforms the signal into frequency-modulated digital pulses by employing relaxation oscillators. The next block such as the impulse generator converts the digital pulses into impulse signals for impulse-radio-based wireless telemetry.

AI is a commonly used technique for signal processing information from biosensors. For example, in an application a biosensor was simulated employing a feed-forward neural network with three layers and trained using a back-propagation (BP) algorithm [23]. Spectra generated from an optical phenolic biosensor at selected wavelengths were used as input data for an ANN. The network architecture of 5 inputs neurons, 21 hidden neurons, and 1 output neuron was found suitable for this application. The results had been compared with the information obtained from the operational biosensors.

A new trend in bio-inspired sensors is the use of field-programmable gate arrays (FPGAs) as they inherently offer greater flexibility in system configuration, application of AI, and flexibility in software development. In a study attempt has been made to replace microcircuits by FPGAs in portable biosensor devices [24]. Thin film technology electrochemical-based sensor chips such as pH, oxygen partial pressure, impedance, electrical potentials, and temperature can be used for the simultaneous in vitro measurement of metabolic, morphologic, and electrophysiological parameters. All these can be combined and the signals processed by using mixed signal electronic and local (point-of-care) analyses.

3.8 Bio-Inspired Sensors in Industry

Many of the interesting behaviors that can be found in nature are the result of nervous systems. Nervous systems include the senses and muscles to interact with the environment. Among species, vertebrates have evolved the most sophisticated nervous systems. Hence, they are a good source of inspiration for the investigation of bio-inspired systems.

The nervous system of mammals is made out of neurons with different functions according to where they are located in the sensory–motor cycle. In its simplest form, the sensory–motor cycle comprises three functional levels: the peripheral nervous system (PNS) that perceives and interacts with the environment, the spinal cord that transmits electrochemical signals, and the brain that receives signals generated by

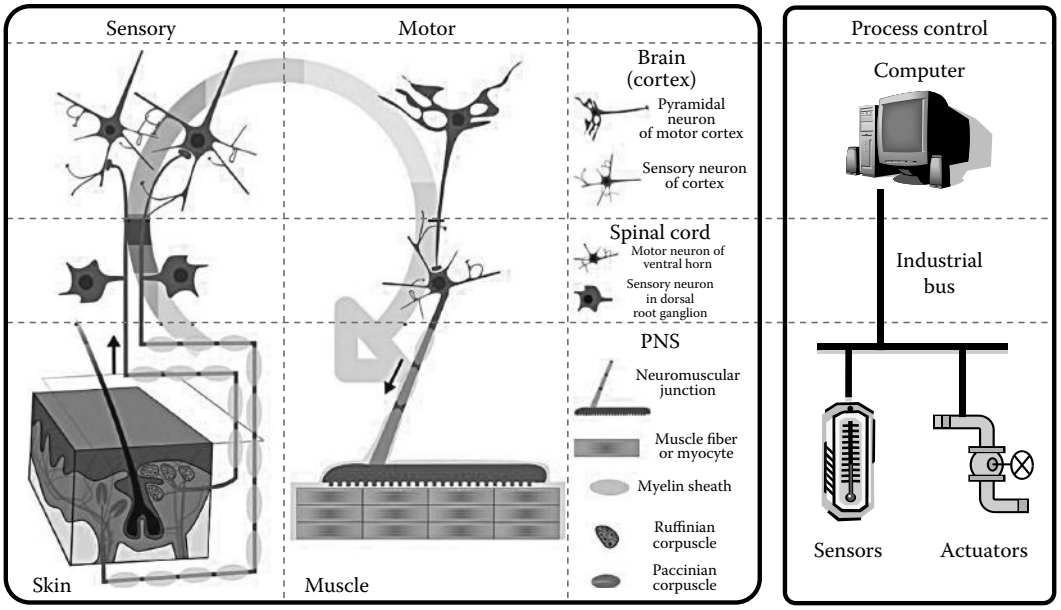

FIGURE 3.6 Sensory–motor and process control systems. (Courtesy of Wikimedia Commons, http://commons.wikimedia.org/wiki/File:Nervous_system_organization_en.svg)

sensory cells, processes them, and produces signals to control motor cells in the PNS. These three levels can be associated with the main components of a conventional control system, as shown in Figure 3.6.

Figure 3.6 suggests that in a first approximation, conventional control systems already have the hardware needed to implement bio-inspired systems. Bio-inspiration may apply to the way elements are interconnected and how software deals with sensor information to produce control signals. Good examples of this approach can be found in distributed control systems where intelligent sensors and actuators take low-level fast decisions at node-level while transmitting information to a central computer for high-level coordination. Properties like redundancy, event-driven processing, and fault-tolerance can be incorporated using additional hardware or software.

To achieve fault-tolerance, researchers are studying artificial immune systems (AIS) [25]. By using concepts like "the self" and "antigens," systems are given the ability to recognize unexpected states (*antigens*) that do not belong in an expected state set (*the self*) and apply corrective measures to return the system to a "*healthy*" state.

3.8.1 Bio-Inspired Sensors in Control Systems

Process control is a typical area where bio-inspired systems find applications. In modern control practices, it is ever more frequent to find what are called "intelligent instruments." These devices usually incorporate transducers, conditioners, analog-to-digital converters (ADCs), and a small local computer that can perform simple signal preprocessing and control. Information is transmitted from intelligent instruments to central computers using industrial buses and communication protocols. Figure 3.7 shows a typical control system that incorporates intelligent instrumentation.

Actuators are typical examples of bio-inspired systems [26,27]. They are essential elements within mechatronic systems due to their important role in motion control systems, and hence there is a need to develop new trend of actuators that can be inspired from biological actuation systems in nature and can be associated with different levels of control. Making intelligent devices by biologically inspired modern

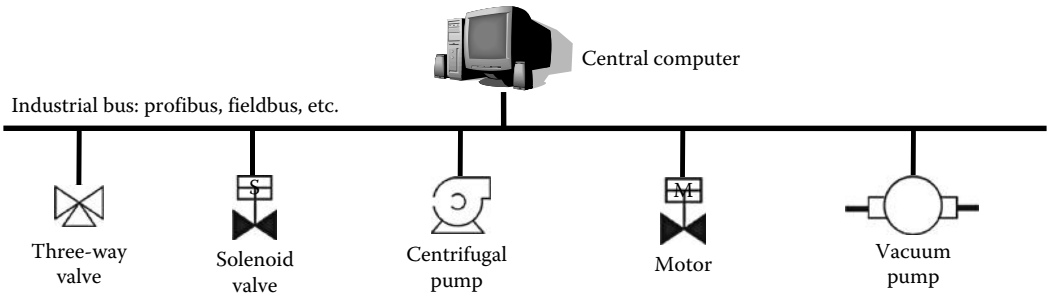

FIGURE 3.7 Industrial control system using intelligent instruments and network buses.

actuators and artificial muscles can create a new reality with greater potential in comparison to conventional techniques. Electroactive polymers (EAPs) are a good example of materials that find usage as bio-inspired motion systems in industrial applications. EAP actuators are electrically responsive materials that have common characteristics with natural muscles and hence are suitable for "artificial muscles" in biomimetic motion applications. EAP materials can be activated either by electrically induced transport of ions or by electrostatic forces. EAPs are finding numerous industrial applications.

In one study, algorithms for bio-inspired tracking systems have been developed as the control algorithm for sensor-mediated chemical plume tracking in a turbulent flow environment. This study focused on development of a signal processing strategy capable of replicating behavioral responses of actively tracking strategies of blue crabs to chemical stimuli. The geometric arrangement of the sensor array is inspired by the location of blue crab sensor populations. Upstream motion is induced by a binary response to suprathreshold spikes of concentration, and cross-stream steering is controlled by contrast between bilaterally separated sensors [28].

Image Sensors

Mehdi Habibi
University of Isfahan

4.1 Introduction

Image sensors play an important role both in everyday life and in highly specialized tasks. Image sensors are used in webcams, cell phones, and digital cameras. As shown in Figure 4.1, their application can be confined to tasks such as low-powered miniaturized sensors, high-resolution imagers, high-speed acquisition systems, and machine vision processing. Each application requires certain specifications and characteristics of the image sensor. For example, in one instance, the power consumption can be the dominant factor, while in another application the sensor speed is critical. In portable devices such as mobile phones, low power consumption is preferred [1]. High-speed machine vision task used in industrial plants for food grain separation based on the grain size is an example where high-speed imagers with possible in-pixel processing are appropriate [2].

Conventionally, image sensors were designed using charged-coupled device (CCD) technology. CCDs have the ability to accumulate and transfer charge using potential wells produced by the device gate, but it is not possible to implement active devices that provide signal processing power. Currently, CMOS technology has an advantage over the CCD process in image sensor implementation due to the fact that it is possible to integrate active circuits in the pixel structure. For example, the integration of a simple source follower amplifier in the pixel structure can help reduce noise due to cross talk and neighbor cell signals. This structure is known as the active pixel sensor (APS) in contrast to passive pixel sensors (PPSs), which do not incorporate any in-pixel amplifiers. CMOS image sensor technology benefits from several other advantages such as higher sensor speed due to in-pixel processing of data, higher signal data range, and lower power consumption. CCD technology has the advantage of better charge transfer characteristics, which is important in correlation procedures. Thus, in certain correlation image sensors that are used in 3D range estimation, combinational CCD/CMOS processes are also used. The three different processes of CCD, CMOS, and CCD/CMOS are shown in Figure 4.2. Due to the diverse variations that exist in CMOS image sensor design, this chapter mainly focuses on CMOS image sensors. In the following sections, three groups of image sensors are discussed. Section 4.2 explains the main trends in CMOS imager design. Section 4.3 focuses on digital image sensors and different approaches in digital imagers. Section 4.4 presents image sensors with basic machine vision processing power. Finally, in the last section, some of the remaining image sensors with specialized functions are introduced and concluding remarks are presented.

4.2 Basic Pixel Trends

The basic pixel of an image sensor consists of a photoreceptor and photocircuitry. Common photoreceptors include photodiodes and photogates. Photodiodes have a simpler structure, are easier to operate, and have higher quantum efficiency. In contrast, photogates have lower quantum efficiency due to the absorbance effect of the gate layer but have better photo charge transfer characteristics. Currently, photodiodes are commonly used in image sensors built using CMOS technology. The current–voltage characteristic of a photodiode is shown in Figure 4.3. As the figure shows, there are three possible operation regions for the photodiode. The first is forward bias that is not used in image sensor designs since the photocurrent is completely insignificant compared to the main diode forward current and subsequently forward random noise. The second is the solar cell region where the photodiode is able to deliver power. This region is also not commonly used in image sensors since the capacitance effect of the photodiode is high, which results in a low-speed response of the photodiode to incident illumination. The region best suited for the photodiode to operate as a photoreceptor is the reverse bias region where the amount of current is proportional to the incident illumination.

The other part of a basic pixel is the photocircuitry, which includes devices attached to the photoreceptor and is used to convert the photocharge to an electric voltage or current signal. In its simplest form, the photocircuitry can be a simple reset switch that precharges the photodiode to a predetermined voltage. After the reset phase, the photocharge is integrated on a capacitor (namely, the capacitance of the photoreceptor itself). Subsequently, after an appropriate integration period, the amount of voltage on the capacitor is proportional to the photocharge. The photocharge in turn is proportional to the photocurrent, which is dependent on the amount of received illumination. Several issues have to be considered for the simple reset switch. For example, the implementation of the reset switch similar to the photoreceptor can significantly reduce the size of the reset switch (since no extra well is required) and hence increase the fill factor (ratio of pixel photoreceptor area to the overall pixel area) [3]. However, this configuration places the reset switch in the active region, and thus the precharge voltage will experience a threshold voltage difference from the supply potential. This voltage difference limits the output signal swing and can be important especially in submicron technologies where the supply potential decrease is faster than the threshold voltage decrease. Furthermore, as the precharge voltage increases, the current delivered by the reset switch decreases, which means that if the reset time is not sufficiently large, the amount of final precharge potential will be dependent on the previous potential of the photoreceptor. This effect results in an effect known as lag which can be suppressed using correlated double sampling (CDS) explained later. The use of a complementary reset device can solve both the precharge potential and voltage lag but suffers the drawback of smaller fill factor [4]. Another drawback of the complementary reset switch compared with the ordinary reset switch is as follows: In deep submicron technology, the short channel devices show considerably high leakage currents even at zero gate–source potentials. The solution is to use a negative gate–source voltage (for an nMOS device) to reduce the leakage current in the off state. The use of negative potentials is possible for an nMOS reset switch, but for pMOS switches, charge pump circuits are required to increase the gate voltage above the power supply

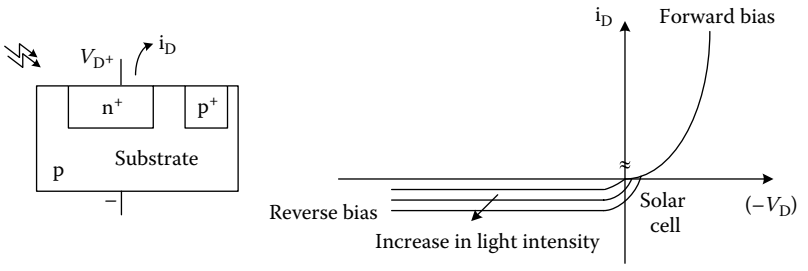

FIGURE 4.3 Photodiode current–voltage characteristics.

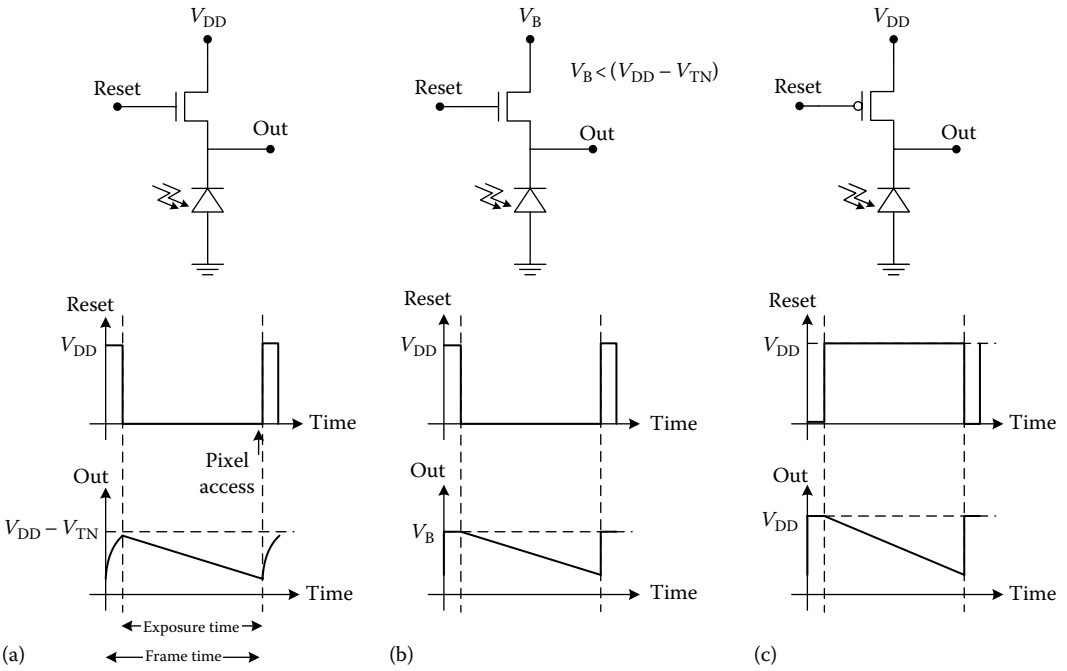

FIGURE 4.4 Reset switch configuration: (a) nMOS reset switch with supply voltage precharge potential, (b) nMOS reset switch with V_B precharge potential, and (c) pMOS reset switch.

precharge potential, or a precharge potential lower than the supply voltage should be provided. Note that if a lower potential is provided for the nMOS reset switch, the problem of image lag can be solved since the reset switch will be placed on the triode region. Figure 4.4 shows the three configurations, their control waveforms and output signals.

Diode-connected loads can also be used as photocircuits, which logarithmically convert the photocurrent into a voltage signal. This structure covers a wider dynamic range of illuminations (due to the logarithmic effect) but lower sensitivity is obtained, since a wider illumination range is mapped to a limited voltage swing range. Furthermore, since the photocurrent is relatively limited, the photodiode load MOSFET will operate in the subthreshold region, and thus mismatches in different load devices result in substantially different signal conversion characteristics from one pixel to another, which produces fixed pattern noise (FPN). There have been circuits presented that compensate this FPN using in-pixel methods [5,6]. The speed of diode-connected photocircuits can be increased by gain boosting methods.

Currently, the most common method remains to be the integration setup due to lower random noise. The reason is that the capacitor will act as an element that calculates the average current and thus random noise effects will decrease with higher integration periods.

Other common components in a basic pixel include a select switch MOSFET, which places the signal data on the common column bus. In the PPS array of Figure 4.5, no amplifier is used in the pixel circuit. A single reset switch can be used for the entire column of a PPS structure [7].

With the incorporation of a common drain MOSFET that acts as a unity gain voltage buffer in the pixel structure, an APS is achieved. This configuration is shown in Figure 4.6a. If the pixel voltage is to be placed on the common column bus directly (similar to the PPS case), charge charging happens between the column data bus capacitance and the photoreceptor capacitance, and thus the final column signal will be dependent on the previous pixel data on the column bus. Also, the parasitic capacitances between the column bus and the photodiode will change the actual photodiode potential during the column bus activity and create substantial cross talk. With the voltage buffer, the photoreceptor crosstalk

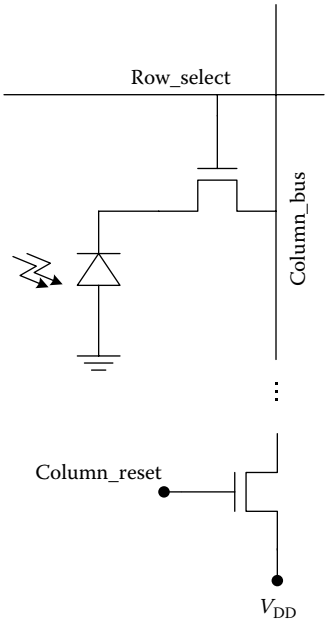

FIGURE 4.5 PPS sensor structure with a common reset switch per column.

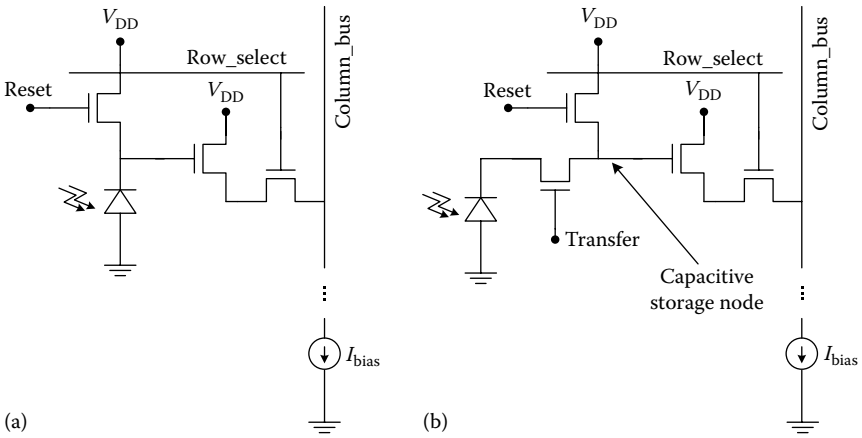

FIGURE 4.6 APS sensor: (a) Without storage site and (b) with an extra analog storage site and transfer gate.

and column bus charge sharing is eliminated. Still, mismatches between the source followers result in FPN effects, which can be compensated by CDS methods.

Analog pixel arrays usually have a common reset signal. After the pixel array readout, all cells are precharged simultaneously. After the desired amount of exposure time, the pixel data needs to be accessed. To avoid further charge accumulation on the remaining pixels during the readout cycle, a mechanical shutter can be used. If the pixel access time is short, the use of this shutter will not be necessary. Another option to avoid the mechanical shutter is the use of electronic shutter. As shown in Figure 4.6b, in the electronic shutter method, an extra transfer gate and storage site are required to keep the analog photodiode signal while other pixels are accessed [8]. The use of photogate in Figure 4.7 can enhance the transfer operation since by changing the photogate potential, the charge displacement is controlled more effectively. The timing waveform of Figure 4.8 shows one possible approach to control the electronic shutter pixel. In the figure, the difference between exposure time and frame

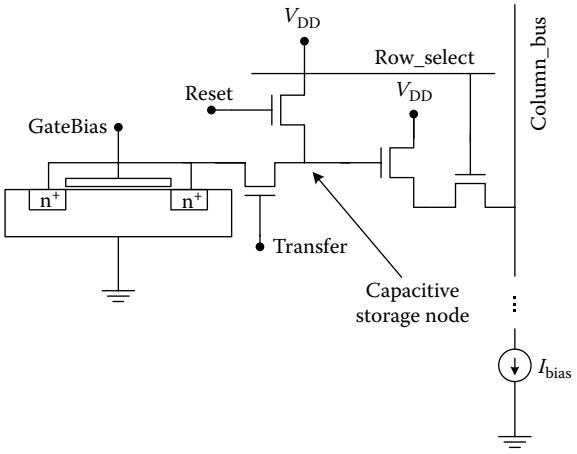

FIGURE 4.7 Electronic shutter implementation with photogate.

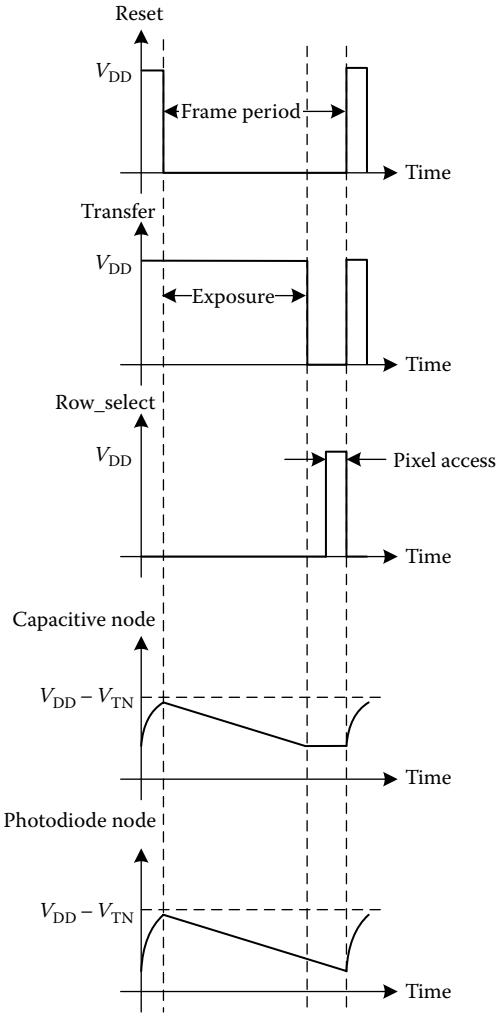

FIGURE 4.8 Electronic shutter control waveform.

rate should be noted. The exposure period is the effective amount of time that the photodiode integrates photocurrent, but the frame rate is the inverse of average time where a frame is transferred to the output and a new frame capturing sequence begins. The maximum frame rate will be limited by the required exposure time.

In order to increase the fill factor, the number of required transistors per pixel in an APS device can be reduced by using one amplifier for a group of photodiodes. This configuration is shown in Figure 4.9. The different colors of a pixel are an appropriate choice for sharing a common amplifier. Note that as the number of pixels per common amplifier increases, the charge sharing and cross talk also increase. Amplifier sharing of 4 or 5 photodiodes results in 1.75 and 1.5 transistors per pixel in APS devices, respectively [9,10].

Another important issue in the basic pixel structure is the color consideration. A photodiode's photocurrent varies with wavelength (or color), but a single photodiode itself cannot distinguish one color from another since the photocurrent also varies with intensity. Color filters are an effective solution to assign certain colors to different pixels. These filters are repeated throughout the sensor in an appropriate color pattern. For example, the Bayer RGB is the one that is usual among image sensors. Different polymeric dye masks are available for this purpose. Another alternative for color implementation is the use of metal grids that act as gratings [11,12]. These gratings can separate different wavelengths of light and focus each color on appropriate photodiodes. The advantage with this technique is that it can be implemented with the standard CMOS process using the metal layers. Another option for implementing color pixels is to use multiple photodiodes with different quantum efficiencies within a single pixel [13,14]. For example, a pixel might contain three different photodiodes where each has peak quantum efficiency at red, green, and blue wavelengths. Considering the signal produced on the three photodiodes, the pixel circuitry can extract the three essential intensity, color, and saturation information of that pixel. Fortunately, the implementation of different photodiodes can be easily implemented by implanting multiple p–n junctions at different depths, which is also compatible with the standard CMOS technology [15]. An advantage with this configuration is that unlike the color mask [16] and grating-based method, each

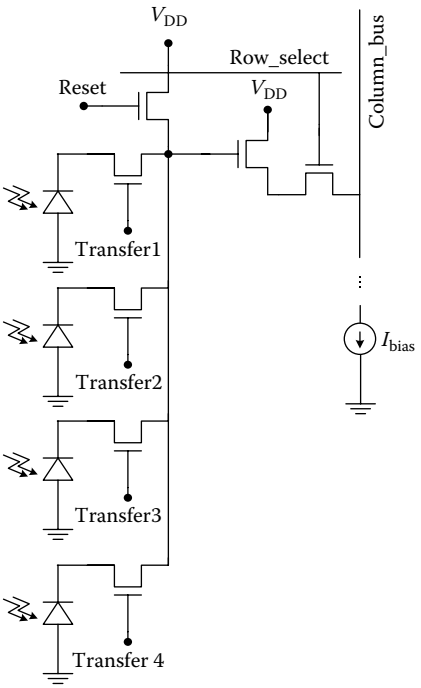

FIGURE 4.9 Pixel structure with amplifier sharing.

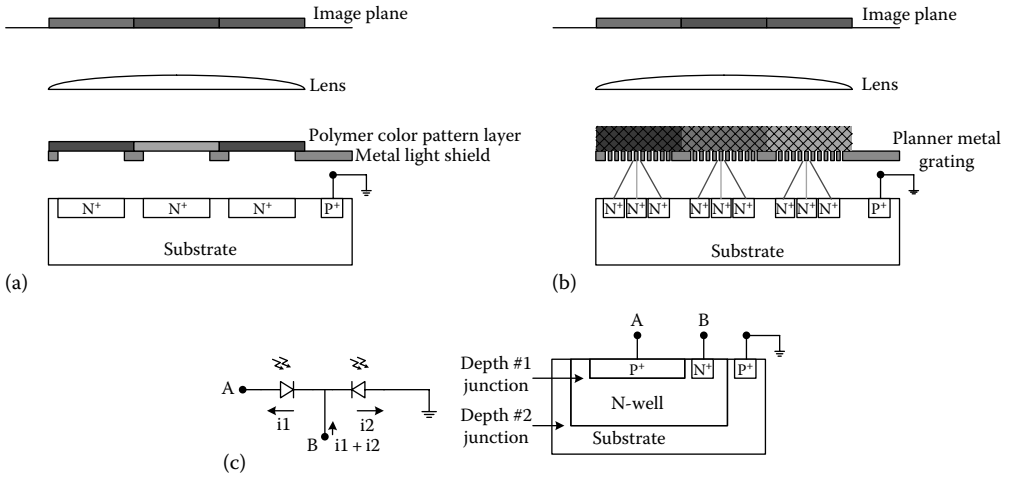

FIGURE 4.10 Color filtering techniques: (a) Polymeric dye color masks, (b) planner metal grid gratings, and (c) multidepth junctions.

pixel can produce the data signals of all the required three colors. Also, no extra metal or dye layers are required, which reduces the chip cost. Figure 4.10 shows some of the different possible configurations for color sensor implementation.

An extra layer that is occasionally used in basic pixel structure is the microlens layer [17]. These lenses act to focus the received illumination directly on the photodiode. This approach is effective in increasing the sensitivity of pixels with low fill factor. With pixels that include significant in-pixel circuitry and the fill factor is low, the microlens can help direct the incident pixel illumination onto the actual photodiode. Planner microlenses that are implemented with metal layers are also used in some sensors [18]. Figure 4.11 shows some of the different structures used in microlens implementation.

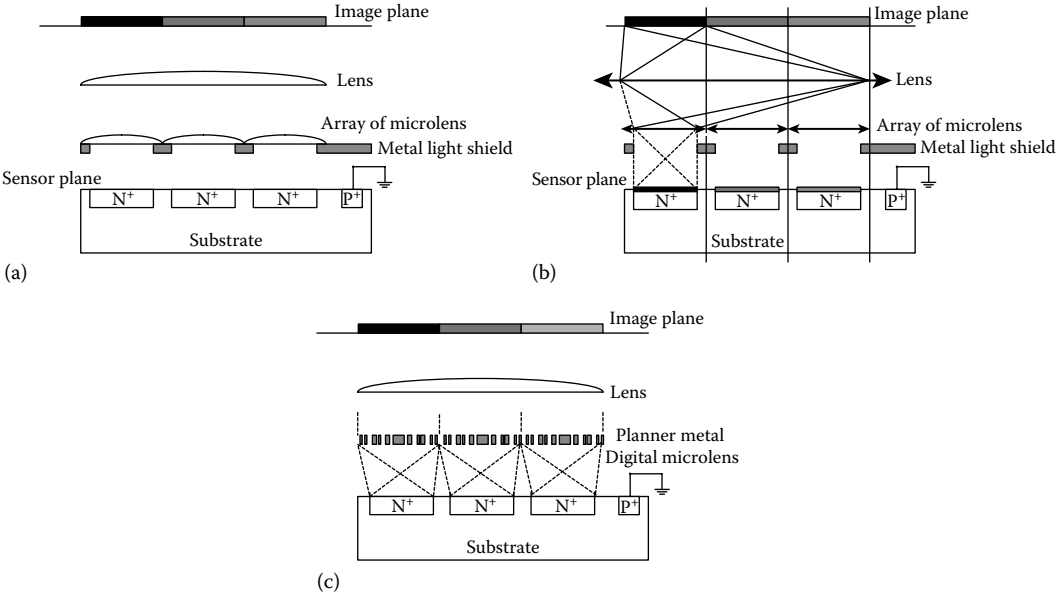

FIGURE 4.11 Microlens implementation techniques: (a) Conventional microlens fabrication using resins, (b) operational principle of the microlens for directing light to the actual photodiode, and (c) planner metal structure for microlens implementation.

FPN and random noise are other important aspects in a basic pixel that need to be addressed. If an image is captured in complete dark conditions, it will contain two components. One is the FPN, which is referred to as the part that is constant in successive image captures, and the other is random noise, which randomly changes in successive captures. These two noise sources have different natures. Since the FPN is constant, it can be easily removed in further processing steps. There have been sensors designed that can eliminate FPN. Since the random noise has nondeterministic characteristics, it mainly determines the sensor noise floor and specifies the minimum sensor detectable signal.

The random noise originates from the photodiode shot and thermal noise and also amplifier flicker noise, shot noise, and thermal noise. The reset switch also produces random noise but can be removed with appropriate methods. The FPN originates from device mismatches and difference in MOSFET parameters. Since the device mismatches are formed during fabrication and are constant afterward, the noise effect caused by this factor is considered fixed. For example, the most important factor that produces FPN in APS pixels is the threshold voltage variations of the source follower MOSFET. The nMOS reset switch will also produce FPN due to the threshold voltage drop variations on the photodiode precharge potential. The pMOS reset switch however does not contribute to FPN since it operates in the triode region and directly precharges the photodiode node to the supply voltage.

The CDS method is an effective solution for eliminating FPN and also random reset noise by capturing two samples before and after integration. The subtraction of the two samples eliminates the noise due to the reset switch random and fixed noise and also the amplifier fixed noise. An issue with this approach is that if the samples are to be taken at the beginning and end of integration, an analog memory array is required to store all samples captured at the beginning of the integration and wait for the integration to complete and start the second capture period and subtraction. The solution for this problem is to use the structure of Figure 4.6b, reset the photodiode, wait for the integration period to complete (give the photodiode the required exposure time), and perform the two captures subsequently before and after the transfer phase [19,20]. With this method, the correlation double sampling can be performed as each pixel is accessed and no extra storage site is required. The corresponding signal waveform required for CDS is shown in Figure 4.12.

Section 4.3 will focus on image sensors that are able to convert the pixel analog signal to a digital data.

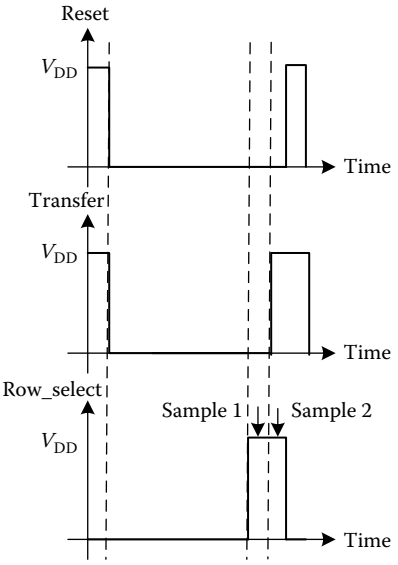

FIGURE 4.12 CDS control signals.

4.3 Digital Image Sensors

As pointed out earlier, a significant advantage of CMOS image sensors is that they can incorporate processing circuitry in the sensor structure. The processing circuitry can help amplify the pixel signal, increase the signal dynamic range, reduce FPN, etc. The processing circuitry can also be used to convert the analog pixel data into digital form.

The analog-to-digital conversion of data in a digital image sensor can be performed on-chip, in-column, or in-pixel. With the on-chip configuration, an embedded analog-to-digital converter (ADC) is used to convert the scanned pixel array analog data into digital code. Since most signal processing systems work with digital data, system costs will be reduced by eliminating the external ADC. Furthermore, basic and common digital signal processing stages such as color and white balance correction, focus enhancement, and 50/60 Hz flicker correction can also be imbedded in the sensor chip [1].

With the column parallel ADC structures, an ADC is placed at each column, and analog data are converted to digital in a column parallel sequence. The speed of the sensor can be significantly increased since the main bottleneck in an ordinary image sensor is the time required for each conversion. Usually with the column parallel ADC, no mechanical or electronic shutter mechanism is required, since all pixels can be accessed and converted to digital in a short time after the desired duration of exposure period. Furthermore, image sensors with column parallel ADC have been presented, which can accept extended image dynamic range by changing the shutter (integration) period for different pixels [21]. This is accomplished by using multiple exposure captures on the array. On each column, the sensor uses a single-slope ADC for one long-exposure capture and a variable-slope ADC for multiple short-exposure captures.

The column parallel approach can increase the frame rate, but for high-resolution and high-speed imagers, reduction of the data conversion time remains a challenge. In this case, the in-pixel conversion of pixel data is appropriate. This pixel configuration is also known as the digital pixel sensor (DPS). Versatile and different DPSs have been proposed, which operate on different principles. They mainly differ in complexity, dynamic range, and error. In a DPS, the photodiode potential is usually compared against a reference voltage to create a digital match signal. As shown in Figure 4.13, they can be divided into major oscillatory and nonoscillatory groups. In the nonoscillatory approach, the pixels match signal changes once in each frame. After the reset phase (with the starting of each frame), the procedure is repeated. The match signal pulse width can be used to evaluate the analog signal intensity. In the oscillator category, the match signal is used in a positive feedback loop to reset the photodiode, and thus a periodic output signal during one frame capture is produced. The pixel design is such that the pixel photocurrent changes the periodic digital output pulse characteristics. Figure 4.14 shows the different output signals that can be produced based on the two methods.

Figure 4.15 shows some of the different methods that can be used to create a match signal in the nonoscillatory approach. In Figure 4.15a, the reference signal is initially constant until the integration

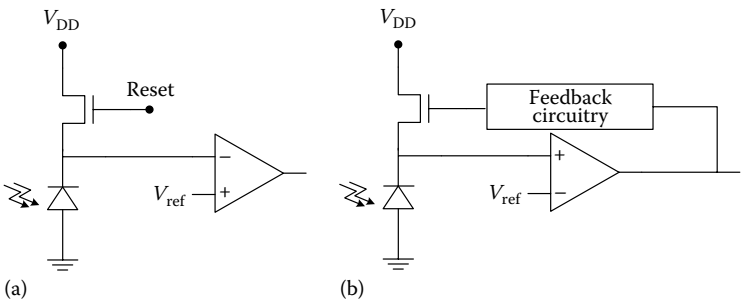

FIGURE 4.13 DPS pixel concept: (a) In-pixel circuitry for the oscillatory approach and (b) in-pixel circuitry for the nonoscillatory approach.

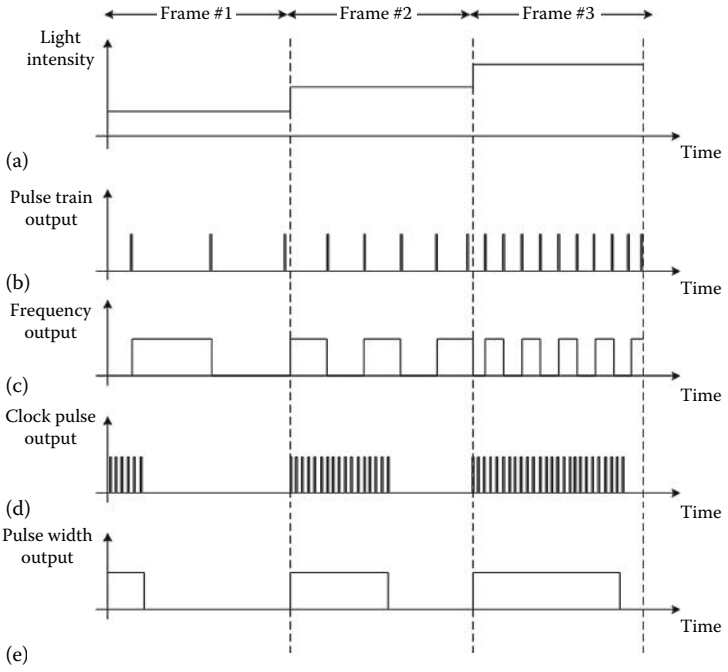

FIGURE 4.14 Different output waveforms that can be produced by the oscillatory and nonoscillatory methods. Waveform in (a) shows an arbitrary incident illumination in different frames. In each frame, the incident illumination is dependent on (b) the number of output spikes, (c) the frequency of the output pulse, (d) the number of clock pulses transferred to the output, and (e) the pulse width.

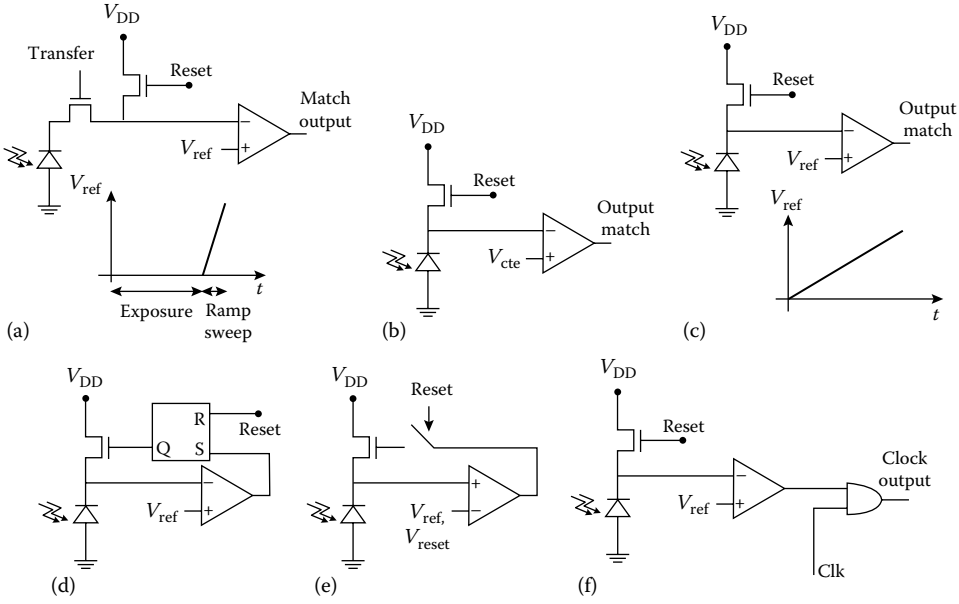

FIGURE 4.15 Different methods of the nonoscillatory approach: (a) Simple ramp sweep, (b) photodiode voltage sweep, (c) combined ramp sweep and photodiode voltage sweep, (d) reset latch method, (e) comparator offset voltage compensation method, (f) clock gating technique.

period is completed on all pixels. Then the reference signal is swept across the photodiode voltage output range using a ramp waveform. This method produces an output match signal where the pulse width is linearly proportional to the light intensity [22]. The drawback is that all pixels should have the same integration period, and hence the supported light dynamic range can be limited. In Figure 4.15b, the reference signal is kept constant, and the match signal pulse width is the time required for the descending photodiode voltage to reach the reference value. In fact, the photodiode ramp signal is used to produce the match output. Since the photodiode ramp signal steepness is dependent on the photocurrent, the output signal width will vary with the incident light intensity. In this method, the light dynamic range is relatively extended, but the pulse width is not linearly dependent on the photocurrent. The drawback of this method is that the conversion resolution is low for small photocurrents (since at low light intensities and illuminations, the ramp signal variation is small). The pixel structure of Figure 4.15c combines the two methods and uses both the photodiode ramp signal and a ramp signal on the reference voltage to increase the output signal resolution at low illumination levels. DPS structures with multislope ramp signals have also been presented to achieve both high dynamic range and desired resolution. In Figure 4.15d, a feedback is used to reset the photodiode as soon as the match signal occurs [23,24]. Due to the latching effect of the RS flip-flop feedback, this method does not produce any oscillations but will enhance the sensor's performance by preventing photodiode saturation and blooming (due to the photodiode entering forward bias and producing a negative potential on the photodiode output node) and also allowing more time for the reset switch to bring the photodiode node potential to its final value and preventing image lags. A major issue that needs to be considered in the design of DPS structures is the offset voltage of the comparator. The comparator can show substantial offset voltage specifically at submicron channel lengths. Since the comparator should be fitted inside each pixel, the use of small MOSFETs will give more space to the photodiode and hence increase fill factor. With small MOSFETs, however, random parametric variations and offset voltages are greater. The method used in Figure 4.15e to overcome this issue is to reset the photodiode to its precharge potential through a negative feedback loop which contains the comparator [25]. With this method, the comparator's offset voltage will be included in the reset potential, and the amount of time required for the photodiode to reach the reference voltage plus the offset value will be independent of the offset itself. As explained briefly, each method gives different dynamic range, complexity, fill factor, and power consumption. The comparison signal provided by this method can be used in a number of ways. One is to use this signal to store the corresponding time stamp in an in-pixel memory. The time stamp is provided by a global digital counter, and when the comparison signal occurs, the counter value is stored in the corresponding memory, producing a digital code per pixel. Other sensors use the comparison signal to generate an address event for the pixel readout [26]. The time stamp of the generated signal is a representation of the pixel value.

If the match signal is used to continuously reset the photodiode node, the oscillatory approach is achieved. In Figure 4.16a, a number of inverters are used in the feedback loop to produce some delay [27]. The delay gates provide enough time for the photodiode node to reach its final recharge value. In Figure 4.16b, a clocked delay is used for the same purpose. In the oscillatory approach, it is difficult to use a variable reference signal for the pixels since the resetting of the pixels are not synchronous and thus the ramp signals should be produced individually for each pixel; however, in [28], an in-pixel ramp generator has been presented to solve this issue and obtain an in-pixel pulse train converter with enhanced operation at low illumination levels. The pixel structure is shown in Figure 4.16c.

The sigma–delta approach uses constant charge packets to keep the photodiode potential oscillating around a constant voltage value [29]. The charge packets are transferred with a synchronous clock signal. The result is a constant pulse width signal where its repetition rate varies with the photocurrent. Since the photodiode potential continuously oscillates around a constant dc value, the structure is independent of the comparator offset properties. The pixel structure is illustrated in Figure 4.17.

Usually, in DPSs, a digital code is required for each pixel. As explained earlier, in the nonoscillatory approach where the match signal only changes once in each frame, in-pixel digital memories are used to store the time where the match signal changes state. The digital time stamp is provided by a binary

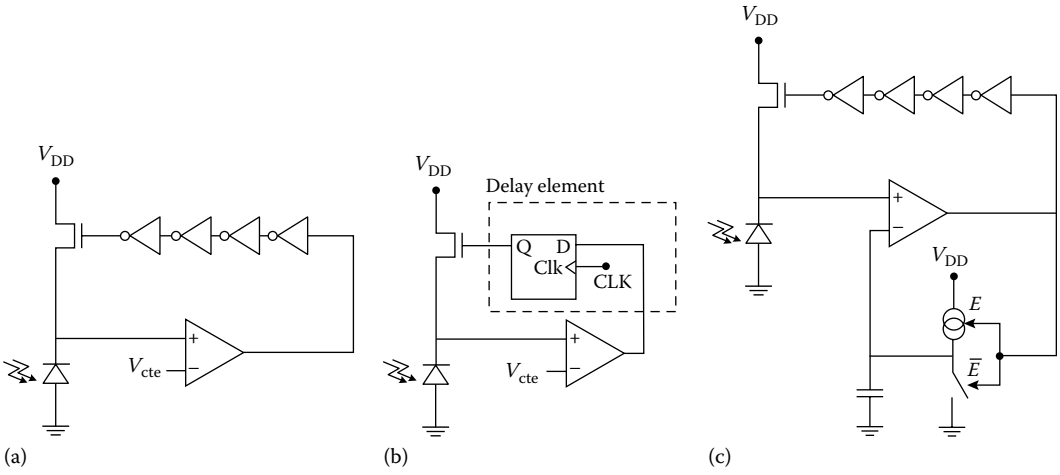

FIGURE 4.16 Different configurations of the oscillatory approach. As can be seen, all the structures contain a positive feedback loop that causes the oscillations: (a) Feedback loop with delay gates, (b) feedback loop with clocked delay, and (c) in-pixel ramp generator.

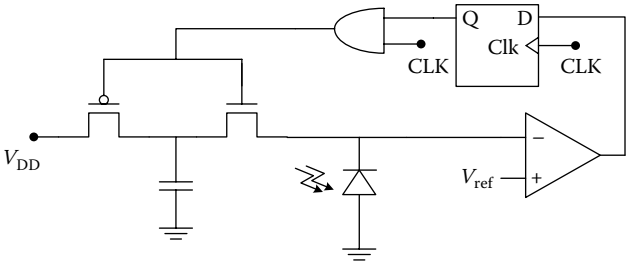

FIGURE 4.17 Sigma–delta approach and concept.

counter routed to all the pixels. Both dynamic and static memories can be used for this purpose. In event-driven sensors, the match signal is used to create an address event and the external sensor processor uses the time stamp where the event has been generated to store the digital value in an external memory. In large pixel counts, this method is less intuitive since the arbitration of several events at the same time is complicated. As will be explained later, the event-driven method is more effective in identifying pixels with value change compared with the previous frame since it can significantly reduce the data to be transferred to the output. In the oscillatory approach where the pixel match signal frequency is changed with the light intensity, in-pixel counters are used to produce the required digital code. Both binary counters [30] and linear feedback shift registers (LFSRs) [31] are used as in-pixel counters. LFSRs do not produce binary codes, but they need less silicon space.

The in-pixel conversion of analog data also benefits from the fact that each pixel can have an independent exposure period. This means that some pixels can be adjusted to accept low illumination levels while others are set for higher values; hence, a higher dynamic illumination range can be supported by the sensor. This is in contrast to an analog array pixel where the exposure time of all pixels should be adjusted simultaneously (i.e., high shutter speeds should be used for high illuminated environments and low shutter speeds at low illuminated conditions).

The main bottleneck for the DPS speed is the photocurrent random noise and the minimum time required for the photodiode to accumulate enough charge that is considerably higher than the charge produced by random and shot noise effects. PIN photodiodes produce less noise, but the current commercial high-speed sensor speeds are around a few 10 kfps. As the shutter speed decreases, more

illumination will be required to accumulate the required charge. Therefore, high-speed image sensors usually require a special illuminated environment. Ultrahigh sensitivity photoreceptors also exist that are able to acquire images at normal illuminations and low shutter exposure time, which will be discussed later.

4.4 Vision Sensors with Processing Power

With the possibility of designing pixels which include active devices, in situ image processing has also become an option.

If static power dissipation is avoided, analog processing circuits can significantly reduce power since analog processing circuits do not require an array of bits and are typically smaller with lower capacitance effect and thus lower dynamic power dissipation.

Image processing functions and machine vision tasks tend to be time consuming, process intensive, and diverse. CMOS image sensors have the power and ability to perform all or part of the required processing using active MOSFET devices. The processing can be on-chip, column parallel, or in-pixel. These types of image sensors with processing capabilities are known as vision chips. Vision chips are able to considerably increase the image processing speed and reduce power consumption. Since image processing and especially machine vision tasks are diverse, usually only fundamental and basic tasks are implemented in the sensor structure. Some of the common tasks implemented on vision sensors are image correction and enhancement functions, edge detection, optical flow extraction, change detection, kernel filtering, morphologic operations, and image compression. Figure 4.18 shows some of the fundamental image processing operations.

A number of general-purpose programmable vision sensors have also been presented, which can be configured to perform most of the basic and fundamental image processing tasks. In the following, some of the structures used in programmable vision sensors will be investigated.

The tasks usually supported by typical programmable vision sensors include kernel convolution for use in different types of common filters (Gaussian, Laplacian, Laplacian of Gaussian, and edge detectors), motion detection, and morphologic operations. Most of these tasks can be categorized and implemented in parallel using the cellular neural network (CNN) concept. These tasks are primarily used in all machine vision applications as the initial processing steps required to prepare the data for further classification, recognition, and decision-making steps. The initial steps have the properties of being performed in parallel and are thus ideal for in-pixel vision chip implementation to increase the processing speed. They can be easily implemented using a single instruction, multiple data architecture model where a single instruction is issued by the sensor for all of the pixels. The pixels then perform the same operation on their own and possibly neighbor data. This type of operation is usually referred to

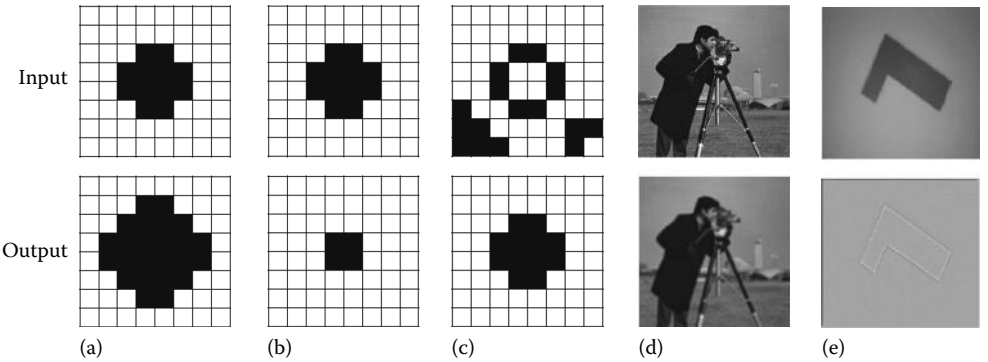

FIGURE 4.18 Fundamental image processing functions usually used in the initial steps of machine vision tasks: (a) Erosion, (b) dilation, (c) flood fill of center circle, (d) Gaussian filter, and (e) Laplacian filter.

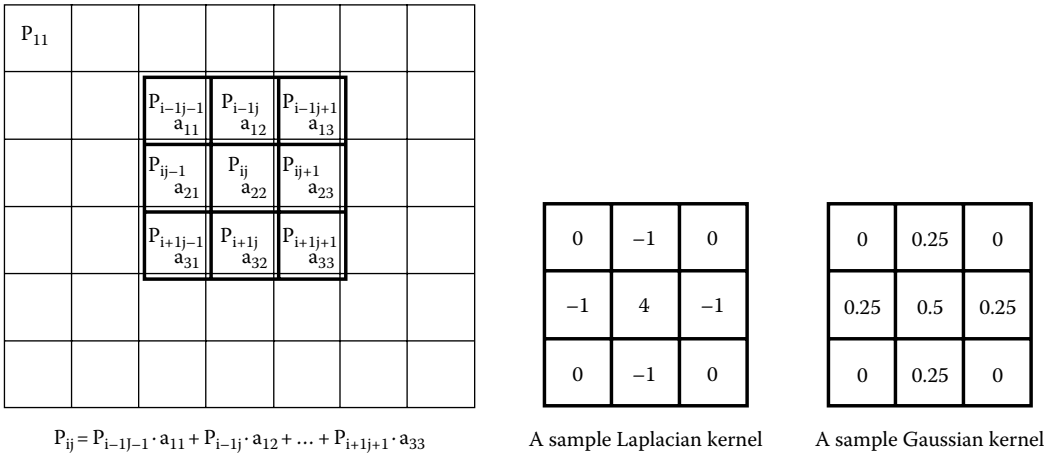

FIGURE 4.19 Kernel convolution process.

as pixel-based local functions. The final processing steps and specially object-based tasks might require sequential programming and are thus left to be performed out of the vision chip sensor. Although there have been dedicated sensors presented that even perform the final object processing step inside the chip with the aim of eliminating mass data output from the sensor, increasing speed, and reducing power consumption [32], such sensors usually have application-specific usages.

The kernel convolution procedure involves the weight sum of each pixel and its neighbors at a specific distance (usually nearest neighbors). The task is performed by multiplication and summation of the 2D matrix known as the kernel on each of the image pixels and its neighbors as shown in Figure 4.19. Edge detection involves extraction of pixel sites where high special intensity change exists in the image. This procedure can be accomplished by calculating the sum of absolute differences of each pixel with its neighbors or using an appropriate kernel convolution sequences like Laplacian of Gaussian. Motion detection is the extraction of pixels with temporal intensity change.

CNN operations refer to tasks that involve the calculation of a result for each image pixel value by considering a function (usually sum, multiplication, and hard limiter) of the pixel value itself, the pixel value of the neighbors, the state of the pixel itself in the previous frame(s), and the state of the neighbor pixel in the previous state. This definition, in general, forms the CNN operations that can accomplish all of the aforementioned procedures. Furthermore, it is possible to perform morphologic operations using multiple iteration executions of a CNN operation on one image capture. Morphologic operators are also fundamental building blocks of machine vision algorithms in the initial step. Examples of such operation include erosion, dilation, region fill, and others. For example, in the fill operation, a desired region is highlighted until the region edges are reached. In this way, a specific object can be separated from the rest of the image. CNN operations need more hardware since the result from the previous states should be stored if the result of previous iterations is required.

Different structures can be used in programmable vision chips. They can be categorized as follows: vision sensors with 1 bit image processing power where the image is initially binarized and all subsequent tasks are performed with single-bit in-pixel digital logic circuits [34]. With the second category, the image data are converted to digital code, and subsequent processing is performed using multibit in-pixel processing circuitry [34–38]. In the third category, digital processing is performed on bio-inspired pulse trains [39,40]. In these types of sensors, a parallel data bus that stores the digital intensity value of the pixel does not exist; instead, the pixel intensity value is represented by a single-bit digital data line using pulse trains. The processing of data is also performed in the pulse train domain by eliminating or adding extra pulses. Figure 4.20 shows a conceptual illustration of the pulse train processing element.

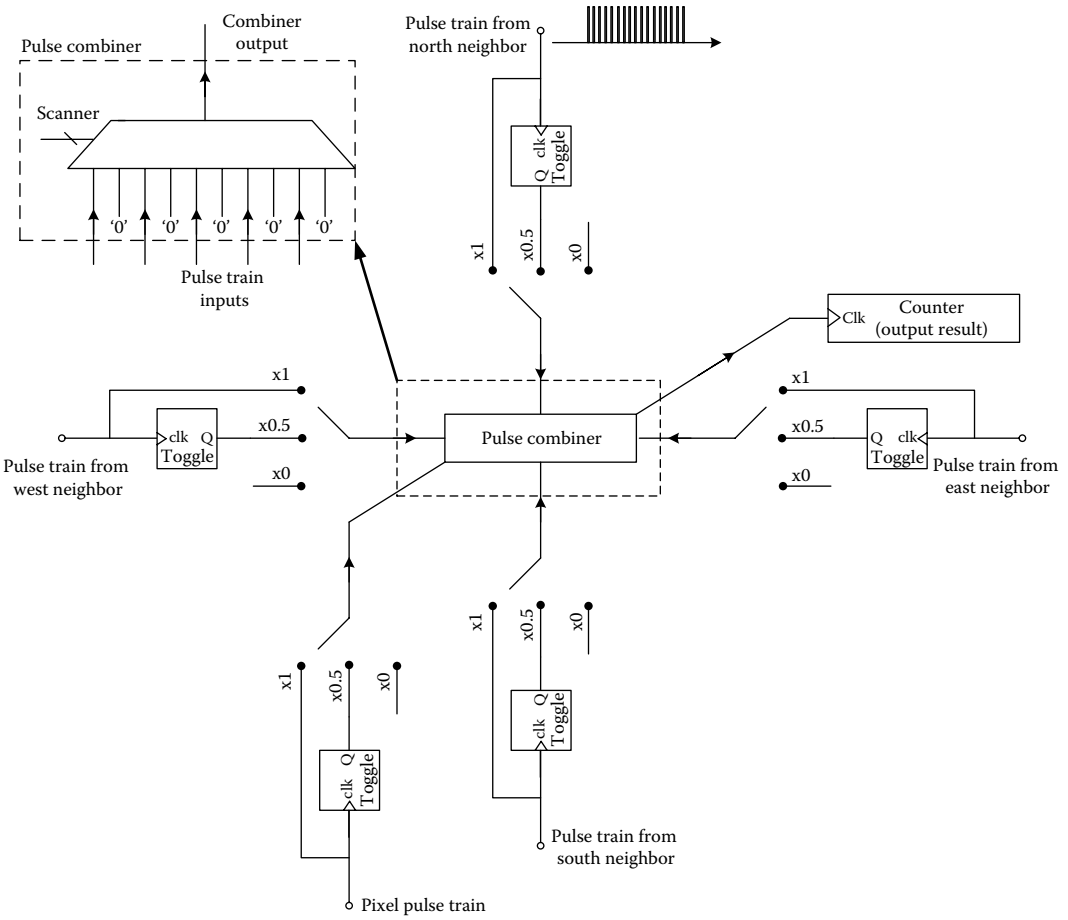

FIGURE 4.20 In-pixel pulse train processing element concept.

In the simple structure, three different coefficients can be applied to each of the pulse train signals, namely, 0, 0.5, and 1. The final pulse signals are added using a combiner that scans the different inputs.

The in-pixel pulse train itself is produced by the circuits presented in the DPS section. This type of processing is more appropriate for use in kernel convolution and is not suitable for CNN tasks since the storage of the previous state is not feasible on pulse trains. The fourth category performs the required processing on analog photodiode data directly [41–43]. Different mixed signal circuits can be used in this case and several options are incorporated: Figure 4.21 shows the voltage processing technique where switch capacitor circuits perform summation [42]. For multiplication, the capacitor weight is adjusted either by using digital code or by repeating the addition step.

Figure 4.22 shows the current processing approach [43]. In this method, addition is performed by current mirrors and current summation in a common node. Multiplication is achieved using multiple addition steps or by adjusting the current mirror ratio by a digital code weight. In this case, special current memories are required to store the current value of previous states. The SCAMP3 programmable image processor is based on this type of architecture.

Figure 4.23 shows the SCAMP-3 commercial product and its associated software for programming the configurable vision chip.

In some designs, differential pairs are used as multipliers where the photocurrent is used as the tail current source and the coefficients are applied as the differential inputs using analog voltage levels stored on floating gate devices. The basic concept is illustrated in Figure 4.24.

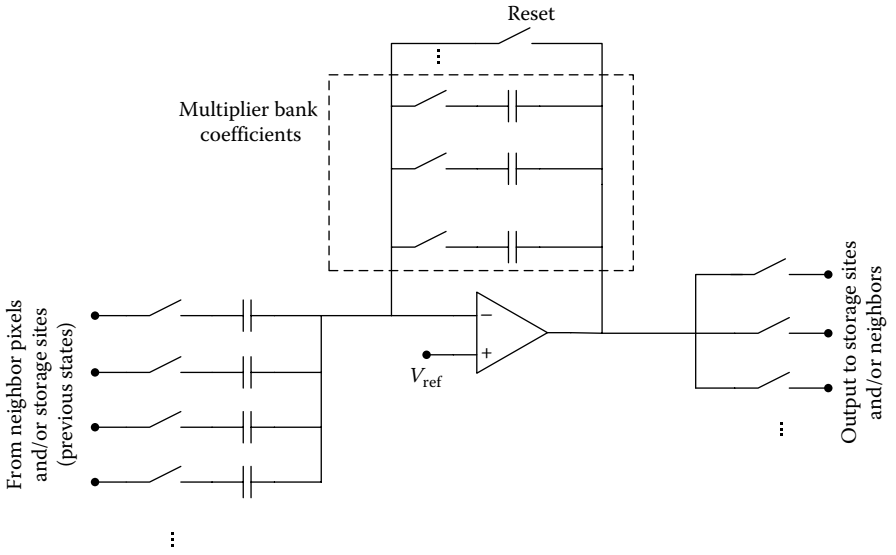

FIGURE 4.21 Voltage processing approach for programmable vision chip.

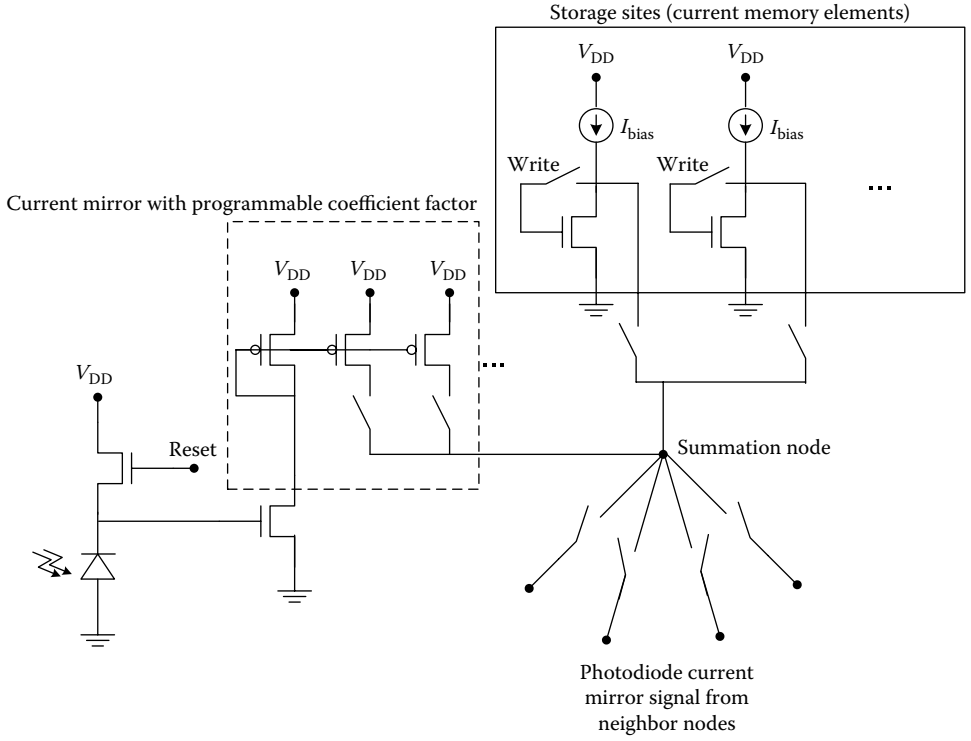

FIGURE 4.22 Current processing approach for programmable vision chip.

For the on-chip and column parallel cases, digital processing circuits are more appropriate since the larger size of the processing circuitry (especially at higher bit counts) does not sacrifice the pixel fill factor.

In-pixel digital processing circuitry is advantageous compared with on-chip digital processors for two main reasons: first, the processing speed can be increased significantly and second, the dynamic

FIGURE 4.23 SCAMP-3 programmable vision chip.

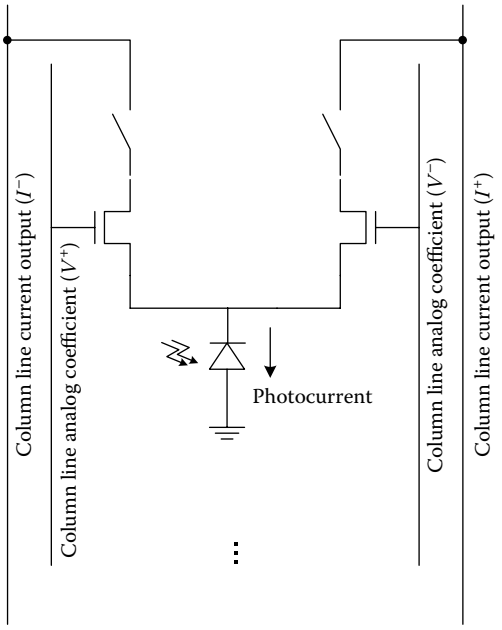

FIGURE 4.24 Current multiplier concept.

power dissipation can be considerably reduced. The reduction of dynamic power is because with multiple in-pixel digital processors, the clock pulse frequency can be reduced. To this point and with a constant processing speed, no advantage will be gained since although the clock frequency is reduced, the number of processors and capacitance effect has increased ($P_{diss} = f \cdot C_L \cdot V_{DD}^2$). But the point is that slower digital processing circuits can be operated with lower supply voltage. Subsequently, with a lower clock frequency, the supply voltage can be reduced, resulting in overall lower-power dissipation.

The problem of low photodiode fill factor due to digital circuits is getting less important with submicron devices. The photodiode cannot be decreased in size since random noise effects will increase, however, the digital circuit area can be decreased in sub micron devices which results in higher fill factors.

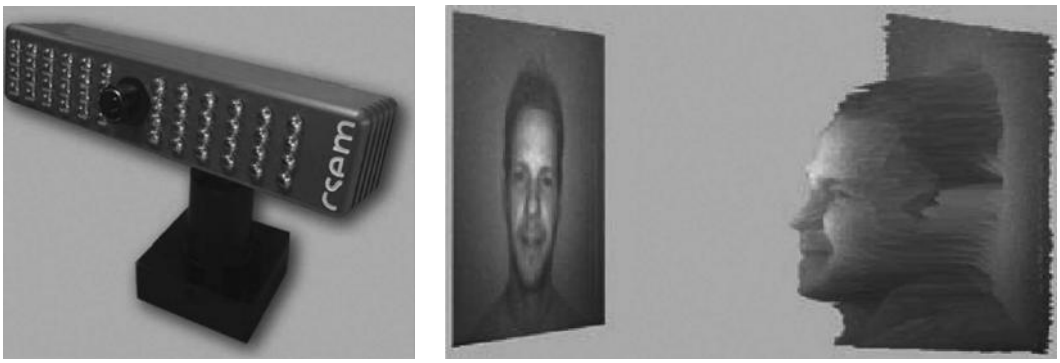

FIGURE 4.25 Swissranger 3D range image sensor.

4.5 Final Remarks

Currently, CMOS image sensors are undergoing extensive progress, and each year, many new enhancements and advances are achieved in sensitivity, resolution, frame rate, dynamic range, processing power, etc. In this chapter, some of the important image sensors that are currently being incorporated in practical applications were presented; still, there are many other image sensors continuously developed for specific tasks. An important image sensor that needs to be addressed here is the correlation image sensor. These sensors are able to route the photocharge to different storage sites. If different weights are considered for the voltages stored at the storage sites, the procedure can be equivalent to multiplication and integration (namely, correlation) of the photocurrent by a reference signal. This procedure can be significantly effective for tasks such as measurement of the phase delay of a transmitted illumination source and the reflected light and thus the detection of object distance and finally extraction of range image. For range image extraction, high-frequency correlation is required, and thus CMOS/CCD process is more appropriate [44]. Figure 4.25 shows a 3D range imager from Swissranger.

The correlation procedure is also effective in identifying and separating modulated beacons and electronic light tags from the rest of the scene [45,46]. Compression image sensors are another field where image sensors are experiencing development [47]. Since the compression is time consuming and also a good candidate for parallel processing, it is suitable for in-pixel vision chip implementation with low-power and high-speed features. Image sensors with power delivery capabilities [48,49] are also of certain interest. They are specifically important in applications with limited energy resources such as insect robots, miniaturized unmanned flying vehicles (UFVs), and prosthesis sensors. Ultrahigh sensitive sensors, another important field in imager design, are used in high-speed imagers, night vision, and 3D image captures [50,51]. Currently, research still continues on enhancement of different image sensors and further developments should be expected in both the sensors' specifications and designs.

Principles and Technology of SQUIDs

Robert L. Fagaly
Quasar Federal Systems

Superconducting quantum interference devices (SQUIDs) have been a key factor in the development and commercialization of ultrasensitive electric and magnetic measurement systems. In many cases, SQUID instrumentation offers the ability to make measurements where no other methodology is possible. In addition to measuring magnetic fields, SQUID sensors can be configured to measure a wide variety of electromagnetic properties.

Because of their superconducting nature, SQUID sensors operate at cryogenic temperatures. Although SQUID electronics have the capability to operate well above 1 MHz, most applications tend to be at lower frequencies. Most commercial SQUID systems utilize the SQUID sensor as a current-to-voltage amplifier, often connected to a separate detection coil for detection of magnetic fields. The ability of a SQUID sensor to measure changes in magnetic fields and currents is based on four effects: superconductivity, the Meissner effect, flux quantization, and the Josephson effect.

5.1 Superconductivity

At temperatures approaching absolute zero, certain materials undergo a transition to what is known as the superconducting state. In 1911, Kamerlingh-Onnes [1] discovered that the resistance of mercury when cooled below 4.2 K dropped to an immeasurably small resistance. This transition from normal resistance to resistanceless behavior takes place over a narrow temperature range—about 0.001 K for pure, strain-free metals and a degree or more for alloys and ceramics. Below this temperature, known as the transition temperature (T_c), the material is characterized by a complete lack of electrical resistance.

Subsequent investigations indicated that a large number of materials undergo a similar superconducting transition. In 1986, Bednorz and Müller [2] discovered a new class of ceramic oxides that became

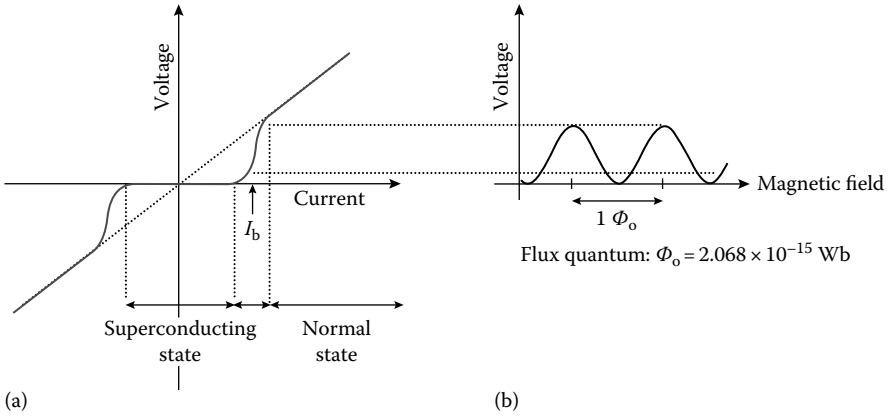

FIGURE 5.1 (a) Bias point (I_b) for the Josephson junction and (b) voltage vs. external flux at constant bias current.

superconducting near 30 K—significantly warmer than any previously known superconductor. Since then, materials have been developed with the superconducting transition temperatures above 130 K, well above the boiling point of liquid nitrogen. $YBa_2Cu_3O_{7-\delta}$, often referred to as YBCO, with $T_c > 90$ K is the most commonly used superconducting ceramic oxide. To distinguish between the types of materials used in making SQUID sensors, we denote the (primarily) metallic superconductors that typically operate at liquid helium temperatures (4.2 K) as low-temperature superconductors (LTSs) and the (primarily ceramic oxide) materials that can operate at liquid nitrogen temperatures (77 K) as high-temperature superconductors (HTSs), although some (e.g., MgB_2) have T_c's around 40 K.

Another property of superconductors—referred to as the Meissner [3] effect—is that they do not allow any magnetic field to penetrate into them (beyond a very thin surface layer known as the skin depth). To prevent magnetic fields from penetrating, a current is induced (via Lenz's law) that opposes any external magnetic field or field changes. A third property is that if a superconducting ring is constructed, one cannot change the level of magnetic field in the ring in a continuous manner. Instead, the magnetic field is quantized in multiples of flux quanta (Φ_o) whose magnitude is 2.068×10^{-15} Wb ($T \cdot m^2$). That is, for a ring with an area of 1 cm^2, the interior magnetic field can only exist in discrete steps of 2.068×10^{-11} T. In the situation where two superconducting (resistanceless) regions are separated by a normal (resistive) region, the Josephson effect [4] permits current (paired electrons) to tunnel through the barrier without any resistance (Figure 5.1a). Above a critical current, characteristic of the junction, the junction behaves like a normal resistor, following Ohm's law.

5.2 Superconducting Quantum Interference Devices (SQUID)

These effects have been used to fabricate a superconducting amplifier. This device known as a SQUID acts as a magnetic flux-to-voltage amplifier. The addition of an input coil allows current to be transformed into a magnetic flux that is inductively coupled into the SQUID loop, transforming the SQUID into a current-to-voltage amplifier.

The SQUID loop is connected to circuitry for detecting changes in the flux penetrating the loop. SQUIDs are operated as either radio-frequency (rf) or direct current (dc) SQUID. The dc SQUID differs from the rf SQUID in the manner of biasing the Josephson junction and the number of junctions. The prefix rf or dc refers to whether the Josephson junction(s) is biased with an rf alternating current (ac) or dc. In the former case, flux changes are detected by a resonant tank circuit that is inductively coupled to the SQUID loop (the rf SQUID). In the latter, the SQUID loop contains two Josephson junctions (Figure 5.2) and a dc is applied (the dc SQUID). Flux changes are detected by monitoring the voltage across the junctions.

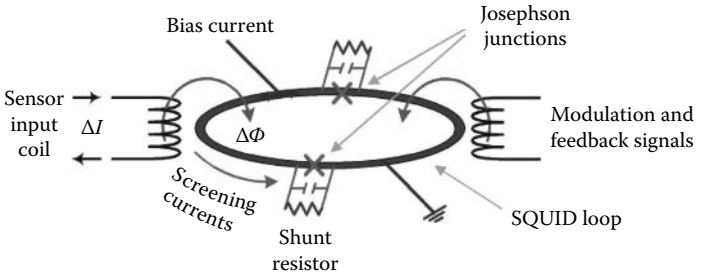

FIGURE 5.2 Dual junction (dc) SQUID loop. The capacitor represents the self-capacitance of the junction.

Since rf SQUID noise is proportional to the square root of the bias frequency (initially 19 MHz), energy sensitivities (E_N) were on the order of 10^{-28} J/√Hz. The major limiting factor in the noise of an rf SQUID is the bias frequency (f_B) used to excite the tank circuit with rf SQUID noise proportional to $1/\sqrt{f_B}$. As f_B increases, the complexity of the electronics also tends to increase.

The minimum noise energy for a dc SQUID is given by [5]

$$E_N \approx 4k_B T\sqrt{\pi L_{loop} C} \tag{5.1}$$

where

k_B is Boltzmann's constant
T is the temperature of the SQUID
L_{loop} is the inductance of the SQUID loop
C is the self-capacitance of the junction

Substituting appropriate numbers indicates that the minimum E_N for a dc SQUID is on the order of $h/2$ and devices with these sensitivities have been constructed [6]. Most commercial dc SQUIDs have $E_N \approx 5 \times 10^{-31}$ J/√Hz. Configured as an ammeter, this translates to pA/√Hz current sensitivities.

From a historical viewpoint, although the dc SQUID was the first type of SQUID magnetometer made, the early development was with rf SQUIDs. The rf SQUID had the advantage of needing only a single point-contact Josephson junction that was essentially handmade. With modern thin film fabrication techniques that allow the fabrication of SQUID devices with two Josephson junctions having identical weak link characteristics, dc SQUIDs have come to dominate the commercial landscape. Additional information on rf SQUIDs can be found in Ref. [7].

External currents are transformed into a magnetic flux and inductively coupled flux into the dc SQUID loop via an input coil. A dc equal to twice the critical current (I_c) of the junction is used to bias the SQUID at an operating point where the junctions are midway between resistanceless and resistive behavior (Figure 5.1a).

Shunt resistors are used to prevent hysteretic behaviors in the I–V curve [5]. Inductively coupling magnetic flux into the SQUID loop creates screening currents ($I_{loop} = \Phi_{loop}/L_{loop}$) that will effectively increase or decrease I_c, depending on the direction of the induced flux. A change in the magnetic flux applied through the SQUID loop induces a wave function phase change that enhances the current through one Josephson junction and reduces the current through the other. This asymmetry, which is periodic in Φ_o, is used to provide a feedback current that nulls the flux penetrating the SQUID loop. The voltage generated by the bias current (across the shunt resistors) is used to monitor the effect of any externally coupled signals. Negative feedback (inductively coupled) allows detection of changes in flux penetrating the SQUID loop to better than $10^{-6}\ \Phi_o$.

The system output voltage is the voltage drop across the feedback resistor in a negative feedback loop controlled by the SQUID electronics (Figure 5.3). The feedback signal is generated in response

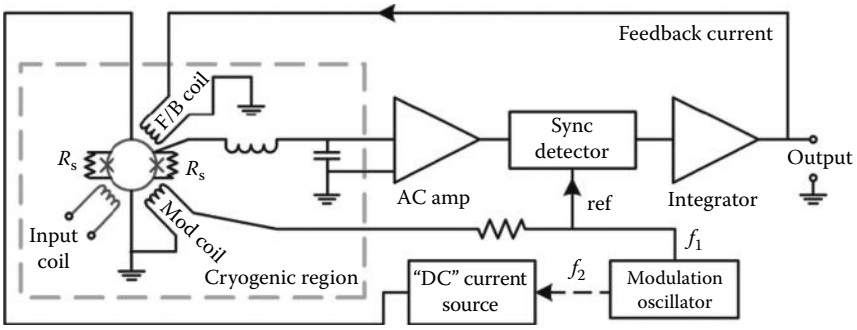

FIGURE 5.3 Schematic of dc SQUID sensor and electronics.

to changes in the output signal of the SQUID sensor. The output of the SQUID sensor is periodic in the field coupled into the SQUID loop (Figure 5.1b). Negative feedback (similar to a phase-locked loop technique) is used to maintain the system operating point at a particular (and arbitrary) flux quantum. When operated in this mode, the system is in a flux-locked loop. The transfer function (V–Φ) for rf SQUIDs differs from the dc SQUID in that—rather than sinusoidal—it has a triangular shape (similar to Figure 5.5b). References [8–10] give a more detailed explanation of the principles of SQUID sensors and the underlying concepts behind the Josephson effect along with qualitative descriptions of the operating principles of SQUID sensors and the properties of materials used to fabricate SQUID sensors.

One important factor of SQUID design is such that the feedback electronics is able to follow changes in the shielding currents. If the shielding current changes so fast that the flux in SQUID loops changes by more than one-half a flux quantum, it is possible that the feedback electronics will lag behind the rapidly changing flux. When the electronics finally "catch up," they can lock on an operating point (Figure 5.1b) different from the original. In this case, the SQUID has "lost lock" because the SQUID has exceeded the maximum slew rate of the electronics. Typical slew rates for SQUIDs are in the range of 10^5–10^6 Φ_o/s. The ability to have multiple slew rates is a convenience that allows for greater rejection of noise (due to a narrower bandwidth of the feedback electronics) for signals that are slowly varying.

Most LTS dc SQUID sensors are configured with an integrated input coil (Figure 5.3) whose input impedance is purely superconducting and can be characterized as an inductance, $L_{input} \sim 1$ μH. This allows the SQUID sensor to act as an ammeter with pA/√Hz sensitivities. Connecting a sensing coil to the SQUID sensor allows it to act as a magnetometer (cf. Section 14.2). Because of the inability to make superconducting HTS joints, HTS SQUID sensors are configured as pure magnetometers using just the Josephson loop as the magnetic sensing area or an inductively coupled input coil that acts as a magnetometer.

5.2.1 Sensitivity

SQUID noise is often presented as the spectral density of the equivalent flux noise $S_\Phi(f)$ as a function of frequency or noise energy per unit bandwidth $E_N(f) = S_\Phi(f)/2L_{input}$ where Φ_N is the flux noise of the Josephson device. To allow devices with differing input inductances to be directly compared, the sensitivity of SQUID devices is best discussed in terms of the energy sensitivity:

$$E_N = \frac{1}{2} L_{input} I_N^2 = \frac{\Phi_N^2}{2L_{input}} \tag{5.2}$$

where I_N is the current noise of the sensor. Because HTS SQUIDs are either pure magnetometers or planar gradiometers, their sensitivities are noted in either field (T/√Hz) or field gradient (T/m · √Hz) values.

There also exists a low-frequency contribution (which typically has a 1/*f* energy spectrum) to the frequency-independent (white) system noise. Note that this low-frequency noise is roughly the same for all types of SQUID sensors (rf vs. dc, thin film vs. point contact, etc.) and is thought to be due to a fundamental noise contribution that is inherent in SQUID sensors.

A substantial contribution to this noise in some dc SQUIDs can arise from the presence of the dc bias. By chopping the dc bias (f_2 in Figure 5.3) in combination with the conventional flux modulation techniques, it is possible to reduce this added 1/*f* noise. This double-modulation approach [11] separates the original signal waveform from the noise associated with the dc bias and is responsible for decreased 1/*f* noise at very low frequencies. While not normally used with LTS SQUIDs (which tend to have 1/*f* knees below 1 Hz), ac biasing is needed for HTS SQUIDs where the 1/*f* knee is well above 100 Hz.

In addition, the relative amount of 1/*f* noise can be dependent on the ambient magnetic field when the SQUID sensor is cooled. When cooled in the Earth's magnetic field (~50 μT), the point at which the 1/*f* noise equals the white (frequency-independent) noise is typically 1–3 Hz. Cooling the SQUID sensor in low ambient magnetic fields (less than 1 μT) may improve the 1/*f* performance by as much as an order of magnitude.

Normally, SQUID electronics utilize an internal feedback technique (Figure 5.3) to cancel changes in magnetic flux. An alternative approach to feedback may be made by coupling the feedback signal to the input coil (Figure 5.4) rather than to the Josephson loop. This can avoid large feedback currents (e.g., due to 50 or 60 Hz) that could exceed I_c for the Josephson junction(s). A second method uses an externally generated signal in addition to the SQUID feedback electronics. One example is a circuit to compensate for an external ac field being applied near the detection coil(s) in a susceptibility experiment.

Several factors are responsible for the excellent performance of SQUID systems including the following:

1. The SQUID operates at a very low temperature minimizing Nyquist noise.
2. In most applications, the detection circuit is superconducting and thus contributes no additional noise.
3. The periodic nature of SQUID devices, due to flux quantization, is responsible for their superb linearity.
4. Because a superconducting circuit has zero resistance and, consequently, the current induced in the sense coil does not decay in time, the frequency response of superconducting circuits can extend down to dc.
5. SQUID sensors offer flat frequency and phase response. This can allow for seamless integration of data from multiple sensors.

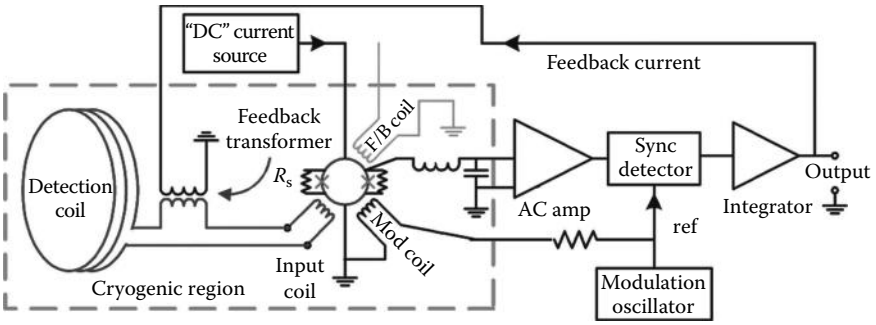

FIGURE 5.4 External feedback circuit. Note that the internal feedback circuitry shown in (Figure 5.3) is not used.

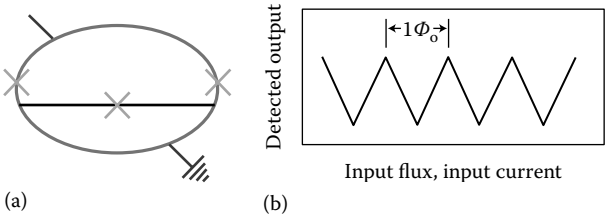

FIGURE 5.5 (a) Schematic of bi-SQUID (shunt resistors not shown) and (b) transfer function (V–Φ).

5.2.2 Bi-SQUID

The standard dc SQUID (Figure 5.2) can be modified by adding a nonlinear inductance, in the form of a third Josephson (Figure 5.5a) junction [12]. This third junction, when combined with the main inductance in the loop, acts as a single-junction SQUID yielding a device (known as a bi-SQUID) that has a triangular V–Φ transfer function (Figure 5.5b) with significantly improved linearity.

5.2.3 Superconducting Quantum Interference Filters

An array of different superconducting loop sizes, in-series or in-parallel configuration or in a 2-D combination of both, acting as grating structures, can be used to form a superconducting quantum interference filter (SQIF) [13]. This type of interferometer is based on the phase-dependent superposition of currents flowing through a nonperiodic multiloop network (series, parallel, or series–parallel as in Figure 5.6a) of Josephson junctions, where the loop areas (A_{ij}) are designed to be nonidentical. The effect of such an arrangement is that the contributions of the loops to the output signal mutually cancel each other for any finite value of the ambient magnetic field. For zero magnetic fields a mutual enhancement occurs by means of the coherent superposition yielding a unique dip at zero field. In contrast to conventional SQUIDs, the characteristic flux dependence of the voltage output (V–Φ) of a SQIF is nonperiodic (Figure 5.6b).

The unique dip in the V–Φ curve allows for the absolute field magnetometry [14] and high-precision rf applications like amplifiers and mixers [15]. The sensitivity [16] and dynamic range of an SQIF scale proportionally to the square root of the number of loops ($N \times M$) in the array. With even a moderate number of loops, this can allow absolute field measurements to be made at sensitivities approaching a few fT/√Hz. Another advantage of SQIFs is that the Josephson junction parameters need not be well matched, making fabrication of SQIF devices from HTS materials significantly easier. SQIFs also have the ability to operate at frequencies above 20 GHz.

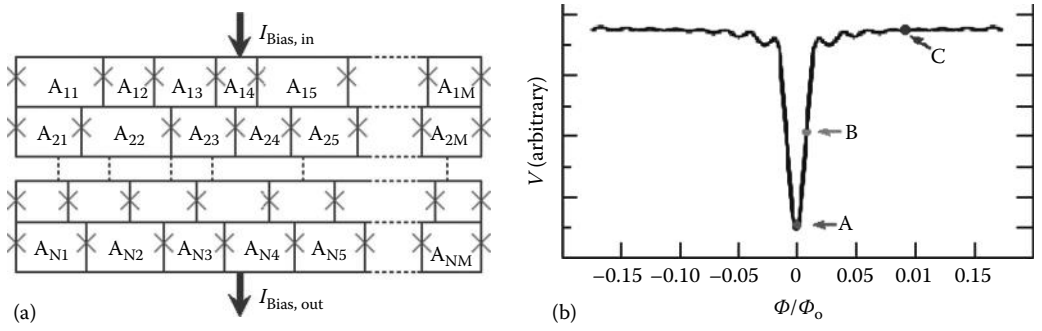

FIGURE 5.6 (a) Schematic of a 2-D (N series by M parallel elements) SQIF array (A_{ij} is the area of the ijth Josephson loop) and (b) SQIF transfer function [(A) mixing mode (V–Φ very nonlinear), (B) detection mode (V–Φ is "linear"), (C) not useful ($dV/d\Phi$ very small)].

5.3 Cryogenic Requirements

The superconducting nature of SQUIDs requires them to operate well below their superconducting transition temperature (9.3 K for niobium and 93 K for $YBa_2Cu_3O_{7-\delta}$). Ideally, the cryogenic environment should provide stable cooling, have no time-varying magnetic signature, be reasonably compact and reliable, and, if mechanical in nature, introduce neither mechanical vibration nor a magnetic signature into the detection system. The thermal environment for the SQUID sensor and detection coil has typically been liquid helium or liquid nitrogen contained in a vacuum-insulated vessel known as a dewar.

As an alternative to the use of liquid cryogens, closed cycle refrigeration [17] can be desirable for several reasons. These include reduction of operating costs, use in remote locations, operations in nonvertical orientations, avoiding interruptions in cryogen deliveries, safety, and the convenience of not having to transfer every few days. Parameters governing suitability include physical size, absence of periodic replacement of cryogenic fluid, and most importantly vibration and magnetic signature. There are two main obstacles to using closed cycle refrigeration with SQUIDs. The first is the mechanical movement that (ultimately) causes the detection coils to move in the Earth's magnetic field. The second is the magnetic signature due to the moving parts of the cryocooler's cold head and compressor. Moving the compressor far away will reduce its relative signature.

If the experiment involves measurements interior to the dewar (*cf.* Figure 5.10), then a metallic dewar is preferable. Metallic dewars offer significant shielding from environmental noise at frequencies above 10–100 Hz. If the system is to measure magnetic fields exterior to the dewar, the dewar must be magnetically transparent and metallic construction is not appropriate. Dewars for external field measurements (e.g., geophysical or biomagnetic) are normally constructed of nonmetallic, low-susceptibility materials to minimize their magnetic interactions with the SQUID sensors and detection coils. Materials used are typically glass-fiber–epoxy composites such as G-10.

5.3.1 Limitations on SQUID Technology

SQUIDs offer the ability to measure at sensitivities unachievable by other magnetic sensing methodologies. However, their sensitivity requires proper attention to cryogenics and environmental noise. This applies not just to laboratory applications but also to every potential use of SQUID sensors. When utilizing SQUID-based measurement systems and data reduction algorithms, it is important to bear in mind several fundamental limitations:

5.3.1.1 Differential Measurements

SQUIDs are sensitive to relative (field or current) changes only. This is a consequence of the fact that the output voltage of a SQUID is a periodic function (Figure 5.1b or 5.5b) of the flux penetrating the SQUID loop. The SQUID is "flux-locked" on an arbitrary point on the V–Φ curve, and the SQUID output is sensitive to flux changes relative to this lock point. If absolute field measurements are required, then a SQIF device should be used.

5.3.1.2 Slew Rate Limitations

If the signal changes faster than the feedback electronics can follow (i.e., the slew rate is exceeded) and the total signal change exceeds 1/2 Φ_o, it is possible for the operating point to shift by one or more flux quanta (Figure 5.1b). If high bandwidths are needed, it is possible to operate the electronics in a limited range mode where the raw output is amplified without use of a feedback signal. Although the SQUID has an intrinsic bandwidth of several GHz, when operated with standard flux-locked loop electronics using ac flux modulation, the maximum usable bandwidth of most commercially available electronics is typically 50–100 kHz.

In reality, the electronics may need to track multiple frequencies, placing further limitations on achievable slew rates. Actual slew rate values tend to be much less than the theoretical (or advertised) values (which are usually based on a single sine wave) due to the multispectral nature of most signal and noise sources.

5.3.1.3 1/*f* Noise

Another limitation is the presence of 1/*f* noise. The use of ac biasing [11] in HTS SQUIDs limits their maximum bandwidth to less than half the bias reversal frequency. If the bias reversal frequency is too high, noise can be induced due to voltage spikes in the transformer-coupled preamplifier input circuit. Because of this, the maximum bandwidth of commercially available HTS SQUIDs is usually limited to ~50 kHz. If MHz bandwidths are required, the ac bias is not used; however, there will be excess (i.e., 1/*f*) noise below 1 kHz.

5.3.1.4 HTS Limitations

A significant difference between LTS and HTS materials is that LTS materials (e.g., NbTi) are ductile and—in wire form—can be made into complex 3-D structures such as axial gradiometers with extremely small bend radii. Additionally, using NbTi (or Nb_3Sn) allows detection coils to be in high-field regions (>9 T), while the actual LTS SQUID sensor can be placed in a low-field environment. Because of the inability to make a truly superconducting flexible 3-D structure, axial HTS gradiometers are not possible, although thin-film planar gradiometers are. Even if it was possible to make a separate HTS coil, the inability to make HTS superconducting joints (or joints with contact resistances at the sub-pΩ level) due to the shorter coherence length of HTS materials prevents true dc response in discrete element HTS circuits [18] (i.e., the in-series resistance acts as a low-frequency high-pass filter). It also prevents the ability to have detection coils remote from the SQUID sensor. The only way to couple flux between two HTS circuits (and maintain their superconducting nature) is to inductively couple them. Reference [19] gives an excellent overview of electrical contact issues in superconductors.

5.3.1.5 Vector Nature of SQUID Magnetometers

SQUID magnetometers are vector magnetometers. For a pure magnetometer operating in the Earth's magnetic field (~50 μT), a 180° rotation can sweep out a total field change of up to 100 μT. If the magnetometer has a sensitivity of 10 fT/√Hz, tracking the total field change requires a dynamic range of 100 μT/10 fT = 200 dB, well beyond the capabilities of current electronics. In addition, the rotational speed must not cause the current flowing through the SQUID sensor to exceed its slew rate limitations. Pure gradiometers would be insensitive to uniform fields and not suffer this dynamic range limitation. In reality, gradiometers are not perfect and have some magnetometer component that can place motion restrictions even on well-balanced gradiometers. If it is necessary to measure absolute fields, then a SQIF device should be used.

5.4 Applications

A simple SQUID system (Figure 5.7) consists of room temperature electronics and a low-temperature probe containing the SQUID sensor, configured with an integrated input coil to measure changes in current. Connecting the input coil to a detection coil allows measurement of magnetic fields. The low-temperature environment is necessary due to the requirement that the SQUID sensor be below its critical temperature.

Whether an rf or dc SQUID, we can consider a SQUID system as a black box that acts like a current-to-voltage amplifier with extremely high gain. In addition, it offers extremely low noise,

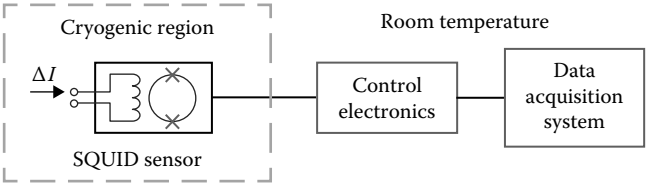

FIGURE 5.7 Schematic diagram of typical SQUID input circuit configured as an ammeter.

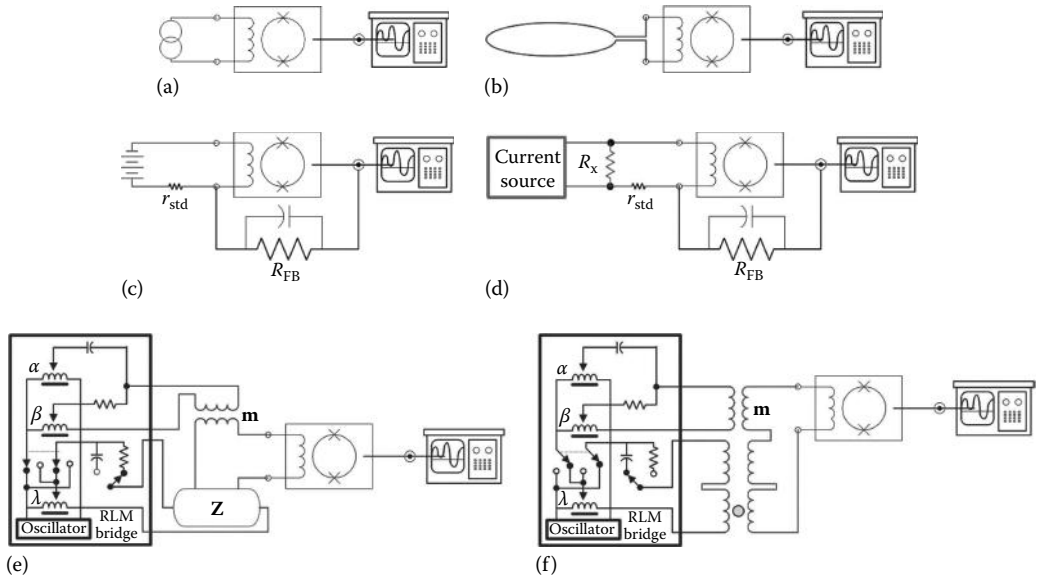

FIGURE 5.8 (a) AC and dc, (b) magnetic field, (c) dc voltage, (d) dc resistance, (e) ac resistance/inductance bridge, and (f) ac mutual inductance (susceptibility bridge).

TABLE 5.1 Typical Sensitivities of SQUID Instruments

Measurement	Sensitivity
Current (Figure 5.8a)	10^{-12} A/√Hz
Magnetic fields (Figure 5.8b)	10^{-15} T/√Hz
DC voltage (Figure 5.8c)	10^{-14} V
DC resistance (Figure 5.8d)	10^{-12} Ω
Mutual/self-inductance (Figure 5.8e)	10^{-12} H
Magnetic moment (Figure 5.8f)	10^{-10} emu

high dynamic range, excellent linearity, and a wide bandwidth that can extend down to dc. A typical SQUID system can provide a transfer function in excess of 10^7 V/A with an input sensitivity better than 1 pA/Hz. Linearities can exceed 1 part in 10^7 and bandwidths typically extend from dc to hundreds of kHz. Specialized SQUID systems have been made to operate with bandwidths extending to 10 MHz.

SQUIDs can also be configured to measure a wide variety of electromagnetic properties (Figure 5.8). As mentioned earlier, there is no method for making true superconducting connections to SQUIDs with HTS wire. As a result, commercially available HTS devices are currently in the form of magnetic sensing rather than current sensing devices.

Table 5.1 shows typical capabilities of SQUID-based instruments. Additional information on laboratory applications of SQUID systems can be found in Refs. [7,8,20,21].

5.4.1 Current Measurements

One common use of a SQUID is as an ammeter (Figure 5.8a). The input can be connected to an experiment at liquid helium temperatures or to room temperature. If the signal is to be inductively coupled to a detection coil that is connected to the SQUID input, then the circuit must be superconducting if dc response is desired.

5.4.1.1 Cryogenic Current Comparator

A current comparator can be used to compare currents and/or to determine current ratios with highest accuracy. Two currents (I_1 and I_2) are fed through separate wires, which are led through a superconducting tube. The Meissner effect causes a screening current that is induced on the inner surface of the tube, flowing opposite to and being exactly as large as the sum of the currents inside the tube. This shielding current exactly cancels the magnetic field inside the tube produced by the currents in the wires. The screening current flows back across the outer surface of the tube, giving rise to a magnetic field in the room outside of the tube, which is detected by a SQUID magnetometer used as a null meter. When the external field is at a null, $I_1 = I_2$. Commercially available [22], sensitivity is at the pA level with an uncertainty of a few parts per million (ppm) [23]. Laboratory systems have achieved sensitivities as low as 0.08 fA/√Hz.

If the measurement is of a current that passes through the detection coil, a toroidal geometry for the detection coil has the advantage of extremely good coupling to the source while rejecting contributions due to external sources. Such configuration has been designed to measure antiproton beam currents [24] and monitor cyclotron beam currents [25]. Another configuration [26] has a room temperature conductor passing through a reentrant dewar with a current sensitivity of better than 100 μA at a current of 250 A.

So far, the majority of applications use superconducting circuits. There are, however, a number of applications where resistive circuits are used. One example [27] passes the current to be (inductively) measured through a room temperature toroid, which was directly coupled into an rf SQUID input coil. Sensitivities of 40 nA/√Hz with a usable frequency response of 3 Hz to above 1 kHz have been achieved. The use of a dc SQUID could improve sensitivity by an order of magnitude.

5.4.2 Voltage Measurements

Voltage (and resistance) measurements are examples where nonsuperconducting elements are used in the measurement circuitry. Figure 5.8c shows the schematic of a SQUID picovolt measuring system. When a voltage (V_{input}) is applied across the input terminals, a current is generated in the SQUID input coil. In this situation, the feedback current (I_{FB}) that would normally be applied to the SQUID loop via the feedback coil is fed back via R_{FB} through r_{std} until the voltage drop across r_{std} is equal to V_{input} and there is no net current through the SQUID. The output voltage (V_{out}) measures the voltage drop across R_{FB} and r_{std} with $V_{input} = V_{out} \times r_{std}/(R_{FB} + r_{std})$. The voltage gain of the system is determined by the ratio of R_{FB}/r_{std}. Typical values for R_{FB} and r_{std} are 3 and 30 μΩ, respectively, giving a voltage gain of 10^8. The standard resistor r_{std} is (like the SQUID) at a temperature of 4.2 K. The voltage source however may be at a completely different temperature. For source resistances less than 10^{-4} Ω and temperatures less than 4.2 K, voltages of 10^{-13} V can be resolved.

Typical applications of picovoltmeters include noise thermometry, measurements of thermopower, and infrared bolometer detectors.

5.4.3 Resistance Measurements

By using a precision, ultralow-noise current source (Figure 5.8d), a SQUID picovoltmeter can be turned into a pico-ohmmeter. Replacing V_{input} with a resistor (R_X) and a highly stable constant current source (I_{CCS}) [28] creates a voltage drop across the resistor. The resistance is determined by $R_X = V_{output} \times r_{std}/[(R_{FB} + r_{std})\, I_{CCS}]$. Resolutions of 10^{-11} Ω can be achieved for resistances as high as 10^{-2} Ω.

5.4.4 AC Impedance Measurements

The SQUID can also be used as the null detector in an ac bridge circuit (Figure 5.8e) to measure both resistive and reactive components of complex impedance. The unknown impedance **Z** is excited by a current generated by an oscillator voltage, which is attenuated by a precision ratio transformer (λ).

The difference between the voltage developed across the unknown impedance **Z** and that developed in the secondary of a nulling mutual inductor **m** is applied to the input of the SQUID circuit. The primary current in **m** is proportional to the oscillator voltage and defined by the setting of the ratio transformer (α). An additional reactive current is supplied by a second ratio transformer (β) that causes the primary current to be passed through a capacitor rather than a resistor, thus generating a 90° phase shift in the voltage applied to **m**. The amplified off-balance signal, which appears at the output of the SQUID control electronics, can be displayed by means of a lock-in amplifier tuned to the oscillator frequency.

The sensitivity is limited inherently by Johnson noise in the resistive components of the unknown (including the potential connections) and by the device noise of the SQUID sensor. Assuming a SQUID noise of 8 pA/√Hz (equivalent to a noise temperature of 5 μK), the system is capable of measuring resistances between 0.5 and 10^{-10} Ω and inductances (both self and mutual) between 10^{-12} and 10^{-3} H. Its resolution depends on the value of **Z** but can be as high as 10 ppm. Using a current comparator as the bridge excitation **V**, a four-terminal resistance bridge with a resolution of 0.1 ppm can be constructed [29].

5.4.5 Magnetic Susceptibility

The SQUID ac measurement system can be modified to measure magnetic susceptibility by the addition of an excitation coil around the sample.

Figure 5.9 shows a typical experimental setup for measurement (Figure 5.8f) of ac susceptibility. Such a configuration can be used for thermometry at mK and even μK temperatures [21] by measuring the low (mT)-field magnetic susceptibility of paramagnetic salts such as $Ce_2Mg_3(NO_3)_{12} \cdot 24\ H_2O$—usually referred to as CMN [7].

5.4.6 Variable Temperature SQUID Susceptometers

Instead of using a secondary ac excitation coil (Figures 5.8f and 5.9b), a dc field can be used to magnetize samples. Typically the field is fixed and the sample moved into the detection coil's region of sensitivity (Figure 5.9c). The change in detected magnetization is directly proportional to the magnetic moment of the sample.

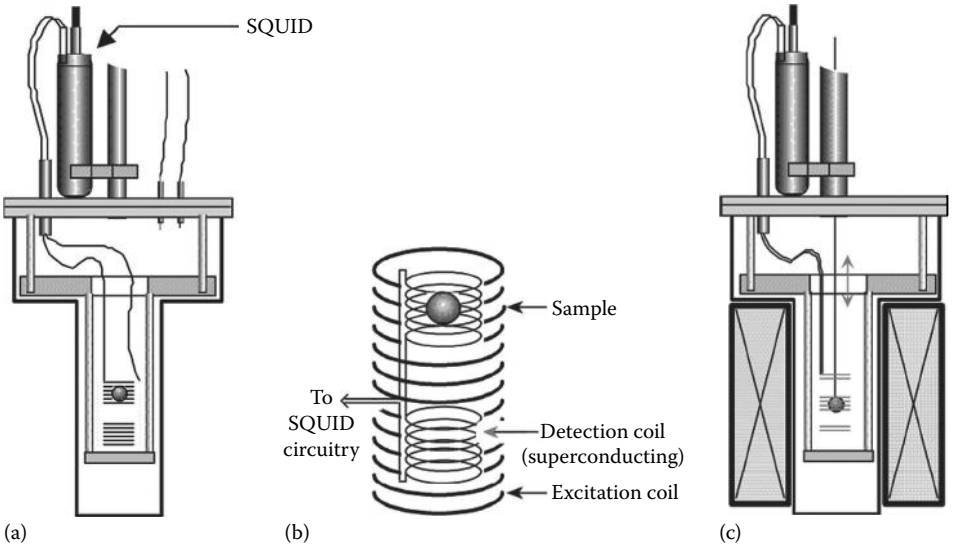

FIGURE 5.9 Magnetic susceptibility measurement apparatus (liquid helium dewar not shown): (a) AC susceptibility, (b) signal and excitation coil details, and (c) second-derivative oscillating magnetometer for dc measurements with external dc field coils.

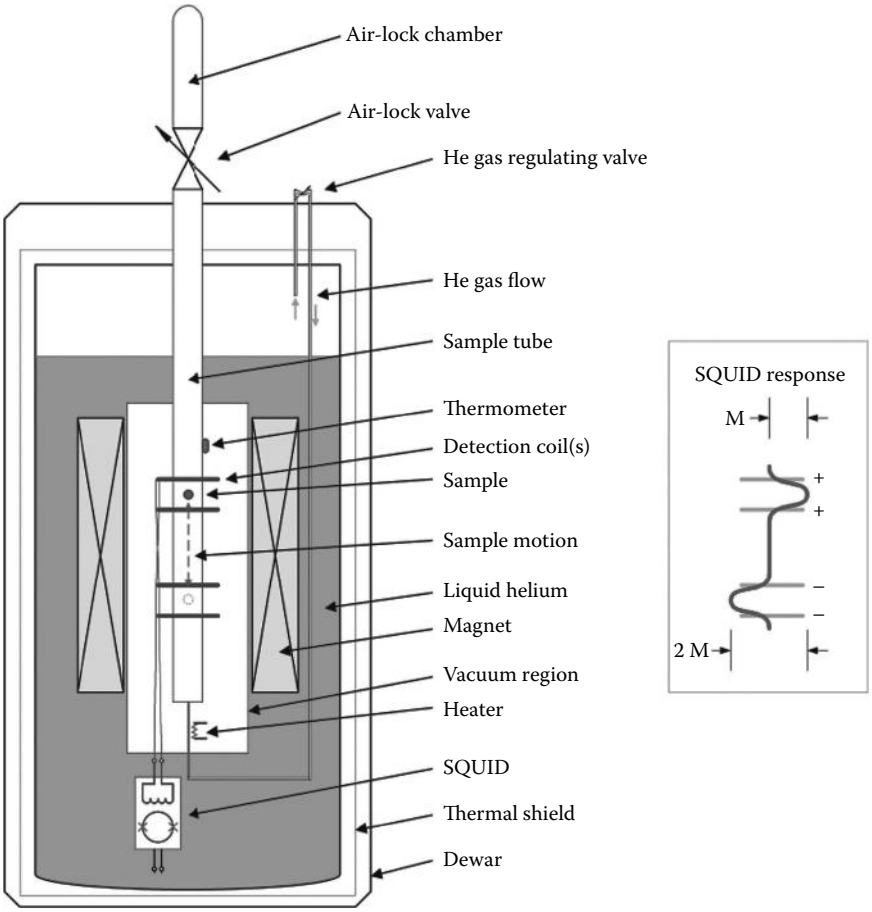

FIGURE 5.10 Variable temperature susceptometer (various electrical leads omitted for clarity). The trace on the right shows the response of the detection coil(s) as a function of sample position height.

The use of a variable temperature insert can allow measurements to be made over a wide range (1.8–400 K). Typically, the sample temperature is controlled by helium gas flowing slowly past the sample (Figure 5.10). The temperature of the gas is regulated using a heater located below the sample-measuring region and a thermometer located above the sample region. This arrangement ensures that the entire region has reached thermal equilibrium prior to data acquisition. The helium gas is obtained from normal evaporation in the dewar and its flow rate is controlled by a precision regulating valve. The use of an oven probe can raise the sample temperature to 800+ K (at the expense of smaller sample measurement volume).

Commonly referred to as SQUID magnetometers, these systems are properly called SQUID susceptometers. They have a homogeneous superconducting magnet (as large as 9 T) to create a uniform field over the entire sample-measuring region and the superconducting pickup loops. The magnet induces a moment allowing a measurement of magnetic susceptibility. The superconducting detection loop array is rigidly mounted in the center of the magnet. This array is configured as a gradient coil to reject external noise sources. The detection coil geometry determines what mathematical algorithm is used to calculate the net magnetization. Oppositely paired Helmholtz coils [30] (Figure 5.10), transverse detection coils, and first- and second-derivative gradiometers have all been successfully used. The system shown in Figure 5.10 is capable of 10^{-8} emu sensitivities.

The most popular detection coil configuration is that of a second-order coil configuration (Figure 5.9c) [31]. In this situation, the detected output is compared with that of an ideal response to determine the magnetization. This technique has the advantage of eliminating noise. Additionally, the intentional choice not to use a NbTi shield allowed swept field scans to be performed. Coupling two axial channels of differing gradient orders (e.g., first and second) can significantly improve noise rejection. The detection coil does not necessarily need to be in an axial configuration. Planar gradiometers have been used to detect the onset of superconductivity in diamond pressure cells [32]. Placement of secondary excitation coils can allow ac susceptibility measurements approaching 10^{-8} emu to be made in the presence of a significant dc bias field. Rock magnetometers for paleomagnetism use a configuration similar to variable temperature susceptometers but without the superconducting magnet.

5.4.7 Gravimetry

Superconducting accelerometers have been in gravity wave detectors [33] to detect dimensional changes smaller than 10^{-19} m on test masses exceeding 10^4 kg. SQUIDs were also used as ultrahigh-resolution (nanoradian) angular position detectors in NASA's Gravity Probe B program [34], which tested several predictions of Einstein's general theory of relativity. Airborne superconducting gravity gradiometers with sensitivities at the 10^{-12} m/s^2/m level have been used for oil and mineral deposit detection. Although SQUIDs are not normally used in superconducting gravimeters [35], they have the potential to increase sensitivities beyond the current 10^{-12} m/s^2 sensitivity (0.01% linearity) of commercial systems.

5.4.8 Other SQUID Measurement Techniques

In addition to the detection of magnetic fields, SQUID detection coils can also be used for detection of nuclear magnetic resonance (NMR). NMR signals [36] can be measured by placing a sample (e.g., protons or ^{19}F) in the center of SQUID detection coils and either sweeping the external field or applying an rf excitation to the sample. The same concept can be used to measure electron paramagnetic resonance (EPR) signals. Although limited to 100 ppm field uniformities, SQUID susceptometers (e.g., SHE VTS [Figure 5.10], Quantum Design MPMS [Figure 5.9c], or Conductus χMAG) are excellent platforms for basic demonstrations of NMR measurements. SQUIDs can also be used as detectors for low-field MRI.

In addition, there are many exotic uses for SQUID sensors. Because SQUID magnetometers are vector devices, they can detect rotational movement of a magnetometer coil in the Earth's magnetic field (~50 μT) as small as 10^{-3} arc-s. SQUIDs have been used for more esoteric applications including temperature measurements [37] with resolution near 10^{-12} K. SQUIDs have been used in searches for dark matter such as weakly interacting massive particles (WIMPs) [38] and axions [39] along with attempts at detecting magnetic monopoles [40] and free quarks [41]. Other exotic applications are proposed experiments to use SQUID systems for the detection of neutrinos [42].

While this chapter is focused on low-frequency applications, there is a need for higher frequency SQUID instruments. In particular, applications such as radio astronomy and NMR are examples where SQUIDs and SQIFs offer superior sensitivity at frequencies that can exceed 20 GHz [43].

Next Generation of Smart Sensors

Michael E. Stanley
Freescale Semiconductor

Stéphane Gervais-Ducouret
Freescale Semiconductor

6.1 Introduction

IEEE STD 1451.0 (IEEE, 2005) defines standard interfaces in support of plug and play operation of smart sensors and actuators on a network. Key components of the standard include

- A format for transducer electronic data sheet (TEDS)
- Transducer interface modules (TIMs)
- Network capable applications processor (NDAP)

The standard is optimized for network-based sensors and trade-off complexity and overall system power for interoperability. It is not optimized for sensor subsystems deeply embedded in portable consumer electronics. A new generation of smart sensors is evolving to meet the needs of this market. These include the following features (Gervais-Ducouret, 2011):

- Competitive in terms of cost, area, and power.
- Virtual sensors can be created by fusing data from multiple physical transducers.
- Ability to detect events.
- Ability to determine current context (both spatial and activity).
- Sensor subsystems must be easy to integrate by product designers.

Nine- and ten-axis sensor subsystems will be used as the basis for discussions to follow. They include the following components:

- 3 axes (*XYZ*) of acceleration (*A*) data
- 3 axes (*XYZ*) of magnetic field (*M*) data
- 3 axes (*XYZ*) of angular velocity (*G*) data
- 1 axis of air pressure (*P*) data

Next-generation devices will incorporate combinations of these and other sensors, as well as the ability to abstract the measured data to make it more useful to the user.

6.2 Need for Sensor Fusion

Each of the sensors in the sensor subsystem outlined in the previous section comes with its own set of strengths and weaknesses. As an example, let us consider the case of an accelerometer and a magnetometer at rest. Both provide the magnitude and direction, in the sensor's frame of reference, for physical quantities being measured. In this case, these are gravity and earth magnetic field, respectively. Both sensor types are unable to detect rotation about the vector in question when one of *X*, *Y*, or *Z* sensor axes is aligned with that vector. Since the earth's magnetic and gravity vectors are guaranteed to be non-colinear,* we can combine the two sets of measurements to provide a complete description of the device orientation in space. The ability to extract knowledge from the sum of multiple sensor outputs that could not be determined from any individual sensor is a key feature of *sensor fusion*.

Table 6.1 expands on this theme to outline key strengths and weaknesses of the various sensors contained in our representative sensor subsystem. The sensors shown represent only a small (but important) fraction of device types that might be included in specific products.

Figure 6.1 summarizes basic market requirements for sensor fusion at the time of writing. They include the following outputs:

1. "Corrected" sensor outputs in which sensor errors have been minimized
2. Current device orientation, which can be expressed in several ways
   a. Rotation matrix to take the device from a defined reference orientation to the current device orientation
   b. A quaternion representation of the same rotation
   c. Euler angle representation of the same rotation (Φ, θ, and ψ)
3. Tilt-compensated compass heading

TABLE 6.1 Trade-Offs between Sensor Types

Sensor	Strengths	Weaknesses
Accelerometer	Inexpensive Extremely low power Very linear Very low noise	Measures the difference of gravity and acceleration We need them separate
Magnetometer	The only sensor that can orient itself with regard to "north" Insensitive to linear acceleration	Subject to magnetic interference Not constant with location within office environments
Gyroscope	Relatively independent of linear acceleration Can be used to "gyro-compensate" the magnetometer	Power hog Long start-up time Zero rate offset drifts over time
Pressure sensor	The only stand-alone sensor that can give an indication of altitude	A "relative" measurement Subject to many interferences/ environmental factors

* Except at the north and south magnetic poles. Since the human population of both is nominally zero, we can discount this case.

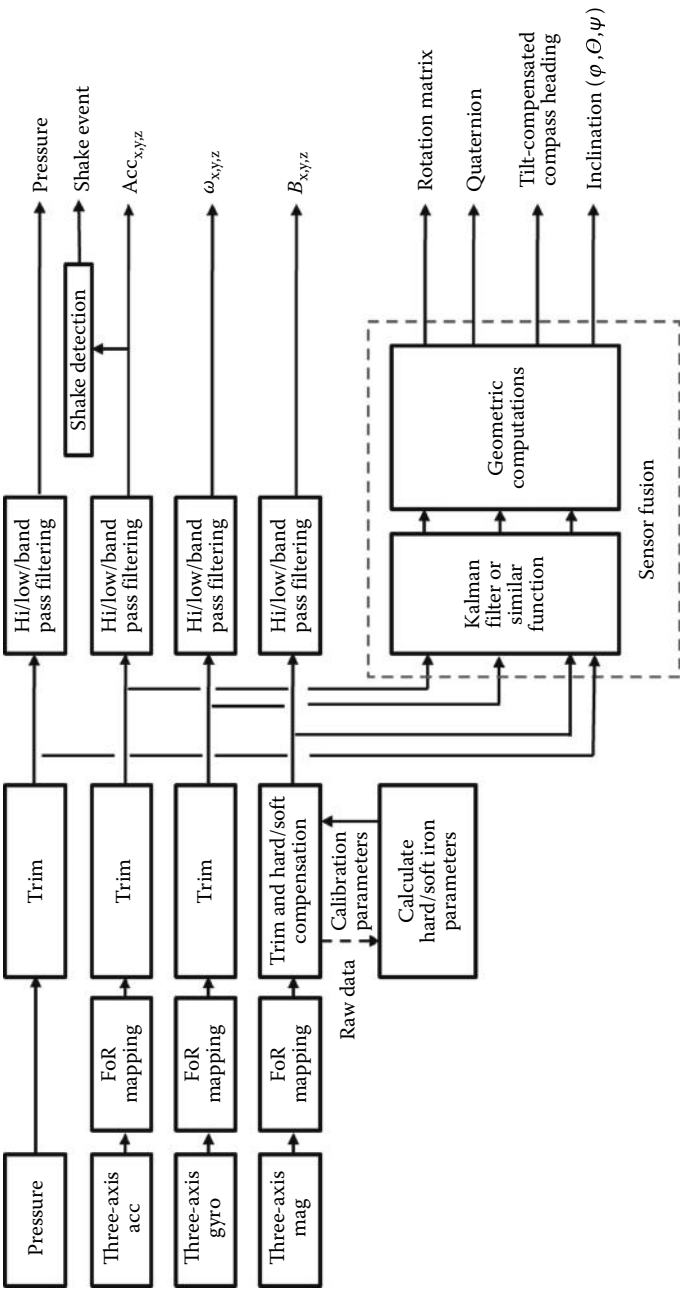

FIGURE 6.1 Base-level sensor fusion for consumer devices. FoR = Frame of reference mapping. (Stanley M. and Kelliher T., *Xtrinsic Sensor Fusion Part 1: Terms, Trends, Challenges and Advantages*, Freescale Technology Forum, San Antonio, TX, June 2012.)

The outputs of Figure 6.1 represent a basic set of foundation functions upon which higher levels of software abstraction are layered. These would include

- Pedometry
- Gesture recognition
- Head tracking
- Motion capture
- Fall detection
- VR tracking
- Augmented reality
- Navigation

6.3 Use Cases

The sensor subsystem outlined in the previous sections can support a variety of features, applications, and use cases. Table 6.2 presents a variety of features and applications versus the minimum set of sensors required for implementation. In almost every case, inclusion of additional sensor types over the minimum shown will improve accuracy.

It is common for combinations of the previously mentioned features to be executing concurrently on the same device. Some applications may continue to run even when the end user is not actively interacting with the device. Pedometry is a good example of this: you probably want to count steps all day, even when the smartphone on which it is running is not in "active use."

6.4 Power Considerations

The time between battery charges is a primary figure of merit for any portable consumer device; hence, every milliwatt is precious. A properly designed sensor subsystem can enable major improvements in battery life.

Figure 6.2 illustrates the case where the main applications processor (AP) in a system is responsible for sensor fusion. Most commonly, the AP bus interface is comprised of one or more serial interfaces (I^2C or SPI). Every sensor sample must be individually read across the bus interface by the AP, which is subject to a high interrupt rate.

APs are typically manufactured using state-of-the art complementary metal-oxide-semiconductor (CMOS) processes. These are designed to minimize run mode currents for the AP; however, this is

TABLE 6.2 Minimum Sensor Sets for Various Applications

Feature/Application	Accelerometer	Magnetometer	Gyroscope	Pressure Sensor
Portrait/landscape, tap detection, fall detection	X			
Pedometry, vibration analysis	X			
Electronic compass, pointing/remote control, augmented/virtual reality, gesture recognition	X	X		
Virtual gyroscope	X	X		
Gyro-compensated electronic compass	X	X	X	
Activity monitors	X	X		
	X		X	
Motion capture	X	X		
3D mapping and localization	X	X		X
Image stabilization, gesture recognition	X			

Note: X indicates that the indicated sensor type is a minimum requirement for the feature/application.

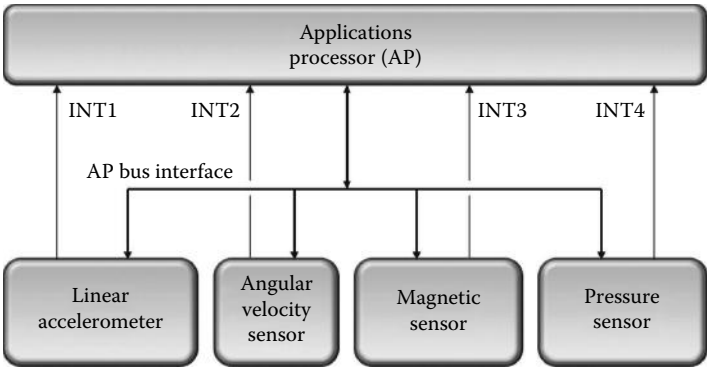

FIGURE 6.2 Sensor fusion via AP.

normally at the expense of increased start-up latency coupled with multiple modes of operation (each with their own power trade-offs). Deep pipelines for the AP result in substantial power wasted during context switching. If the AP is otherwise idle, additional power is burned during wake-up/sleep transitions.

Another problem with the system of Figure 6.2 is that the operating system running on the AP doesn't normally support real-time operation. The AP may have, at best, a rough idea of exactly when each sensor sample was taken. This uncertainty in the time domain leads directly to errors in sensor fusion algorithms performed on the AP.

In contrast to the previous text, with the system of Figure 6.3, the sensor fusion is performed by a local compute engine residing on an intelligent sensor hub. The compute engine may be a microcontroller, dedicated fusion logic implemented in gates, or a combination of the two. Use of a dedicated microcontroller offers maximum flexibility for enhancing the fusion feature mix over time. Once specific algorithms have proved to be matured, they can be moved into gates. Logic-based solutions are almost guaranteed to have lower power than other architectures, but should only be used when algorithm maturity has been proven. We expect a mixture of both methods to be used for some years to come.

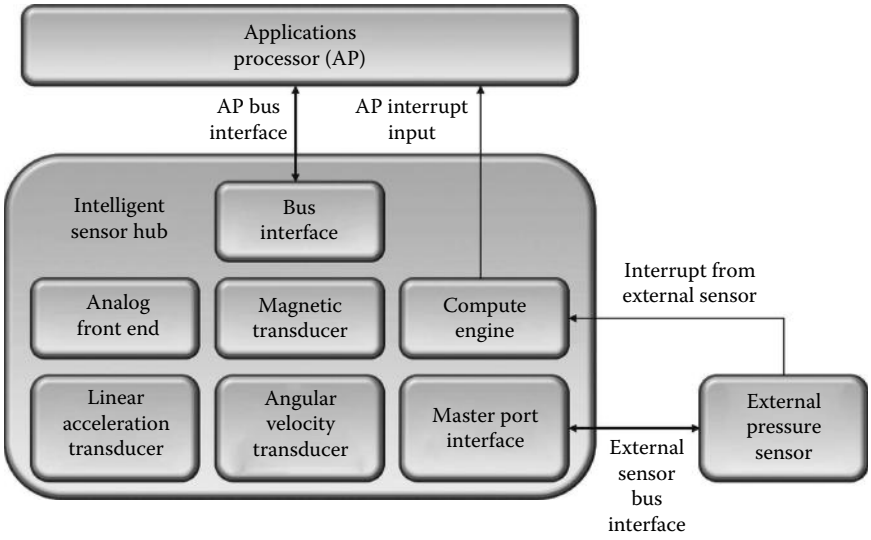

FIGURE 6.3 Sensor fusion via an intelligent sensor hub.

A number of advantages are obtained by moving sensor fusion out of the main AP:

- Sample times are tightly coordinated in time.
- MCU-based sensor hubs can utilize a real-time OS (RTOS) to manage external sensor inputs and algorithm timings.
- AP bus traffic can be orders of magnitude less than the system of Figure 6.2 because only processed and aggregated data need to be passed up to the AP.
- Because the local compute engine does not have the context/power mode switching overhead of the AP, milliwatt per computation is minimized.
- The AP can be completely asleep while the sensor hub continues to process sensor-related functions. Consider a smartphone equipped with a sensor hub: the application software for a pedometer can be executed completely on the sensor hub. Therefore, the AP can remain asleep, even while steps are counted.
- The sensor hub can use heuristic methods to manage power for the overall subsystem without any oversight from the AP. For the case shown in Figure 6.3, the magnetometer and gyroscope could be completely powered down until movement is detected via accelerometer inputs.

6.5 Integration and Partitioning Issues

A variety of physical mechanisms can be used to measure the previously mentioned components. Microelectromechanical systems (MEMS) are commonly used to measure acceleration, angular velocity, and pressure for consumer-grade devices. Magnetic sensors can be fabricated using a number of different technologies, including tunneling magnetoresistance (TMR) and anisotropic magnetoresistance (AMR).

First-generation MEMS devices included only one or two measurement axes in a single packaged device. As time proceeds, the trend is to consolidate more axes into a single package. Three-axis sensors are now common, and 2012 has seen the introduction of 6 (*X*/*Y*/*Z* of both accelerometer and gyroscope) and 9 axes (*X*/*Y*/*Z* of accelerometer, magnetometer, and gyroscope) devices. There are a number of items that need to be taken into consideration Stanley (2012) when selecting components of this type:

- Equations of motion incorporating acceleration are simpler when the sensor is located in the center of mass of the device in question.
- Magnetic sensors are subject to interference from ferrous and magnetic materials within the unit. Typically, a magnetic sensor performs best when situated near the center of one edge of the device because the magnetic field will suffer less distortion in that area.
- The first two bullets suggest different sensor placement on the PCB. If a single device incorporating both magnetic and acceleration transducers is used, the fusion algorithms need to include the ability to specify sensor offset from center of mass.

From a physical perspective, the trend is clearly toward more and more integration into smaller and smaller packages. In 2010, discrete packages for accelerometer, gyrometer, and magnetometer were the norm. $3 \times 3 \times 1$ mm packaged sensors were the state of the art. At the time of writing, 2×2 mm is standard for 3-axis accelerometers, and gyroscopes are at 4×4 mm and trending to 3×3 mm. Combinational devices are trending to 15–20 mm^2, including the sensor hub. Issues being managed by sensor providers are discussed in the following paragraphs.

6.5.1 Consolidation of MEMS Devices onto a Single Die

Stand-alone consumer accelerometers do not usually have their chambers evacuated. Gas molecules within the MEMS chamber provide a damping effect that is advantageous in shaping the transfer function of the accelerometer. Conversely gyroscopes work better when motion damping is not present.

The Coriolis effect leveraged by gyroscopes requires a proof mass that oscillates at high speeds. The same effect that is helpful for accelerometers increases power required for the gyro drive circuitry. To support higher levels of integration, MEMS structures will most likely be designed to operate at the same pressure. The accelerometer circuitry will need to be designed for force feedback (to ensure the accelerometer proof mass stays centered) if vacuum is used for both gyro- and accelerometer. Conversely, additional drive capabilities may be required if the gyroscope pressure is raised. Finding the right "sweet spot" will be even more complicated when we consider inclusion of a pressure sensor on the same die.

6.5.2 Magnetic Interference

By their very nature, magnetometers are sensitive to electronic currents. Placing them in close proximity to a microcontroller or logic core requires care. The Biot–Savart law can be used to estimate the effect of wire/trace currents on magnetic sensors. For long wires and traces, it can be simplified to

$$|B| = \frac{\mu_0 I}{2\pi r}$$

where

$|B|$ is the magnetic field strength in T (teslas)
μ_0 is the $4\pi \times 10^{-7}$ T m/A
I is the current in amps
r is the distance from wire/trace to sensor in meters

This can be rearranged to yield

$$I \leq 5\ r\,|B|$$

where

$|B|$ is the magnetic field strength in μT that you can afford to ignore
I is the current in milliamps
r is the distance from wire/trace to sensor in mm

As an example, if B = 0.1 μT and r = 0.1 mm, then I must be roughly less than 50 μA in order to not affect the accuracy of the result. While these numbers may sound small, they must be considered when designing within the context of an MCU-equipped smart sensor in a 3 × 3 × 1 mm package.

Today, the magnetic sensor component of a composite device is commonly implemented as a separate die that is stacked on top of the controller Application Specific Integrated Circuit (ASIC). Depending upon the technology used, it should be possible to place the magnetic sensor on the same die as the compute engine. Ultimately, a 9-axis fused solution will probably only require two stacked dies.

Figure 6.4 illustrates this process of continuing integration. Notice that at any point in time, several alternative solutions may exist. These may be driven by both logistical (supply) and technical considerations. Typically, no one solution fits all problem spaces.

6.5.3 Soft Partitioning

A benefit of the sensor hub partitioning is that fusion algorithms can be packaged with the hub itself, simplifying hardware and software system design and integration. System integrators are increasingly looking for a single source capable of providing sensors, compute engine, and associated software. Microsoft Windows 8 is architected with this division in mind. Microsoft supports specific bus

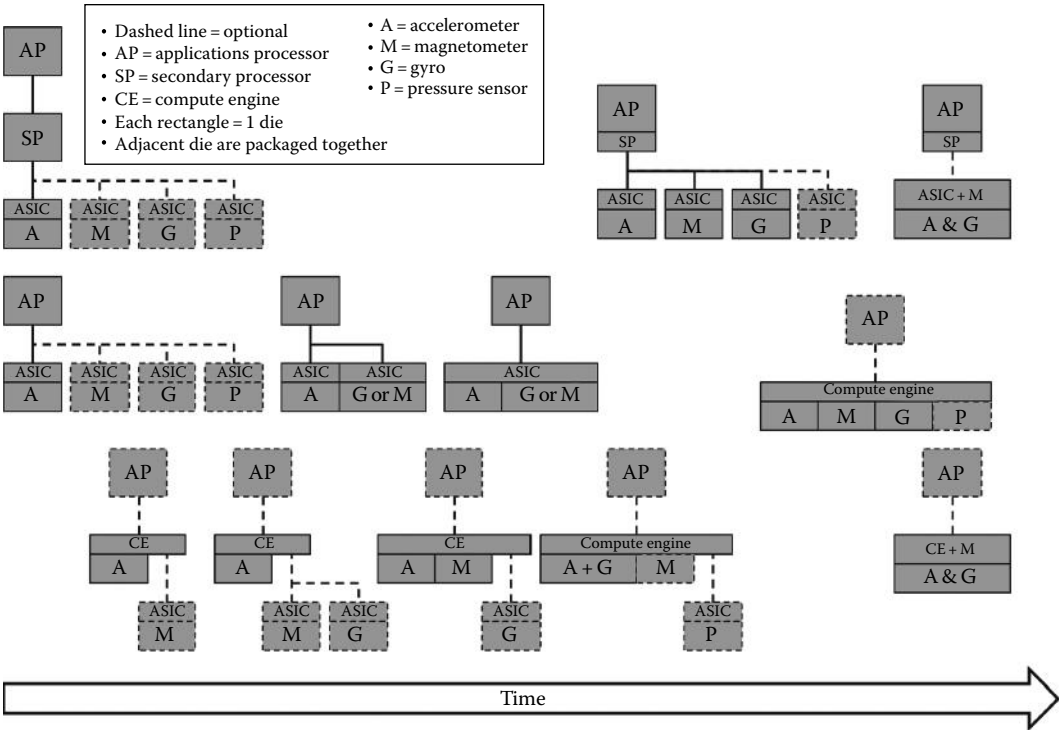

FIGURE 6.4 Increasing levels of integration over time.

protocols for communications with sensor subsystems. These include HID* over Universal Serial Bus (USB) and HID over I²C. Microsoft requires vendors to meet all Windows 8 Hardware Certification Requirements (Microsoft, 2012c) before the vendor's solution can be marketed as Microsoft-approved. Google has created the Android Compatibility Test Suite (CTS) for similar purposes (Android, 2012).

A high-level view of the Android software stack utilizing an intelligent hub is shown in Figure 6.5. By agreeing to a common communications protocol over I²C, SPI, or USB, sensor providers and system integrators can cleanly divide software development tasks. An alternate approach that is even more hardware/software agnostic could be based upon the Multicore Communications API (MCAPI, 2012). This standard message passing protocol could be used to completely abstract the smart sensor interface at the software level. Regardless of which approach wins out in the end, industry-wide definitions will enable the ability to swap out sensor subsystems with the substitution of a single component—with no impact to system software.

Physically, the systems of Figures 6.3 and 6.5 are the same. They support a clean division of efforts between sensor providers and system integrators and improved performance (both power and accuracy) over previous generations of devices. However, power can be improved even more by moving the compute engine onto the same die as the AP. This is shown in Figure 6.6.

The controller IC for the Figure 6.3 intelligent controller will be built upon CMOS processes that include support for flash memory. This allows fusion software to be stored directly in the sensor hub, simplifying distribution and integration of that software. The disadvantage is that flash-based technologies tend to "lag" the more advanced processes used for APs in terms of instructions/mW. In Figure 6.6, the secondary CPU can be designed for real-time operation with fast transitions to/from sleep mode. Improvements in power come from using the same advanced CMOS technology for the secondary CPU

* HID, human interface device. See Microsoft (2012b).

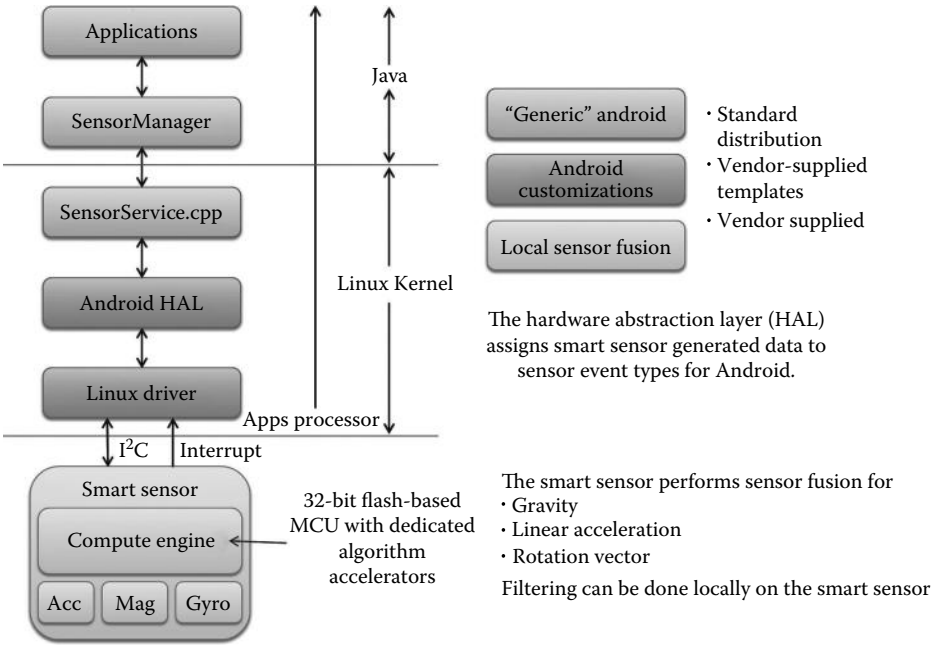

FIGURE 6.5 Software stack based upon an intelligent sensor hub.

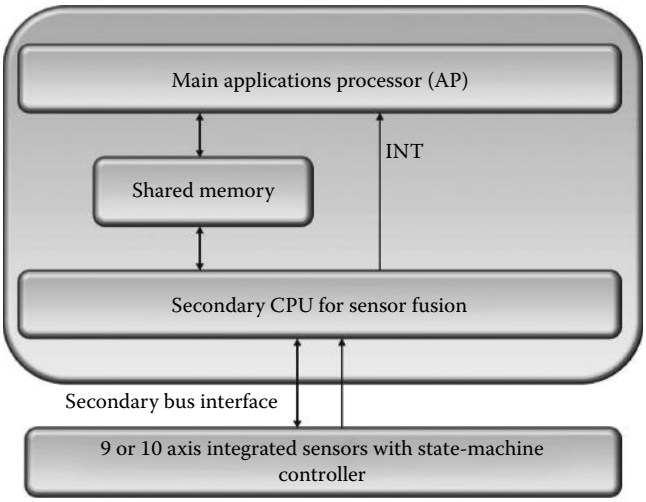

FIGURE 6.6 Sensor fusion as a secondary engine within the AP.

as for the main AP. The architecture of Figure 6.6 allows the system designer to choose best in class options for each individual sensor, providing a more "a la carte" option to the partitioning shown in Figure 6.3, which is more likely to be provided by a single vendor. This comes at the expense of additional traffic on the secondary bus and a tighter coupling between the sensor subsystem and the rest of the system from a software perspective. The latter may be reduced by implementing a software protocol such as MCAPI, which hides details of the physical transport mechanism from the application. Ultimately, the market will determine which of the two sensor hub approaches wins out.

Trade-offs between the systems of Figures 6.2, 6.3, and 6.6 are outlined in Table 6.3.

TABLE 6.3 Trade-Offs Associated with Choice of Processor for Sensor Fusion

System Option	Pros	Cons
Figure 6.2: Fusion on the AP	Least expensive option Supported by 2012 technology	Higher power Highest software burden on-system designer
Figure 6.3: Fusion within the smart sensor hub	Highest level of decoupling between top-level OS and sensor subsystem	Significantly improved power over 100% discrete option
Figure 6.6: Fusion on a secondary processor on the AP	Best power	Physical (and possibly software) partitioning between the main AP and secondary processor will tend to be different for each AP design

6.6 Trend and Market Segments

Improvements in sensor performance and intelligence are driven by new applications that are themselves enabled by the availability of affordable, small, and low-power sensors. An overview of some of the main trends of automotive, industrial, healthcare, and consumer markets is provided as follows.

6.6.1 Automotive

The automotive market segment has used sensors for many years for monitoring and controlling engine performance. The explosion of sensor usage in this market has been driven by the need for increased safety, starting with airbags (which utilize accelerometers for triggering purposes) and tire pressure monitoring systems (TPMSs). The current trend is to further improve automotive security by adding active safety features to the existing passive safety feature set. Electronic stability control (ESC) can prevent some crashes due to loss of control by actively managing the braking of each wheel. ESC uses a combination of a gyroscope (1–3 axes) and accelerometer (2–3 axes) in a common package with an ASIC to efficiently monitor yaw, pitch, and rollover. The trend is clearly driving further integration of sensors and sensor fusion for proactive safety. Adoption of 6-axis sensors (3-axis gyroscope and 3-axis accelerometer) and the fusion of these sensors should increase in this market.

6.6.2 Industrial

The industrial market also benefits from smart sensors. Usage of sensors is as diverse as the industrial applications themselves. For instance, physical tamper detection, utilizing extremely low-power 3-axis accelerometers running for years on battery power, can now be seen in smart meters and other devices. Accelerometers are also used for vibration monitoring to detect machine defects and trigger maintenance prior to a real failure. Associating sensors with low-power wireless transceivers may enable the most pervasive technology for industrial: building and home automation. The main benefits are energy saving (heater, light, HVAC, etc.), cost saving (manpower, cables, maintenance, etc.), and security (alarm, detection of fire and gas, malfunction of devices, etc.). Smart sensors are crucial for such applications since power consumption is critical: 10 years is the minimum battery life for building automation sensors. Dedicated processing at the sensor level is one of the solutions used to minimize data flow and communication and therefore power consumption. Association of smart sensors together with very low-power wireless transceivers, such as ZigBee Smart Energy (Zigbee, 2012) and even energy harvesting (using differential temperature or vibration), will dramatically increase the spread of wireless sensor networks for better management of our energy.

6.6.3 Healthcare

Health monitoring applications benefit from smart sensor's low-power and quality of data. For instance, seamless monitoring of blood pressure, physical activity, and heart rate can be achieved using smart

accelerometers and pressure sensors. Data can be recorded and displayed on any device acting as a health hub (e.g., smartphone). Accurate and low-power monitoring is possible thanks to smart sensor features such as First-In-First-Out (FIFO) buffers, which allow the transmission of measured data in burst mode. This minimizes the number of context changes required by the main processor, again, minimizing overall system power consumption.

Smart sensors and resulting fused data will be increasingly used to enable seamless and more detailed health monitoring. Data can be used for sport activity monitoring and accident prevention. It can also be collected and analyzed on a continuous basis, opening the possibility of adapting medication regimens to each individual patient's daily routine.

6.6.4 Consumer

The consumer market benefits from smart sensors more than any other, since these devices enable high-volume applications such as gaming, intuitive user interfaces, augmented reality, localization, and context awareness. The 10-axis sensor system discussed in the introduction to this chapter forms the basis for many consumer applications.

Figure 6.7 breaks applications into three levels of complexity. Bottom tier applications are supported by a 3-axis accelerometer and 3-axis magnetometer. This tier includes basic gesture recognition such as tilt or tap detection.* It also requires functions for soft and hard iron compensation, which must be performed prior to electronic compass calculations. The first level of smart sensor and sensor fusion provides improved sensor performance in terms of drift, calibration, and ease of use. It forms the foundation for applications in the upper levels.

The middle level in Figure 6.7 includes applications such as a high-performance pedometer (with an accelerometer to detect steps, a gyroscope to remove parasitic movement linked to the handling of the

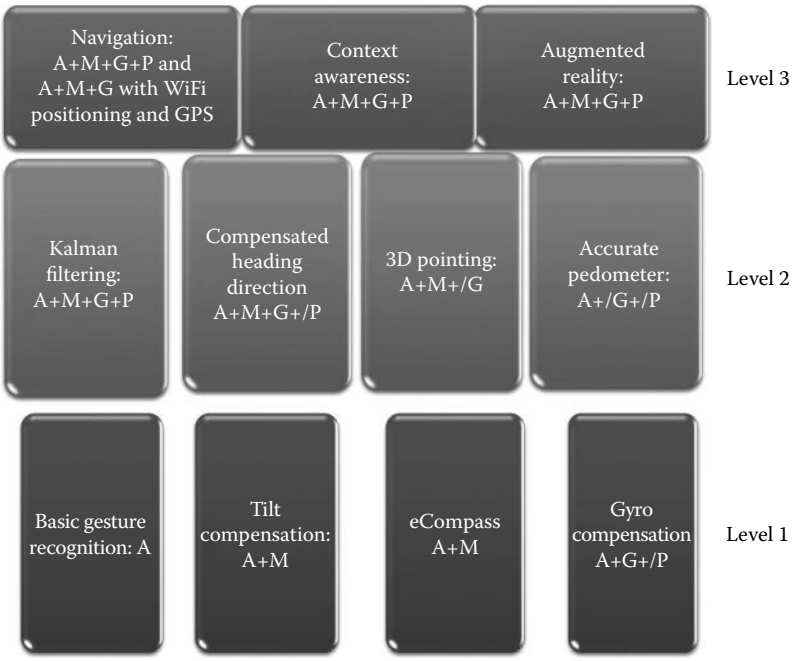

FIGURE 6.7 Sensor fusion complexity levels/indicates optical sensors.

* Basic functions like tilt and tap are often implemented in dedicated CMOS logic today. As other algorithms increase in maturity, it will be natural that many of these functions also move into "hard logic."

device, and a pressure sensor to detect altitude), pointing device (used in remote controls to improve intuitive interface for smart TV), and Kalman filtering to get reliable and more accurate sensor data as described in earlier sections.

Level 3 applications leverage sensor and general *data fusion*. Navigation applications can use the outcome of sensor fusion to lower the power consumption of GPS by extrapolating the trajectory between two navigational fixes. However, the most dramatic improvements are for indoor localization. These systems utilize inertial/magnetic sensor fusion coupled with diverse techniques such as Wi-Fi positioning, cell IDs/triangulation, and soft maps to enable indoor navigation via smartphones. Going forward, they will also combine pressure readings with map/GPS data to estimate altitude.

Smart sensors play a key role in decreasing power consumption in these systems, since the power consumed by GPS/Wi-Fi is of two orders of magnitude higher than other sensors. They also help improve accuracy of position estimates. Today's consumer sensors are not accurate enough to support purely inertial navigation equations. But by coupling pedometry techniques with orientation data provided by the same sensors, reasonable (linear) bounds can be placed on position estimates.

Another new trend is inclusion of context awareness. This involves gathering information from different sensors and data sources to characterize the user's environment and activity within that environment. Examples might include entering/exiting an elevator, recognizing that user is at rest, eating, and walking. Indeed, understanding the context is as important as knowing the location of a person for location-based services (LBSs), contextual services, and menus. Knowing if a person is stressed, rushing about town, or just browsing in a shopping mall can be achieved by doing pattern analysis of sensor outputs—primarily accelerometers but also gyroscopes.

Modern operating systems include the ability to register software functions as *event listeners*. Think of these as callback functions that are invoked when something interesting has happened in the physical world. To enable innovative applications, the sensor fusion layer should provide ready to use data for pattern recognition, which then provides trigger events for application-level software to log context changes and/or perform event-triggered actions. The goal is to continually raise the level of data abstraction to make it easy for software developers to develop applications that interact in the world in natural and innovative ways. Hence, data fusion of smart and low-power sensors combined with wireless connectivity is enabling new applications for multiple markets. Indeed, since the role of smart sensors in context awareness, positioning, healthcare, and safety is essential, this technology is becoming pervasive for most of related IoT (Internet of Things) applications.

6.7 Summary and Conclusions

This chapter has examined trends in smart sensors using a basic 10-axis sensor subsystem as a basis for discussion. Clear trends include

- Continued focus on reducing cost and power
- Continued improvement in raw sensor performance, as well as performance improvements resulting from intelligent sensor fusion
- Consolidation of more sensors into fewer dies within fewer packages, utilizing less board space
- Localized computation
- Standardizing interfaces to sensor subsystems
- Raising levels of data abstraction, including inclusion of higher-level functions like gesture recognition and context awareness

Partial List of Sensor Manufacturers

AKM, manufacturer of magnetometers and 6-axis combo eCompass.

Analog Devices, manufacturer of accelerometers, pressure sensors, gyroscopes, microphones, 6-axis combo sensors, sensor fusion, and inertial modules.

Bosch Sensortec, manufacturer of accelerometers, pressure sensors, magnetometers, microphones, sensor fusion, and 6-axis combo sensors.

Freescale Semiconductor, manufacturer of accelerometers, gyroscopes, pressure sensors, magnetometers, touch sensors, sensor fusion, 6-axis sensors, and intelligent sensor platform.

Infineon, manufacturer of magnetometers and pressure sensors.

Honeywell, manufacturer of magnetometers.

Invensense, manufacturer of gyroscopes and combo sensors of a gyroscope with an accelerometer and/or magnetometer and sensor fusion.

Kionix, manufacturer of smart sensors: accelerometers, gyroscopes, 6-axis combo sensors, and sensor fusion.

Knowles Electronic, manufacturer of MEMS microphones.

Memsic, manufacturer of accelerometers, magnetometers, and flow sensors.

Murata, manufacturer of accelerometers, pressure sensors, gyroscopes, 6-axis combo sensors, and sensor fusion.

Panasonic, manufacturer of accelerometers, gyroscopes, and RF MEMS.

STMicroelectronics, manufacturer of MEMS and smart sensors: accelerometers, pressure sensors, magnetometers, gyroscopes, microphones, 6-axis combo sensors, and inertial modules.

7.1 Introduction

The development of environmental microsensor techniques is a revolutionary advancement in the measurement of both absolute levels and changes in chemical species in engineered and natural aquatic systems. This advancement has utilized microscopic monitoring to contribute a greater understanding of biological mechanisms in many environmental processes for decades. Currently, microelectromechanical systems (MEMS) microfabrication technology, which is intimately connected to a microelectronic circuit for amplifying, processing, and transmitting microelectrode (ME) signals, is being successfully applied to the development of multianalyte sensor systems for in situ monitoring.

The needle-type electrochemical microsensor is one of the most prominent, novel methods for studying biofilms. Biofilms are colonies of microbial cells in an organic polymeric matrix (usually polysaccharides) attached to a surface in water systems. They have complex structures consisting of highly stratified microbial communities. The ability of bacteria to attach to surfaces and to form biofilms often is an important competitive advantage for them over bacteria growing in suspension. Biofilms allow for mixed microbial communities, concentration of nutrients, and protection from antibiotics. The formation of biofilms has been associated with a broad range of industrial problems at an annual cost of billions of dollars. For example, biofilms are ubiquitous in water distribution systems,

and the control of their growth has been a great challenge, with many water utilities in the United States reporting biofilm survival in water distribution systems despite the continuing presence of disinfectants. Biofilm may also harbor various types of microorganisms including opportunistic pathogens and thus can threaten public health. On the other hand, biofilm plays a major role in many water reclamation and reuse technologies as well as bioremediation of contaminated soil. Therefore, whether we want to promote good biofilms or eliminate bad biofilms, it is important to understand how they work and what works to control them [1]. They are critical for effective design and operation of many environmental systems.

The tiny tip (3–15 μm diameters) of the microsensors makes them very attractive experimental tools for direct measurement by penetrating biological samples (e.g., biofilm sediments, pore water, activated sludge flocs). Most commercial sensors have a large tip (e.g., 3 cm diameter), so they are difficult to use for microscopic analysis. Using a microsensor, a concentration profile is measured at a microscale, and parameters are estimated from the measured concentration profiles to determine rates of activity and transport of biological and chemical compounds. The important kinetic parameters at a given location in a floc or biofilm include constituent flux (J), net specific consumption (or production) rates, diffusion coefficient (D), maximum reaction rate (K_s), and disinfectant penetration rate. Therefore, the microsensors are very useful for the analyses of dynamics and kinetics in complex environmental systems such as biofilm processes and bioremediation.

In this chapter, we describe needle-type environmental microsensors that can measure at high spatial resolution and that are yet sensitive enough to detect concentration changes of a target compound (or constituent) that are relevant in environmental settings. Subsequently, the applications of environmental microsensors are demonstrated in engineered and natural stratified microbial communities (e.g., nitrifying biofilm, marine sediments, activated sludge flocs, microbial mats).

7.2 Microelectrode Sensors

In many cases, the laboratory analysis of environmental samples is either undesirable or not possible. In situ analysis is often necessary to preserve sample integrity, while in other cases on-site analysis is needed to ensure that temporal or chemical changes to samples do not occur. Microsensors for in situ environmental applications must achieve four major requirements in order to accurately assess complex environmental samples:

- Good sensitivity in the concentration range of interest
- High spatial resolution at the microscale level
- Robustness sufficient to penetrate biological samples (e.g., sediment, biofilm, activated sludge flocs)
- High selectivity against possible interferences (e.g., minimization of pH, oxygen, or other ionic interferences must often be achieved in the presence of relatively high concentrations of interfering cations [or anions])

Key parameters of an optimal microsensor include response time, stability over time, lower detection limits, and selectivity (independence of response). Most recent improvements are based on these parameters. Generally, there are two types of electrochemical microsensors (Figure 7.1): (1) amperometric sensors and (2) potentiometric sensors. The selection depends on cost factors, required data reliability, the materials to be analyzed, and available technologies. Amperometric sensors measure current under a controlled potential and convert it to the target concentration. Potentiometric sensors measure the voltage output (i.e., Nernstian electrode response), which is proportional to the concentration of a target ion. Table 7.1 summarizes current developments in environmental microsensors according to their type and measured analyte. Figure 7.2 shows schematic descriptions of various types of environmental microsensors. Most of them are not commercially available and thus have been fabricated in the laboratory. Table 7.2 summarizes the representative materials and equipment necessary to fabricate needle-type environmental ME sensors.

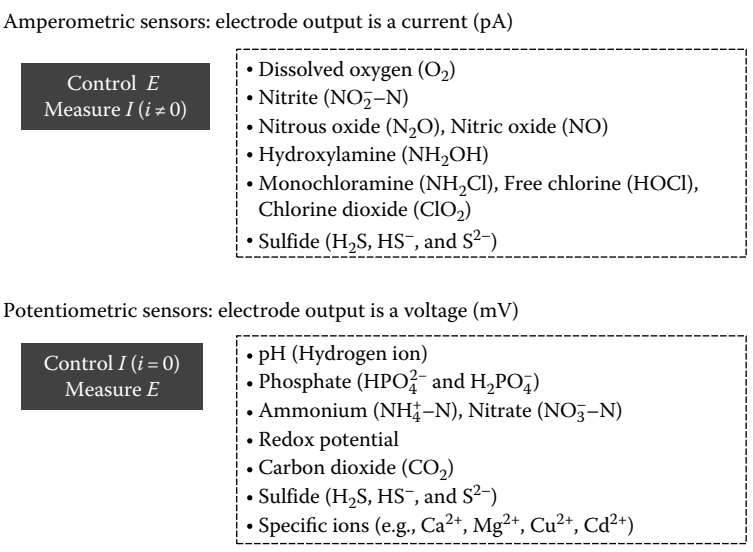

FIGURE 7.1 Principles of needle-type electrochemical environmental microsensor operation. *E*, potential (mV); *I*, current (pA).

A number of microsensors (e.g., oxygen, sulfide gas, hydrogen, nitrous oxide [N_2O], nitric oxide, redox, and nitrite) are commercially available from Unisense A/S (www.unisense.com) or other manufacturers. Typical environmental microsensors have diameters of about 3–15 μm (Figure 7.2), while a specific combined Clark-type microsensor, which needs an outer chamber (or casing), has a diameter of 50–80 μm. Smaller sensors have the advantage of causing less disturbance when introduced, but there is some decrease in sensitivity [2].

7.3 Amperometric Microsensors

The most well-known amperometric microsensor is the oxygen sensor (Figure 7.2a) because oxygen has been used as a critical indicator for microbial activity in many environmental processes [3,6,9,24–26]. The method used for ME sensor fabrication depends on the type of microsensor being constructed. Oxygen (or dissolved oxygen [DO]) MEs are made by filling a micropipette with a low-melting-point alloy; the tip is then electroplated with a thin layer of gold (Au) [27]. It measures DO amperometrically based on oxygen reduction in the cathode reaction [6]. The current is proportional to the bulk oxygen concentration (Equation 7.1):

$$I = \frac{nFASDP_{O_2}}{Z} = kP_{O_2} \tag{7.1}$$

where

I is the current
n is the number of electrons involved in oxygen reduction
F is the Faraday number (96,487 °C/mol)
A is the cathode area (cm^2)
P_{O_2} is the oxygen partial pressure
Z is the oxygen diffusion layer thickness
S and *D* are solubility coefficient and oxygen diffusivity, respectively

TABLE 7.1 Overview of Various Needle-Type Environmental Microsensors

Measurement	Type	Analytical Methods/ Mechanisms	Slope[a], Response Time	Conc. Range, (LOD[b])	Key Materials/Compound/ Procedures	References
Oxygen (O_2)	Clark[c], Solid[d]	• Amperometry • Oxygen reduction in the cathode reaction at Au	13 pA/(mg O_2/L), <5 s	0–8.3 mg O_2/L (23°C)	• Low-melting-point (47°C) bismuth alloy • Au electroplating • Polarization	[3–5]
pH	ISE[e]	• Potentiometry • Nernstian electrode response from neutral carrier	45–60 mV/pH	pH 6–10	• Salinization of the tip • Electrolyte: pH 7 buffer solution • Liquid membrane: Fluka 95293 • Cellulose acetate and protein layer at the tip	[3]
			55–59 mV/pH	pH 1.3–9.8	• Salinization of the tip • Electrolyte: NaCl (100 mmol/L), KH_2PO_4 (250 mmol/L), and Na_2HPO_4 (250 mmol/L) • Liquid membrane: Fluka 95297	[6]
	Solid	• Potentiometry • Nernstian electrode response	70–80 mV/pH, <1 min	pH 1–12	• Iridium wire • IrOx formed by potential cycling in 0.5 M sulfuric acid • H_2S interference	[7]
Ammonium (NH_4^+–N)	ISE	• Potentiometry • Nernstian electrode response (NH_4^+–N) from neutral carrier	54.5 mV/dec	10^{-4}–1^{-1} M ($10^{-5.8}$ M)	• Salinization of the tip • Electrolyte: 0.01 M NH_4Cl • Liquid membrane: Fluka 09879 • Cellulose acetate and protein layer at the tip	[8]
Nitrate (NO_3^-–N)	ISE	• Potentiometry • Nernstian electrode response (NO_3^-–N) from neutral carrier	55.6 mV/dec	10^{-4}–10^{-1} M (20 μM)	• Salinization of the tip • Electrolyte: 0.05 M KNO_3 + 0.05 M KCl • Liquid membrane: Fluka 72549 • Cellulose acetate and protein layer at the tip	[9]

Nitrite (NO_2^-–N)	Solid	• Amperometry • Direct electrochemical oxidation of nitrite (NO_2^-N) on solid electrode surface	242 pA/(mg N/L)	0–20 mg N/L (0.02 mg N/L)	• Carbon fiber • Polarization	[10–12]
Nitric oxide (NO)	Clark	• Amperometry • Oxidation of nitric oxide at electrocatalytic surfaces	2 pA/μM, ~1 s	0–4 μM (~30 nM)	• Carbon fiber • Deposition of Ni-TMPP[f] • Internal electrolyte (100 mM sodium phosphate, 100 mM KCl at pH 7.2) • Polarization • H_2S interference	[13]
N_2O	Clark	• Amperometry • N_2O reduction	0.2 pA/μM, 40–50 s	0–1.2 mM (1 μM)	• Polarization (–0.75 V) • Use of an ion-tight silicon (Si) membrane in the oxygen guard • Use of alkaline ascorbate solution to eliminate oxygen interference	[2]
Phosphate (P)	Solid	• Potentiometry • Oxidation corrosion potential (mV) measurement • Reaction between CoO and phosphate ion ($H_2PO_4^-$ and HPO_4^-) between pH 6.7 and 8.4	33–84 mV/dec, <1 min	10^{-6}–10^{-1} M (2.2×10^{-6} M)	• Co wire (50–100 μm diameter) or Co electroplating • Conditioning in DI water to generate CoO layer at the tip • Required simultaneous DO measurement	[14–16]
Free chlorine (Cl_2)	Solid	• Amperometry • Reaction between PtOH and HOCl (and/or ClO^-)	1 pA/μM <1 s	0–7.5 mM	• Pt wire • Polarization • Conditioning in DI water to generate platinum hydroxide (PtOH) at the tip	[17]

(*continued*)

TABLE 7.1 (continued) Overview of Various Needle-Type Environmental Microsensors

Measurement	Type	Analytical Methods/ Mechanisms	Slope[a], Response Time	Conc. Range, (LOD[b])	Key Materials/Compound/ Procedures	References
NH_2Cl	Solid	• Amperometry • Reaction between PtOH and NH_2Cl	18 pA/(mg Cl_2/L), <5 s	0–10 mg Cl_2/L (0.3 mg Cl_2/L)	• Pt wire • Polarization • Controlled condition where predominant chlorine species are NH_2Cl (i.e., Cl_2:N = 4:1, pH 8.0)	[18]
Redox potential	Solid	• Potentiometry • Nernstian electrode response	1 mV/mV, <1 min	—	• Pt wire • Etching in 2 M KCN solution • Within 10 mV of the nominal redox potentials (ASTM D 1498-93)	[3]
Sulfide (S^{-2})	Solid	• Potentiometric measurement of sulfide (S^{-2}) at alkaline pH and total dissolved sulfide ($S_T = H_2S + HS^- + S^{-2}$) at neutral pH • Nernstian response	31 mV/dec (pH >13.5) 51 mV/dec (pH 7.2)	5×10^{-7}–5×10^{-3} M (pH >13.5) 5.8×10^{-6}–5.8×10^{-3} M (pH 7.2)	• Silver wire • Etching in 2M KCN solution • Chemical treatment of Hg^{2+} ($HgCl_2$) to form the sulfide sensing layer • Sulfidization of the silver surface with Na_2S • Required simultaneous pH measurement	[3]
	Clark	• Amperometry • Oxidization of H_2S by $K_3[Fe(CN)_6]$, resulting in the formation of elemental sulfur and ferrocyanide	1.2–0.6 pA/μM H_2S, <100 ms	2–300 μM H_2S (2 μM)	• Polarization (+85 to +150 mV) • Internal electrolyte: ferricyanide ($K_3[Fe(CN)_6]$) as redox mediator • Si membrane	[19]
Carbon dioxide (CO_2)	ISE, Clark	• Potentiometry • Nernstian response from changes in pH (buffer action)	100 mV/dec, ~10 s (or 2–5 min)	0–2 mM (3 μM)	• LIX membrane (pH measurement) • Internal electrolyte: 2 mM $NaHCO_3$ + 0.5 M NaCl • Si membrane	[6,20]

Copper (Cu_2^+)	Solid	• Potentiometry • Reaction of selenium with the copper surface as adsorbed hydrogen reduces $HSeO_3^-$ ions to selenium	29 mV/dec, 10 s	10^{-6}–10^{-1} M (10^{-7} M)	• Copper wire (75 µm diameter) • Copper selenide (CuSe) formed by cathodic deposition (2 mA/cm² from a 0.1 M Na_2SeO_3, pH 4–6) • pH interference	[21]
	ISE	• Potentiometry • Nernstian electrode response (Cu^{2+}) from neutral carrier	33.1 mV/dec	10^{-9}–10^{-4} M (2×10^{-9} M)	• Membrane containing ionophore, NaTFPB[g], *o*-NPOE[h], and PVC • THF[i] • Inner filling solution: Et_3NNO_3[j] and $Cu(NO_3)_2$ • Conditioning for 1 day in 10^{-5} M $Cu(NO_3)_2$	[22]
Cadmium (Cd_2^+)	ISE	• Potentiometry • Nernstian electrode response from neutral carrier	25.2–27.7 mV/dec, 15–30 s	>0.001 mM (10^{-10} M)	• Salinization of the tip • Electrolyte: 10 mM $Cd(NO_3)_2$ + 100 µM KCl • Liquid membrane (200 µm): 10% Fluka 20909 + 10% Fluka 60588 + 80% Fluka 73732 • Cellulose acetate and protein layer at the tip	[23]

[b] Limit of detection.

[c] The Clark-type microsensor is a combined microsensor. In this microsensor, the sensing cathode (or anode) is placed behind an electrically insulating gas-permeable Si membrane, which is extremely permeable to oxygen. The cathode (or anode) is bathed in an electrolyte solution into which a Ag/AgCl reference electrode is immersed [24].

[d] The solid-type microsensor is a single barrel microsensor (i.e., single-anode or cathode-type ME) with the solid metal tip sealed with a glass micropipette and with external reference electrode placed in the sample.

[e] ISE: Ion-selective electrode that contains LIX membrane.

[f] Ni-TMPP: nickel (II) tetrakis (3-methoxy-4-hydroxyphenyl) porphyrin.

[g] 2-Nitrophenyl octyl ether (*o*-NPOE).

[h] Sodium tetrakis [3,5-bis(trifluoromethyl)phenyl] borate (NaTFPB).

[i] Tetrahydrofuran (THF).

[j] Tetraethylammonium nitrate (Et_4NNO_3).

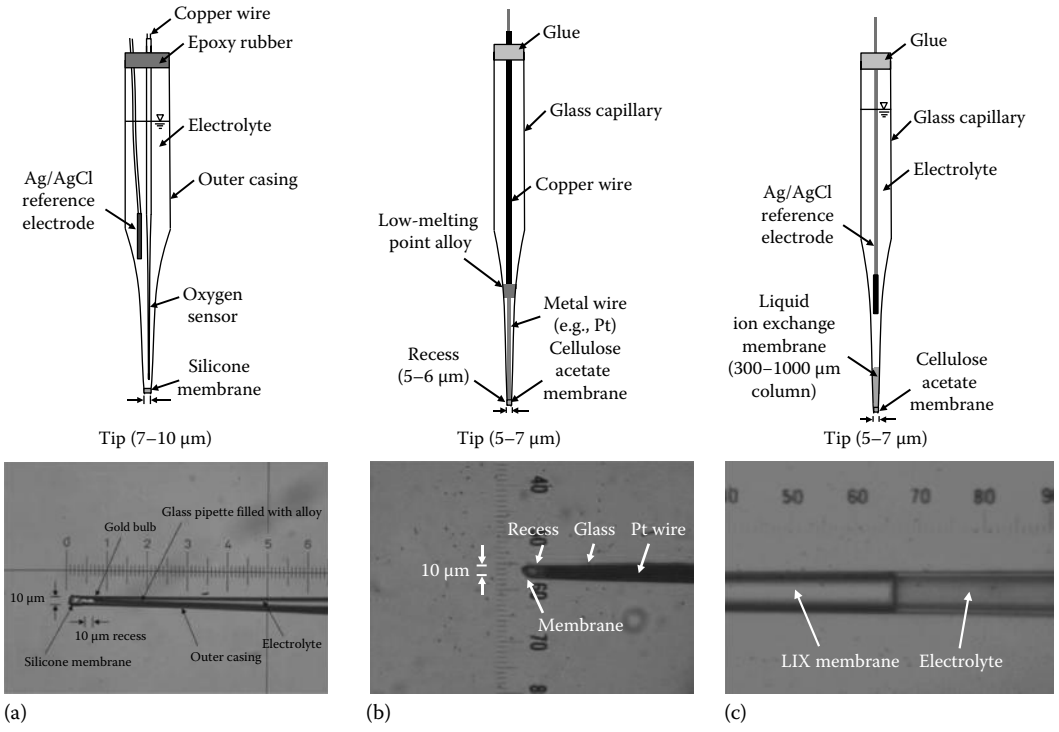

FIGURE 7.2 Schematic descriptions and images of needle-type environmental microsensors: (a) Clark-type combined microsensor (i.e., amperometric oxygen microsensor) and a tip of a combined oxygen microsensor, (b) solid-state microsensor (i.e., amperometric NH_2Cl microsensor) and a tip of a NH_2Cl microsensor, and (c) LIX microsensor with an image of a liquid membrane that is separated from an electrolyte.

Both platinum (Pt) and Au exhibit sensitivity to oxygen at negative potential (i.e., −0.75 V vs. Ag/AgCl), but Au has a higher sensitivity than Pt. As Au wire has different heat expansion coefficients and it is too soft to insert into the glass micropipette, Au electroplating methods have been used [3,5]. For the use of a bare Au wire (50 μm), a modified procedure is needed: the etched Au wire connected to a copper wire (for electric connection) is inserted into the glass micropipette and then pulled out using a micropipette puller (P-1000, Sutter Instrument) with an appropriate setting (e.g., heat: 460, pull: 120, vel: 100, delay: 1, pressure: 500, and ramp: 445). The response time of an amperometric microsensor is very short (within few seconds), and the shelf-life time of a solid-state microsensor (e.g., oxygen microsensor, free chlorine microsensor) is typically 1–2 years, depending on its contamination status.

In amperometric sensing, each microsensor must operate at a specific applied potential (or polarization potential) (e.g., −0.75 V for oxygen sensor, +0.15 V for monochloramine [NH_2Cl] sensor, and +1.2 V for nitrite sensor) depending on the electrochemical reaction between the sensing material and the analyte to be measured. Cyclic voltammetry (CV) has been used to evaluate the applied potential of the microsensors (Figure 7.3). Generally, oxygen reduction in a noble metal occurs at a negative potential: therefore, most microsensors, except oxygen sensors, have positive potentials for their operation unless they have a special treatment to remove the oxygen interference (e.g., ascorbate chamber in front of the microsensor [2]).

TABLE 7.2 Materials and Devices Necessary for Needle-Type Environmental Microsensors Fabrication[a]

Item	Use	Description	Sources
Metal wires	• Sensing materials for solid-state working electrodes	• 99.99% pure 50–100 μm diameter • Noble metals (Pt or Au) • Other metals (Co, iridium, or silver)	• California Fine Wire (Pt: 100-896, Ag: 100-183, Au: 100-542) • Alfa Aesar (Au wire: 0.1 mm, 10968) • Sigma-Aldrich (Pt wire: 26716-3, Co wire: 52344-5, discontinued)
Carbon fiber	• Nitrite microsensor • Nitric oxide microsensor	• PAN-based carbon fiber (7 μm) • Carbon finer (30 μm)	• Cytec Industries, Inc. (T300 12K) • WPI[b]
Nichrome wire	• Heating filaments for meting glass pipettes	• Nichrome wire, 22 gauge	• Fisher Scientific (S49085) • VWR (66258-066)
Silver wire	• Reference electrode	• 99.99% pure, 0.25 mm diameter	• Sigma-Aldrich (32703-4)
Graphite rods	• Counter electrodes for etching process	• High density, nonporous (e.g., glassy graphite)	• Sigma-Aldrich (49654-5)
Glass pipette	• Outer casing of combined sensors	• Disposable Pasteur pipettes	• Fisher Scientific (13-678-20C)
Glass micropipette	• Glass capillary tubing	• Low electric conductivity glass[c] • Borosilicate glass • Corning 8161 (potash rubium lead): amperometric microsensor • Corning 7056: LIX microsensor	• Warner Instruments (G86150T-4, G75150T-4) • Schott (8533) • Macalaster Bicknell Co. • Sutter Instrument (B12069-15) • WPI (PG10150-4)
Au solution	• Au electroplating	• $HAuCl_4 \cdot 3H_2O$ • Au plating solution	• Sigma-Aldrich (G4022-5G) • Sifco Metachemical (Dalic 3020)
KCN	• Electrochemical etching	• Potassium cyanide ACS grade	• Sigma-Aldrich (31252-250G)
Cellulose acetate	• Membrane used on amperometric microsensor	• Cellulose acetate solution 5%–10% (w/v) in acetone	• Sigma-Aldrich (180955)
Bismuth alloy	• Conductive filling material for electroplating Au for DO microsensors	• 117°F low-melting-point alloy: 44.7% bismuth, 22.6% lead, 19.1% indium, 8.3% tin, and 5.3% cadmium	• Belmont Metals, Inc. (2451A)
Si	• Membrane for DO or N_2O microsensor	• Silastic medical adhesive Si type A	• Dow Corning (Silastic or 732)
Injection needle	• Backfilling of internal reference solution	• Fine injection needle	• WPI (MF28G-5)
Liquid membrane	• LIX[d] membranes for ion-selective microsensors	• Hydrogen ionophore • Ammonium ionophore • Nitrate ionophore	• Fluka, Sigma-Aldrich (95293, 95297, 09879, or 72549)
Salinization solution	• Used to make glass pipette surface hydrophobic	• Salinization solution • *N*,*N*-dimethyltrimethylsilylamine	• Fluka, Sigma-Aldrich (85120, 41716-5ml)
Puller	• Pulling glass micropipette	• Flaming/brown micropipette puller	• Sutter Instrument (P-1000)

(*continued*)

TABLE 7.2 (continued) Materials and Devices Necessary for Needle-Type Environmental Microsensors Fabrication[a]

Item	Use	Description	Sources
Illuminator	• Light source	• NOVAFLEX fiber optic illuminator	• WPI (NOVA)
AC power supply	• Etching process • Heating process	• Variable transformer	• Staco (3PN1010B)
DC power supply	• Electroplating • Construction of Ag/AgCl	• Variable single output dc power supply (0–18 V dc at 0–3 A)	• Omnitron Electronics (HY1803D)
Micromanipulators	• Micromovement during construction	• Manual micromanipulator	• WPI (M3301)
Micropipette beveller	• Grinding ME tips	• Grinder, microscope, micromanipulator, and light source	• Sutter Instrument (BV-10)
Faraday cage	• Screen electromagnetic fields	• Bench top Faraday cage	• Technical Manufacturing (81-334-06)
Vibration-free platform	• Prevent vibrations	• Vibration-free platform	• WPI (VFP) • BenchMate (Kinetic Systems)
Stereomicroscope	• Monitor heat element	• Precision stereo zoom binocular microscope	• WPI (PZMIV-BS)
Uptight light microscope	• Monitoring and inspection of ME tips	• Profession grade microscope: 4×, 10×, 40×	• WPI (W30S)

[a] The information in the table is for reference purposes only. We do not promote any of the products specified in the table.
[b] World Precision Instruments (WPI).
[c] There is a need for a special type of glass with high insulation properties (i.e., Schott 8533 green glass) in the fabrication of oxygen microsensors in order to achieve a low background current.
[d] LIX, liquid ion exchange.

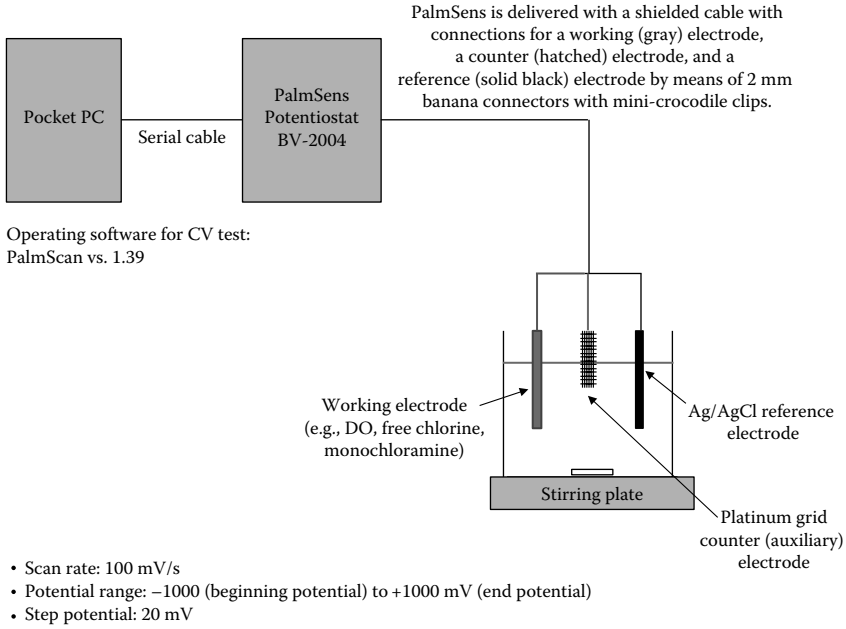

FIGURE 7.3 Schematic drawings of a CV test of amperometric microsensors. An example of the operation range and the connection is described.

7.4 Potentiometric Microsensors

Most ion-selective microsensors are potentiometric sensors where the voltage (mV generated vs. Ag/AgCl) is theoretically dependent on the logarithm ionic activity, according to the Nernst equation (Equation 7.2):

$$\begin{aligned} E_{\text{cell}} &= E_{\text{external ref.}} - E_{\text{internal ref.}} + E_{\text{membrane}} + E_{\text{junction}} \\ &= \Delta E_{\text{ref}} + \frac{RT}{ZF} \ln \frac{A_{i(\text{external})}}{A_{i(\text{internal})}} + E_j \\ &= k + \frac{RT}{ZF} \ln A_{i(\text{sample})} = k' + \frac{0.059}{Z} \log C_{i(\text{sample})} \end{aligned} \tag{7.2}$$

where

E_{cell} is the potential difference between the ion-selective microsensor and the reference electrode
E_{membrane} is the membrane potential
$E_{\text{external ref.}}$ and $E_{\text{internal ref.}}$ are potentials of the external and internal reference electrodes, respectively
E_{junction} is the liquid junction potential
A_i is the ionic activity [A(activity) = γ(activity coefficient) × C(concentration)]
z is the number of electrons involved in the reaction
F is the Faraday constant
R is the gas constant
T is the absolute temperature

The response time of a potentiometric microsensor depends on the concentration of the target ions. Therefore, it varies from a few seconds (at high concentration) to several minutes (low concentration). For example, the response time of a copper ion-selective microsensor varies from less than 60 s ($\geq 10^{-6}$ M Cu^{2+}) to 10 min ($<10^{-6}$ M Cu^{2+}) [22].

Liquid-ion-exchange (LIX) membrane ion-selective microsensors (Figure 7.2c) have been fabricated and used to measure specific ions such as pH, ammonium, and nitrate in biological samples. The key to the ion-selective microsensor is the LIX membrane, which contains a specific neutral carrier for the target ion. This neutral carrier makes it possible to measure the potential of the target ion's activity in the presence of other ions. Therefore, it can detect the target ion without any ion interference. Figure 7.2c shows the LIX membrane of the microsensor that is separated from the electrolyte. Liquid membrane length is generally 300 (50–1000) μm, and its lifetime depends on the length of the membrane, varying from 1 day to several weeks. A typical lifetime of an ion-selective microsensor for pH, ammonium, and nitrate is 2–3 days with a 500–1000 μm length of liquid membrane. Most ionophores for ion-selective MEs can be purchased from Fluka, Sigma-Aldrich (Switzerland) under the trademark Selectophore™ (http://www.sigmaaldrich.com/analytical-chromatography/analytical-reagents/sensoric-applications.html). Recently, ion-selective microsensors with a built-in reference electrode have been introduced to remove outer environmental interferences (e.g., low conductivity) during microprofile measurements [28]. Detailed fabrication procedures are described elsewhere [5,24]. One of the important steps is the silanization step. If LIX is not contained at the tip of the microsensor, this indicates that the silanization step was not done correctly. One possible reason is the contamination of the furnace (i.e., if the furnace is a general use one, organics may be deposited and the silanization will fail. Avoid any dirt, grease, or organics on the case before silanization).

7.5 Data Acquisition and Processing

The microsensor is positioned above the sample (e.g., biofilm) perpendicular to its surface when microprofiles are measured using a microsensor. Then it is moved to the bottom of the biofilm and is used to measure concentration profiles at a microscale (Figure 7.4). From the measured concentration profiles, we can

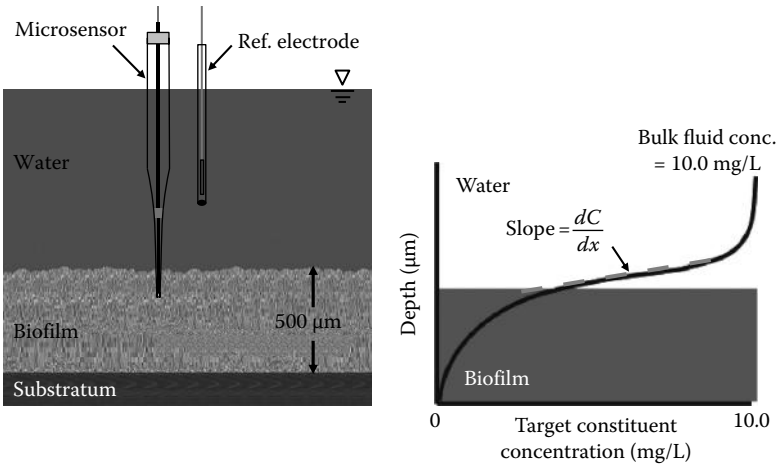

FIGURE 7.4 Schematic drawings of microprofile measurements using a needle-type microsensor and a measured concentration microprofile.

understand transport processes in the biofilm by calculating the rates and net fluxes of constituents (e.g., oxygen, ammonia, and nitrate) and/or diffusion coefficients using Fick's first law of diffusion (Equation 7.3):

$$J = -D_s \frac{dC}{dX} \tag{7.3}$$

where

J is the net flux (nmol/cm^{-2} s)
D_s is the molecular diffusion coefficient of compound C in water
dC/dX is the concentration gradient

The general experimental setup for microprofile measurements [27] includes a flow chamber (custom-made), stereo microscope (Nikon, SMZ-2T; PZMTIV-BS-CCTV, WPI, Sarasota, FL) with CCD camera (Model JE-3662 HR, Javelin Elec., Torrance, CA; 501381, WPI, Sarasota, FL), video display (501385, WPI, Sarasota, FL), data acquisition system (Diamond General Corp, Product 1231 for amperometric sensors; mV meter [Model 215, Denver Instruments] for potentiometric sensors; microsensor multimeter [Unisense A/S, Denmark] with SensorTrace Pro 2.0 software [Unisense A/S, Denmark] for multisensors), 3-D micromanipulators (Model MO-203, Narishige, Japan; MMS, Unisense A/S, Denmark), Faraday cage (Technical Manufacturing Co., Peabody, MA), vibration isolation table, and peristaltic pump systems to flow the medium.

7.6 MEMS Sensor Arrays

As discussed earlier, MEs can be fabricated in a number of ways [29,30], most commonly by pulling a glass micropipette, inserting a noble metal wire such as Pt or Au, and then filling with a low-melting-point alloy [3,4]. Although these ME fabrication methods are well established, there are a number of inherent disadvantages including low success rate, poor reproducibility, fragility, and difficulty in making a multianalyte sensor device [31–33]. Further, these ME sensors are susceptible to electric interference and have to be operated in specialized laboratories under highly controlled conditions. Therefore, there is a critical need for robust, sensitive, and easy-to-fabricate sensors for in situ measurements.

ME miniaturization and integration using MEMS technologies can offer many advantages for overcoming current difficulties for fabrication and integration of sensor components [16,27,33–43].

The key advantages of MEMS microfabrication technologies are (1) the reduction of costs due to batch fabrication, (2) an increase in integration, (3) reduction in power consumption due to smaller size, (4) reduction in complexity, and (5) increased reproducibility, thus producing a large number of uniform sensors. However, the most important advantage of using MEMS fabrication is the increase in sensor reliability due to redundancy and better process control.

Many researchers that apply MEMS technologies to solve sensor problems have focused on microfluidic lab-on-a-chip (LOC) systems [44–46]. Such systems typically contain microfluidic channels for sample collection, preparation, or transport with planar sensing areas for specific target analytes. Nevertheless, the key drawback of such systems is that samples still must be extracted from the site of interest, which often is not acceptable for in situ measurements. MEMS technologies have also been used to develop penetrating 3D ME sensors for neuroscience applications [47–50]. However, all of these needle-type MEMS electrodes have been designed for neural recording and can only measure potential (e.g., neuronal activity).

The recently developed needle-type environmental MEMS sensors, as summarized in Table 7.3, were tapered using the HF etch process, which is a typical MEMS fabrication process. The basic sensing principles are the same as described in Figure 7.1 for these miniaturized MEMS sensors. Figure 7.5 shows schematic diagrams and SEM images of various needle-type environmental MEMS sensors. There are currently no environmental MEMS sensors that are commercially available. The representative materials and fabrication equipment for needle-type environmental MEMS sensors are summarized in Table 7.4.

7.7 Amperometric MEMS Sensor Arrays

The DO MEMS sensor has a recess created at the tip of the ME, as shown in Figure 7.5b [27,36,37,40,43]. The fabrication process has five major steps:

- Dicing to form the array structure
- Etching to sharpen the probes
- Metal deposition for the conductive layer
- Packaging for electric connection
- Sensor tip formation for recessed DO MEMS sensor applications

The following sections are a brief description of the MEMS sensor fabrication process.

7.7.1 Dicing to Form the Array Structure

Glass cover slips are diced to form the array structure of the glass probes. The probe length is 2 cm with 900 μm center-to-center spacing between each glass probe. The cut wafer is then annealed at 550°C for 10 min to relieve stress from the dicing process.

7.7.2 Etching to Sharpen Probes

The probes are first etched in the HF-based etchant solution to smooth the diced surface and reduce the probe dimensions from 175 μm in thickness × 190 μm in width to 85 μm × 90 μm. Next, the glass probes are gradually pulled out to taper them down to 20 μm × 20 μm at the tip. In the final etching step, the glass probes are sharpened to ~200 nm tips using chemical meniscus etching, which forces surface tension at the glass–etchant interface. The process is schematically illustrated in Figure 7.6a.

7.7.3 Metal Deposition for Conductive Layer

The sharpened probes are deposited with a conductive layer, Ti/Au (20 nm/200 nm thick), on all sides by thermal evaporation. Figure 7.6b shows that twelve ME arrays containing 48 MEs were all metalized at the same time.

TABLE 7.3 Overview of Needle-Type Environmental MEMS Sensors

Measurement	Type	Analytical Methods/Mechanisms	Slope[a], Response Time	Conc. Range (LOD[b])	Key Materials/Compound/Procedures	References
Redox potential	Solid	• Potentiometry • Electrode potentials between a metal electrode and a standard reference electrode given by the Nernst equation • Measures the oxidized and reduced forms of all chemical species in the solution (nonselective)	1 mV/mV, <1 s	—	• Core material is a glass or a Si • Au thin film as a working electrode • Meniscus etching (chemical sharpening process) to sharpen penetrating needle-type ME • American Society for Testing and Materials (ASTM) recommends four calibration redox standard and reference solutions within 10 mV of the nominal redox potentials (ASTM D 1498-93)	[27,35,42]
Oxygen (O_2)	Recessed[c]	• Amperometry • Diffusing DO is reduced at the cathode to create a measurable electric current. • Linear relationship between the oxygen concentration and the electric current	~147 pA/mg/L DO, <20 s	0–8.3 mg O^2/L (23°C)	• Parylene C layer (1.5 μm thick) to insulate individual MEs • The recess process: Parylene C deposition, beveling tip end, and etch glass/Au • Au thin film as a working electrode • Apply −750 mV polarization voltage	[27,36,37,40,41]
Phosphate (P)	Solid	• Potentiometry • Co metal electrodes detecting the inorganic[d] and organic[e] phosphate • Oxidation corrosion potential (mV) measurement on CoO surface • Reaction between CoO and phosphate ion depending on the solution pH	96 mV mV/dec, <1–30 s	10^{-6}–10^{-1} M (2.2×10^{-6} M)	• Co electroplating using Co plates as anodes • Oxidize by immersing in DI water along with a Ag/AgCl reference electrode to generate CoO layer at the tip • Oxygen affect for activity of phosphate ions	[16,38,40–42]
pH	Solid	• Potentiometry • IrOx electrode without an ion-selective membrane • Electrode potentials given by the Nernst equation	~62.0 mV/pH, <5 s	pH 2–12	• Electroplate IrOx using IrOx electrolyte solution • Plasma oxygen etch to remove Parylene C insulate layer	[27,41,42]

[a] Slope of linear regression indicating sensitivity.

[b] Limit of detection.

[c] Three types of DO ME are used for DO measurements: the Clark-type, the open-type, and recessed DO ME. The Clark-type DO ME consists of a working electrode with a gas-permeable membrane and an internal reference electrode in the electrolyte. The open-type and recessed DO MEs use an external reference electrode; thus, the miniaturization of these sensor types can be achieved easily with simpler fabrication and smaller working electrode size.

[d] Inorganic phosphate including $H_2PO_4^-$, HPO_4^{2-}, and PO_4^{3-}.

[e] Organic phosphate including disodium adenosine 5′-triphosphate (ATP), disodium adenosine 5′-diphosphate (ADP), and disodium adenosine 5′-monophosphate (AMP).

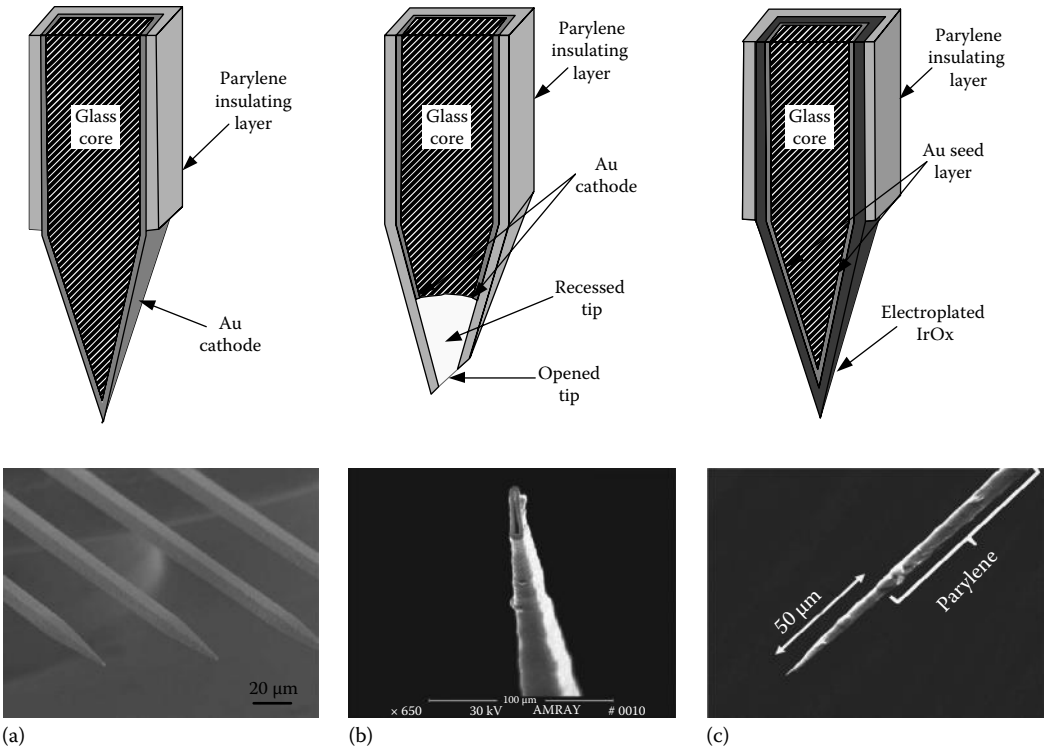

FIGURE 7.5 Schematic diagrams and SEM images of various MEMS sensors: (a) ORP MEMS sensor; (b) DO MEMS sensor: amperometric recessed DO sensor. (From Lee, J.H. et al., *J. Micromech. Microeng.*, 19, 025022, 2009.); and (c) IrOx pH MEMS sensor: solid-state pH sensor. (From Lee, W.H. et al., *Meas. Sci. Technol.*, 22, 042001, 2011.)

7.7.4 Packaging for Electric Connection

To establish electric connections with individual sensors, ME arrays are packaged on a printed circuit board (PCB) with conductive silver epoxy. Parylene C is coated over the entire substrate to insulate individual MEs.

7.7.5 Sensor Tip Formation

To create the recess, the HF-based etchant is used to etch the glass core, and the Ti is exposed by beveling. The beveling and etching steps permit precise control of the recess opening size and depth to relocate the Au sensing area inside the formed recess.

The finished MEA sensor consists of four 2 cm long sharpen MEs packaged on a PCB carrier as is shown in Figure 7.6d. The tip sizes and the overall dimensions of the MEMS sensor array are compared with those of commercially available millielectrodes (COMs) and ME sensors in Figure 7.6c. Then, the DO MEMS sensors are polarized with an applied −0.75 V and calibrated with a commercial Ag/AgCl reference electrode. The completed MEMS sensor has a high sensitivity of ~147 pA/mg/L DO, with less than 20 s required reaching 90% response (Table 7.3).

7.8 Potentiometric MEMS Sensor Arrays

Table 7.3 shows three potentiometric MEMS sensors including redox potential (oxidation–reduction potential [ORP]), phosphate, and pH sensors. These MEMS sensors are good examples for potentiometric sensors with/without an ion-selective membrane. The ORP sensor is the most basic electrode

TABLE 7.4 Materials and Devices Necessary for Needle-Type Environmental MEMS Sensor Array Fabrication

Item	Use	Description	Sources
Borosilicate glass wafer	• Core structure material for working electrode	• 175 μm thick, 45 mm × 50 mm	• Erie Scientific, Pittsburgh, PA
Dicing saw	• Cut individual glass probes	• 45 μm diamond grit resinoid blades (MicroSwiss)	• K&S (740)
Programmable box furnace	• Anneal glass wafers to relieve stress from the dicing process • Use cooling steps to reduce thermal shock	• Programmable target temperature and hold time • Reliable uniform temperature inside furnace	• Thermo Scientific, Norwood, MA (Lindberg/Blue M)
Motorized linear translation stage	• Control glass probes to pull out gradually from glass etchant • Taper glass probes	• Computer-controlled (via LabView v.7) translation stage • Minimum step size is 1.57 μm	• Newport Corp., Irvine, CA
Organic layer	• Modify the contact angle at the glass–etchant interface • Prevent vaporizing toxic HF-based etchant solution	• Vegetable oil • Paraffin oil	• Fisher Scientific
Metal targets	• Evaporation targets	• 99.99% pure • Titanium (Ti), chromium (Cr), Au, Pt	• Sigma-Aldrich
E-beam evaporator	• Metal deposition	• Evaporation Ti, Cr, Au, Pt	• Airco Temescal (FC-1800)
PCB	• Establish electric connections with individual sensors • Carriers for easier handling	• Copper-clad laminate glass epoxy • Laminate (790 μm thick) • Copper (35 μm thick layer) and dry film negative photoresist (33 μm thick layer) • Photolithographically pattern and etch in ferric chloride to define designed traces on the PCB surface	• D&L Products, Inc.
UV-cured epoxy	• Fix MEs on PCB carriers	• Epoxy bond	• Loctite, Rocky Hill, CT (3301)
Conductive silver epoxy	• Conductive filling material for electroplating Au for DO microsensors	• Conductive silver-based low curing temperature (120 °C)	• Emerson & Cuming, Billerica, MA (Ablebond 8700E)
Parylene C	• Insulate individual MEs	• A well-known biocompatible polymer material • Inert and optically transparent material with the pinhole-free surface	• Specialty Coating Systems, Indianapolis, IN

TABLE 7.4 (continued) Materials and Devices Necessary for Needle-Type Environmental MEMS Sensor Array Fabrication

Item	Use	Description	Sources
Parylene coater	• Deposit Parylene C easily and uniformly on any substrate	• Simple vapor deposition	• Specialty Coating Systems (PDS 2010 Parylene Labcoter)
Micropipette beveller	• Bevel ME tips	• Beveler, microscope, micromanipulator, and light source	• Sutter Instrument (BV-10)
Potentiostat	• Electroplate metal layers • Supply the polarization voltage and current	• Galvanostatic mode • Control current and voltage	• Gamry, Inc. (Reference 600) • Diamond General Development Corp. (No 1231)—Chemical Microsensors II potentiostat
pH/mV meter	• Measure pH and potential	• Data acquisition system • Integrate with BalanceTalk software (Labtronics, Inc.)	• Denver Instrument (model 225)
IrOx	• Use solid-state working electrode for pH sensor	• Electroplate IrOx film	• Sigma-Aldrich
IrOx electrolyte solution	• Pulling glass micropipette	• Mixture of iridium tetrachloride ($IrCl_3$), hydrogen peroxide (H_2O_2), oxalic acid ($C_2H_2O_4$), and potassium carbonate (K_2CO_3) in DI water	• Sutter Instrument (P-1000)
Cobalt (Co) electrolyte solution	• Grinding ME tips	• Mixtures of 33 g $CoSO_4$ and 3 g H_3BO_3 in 100 mL of DI water	• Sigma-Aldrich
Piranha etchant	• Clean glass surface	• H_2SO_4 and H_2O_2 in a 7:3 (v/v) ratio	• Fisher Scientific
HF-based etchant solution	• Glass etchant • Smooth the diced surface • Reduce the probe dimensions	• HF, HNO_3, and H_2O in a 10:7:33 (v/v/v) ratio	• Fisher Scientific
Au etchant	• Etch Au	• Mixtures of I_2, KI, and H_2O (1:4:40 (m/m/v)) (1:4:40 (m/m/v))	• Fisher Scientific
Ag/AgCl reference electrode	• Construction of Ag/AgCl	• Commercial Ag/AgCl reference ME	• Microelectrodes Inc. (MI-401)
Thick photoresist buffer	• Buffer for beveling and plasma ashing	• 5–8 μm	• Clariant Corporation (AZ 4562)
Plasma oxygen ashing	• Etching tip of electrodes	• 50 μm	• March CS-1701 RIE

and is used to measure the oxidized and reduced forms of all the chemical species (nonselective) in the solution. The working electrode just needs to have its exposed conductive area in contact with a solution without the need for an ion-selective membrane, as shown in Figure 7.5a [35,42]. ORP electrodes directly measure the potential of a solution between a metal electrode and a standard reference electrode, given by the Nernst equation (Equation 7.2).

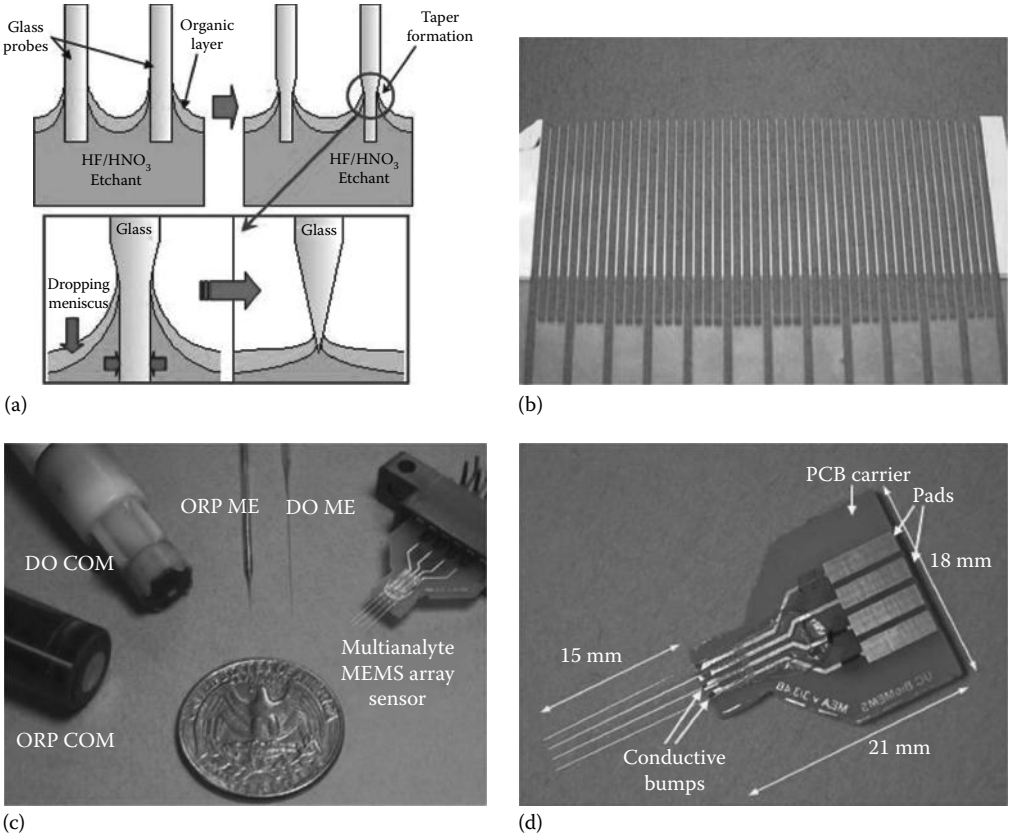

FIGURE 7.6 (a) Schematic diagram of fabrication of sharp MEMS sensor array tips using meniscus etching (meniscus height falls dynamically to form a taper with geometry dependent on the initial meniscus height) [27], (b) a metalized cover slip glass with sharpened probe tips, (c) the fabricated multianalyte MEMS sensor arrays packaged on a PCB carrier compared with COMs and ME sensors, and (d) integrated multianalyte MEMS sensor arrays with ORP, DO, and phosphate sensor. (From Lee, W.H. et al., *Meas. Sci. Technol.*, 22, 042001, 2011.)

For phosphate MEA sensors, cobalt (Co) is electroplated to form a Co film as an ion-selective membrane filling the empty recessed area, as depicted in Figure 7.5b [38]. Two Co plates are used as anodes in the prepared Co electroplating electrolyte solution. Co is electrodeposited to a ~0.2 μm thickness on the Au tips. The MEMS phosphate sensor measures oxidation corrosion potential (mV) on the cobalt oxide (CoO) surface, in conjunction with a reference electrode.

The MEMS pH sensor uses an electroplated iridium oxide (IrOx) film as a working electrode in place of an ion-selective membrane [42]. To achieve a more durable sensor for penetrating into a sample, the IrOx film is used in a solid-state electrode without the attachment of an ion-selective membrane. The fabrication process for the needle-type pH sensor is composed of six major steps: dicing, etching, metallization, IrOx electroplating, packaging, and sensor tip formation. The first three steps are the same as the batch fabrication processes previously described in Section 7.3. The final three steps to form a solid-state electrode for the pH MEMS sensor are discussed in detail later.

7.8.1 IrOx Electroplating

After the Ti/Au conductive layer deposition, IrOx is electroplated on the entire Au seed layer. Dark blue IrOx films are obtained with a thickness of 100–150 nm. Fresh IrOx-coated sensors are stabilized in pH 7 buffer for 2 days to reduce potential drift during measurements.

7.8.2 Packaging for Electric Connection

ME arrays are packaged on a PCB, followed by IrOx electrodeposition. Parylene C is coated over the entire substrate to insulate MEs.

7.8.3 Sensor Tip Formation

Two steps are used to expose a ~50 μm long IrOx sensing tip. The first step is to cover the entire sensing tip using photoresist, and then ~50 μm long sensing tips are stripped by acetone. Secondly, the plasma oxygen process is used to etch Parylene C on the exposed sensor tip end. The schematic diagram of the MEMS pH sensor is illustrated in Figure 7.5c.

7.9 Multianalyte MEMS Sensor Arrays

The individual needle-type MEA sensor for measuring ORP, DO, and phosphate, respectively, can be integrated into a single multianalyte sensor array as shown in Figure 7.6d, exhibiting higher sensitivity, faster response time, and higher stability with a smaller tip size than the conventional sensors. The major advantages of these new MEMS sensors include the ability to penetrate samples to perform measurements, the small tip size for in situ measurements, array structure for higher robustness, and the possibility of multianalyte detection. The sensors demonstrate the ability to monitor local concentration changes in small structures with a high spatial resolution and offer the versatility of the ME technique as well as the capability for repetitive measurements.

The integration process was aimed at easier and simpler fabrications for mass production with a minimum number of steps. Following the metallization step, the integration process begins with the application of Parylene C insulation to the ME tips. All four MEs in an array were beveled at the same time to expose glass and Ti/Au layers. The recess etching process was used to form the recessed structure. Since Au exposed to the solution enables ORP measurements, the recessed structure can measure not only ORP but also DO. For phosphate sensors, Co was electrodeposited on the exposed Au tips. Ultimately, the multianalyte MEMS sensor array will enable in situ measurements in a wide variety of small sample applications in environmental engineering and life sciences.

7.10 Data Acquisition and Processing

MEMS sensors can use the same general experimental setup for microprofile measurement described in the Section 7.2. However, the ability to perform an in situ measurement outside of the controlled laboratory environment of a well-grounded Faraday cage is based on the integration of the MEs with a complementary metal oxide semiconductor (CMOS)-based integrated circuit (IC) for noise cancellation.

The CMOS chip has been developed to perform both signal acquisition and processing [35] and then integrated with the MEMS sensor. The circuit for potentiometric measurements with MEMS sensors is based on the CMOS ASIC design. The circuit block is divided into three stages: a low pass filter, an isolation amplifier, and an instrumentation amplifier. The built-in noise cancellation design eliminates both environmental and instrumental noise, permitting measurement of voltages in the 10^{-3}–10^{-6} V range outside the Faraday cage.

7.11 Application for Environmental Processes

Figure 7.7 shows the areas where microsensors are or could be applied in engineered and natural water systems. Biofilm control issues in drinking water have been one of the high-priority research areas. A NH_2Cl microsensor has been used to evaluate biofilm control strategies and nitrification in

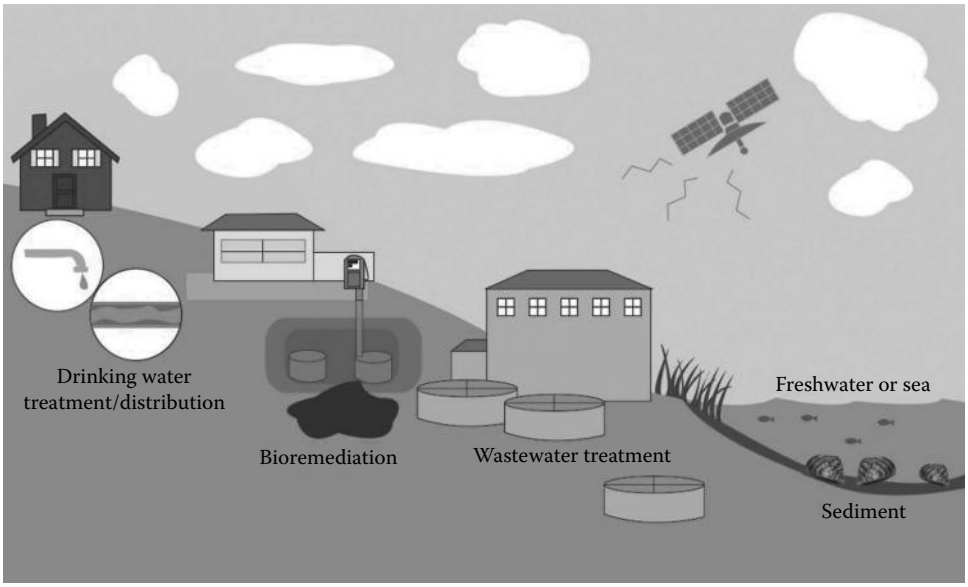

FIGURE 7.7 Various needle-type environmental microsensor applications for engineered and natural water systems. (Graphic created by Emily Nauman.)

chloraminated drinking water distribution systems, by combining with environmental microbiological approaches (e.g., confocal laser scanning microscopy [CLSM], cryo-cross sectioning, fluorescent in situ hybridization [FISH]) and other microsensors (e.g., oxygen, free chlorine, ammonium, pH, and nitrate) [25,26]. Microsensor applications can extend to the characterization and evaluation of corrosion and biocorrosion (e.g., localized corrosion and electrochemical activity distribution on pipe surfaces in real time with high spatial resolution) during disinfection in water infrastructure (e.g., ductile/cast iron pipe, copper, lead, and concrete pipe materials) and also provide significant impact on other industrial water infrastructures (e.g., ship hulls, ballast water disinfection, and cooling water systems), which experience corrosion and biocorrosion. One example of future applications is an envisioned field-deployable version of real-time monitoring of chloramine species in drinking water distribution systems (including premise plumbing).

In the bioremediation processes, it is important to investigate the dynamics of soil biofilm structure and function, related kinetics, and reaction mechanisms for better understanding of bioremediation processes such as degradation of hydrophobic petroleum compounds [51]. The appropriate modeling kinetic parameters can be determined using microsensors for better biological processes.

In wastewater treatment plants, environmental microsensors have been used for decades to understand the mechanics of relative biological processes and/or lead to the improvement of modeling, design, and operation of existing biological water/wastewater treatment processes including membrane processes for nutrient removal [3,8,13]. Microsensor applications for membrane biofilm processes [52] and microbial fuel cells (MFCs) [28,53] have also increased to improve engineering processes that produce renewable energy while reducing the energy requirements for a treatment plant. In situ monitoring using microsensors also prevents possible contamination of natural systems and/or treatment systems, and thus we can readily and continuously monitor water quality and prevent an impending event such as toxicity breakthrough or operational malfunction.

Microsensors have also been used in the fields of ecology and environmental science, such as to study the microenvironments in lake (or marine) sediments [54], with zebra mussel issues (e.g., nitrification in shell biofilms) [55], with invertebrates (e.g., denitrification in the gut) [56], with rhizosphere soil [57], and with roots of submerged plants [58] where important constituents' transport

(e.g., oxygen, phosphate) or nitrogen cycling occurs. The sensor techniques can be extended to in-field integrated water quality monitoring systems (e.g., monitoring of global climate change and eutrophication control) over a large area, providing real-time water quality data by combining with geographic information system (GIS) technology.

7.12 Outlook of Needle-Type Environmental Sensors

Needle-type environmental microsensors have been used to monitor environmental conditions and contaminant profiles in situ in various environmental samples (e.g., biofilm, pore water, and sediments). Their use for protection of human health and the environment has increased with the advanced fabrication techniques and improvements for stable data acquisition. In this chapter, we focused on needle-type microsensors for environmental monitoring, but they can also be applied to industrial and biomedical areas. Consequently, the development and application of microsensors have a great potential for collaboration with a wide range of disciplines. Potential research areas for new environmental microsensors would be hydroxylamine (NH_2OH), polychlorinated biphenyls (PCBs), polycyclic aromatic hydrocarbons (PAHs), and heavy metal (e.g., lead, mercury, and arsenic) monitoring sensors. For example, NH_2OH is a key intermediate during the process of the nitrogen cycles (e.g., ammonia oxidizing bacteria) and the production of N_2O, a major greenhouse gas. Therefore, a sensor for quantitative determination of NH_2OH will be very important, both in studies of biological processes and for industrial purposes. Antifouling methods (e.g., functionalized and controlled surface design and biomimetics) are also challenge areas to prevent biofouling during in situ monitoring and will provide more reliable sensor surface technology. Furthermore, there is a critical need for highly sensitive and selective low-power chemical sensors for a broad range of applications from environmental monitoring, food safety, health diagnostics, as well as global security and global warming. Although many sensitive transducer platforms have been developed, including microsensors, the long-standing fundamental problem of sufficient sensitivity (sub-ppm) and selectivity has not yet been solved. The key component for accomplishing ultrahigh sensitive sensors is an innovative improvement of sensor technology. Nanoelectromechanical systems (NEMS) technologies can permit the integration of different mechanical elements, sensors, and electronics in a small device and therefore can be suitable for the development of multianalyte sensors. The current roadblock to the implementation of such ultrahigh sensitive multianalyte sensors is the lack of nanotransducer platforms, which can be integrated with various reliable membrane materials.

Robert G. Lindquist
The University of Alabama in Huntsville

8.1 Introduction

Detection of very small amount of chemical and biological agents had been an active area of research for many years. From carbon monoxide detection for environmental applications to biological and biomedical monitoring, missile fuel leakage detection and security applications require high-sensitivity sensors that can measure low parts per billion (ppb) or part per million (ppm) of chemical or biological agents. Recent development of microelectronic technology has provided a good opportunity for fabrication of sensor and the interface circuit on a single chip. Single-chip fabrication of the sensor and the interface circuit provides higher-resolution, better accuracy, and lower-noise signal conditioning and amplification. In addition, better control over the sensor operating condition such as temperature and linearity can be provided. When the sensor is close to the interface circuit, higher sensitivity and lower noise can be achieved by omitting long wire capacitance and electromagnetic interface. The array of sensors can be built on a single chip for minimizing false alarms and selectivity of the sensor.

Biosensors that include transducers based on integrated circuit are often referred as biochips. A biochip normally consists of array of biosensors that can be monitored individually and can be used for the analysis of multiple analyte. The interaction between the analyte and the bioreceptor is designed to produce a measurable effect. A transducer converts the measurable effect into a signal (usually electrical) that can be monitored and recorded. The most common biosensors include antibody/antigen interaction, nucleic acid interactions, enzymatic interactions, cellular interaction (microorganism, proteins), and interaction using biomimetic materials (synthetic bioreceptor). For transducers, conventional methods are optical measurement (luminescence, absorption, surface plasmon), electrochemical, and mass-sensitive measurement (surface acoustic waves, microbalance) [1]. In the next section, some of the reported methods used for on-chip transducers will be reviewed. The principle of operation of single-chip chemical and biological sensors will be introduced, and liquid crystal (LC) chemical and biological sensors as a special case will be discussed in detail.

8.2 Transducers

Different transducers have been reported for gas sensors; mass-sensitive, capacitive, calorimetric, and electrochemical nanowire (NW) FETs have been reported for on-chip implementation [1–7]. Many of the sensors are based on a change in a polymer material due to exposure to a chemical or biological agent. The physical property of the polymer changes due to the analyte, and these changes can be detected using a microtransducer fabricated on the chip. The transducer shown in Figure 8.1 responds to the mass change of a cantilever beam due to the presence of a chemical agent. Resonating micromachined cantilever is a promising mass-sensitive chemical sensor especially when fabricated with the interface circuit on a single chip. The absorption of the agents in the chemically sensitive polymer causes a shift in the resonance frequency of the cantilever transducer. The change of the frequency of the cantilever or plate can be detected in a bridge circuit and simply measured using a frequency counter.

The transducer in Figure 8.2 is sensitive to change of heat when absorption happens in the polymer due to the presence of agents. The thermoelectric calorimeter is based on Seebeck effect. This transducer detects the heat when a change of enthalpy happens on absorption (condensation heat) or desorption (vaporization heat) due to the presence of chemical agents. An array of 256 polysilicon/aluminum thermocouples connected in series has been used in [2] to record temperature change in milli-Kelvin range. The calorimetric transducer only detects transitions and change of concentration of analyte in contrast to microcantilever and capacitive type.

In the Figure 8.3 transducer, the change in the dielectric of a material is detected using a capacitive transducer. The capacitive sensor relies on interdigitated electrodes, which corresponds to a basic two-plate capacitor that monitors dielectric change of a polymer sensitive to a chemical agent. The capacitor electrodes can be made of metal layers available on CMOS IC processes. For increasing transducer sensitivity, the number of electrodes per volume of the dielectric can be increased. Electroplating can also

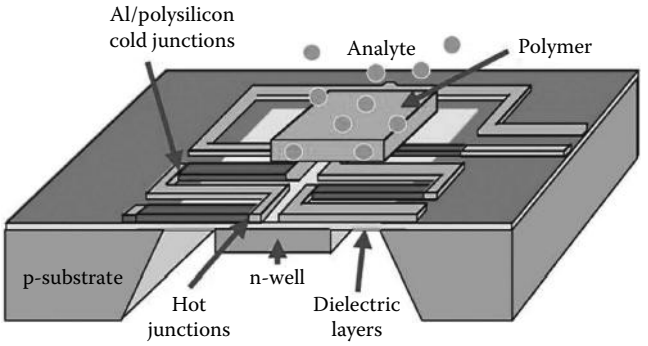

FIGURE 8.2 Calorimetric transducer. (From Hierlemann, A. and Baltes, H., *R. Soc. Chem*., 128, 15, 2003.)

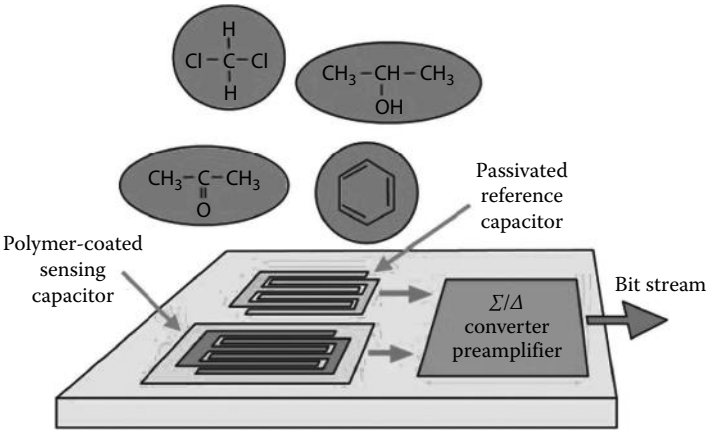

FIGURE 8.3 Capacitive chemical transducer. (From Hierlemann, A. and Baltes, H., *R. Soc. Chem.*, 128, 15, 2003.)

be used to elevate electrodes and improve capacitive sensor sensitivity. More details about interdigitated capacitor (IDC) transducer are provided in the LC section.

NWs have also been reported as a compatible technology for the detection of chemical species at low concentration of protein and viruses. Detectors based on NWs are field effect transistors (FETs) that show conductivity change when certain chemicals are attached to the NWs. In an FET, the current in the transistor is dependent on the electric field in the channel. Semiconductor NWs can function as FET devices, and silicon NWs are one of the best characterized that can be built as small as 2–3 nm for detecting applications. The NW acts as the gate of the transistor and the chemicals attaching to it having positive (or negative) net charge affect conduction in the channel. Macromolecules such as proteins have a net positive or negative charge that when attached to the NW will change the surface potential resulting in a change in the FET conductivity. Microfluidic channels can be used to carry the solution to the specific location on the chip area. Figure 8.4 shows fabricated NWs used for chemical and biological detection in this case single virus detection by the Harvard University researchers [4].

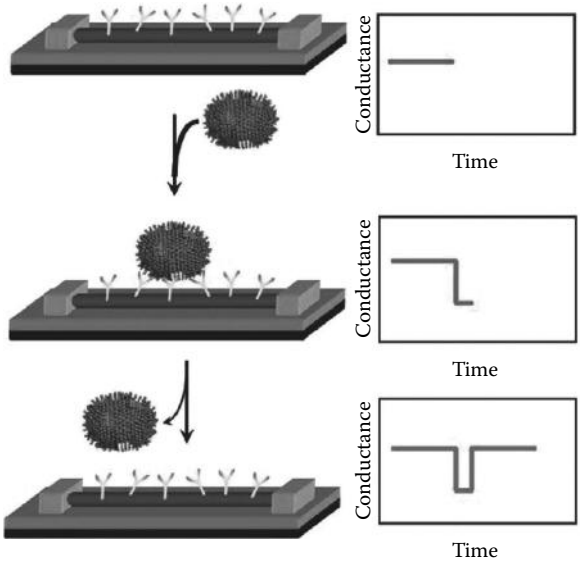

FIGURE 8.4 Single virus detection using NWs. (From Patolsky, F. et al., *Anal. Chem.*, 78, 4260, 2006.)

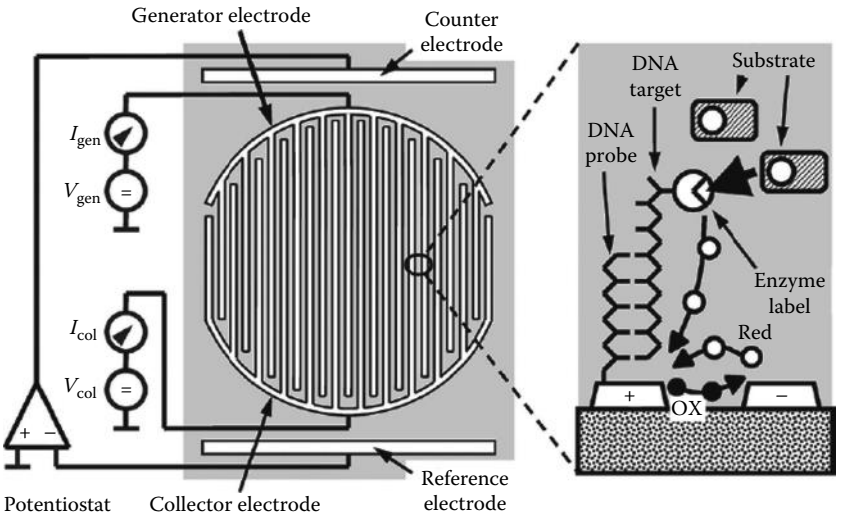

FIGURE 8.5 Interdigitated electrodes used in DNA detection in a sensor array. (From Schienle, M. et al., *IEEE J. Solid State Circuits*, 39(12), 2438, 2004.)

Similar techniques have been used such as extended gate FET that works on the same principle for the detection of chemicals [5]. Similarly, carbon nanotubes (CNTs) have also been fabricated on a chip for chemical and biological detection as reported in [6].

A DNA sensor microchip has been reported in [7] that is based on interdigitated gold electrodes with immobilized single-stranded DNA receptor molecules on them. When certain DNA attaches to the already existing DNAs, it will cause a change of the current in the sensor electrode detected and measured by an on-chip A/D converter. The method is called redox-cycling detection method for DNA detection. Figure 8.5 shows the principle of operation of the sensor as used in the 128 sensor array on a single chip.

In the next section, LC chemical and biological sensors will be discussed in detail.

8.3 Liquid Crystal Chemical and Biological Sensors

LC systems have proved to be an excellent candidate for reliable and sensitive detection for chemical and biological agents. They have been used to detect mustard gas, pesticides, and various viruses (West Nile, influenza, etc.) and have been used to amplify protein-binding events at an interface. A biological agent causes a change in the orientation of LC molecules; small changes at the nanoscale are amplified to micron level changes in the LC film. Therefore, the detection of very low level of chemical and biological agents is possible [8–15].

Recently, a novel technique developed by Dr. Lindquist and his colleagues in NMDC (Nano and Micro Device Center) at UAHuntsville uses a capacitive detection technique instead of optical inspection of LC alignment change [16,17]. This method brings a lot of worthy advantages over the conventional optical detection method. First, it provides greater insight into the fundamental distortion occurring in LC film by tracking the deformation, rather than just simply sensing the distortion by the optical method. Second, the removal of the optical transparency requirement of the substrate allows for a broader class of substrate selection. For instance, one of the substrates could be silicon to allow for the integration of electronics, and the other could be a porous ceramic to help facilitate the movement of chemical or biological agents to the sensing interface. The integration of the capacitive sensing method with signal processing on a chip leads to higher sensitivity and minimization of false positives.

8.3.1 Liquid Crystal Material

LC is a phase of material between crystalline solid and isotropic liquids. An Austrian botanist named Friedrich Reinitzer in 1888 discovered LC material. He found that an organic substance has two melting points; at the first melting point, it changes from solid to a cloudy liquid crystalline, and at the second point, it changes from LC to a clear liquid. Molecules of these kinds of materials are rod-like (calamitic) or disc-like (discotic) and typically are in the range of few nanometers (nm). The ratio between the length and diameter in rodlike or diameter and thickness for disklike materials is usually about 5 or greater [18,19]. Figure 8.6 shows two typical LC molecules, rodlike and disklike.

In addition to positional order, these molecules also may possess orientation order in the crystal. Figure 8.7 shows different states of an LC material, from solid to isotropic liquid. Different LCs may pass through different states before they reach isotropic liquid.

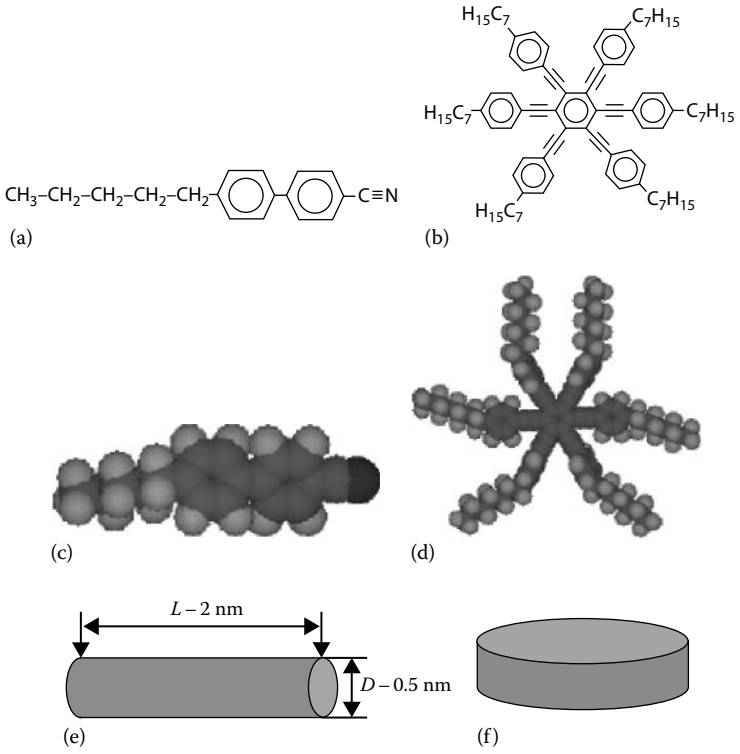

FIGURE 8.6 Rod-like and disk-like LC molecules: (a) Chemical structure, (c) space-filling model, and (e) physical model. Discostic liquid crystal: (b) chemical structure, (d) space-filling model, and (f) physical model. (From Wu, S.-T. and Yang, D.-K., *Fundamentals of Liquid Crystal Devices*, John Wiley & Sons, New York, 2006.)

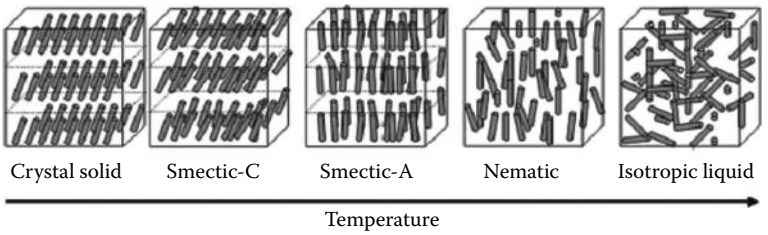

FIGURE 8.7 Phase change of rodlike molecules versus temperature. (From Wu, S.-T. and Yang, D.-K., *Fundamentals of Liquid Crystal Devices*, John Wiley & Sons, New York, 2006.)

Note that an LC might not have all phases shown in Figure 8.7. A unit vector $\vec{n}$, the LC director axis, represents the direction of the long molecular axis [19]. In nematic phase, LC molecules have orientation order but do not have positional order. As the temperature decreases, they tend to have positional orders in addition to orientation order. The LCs that change their behavior due to temperature change are called thermotropic. Lyotropic is another type of LC that has molecular structure changes due to the concentration of the solvent. LCs have many applications in different fields of science, medicine, industry, and engineering. Due to the LC anisotropic behavior, they have been widely used in LC displays, optical devices, optical tunable filters, and sensors [20].

As mentioned before, thermotropic LC phase changes when temperature changes. The nematic phase of thermotropic LC is a phase that molecules have long-range orientation order. The average molecule orientation is denoted by director axis $\vec{n}$. In this phase, molecules are free to move and do not have positional orientation. Molecules move freely but keep their long-range orientation order. Nematic LCs have uniaxial symmetry in director axis direction; therefore, $\vec{n} = -\vec{n}$. Because of the anisotropic property of LC, it will exhibit different permittivities in different directions. A uniaxial anisotropic LC has parallel permittivity for electric field parallel to the director axis and perpendicular permittivity for electric field perpendicular to the director axis $\vec{n}$. The dielectric anisotropy is defined as $\Delta\varepsilon = \varepsilon_{\parallel} - \varepsilon_{\perp}$, which could be either positive or negative. For instance, 5CB $\Delta\varepsilon = 10.5$ and BL006 $\Delta\varepsilon = 17.5$ are positive, and MBBA $\Delta\varepsilon = -0.59$ shows negative permittivity. Because of the anisotropy of LC dielectrics, it is possible to use an electric field to detect changes in the orientation of the director axis.

8.3.2 Capacitive Transduction Technique

Capacitive sensors have been widely used in sensor applications. The principle of capacitive transduction is that the value of a capacitive sensor changes because of a change in the physical quantity. This feature has been used for measurement of humidity, temperature, distance, pressure, etc. Although capacitive transduction is not new to the sensor world, UAHuntsville has been the first to use the capacitive sensor for LC sensor application [16,17,21]. The uniaxial anisotropic nematic LC has been used as the dielectric material of a capacitor. A change in the director axis of the LC in the presence of a chemical or biological agent causes capacitance change that can be measured and monitored accurately.

Figure 8.8 shows a typical director axis of a uniaxial calamitic LC material in the presence of vertical and horizontal electric fields. The nematic LC shows two permittivities, $\varepsilon_{\parallel}$ in the direction of electric

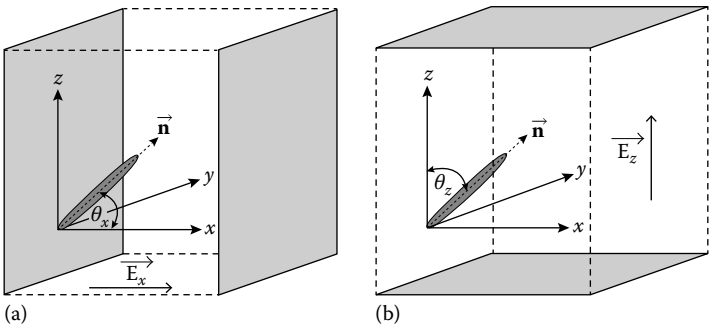

FIGURE 8.8 LC director axis and electric fields for horizontal and vertical parallel plate electrodes: (a) Vertical plates and (b) horizontal plates. (From Abu-Abed, A., Capacitive transduction for liquid crystal based sensors in ordered and partially disordered systems, PhD dissertation, University of Alabama in Huntsville, Huntsville, AL, 2007.)

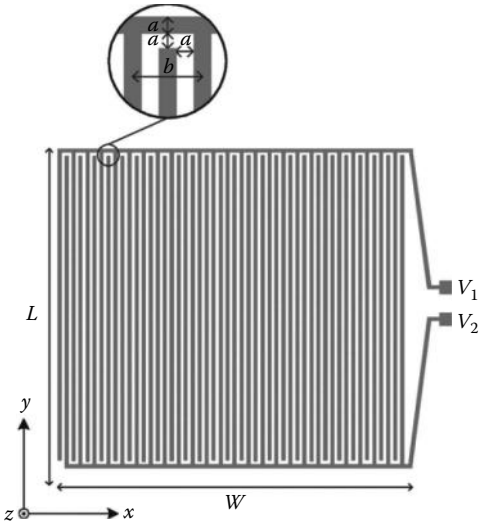

FIGURE 8.9 IDC structure. (From Abu-Abed, A., Capacitive transduction for liquid crystal based sensors in ordered and partially disordered systems, PhD dissertation, University of Alabama in Huntsville, Huntsville, AL, 2007.)

field parallel to molecule director axis and $\varepsilon_{\perp}$ for electric field perpendicular to the molecule director axis. In the molecule principal director axis coordinate, the permittivity tensor can be written as

$$\varepsilon_{\mathrm{m}} = \begin{bmatrix} \varepsilon_{\perp} & 0 & 0 \\ 0 & \varepsilon_{\perp} & 0 \\ 0 & 0 & \varepsilon_{\parallel} \end{bmatrix} \tag{8.1}$$

Considering homogeneous material, the director axis orientation can be determined using two capacitance measurements. Two parallel plate capacitors in the horizontal and vertical directions can provide enough information to determine the director axis angles as shown in Figure 8.8. The capacitance value can be calculated using a simple parallel plate capacitance equation:

$$C_i = \frac{\varepsilon_{\mathrm{eff},i} \cdot \varepsilon_0 \cdot A}{d} \tag{8.2}$$

Although vertical and horizontal electrodes provide enough information to determine director axis orientation, in order to have an open interface of the LC and chemical agents, an IDC can be used. Figure 8.9 shows the IDC structure.

An IDC consists of two latticed electrodes in the *XY* plane, and each electrode consists of *N* fingers. Each finger has a width of "*a*" and a spacing of "*a*" to the adjacent finger. The number of fingers can be large to provide a larger capacitance value. Electroplating can also be used to elevate electrodes of the finger and increase capacitance value and sensor sensitivity.

8.3.3 Excitation of the Liquid Crystal Sensor

Since the LC capacitive sensor is a passive component, an excitation voltage should be applied to the sensor in order to measure the capacitance. The amplitude and frequency of the ac excitation signal are important for a high-accuracy measurement. If the excitation voltage amplitude is

higher than Friedrich's voltage, the applied voltage can change the orientation of molecules and so the capacitance value. Excitation frequency of the LC sensor is very important for the determination of bandwidth and operating frequency of the charge preamplifier. One of the limiting factors in the resolution of the charge amplifier is the noise floor of the measurement system. In CMOS amplifiers, flicker noise or $1/f$ noise is dominant in low frequencies, and as the frequency of measurement decreases, this noise increases as shown in Equation 8.3. The first term in Equation 8.3 is the thermal noise, and the second term is the flicker noise that is inversely proportional to the frequency of operation:

$$v_N^2 = \left[\frac{8kT(1+\eta)}{3g_m} + \frac{K_F}{2fC_{OX}WLK'} \right] \Delta f \tag{8.3}$$

where
- k is Boltzmann constant
- T is temperature
- g_m is transistor transconductance
- η is a constant
- K_F is flicker noise coefficient
- f is frequency
- C_{OX} is oxide capacitance
- W is transistor width
- L is transistor length
- K' is a constant

Therefore, it is important to design the amplifier at a frequency that maximizes the resolution (lower noise) and accuracy of measurement. As a result, very low ppb agents can be detected with an integrated sensor microchip. Voltage investigation is important because low voltages are used for sensor capacitance measurement and high voltages are used to monitor anchoring energy for higher sensor sensitivity [22]. In order to measure voltage and frequency characteristic of the LC sensor, an experiment has been set up, and capacitance values under different voltages and frequencies of excitation have been measured. Excitation voltage and frequency have been changed from 0.5 to 20 V and 20 Hz to 2 MHz, respectively. Figure 8.10 shows the fabricated interdigitated sensor on a glass substrate.

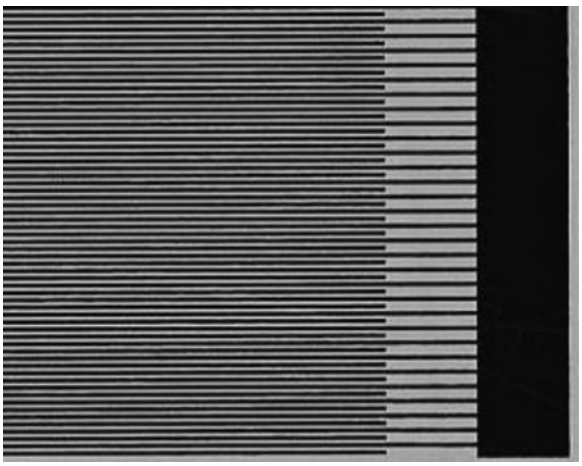

FIGURE 8.10 Fabricated interdigitated capacitive sensor.

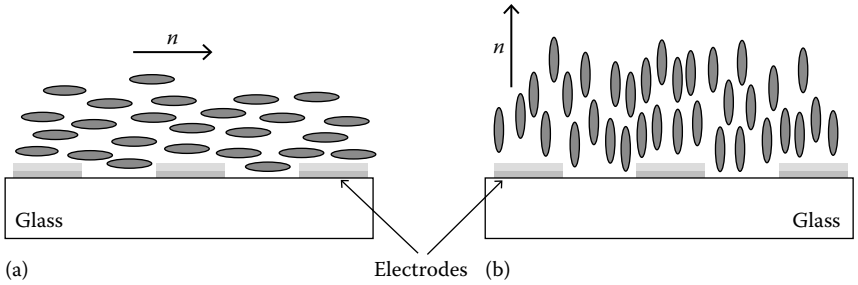

FIGURE 8.11 LC sensor molecule alignments: (a) Homogenous alignment and (b) homeotropic alignment.

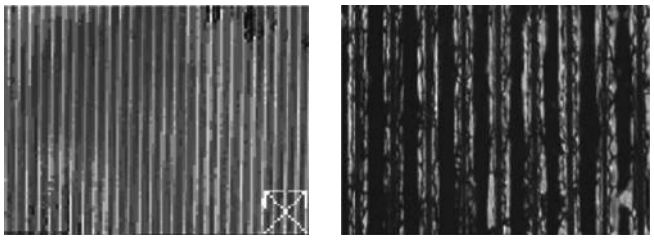

FIGURE 8.12 LC sensor optical observations: (a) Homogenous alignment and (b) homeotropic alignment.

Two different orientations for the LC molecules can be considered, one parallel to the substrate that is called homogenous and one perpendicular to the substrate or homeotropic orientation. These two orientations are shown in Figure 8.11.

In order to obtain homogenous alignment, 4% polyvinyl alcohol (PVA) in deionized water is spin coated on the interdigitated sensor surface and baked for 2 min at 90 °C. Then the surface is rubbed in one direction for a few times. After putting the LC on the surface, molecules tend to align in homogenous orientation. From optical observation, the homogenous alignment will look bright under a cross polarizer with 45° angle as shown in Figure 8.12a. For homeotropic alignment, 0.1% cetyltrimethylammonium bromide (CTAB) solution in deionized water is spin coated on the surface of the IDC. After baking at 90 °C for 5 min, the LC will be spin coated on the substrate. The resulting orientation will have homeotropic orientation and will always look dark regardless of the angle that it makes with the polarizer as shown in Figure 8.12b.

E7 LC has been used for the measurement because its clearing point is higher than room temperature and it remains anisotropic and has been used in LC chemical and biological sensing experiments.

It is has been shown that the sensor exhibits higher capacitance for low frequency rather than high frequency, because of frequency-dependent permittivity. Low-frequency excitation voltage causes LC molecules to vibrate. At high frequencies, LC loses its anisotropy that is not good for sensor applications. Although the higher frequency would provide less flicker noise for the amplifier, available bandwidth is also important for the rms input noise that should be considered for the amplifier design. The proper band for excitation is a flat band where the capacitance does not change very much versus frequency [ECE UAH]. Therefore, the proper range is the range where anisotropy is dominant [23–25].

8.3.4 LC Sensor Interface Circuit

The LC capacitive sensor is fabricated on a CMOS chip with the interface circuit for more sensitivity and accuracy in the detection. Different structures have been used for interfacing capacitive sensors in the literature. The most sensitive and accurate methods are the switched capacitor (SC) and linear differential charge amplifier.

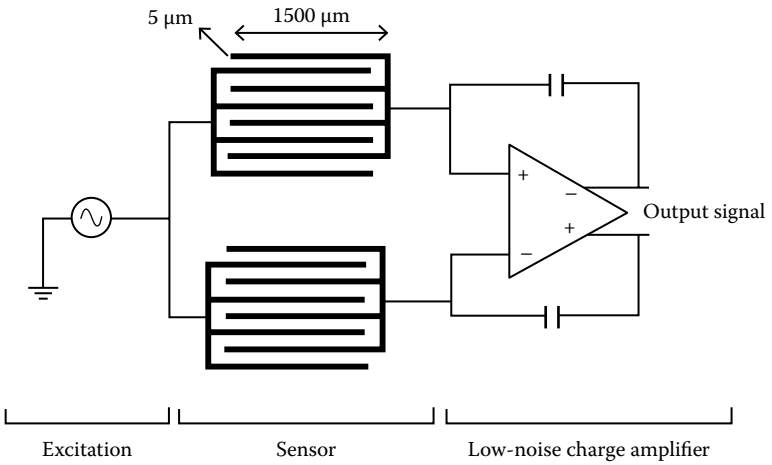

FIGURE 8.13 Block diagram of the differential measurement system.

Special requirements should be considered for interfacing the LC sensors. The LC excitation voltage should not contain dc components since it will cause charge migration in the film. Second, the amplitude of the ac excitation signal for measurement applications should be kept below Friedrich's voltage (a few tenth of a volt) in order not to make LC molecules reorient. These constraints should be considered in the design of the preamplifier. The block diagram of the sensor and the amplifier is shown in Figure 8.13.

The excitation voltage will be applied to the common node of the two sensors, and the signal output is amplified using a differential charge amplifier. Among different amplifier structures, a folded cascode amplifier has been used for this application. This amplifier has high output gain and wide input common mode range and can easily be compensated using loading capacitance. The amplifier has been used in many sensor and MEMS interface applications [26,27]. Furthermore, for reducing common disturbances and parasitic signals, a fully differential structure has been used. As discussed earlier, very low-frequency excitation causes the LC molecules to vibrate. Increasing the frequency of excitation decreases the sensor capacitance, which reduces measurement resolution. In order to have large capacitance and stable measurement, a 1 kHz excitation signal has been selected.

The input noise level of the low-frequency amplifier limits the measurement system resolution. Noise in a CMOS transistor can be modeled as a mean squared voltage noise at the transistor gate [28]. This noise consists of two components: thermal noise and $1/f$ or flicker noise as shown in Equation 8.3. Since thermal and flicker noises together affect the input noise level of the amplifier, they should be minimized simultaneously. A nonlinear optimization method has been used to design the preamplifier that minimizes the total input noise including thermal and flicker with a predefined constraint such as area limited design or power limited design. Note that power dissipation and area of the amplifier have a significant effect on the noise of the amplifier, but using an optimization algorithm can help in finding the best point with minimum loss of chip resources. A total input referred noise of the amplifier of 5.4 nV/$\sqrt{\text{Hz}}$ has been obtained, which corresponds to 15 aF capacitance resolution of the amplifier. The complete amplifier schematic is shown in Figure 8.14.

In order to compensate for the ac offset produced by sensor capacitor mismatch, CMOS switches have been used that change the number of fingers participating in the sensor as shown in Figure 8.15.

Two programmable ring counters provide sixteen-stage ac offset trimming for each interdigitated sensor with approximately 1% resolution. Furthermore, CMOS switches have been used for discharging feedback capacitors at a relatively long period of time to avoid saturation. The amplifier open-loop specifications are reported in Table 8.1.

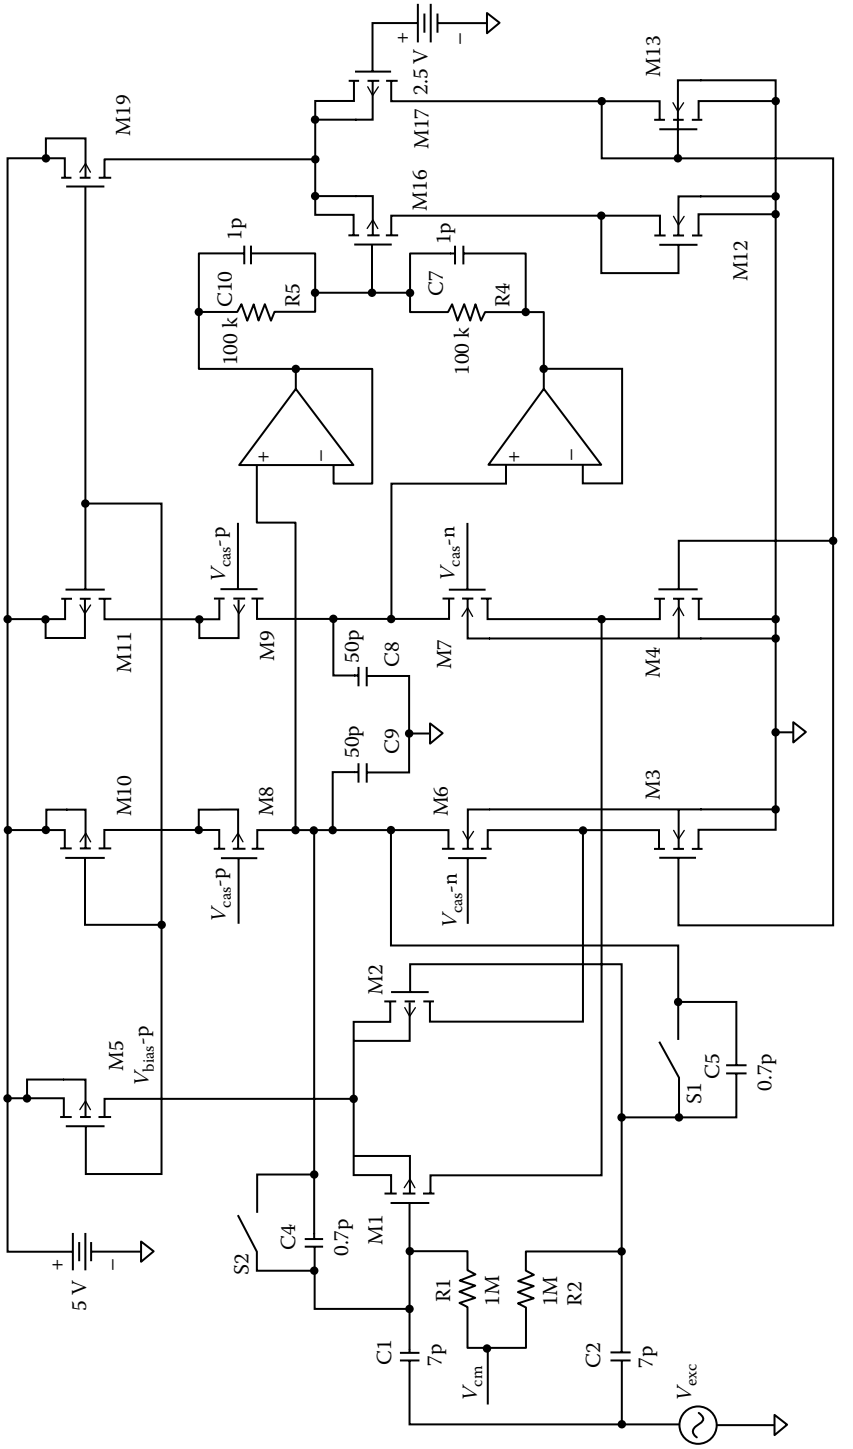

FIGURE 8.14 Fully differential charge amplifier that has been optimized for noise and performance.

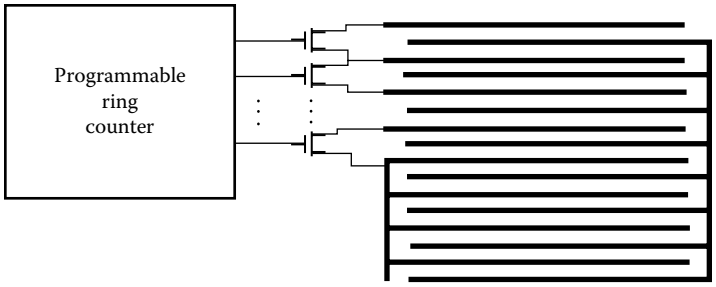

FIGURE 8.15 AC offset compensation using interdigitated sensor fingers and analog switches.

TABLE 8.1 Open-Loop Amplifier Specifications

A_{ol} = 74.5 dB	PM = 84.7°
PSRR = 99.4 dB	Output swing = 4.5 V
CMRR = 118 dB at 1 kHz	Pd = 1 mW

8.3.5 Gain Equation

For the differential amplifier gain in the midband frequency range, Figure 8.16 has been considered. Using charge conservation theory, Equations 8.4 and 8.5 can be written for the differential amplifier:

$$(v_{in} - v_A)C_{s1} = (v_A - v_{o1})C_f \tag{8.4}$$

$$(v_{in} - v_B)C_{s2} = (v_B - v_{o2})C_f \tag{8.5}$$

Subtracting Equation 8.5 from 8.4 and considering that $v_A = v_B$,

$$(v_{in} - v_B)(C_{s2} - C_{s1}) = -(v_{o2} - v_{o1})C_f \tag{8.6}$$

Considering matched feedback capacitors and small v_B, the gain equation can be written as

$$\Delta v_o \approx \frac{\Delta C_s}{C_f} v_{in} \tag{8.7}$$

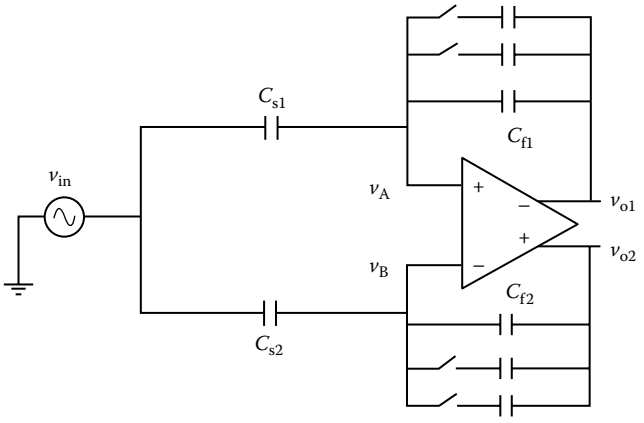

FIGURE 8.16 Sensor amplifier with variable gain.

The output differential signal is proportional to the sensor capacitance change divided by the feedback capacitor. Variable gain is achieved by using different capacitance values for the feedback capacitor. These capacitors are selected using CMOS analog switches as shown in Figure 8.16.

8.3.6 Switched Capacitor Implementation

Although a linear amplifier provides good noise and transfer characteristics without clock feedthrough problems, it has a few disadvantages including dc offset cancellation difficulties and large area-consuming resistors for input biasing. An SC technique is more complicated to design, but it does not need large resistors, and dc offset can be cancelled using auto-zero techniques. The same fully differential amplifier has been used as the core amplifier for the SC circuit. Figure 8.17 shows the schematic of the SC amplifier. Correlated double sampling (CDS) has been used to cancel the amplifier dc offset and low-frequency flicker noise [29]. Sensor capacitors are C2 and C5, the feedback capacitors are C7 and C8, and C9 and C10 are CDS capacitors. The SC circuit clock frequency should be higher than the Nyquist rate and in practice is selected to be more than 10 times of the input signal frequency. Very high clock frequency increases power dissipation of the amplifier.

Two nonoverlapping clocks S1 and S2 are used for the amplifier operation. The input signal is sampled on S1, and the feedback capacitor is discharged, while the dc offset is stored on CDS capacitors. On the amplification phase, clock S2, the differential signal is amplified at the output of the amplifier. High-frequency clock switching provides dc biasing for the input stage of the amplifier; therefore, separate biasing resistors are not required anymore.

Two main automatic offset cancellation techniques called chopper stabilization and CDS have been used for automatic offset cancellation. Chopper stabilization modulates the signal to a higher frequency; therefore, the dc offset and the signal is amplified in different bands and will be omitted. The CDS method is widely used in SC circuits for offset cancellation. The CDS method is a sampled data method that samples amplifier offset and stores it on a capacitor and subtracts it from the signal in the next clock cycle. Since CDS is a sampled data system, the sampling theorem applies to the offset cancellation. The flicker noise of

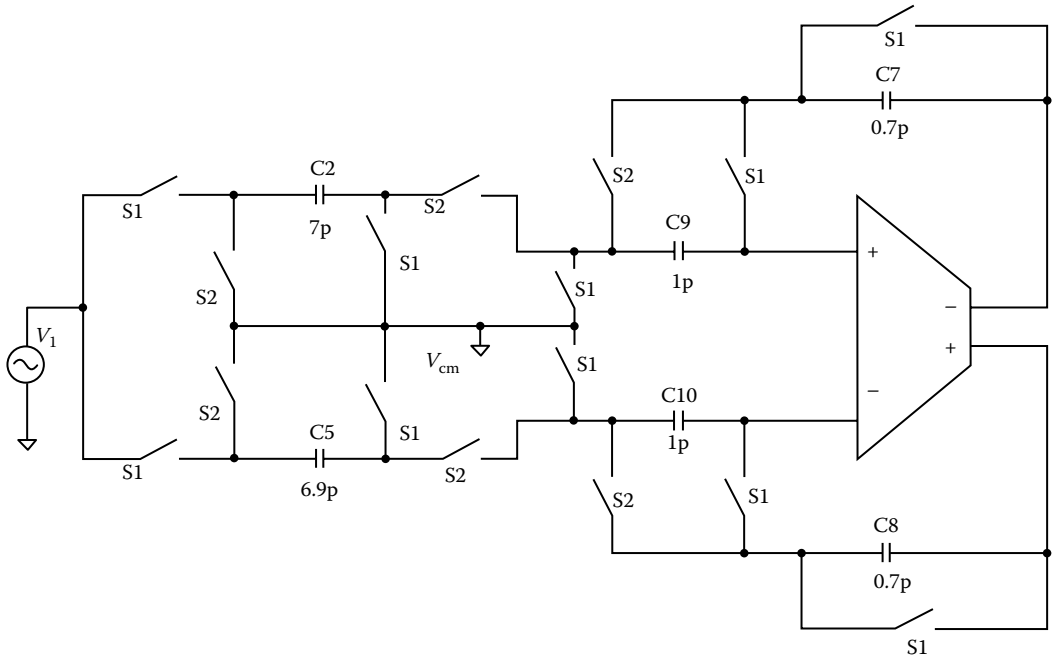

FIGURE 8.17 SC preamplifier with CDS.

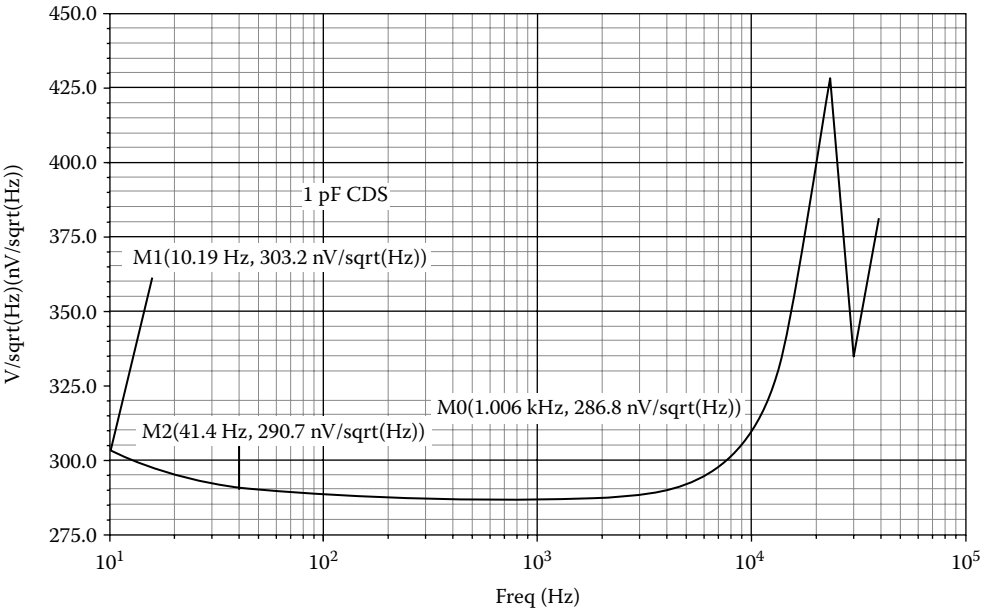

FIGURE 8.18 Input referred noise with a 1 pF CDS capacitor using PSS.

the CMOS amplifier is a low-frequency signal and is sampled by CDS and is decreased. Unfortunately, the amplifier thermal noise is under sampled by the CDS method and folds back to the amplifier signal band. Figure 8.18 shows the simulated input referred noise of the amplifier using Cadence periodic steady-state analysis and the CDS capacitor.

8.3.7 Demodulation and Filtering

After the sensor signal is amplified, demodulation and filtering are required to provide a dc signal for the analog-to-digital converter. The preamplifier output signal is buffered before entering the demodulation stage. The output signal of the demodulator goes to a low-pass filter to provide dc signal for the analog-to-digital converter. The demodulator used in this design is a switch-based multiplier that uses four analog switches as shown in Figure 8.19. The excitation of the LC sensor is amplified and transformed to a square wave after passing through multiple inverters and used for clocking the demodulator.

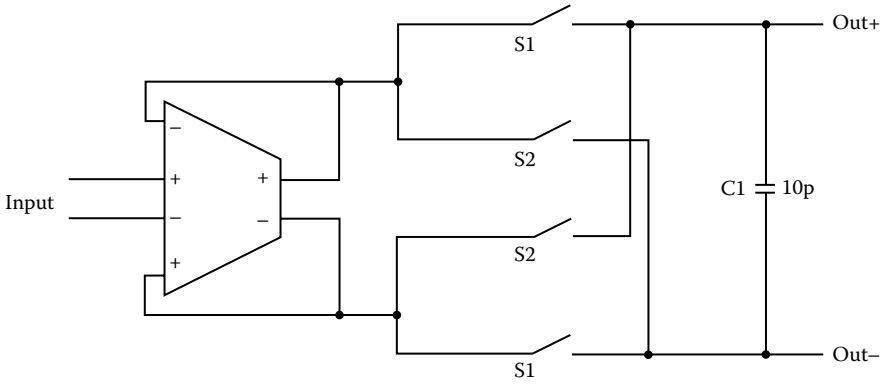

FIGURE 8.19 Buffer and switch demodulator.

Switches are transmission gates and because they do not have high currents, switch resistance is not critical. Furthermore, clock feedthrough and charge injections are highly reduced because of the differential structure. The preamplifier dc offset and out-of-band signals are modulated to higher frequencies, and the original signal that has the same frequency as the demodulator is down converted to a dc signal.

After the demodulation stage, a low-pass filter is required to filter the signal and prepare it for the analog-to-digital converter. Because the original signal has 1 kHz frequency, after demodulation, a filter with a much lower cutoff frequency is necessary to provide the dc output for the next stage. Considering a cutoff frequency of 100 Hz, the filter needs a very large time constant. If an *RC* filter is used, a 1 MΩ resistor with a 1.5 nF capacitor is required for the cutoff frequency of 100 Hz. These values are not practical for on-chip implementation. To achieve this low cutoff frequency, other integrated techniques like SC or *G*m–*C* filters can be used. In order to avoid switching and charge injection problems, the *G*m–*C* or (operational transconductance amplifier) OTA–*C* method has been employed.

The proposed *G*m–*C* filter structure is shown in Figure 8.20. This filter consists of a PMOS differential pair that uses source degenerative MOS transistors. The PMOS transistors have lower mobility, which is more useful in this structure than NMOS transistors. In order to increase output impedance and therefore gain of the OTA, cascade NMOS transistors have been used. The bias current has been selected to be 0.1 μA, and small transistor sizes for low *G*m have been selected. Degenerative transistors M11 and M22 (resistors) have large length for high resistivity that increases input linear range. Since a single-stage filter has negative feedback, it will further improve linearity.

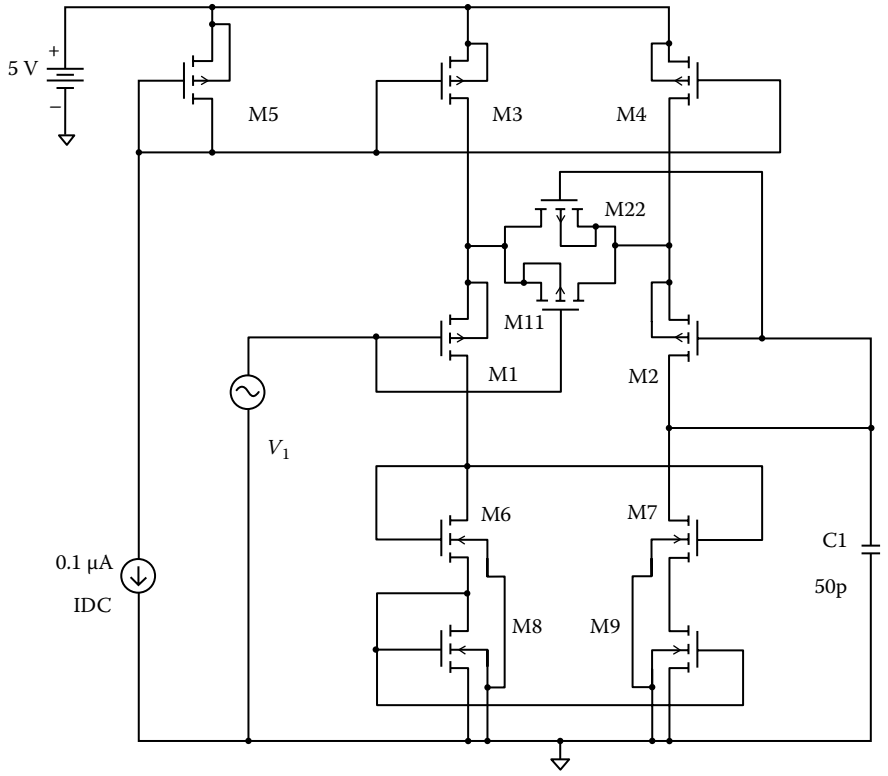

FIGURE 8.20 Schematic of the proposed *G*m–*C* filter.

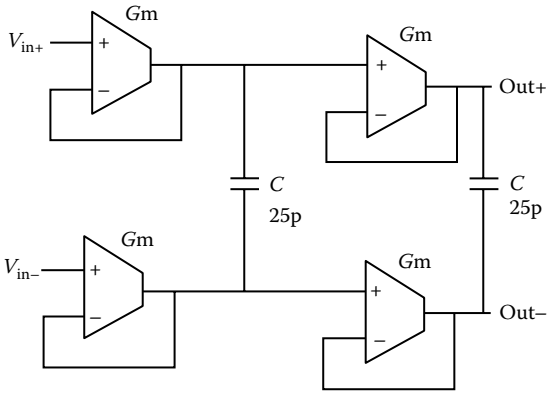

FIGURE 8.21 Differential low-pass Gm–*C* filter.

Figure 8.21 shows the Gm–*C* filter structure used in this design. The differential structure has been used to cancel common mode signals in the signal path.

Normally, the Gm of the Gm–*C* filters is tuned to get the proper cutoff frequency, but in this circuit, no extra tuning is necessary, because the corner frequency is well below 1 kHz. The dc output signal of this stage goes to the analog-to-digital converter section.

8.3.8 Analog-to-Digital Conversion

Among different techniques used for analog-to-digital conversion, sigma–delta is very attractive especially for low-frequency conversion. Other A/D conversion techniques like dual slope integrating and successive approximation need special analog fabrication processes such as laser trimming for high accuracy. The sigma–delta technique can achieve high accuracy (over 20 bits) in a digital process by using oversampling and noise shaping techniques without any postfabrication trimming or sophisticated analog component. This high accuracy can be achieved at the expense of more complicated digital filtering circuitry and time of conversion.

The sigma–delta converter is an oversampling technique where the input analog signal is usually sampled at a much higher frequency than the Nyquist rate. The oversampling rate (OSR) is defined as

$$\text{OSR} = \frac{f_s}{2f_o} \tag{8.8}$$

where

f_s is the sampling frequency

f_o is the signal highest frequency component

Figure 8.22 shows the block diagram of a sigma–delta converter. The input signal passes through an antialiasing filter to band limit the input signal. A sample and hold is used to sample the analog signal at

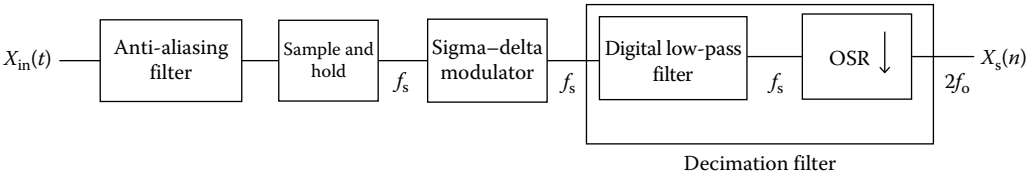

FIGURE 8.22 Block diagram of an oversampling A/D converter.

the first stage of signal processing. The sampled signal is modulated by a sigma–delta modulator stage. After modulation, a decimation filter implemented by a low-pass digital filter and down sampler provides the output digital data [30].

Antialiasing filters can be implemented using a simple first-order analog filter or a simple off-chip *RC* low-pass filter. Because sigma–delta conversion is usually implemented using an SC technique, the sample and hold is already in place by using the SC.

The sigma–delta modulator is a sampled data system and can be implemented using an SC technique. Because an SC samples the analog signal, there is no need for a separate sample and hold circuit. Since the noise of the first stage is important for the resolution of the A/D converter, the same low-noise folded cascode amplifier has been used as the main amplifier. The first-order sigma–delta A/D converter consists of an SC integrator, latch comparator, and feedback loop as shown in Figure 8.23. Two nonoverlapping clocks, S1 and S2, provide switching sequences. The CDS is used to cancel the dc offset and low-frequency flicker noise of the integrator. If a two-stage sigma–delta modulator is used, CDS is only applied for the first stage [31–34].

The output of the one bit quantizer is fed back to the integrator to select either of the reference voltages to integrate with the input signal. The gain of the integrator is set to 0.5 to avoid saturation, and reference voltages are 1 and 4 V. Therefore, the input signal range will be from 1 to 4 V. The differential signal from the previous stage is applied to the V_{in+} and V_{in-} inputs, and according to comparator output level, one reference voltage will be applied to oppose the charging direction of the integrator output (because of negative feedback). The time that comparator level remains high or low is proportional to the input signal level. The digital output pulse train goes to a decimation filter to convert to a baseband digital output. The decimation filter consists of averaging filters and low-pass filters that usually will consume a large part of the chip area.

In order to reduce the OSR and improve the noise transfer function of the sigma–delta modulator, the order of the modulator can be increased. Second-order modulators are common in sigma–delta A/D converters. Figure 8.24 shows the block diagram of a second-order sigma–delta modulator.

Switch capacitor implementation of the second-order sigma–delta modulator is shown in Figure 8.25.

Since the signals for the first and second stages have a phase difference, the feedback signal should be provided at the proper time for stability. Therefore, two flip-flops are used that latch the output signal on S1 and S2 clocks. Because the noise level and offset of the first stage is important, CDS offset cancellation has been used only for the first stage. The second-stage modulator is just a simple integrator.

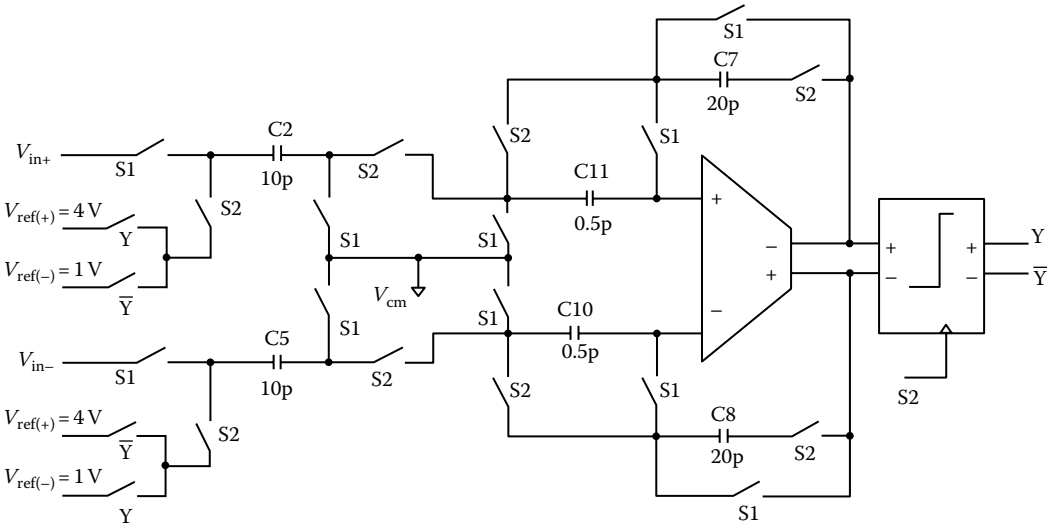

FIGURE 8.23 First-order SC sigma–delta A/D converter.

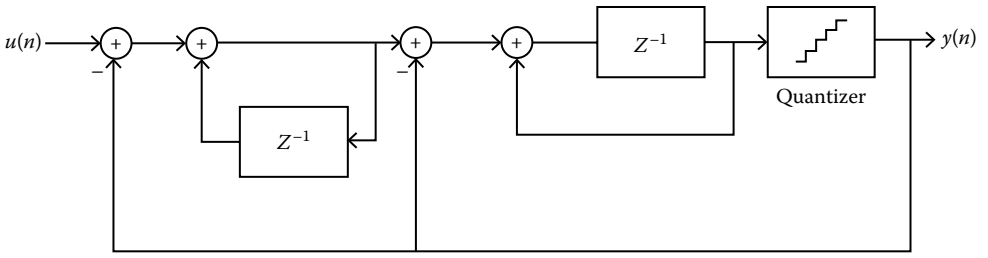

FIGURE 8.24 Second-order sigma–delta modulator block diagram.

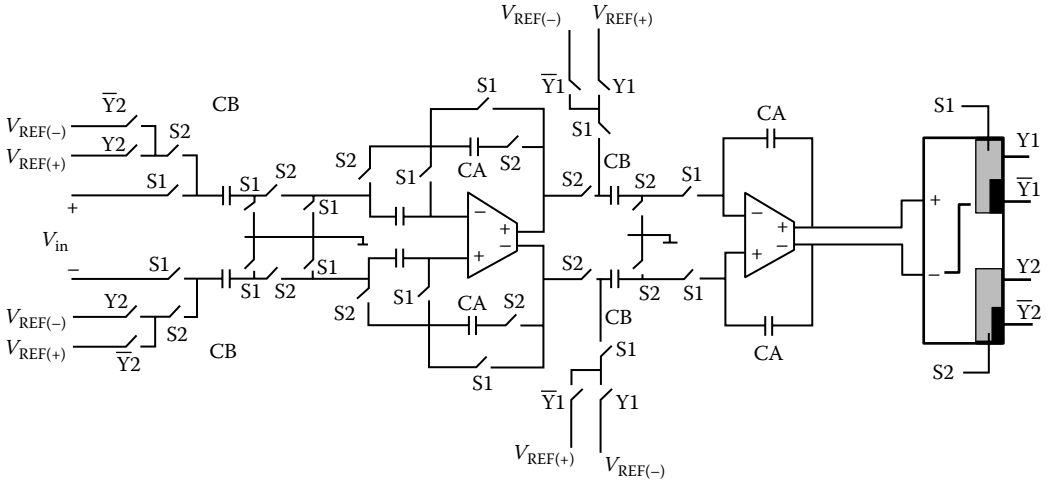

FIGURE 8.25 Second-order SC sigma–delta modulator.

The output signal of the second-stage integrator goes to the comparator. The clock frequency used for the second-order modulator is 51.2 kHz, which is much lower than 400 kHz selected for the first-order modulator and will provide more relaxing conditions for the main amplifier. The output signal of the integrators does not need a high slew rate OTA, because of the integrating function. The total microchip area including sensor and the interface circuit consumes 16 mm^2 of chip area using AMI0.5 technology.

8.4 Conclusion

The concept of single-chip chemical and biological sensor brings a lot of worthy advantages to chemical and biological detection world. Noise immunity, better accuracy, higher-resolution, mass production, and state-of-the-art CMOS fabrication technology bring a lot of opportunity for the researchers and engineers in the field. The challenge is to build the sensor system on an integrated circuit chip with the minimum postprocessing steps. In this case, the product will be very cheap and accurate if mass produced. Even though quite a number of methods have already been fabricated with the interface circuit on a chip, there are still many other methods that can be fabricated for better accuracy and mass production. Even though CMOS is currently the dominant technology for IC and MEMS fabrication, new technologies have also been reported for large array of sensors on other technologies such as amorphous silicon. The report in [35] uses LC chemical sensors on an a-Si:H chip that can be fabricated on glass and for large area electronics. A sensor array, as large as an iPad display, can be fabricated for handheld and deployable applications. The area of single-chip chemical and biological detectors will remain an active area of research as an interdisciplinary area for chemical and electric engineers for the years to come.

Julian W. Gardner
University of Warwick

This chapter provides a comprehensive discussion on the necessity and importance of developing gas sensors on a low-cost complementary metal oxide semiconductor (CMOS) platform technology. The main focus is on the challenges of integrating microhotplate-based gas sensors into a standard CMOS process: microhotplate-based sensors typically operate at much higher temperatures of 200 °C–500 °C. This is beyond the normal limit of CMOS operation at +125 °C. The chapter focuses on both different on-chip circuit schemes to interface these microhotplate-based sensors and also the challenges associated with depositing/growing nanosensing materials (particularly carbon nanotubes [CNTs] and graphene) on a CMOS platform. Finally, there is a brief discussion on the existing gas sensor market and its future outlook.

9.1 Introduction

In the past decade, gas and chemical sensors have been increasingly important because of their desired application in industry, automobiles, health care, and environmental monitoring. Hence, considerable effort is being directed toward the development of miniaturized smart gas sensors and systems. More recently, research has been carried out on the selective detection of specific toxic gases (e.g., CO and NO_2) and combustible gases (e.g., H_2 and CH_4) and to develop innovative technologies to integrate such sensors onto a CMOS platform.

The current gas sensor market is dominated by electrochemical cells, resistive metal-oxide sensors, pellistors, and infrared (IR) sensors. Among them, electrochemical cells hold the largest market share. Most of the gas sensors available today are expensive costing on average $25; this is because the sensors are usually made in small volumes and a semi-automated manufacturing process. These sensors are discrete and hence require separate electronic board to drive and monitor the sensors, which makes them even more expensive (in excess of $100 as a module).

The present gas sensor market has been estimated to be worth around $500 M and is expanding at a rate of 10% [1]; this sustained market expansion is possible because of more awareness within the domestic and commercial world for safer and cleaner environment and also the introduction of stricter

legislation from different governments. Although the gas sensor market is small compared with the main stream electronic markets (e.g., PCs, tablets, and mobile phones), the market can open up drastically for chemical sensors in the near future; this is because there are recent tendencies from the blue chip companies to accommodate gas and other sensors (to give more value-added features) in their cutting-edge electronic gadgets. For example, the NASA Ames Research Center has recently developed a prototype (known as tricorder) that can convert an iPhone into a chemical sensor, which is claimed to be capable of different applications from detecting chemical attacks in future military conflicts to testing blood glucose indirectly by measuring acetone in exhaled breath [2]. The Japanese mobile giant NTT Docomo has announced that it is bringing a smartphone-ready device to measure acetone in breath for diet support [3]. Recently, Nokia has forecasted a novel mobile phone concept known as Scentsory; it evokes the human senses of sight, sound, touch, and even smell for a multisensory experience; the heart of the smell sensor consists of array of chemical sensors (known as e-nose) [4]. But this emerging mass market requires smaller smart gas sensors of much lower cost (each sensor should cost below $1) and much lower power (so that longer battery life can be maintained) compared to present-day available gas sensors.

This penetration of mass market will only be possible when gas sensors can be developed on a high-volume low-cost CMOS platform. This is because CMOS-based sensors do not only give miniaturized devices (<1 mm^2) but also offer lower power consumption and option of batch fabrication, which reduces the cost and also improves the reproducibility of the device performance. Furthermore, the on-chip electronics along with sensors always gives an added cost advantage compared to separate interface electronic chips and sensors on a printed circuit board—provided we can satisfy the process constraints of CMOS when fabricating the integrated or smart sensors.

Although the widely used electrochemical sensors consume very low power, it is not possible to integrate them on CMOS because they require significant volumes of liquid electrolytes and non-CMOS catalytic materials such as platinum or silver electrodes. In addition, electrolyte evaporation limits its life. A common gas sensor is based on nondispersive infrared detection (NDIR) technique; it requires high power consumption (0.5 W) for the infrared (IR) source, and they are difficult to integrate on CMOS because of the requirement of non-CMOS IR band-pass filter.

Research in the last few years has shown that it is possible to integrate microhotplate-based gas sensors on a CMOS platform, so the chapter will focus on the microhotplate-based resistive and calorimetric sensors and their interfacing electronics. The key issues of growing nanosensing materials on a CMOS platform are also discussed; particularly, the growth technique of recently discovered materials like CNTs or graphene and their response in the presence of gas is described.

9.2 Microhotplate-Based Gas Sensors

There are primarily two types of microhotplate-based gas sensors: (1) resistive and (2) calorimetric.

Resistive gas sensors show a considerable change in their electrical resistance upon exposure to reactive gases or vapors; these usually contain films of nonstoichiometric wide-bandgap semiconducting oxides that react with the analytes at elevated temperatures of 200 °C and 600 °C. The Taguchi gas sensor (TGS) is perhaps one of the earliest commercial resistive gas sensors, first patented and sold around 1970; even today they are sold by the millions by Figaro Inc., Japan [5], and other companies now that the patent has elapsed. The device consists of a platinum coil heater (to heat up the sensing material) within a ceramic tube, painted manually with a thick layer of tin oxide. Under the oxide layer is a pair of thin interdigitated gold electrodes to measure the change in resistance of the tin oxide in the presence of an oxidizing or reducing gas (e.g., NO_2 or CO).

Calorimeters (also known as pellistors, which is an abbreviation of the words pellet and resistor) are used to detect gases that are either combustible (catalytic) or that have a significant difference in thermal conductivity (noncatalytic) to that of air (e.g., catalytic pellistors are popular as a methane sensor). This consists of a small catalyst-coated bead (e.g., alumina) around a platinum heater wire and requires

a second pellistor (without the catalytic additive) as a reference arm in a potential divider. This clearly adds to the size and cost of the pellistor.

A new generation of microresistive/microcalorimetric gas sensors is being developed based on a microhotplate structure using CMOS/MEMS technology. A microhotplate can be defined as a miniaturized thin membrane that is thermally isolated from the rest of the substrate and usually consists of a microheater structure (for heating up the sensing material), a temperature sensor (to measure the temperature of the top membrane layer), and lastly contact electrodes for the sensitive layer. These types of thin microstructures are usually power efficient; hence, higher operating temperatures can be reached at lower power consumption (typically <50 mW at 500 °C). Microhotplates are much faster than the existing sensors (thermal time constants of the order of 1–50 ms) due to their lower thermal mass, which also enables a pulsed mode of operation, lowering the power consumption even further. In the case of the latest microcalorimeters, membrane technology is again used and like microresistive sensors except these do not require any electrodes. Two identical sensors (one having an active sensing material and the other playing the role of a reference) are again used, and the difference in temperature is detected between the two due to the combustion of the target gas at around 550 °C.

Microhotplate membrane structure can be realized by the front or back etching of a wafer—or even using a combination of both. If it is through front etching, then the structure is known as a suspended membrane (i.e., the heated area is suspended by, say, four arms with opening between the arms that acts as etch opening), and if the etching is from back side, then it is known as closed membrane.

Researchers have developed microhotplate structure using different materials. The key issue is that the heater material should be able to sustain a high operating temperature and that the membrane material should be a dielectric with a low thermal conductivity (compared to silicon). For example, platinum heaters and also platinum electrodes are one of the popular choices because of their reliable operation at high temperature, but platinum is not a CMOS material. The other used heater materials are doped silicon, aluminum, and doped polysilicon to name a few, though these are standard CMOS materials—but most of the devices were fabricated not using a commercial CMOS foundry; hence, monolithic circuit integration is not possible. It is not easy to develop a microhotplate structure on standard CMOS, because an additional etching step is required to form the membrane and also the heating area has to be properly isolated from the rest of the chip for a faithful operation of the interfacing circuits—however, there are some groups who took up this challenge and successfully demonstrated this integration. For example, a group at National Institute of Standards and Technology (NIST) [6,7], a group at Physical Electronics Laboratory (PEL) of ETH Zurich [8], and a group at High Voltage Microelectronics and Sensors (HVMS) of University of Cambridge in collaboration with Microsensors & Bioelectronics Laboratory (MBL) of University of Warwick [9] are perhaps some of the earliest to report microhotplate-based gas sensors on a commercial CMOS platform.

The microhotplate developed by the NIST group was by using front etch bulk micromachining technique (top view is shown in Figure 9.1a [6]). The hotplate has a polysilicon heater with aluminum metal (provided by the CMOS process) spreading plate for temperature uniformity. A separate gold electrode was deposited as a postprocess for sensing material contact. The outer perimeter of the microhotplate design has a p-type implant that was used as an etch stop. The device was power efficient (10 °C/mW) and fast (thermal time constant 1 ms).

The microhotplate developed in ETH Zurich was released by KOH back etching. There is a silicon island underneath the heater area, which serves as heat spreader that also mechanically stabilizes the membrane; this is obtained by an electrochemical etch stop technique. The formation of such an island can be found in papers published by Kloeck et al. [10] and also in Müller et al. [11]; the latter one discussed the formation of such islands at wafer level. The Zurich group had to use a postprocess Pt/TiW coating on an aluminum electrode to avoid a problem due to aluminum oxide formation.

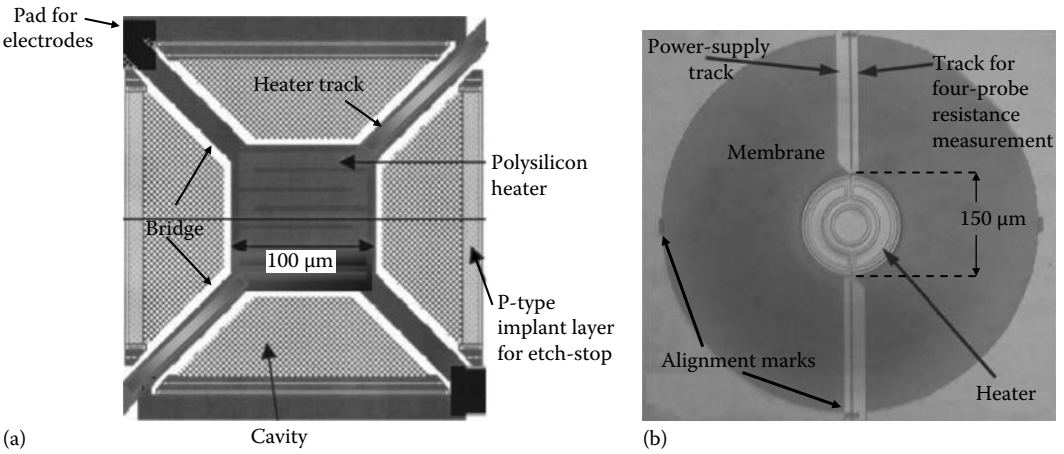

FIGURE 9.1 (a) The microhotplate developed by the NIST group using front etch bulk micromachining technique. (Adapted from Afridi, M.Y. et al., *IEEE Sensors Journal*, 2, 644, 2002.) (b) Cambridge CMOS Sensors Ltd smart ultralow power microhotplate that uses a high-temperature metal microheater. (Adapted from Ali, S. Z. et al., *J. Microelectromech. Syst*., 17, 1408, 2008.)

The microheater was made with polysilicon; later on, they also reported a metal-oxide semiconductor field-effect transistor (MOSFET) heater.

The Cambridge/Warwick microhotplate was developed using a silicon-on-insulator (SOI) CMOS process with an FET as the heater structure. The microhotplate was a closed membrane type made with a silicon oxide/nitride dielectric layer. The membrane was realized by a deep reactive-ion etching (DRIE) technique from the back side to remove the underlying handle silicon as a post-CMOS process at wafer level. Here, a buried oxide acts as an etch stop. However, the device works only up to 300 °C [9]. Later on, the operating temperature range was increased by using metals with a higher melting point (in standard CMOS) instead of aluminum [12,13]. The report of long-term reliability (continuous run over three months) showed that these devices are very stable and more stable than doped polysilicon. The group has launched a spin-off company (Cambridge CMOS Sensors Ltd) based on this patented smart ultralow power microhotplate [14]. The newly developed microhotplate from this group is shown in Figure 9.1b, which uses a high-temperature metal microheater.

9.3 Interface Electronics

The main advantage of CMOS integration is the on-chip interface electronics. The interface circuit can be integrated in two ways: (1) monolithic (sensor and circuit are on the same silicon die), and (2) hybrid (sensor and circuit are on separate dies). The advantage/disadvantage of one approach over another has been discussed in detail in the literature [15]. Briefly, in the case of the monolithic approach, sensors need to be fabricated with CMOS materials and follow strict foundry specifications, whereas it offers lower power consumption and fewer packaging issues. In the case of a hybrid approach, the main advantage is that the sensors can be fabricated with any required materials using much less stringent design rules. However, the parasitic capacitance/resistance, due to having bonding wires between the dies, is clearly larger and less predictable/repeatable than with the monolithic approach.

As far as the front end interfacing is concerned, a common problem with any microsensor is that they tend to generate smaller electrical signals at the sensor output, so the front end circuitry needs to be of very low noise, that is, a good analog design is required. Present submicron CMOS processes offer a very low rail-to-rail supply (say 0–1.1 V); this is good for low power, but this makes front end design much harder when the sensor drifts (i.e., a smaller operating range).

As microresistive sensors are based on a change in the electrical conductivity at high operating temperatures, the main circuit blocks required for interfacing these sensors are (1) driving circuits for microheaters, (2) temperature control circuits, and (3) interface circuits for the gas-sensing material. We will now consider these blocks in turn:

1. Microheaters can be driven with an accurate, stable voltage or current source, which is capable of driving large currents (tens of mA). Circuits can be designed to provide a constant signal (dc) or a modulated signal (ac or pulse signal) to the heater. In the case of a voltage source, it is necessary to use a current-limiting resistor in order to avoid any high current following through the heater. Current sources can be designed in CMOS employing a current mirror circuit. A four-wire (or two-wire) measurement option is often required to measure the change in resistance of the heater with temperature; this can be used to extract temperature information of the sensing layer.
2. The temperature of the sensing material plays a vital role in improving the selectivity of almost all sensing materials. Thus, it is very important to read and control the temperature of the sensing layer accurately. Bota et al. [16] in their work used the same resistor element as the heater and temperature sensor. They used a pulse width modulation (PWM) technique, where during the off mode of the microheater, a small current was driven through the heater to measure its temperature (as shown in Figure 9.2). Now, instead of using the microheater for temperature extraction, separate temperature sensors (e.g., silicon *p–n* junction diode, silicon/polysilicon resistor) can also be used to read the temperature of the sensing layer. A small current (∼μA) is usually used to drive the temperature sensor to avoid any self-heating effect. One of the commonly used interfacing techniques is to have one temperature sensor on the microhotplate and the other identical one outside the hotplate and use an accurate instrumentation amplifier to amplify the difference of temperature readings [13].

   The amount of power required to maintain a constant temperature depends upon the ambient temperature and on the structure of the microhotplate, particularly on the nature and thickness of the sensing material and membrane. Pulse mode heating can be used to reduce the average power consumption; this is achieved by using a switch in series with the microheater. The heating can be controlled by on–off mode (also known as bang–bang control), proportional mode, or proportional integral derivative (PID) mode. There have been some reports of an

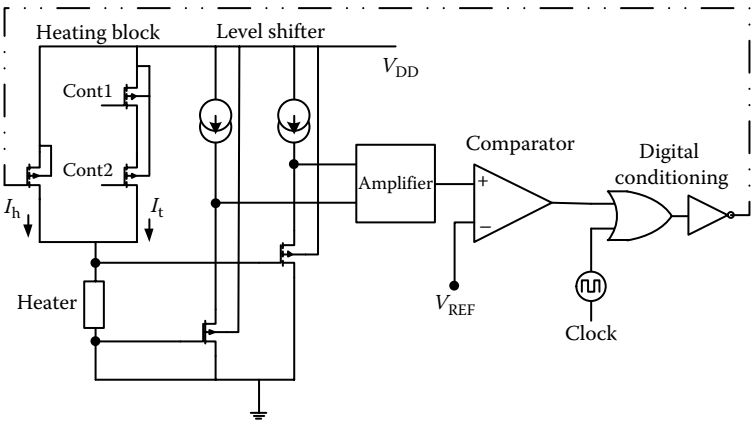

FIGURE 9.2 A PWM technique, where during the off mode of the microheater, a small current was driven through the heater to measure its temperature. I_h, heating current; I_t, temperature measuring current; Cont1 and Cont2, controlling switch for the measuring current; V_{DD}, supply voltage. (Adapted from Bota, S. A. et al., *Analog Integr. Circuits Signal Process.*, 40, 175, 2004.)

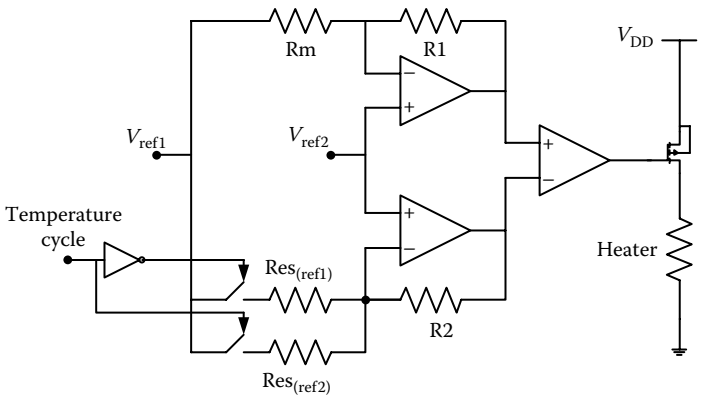

FIGURE 9.3 An on–off control circuit where if the microhotplate is cooler than a set-point temperature, the heater is turned on at maximum power, and once it is hotter than the set-point temperature, the heater is switched off completely. Res(V_{ref1} and V_{ref2}), resistances for setting temperature; V($_{ref1}$ and $_{ref2}$), reference voltages; V_{DD}, supply voltage; Rm, comparing resistor with Res_{ref}. (Adapted from Cardinali, G. C. et al., *Analog Integr. Circuits Signal Process.*, 14: 275, 1997.)

on–off control circuit in the literature (as shown in Figure 9.3) [17]. The on–off controller is the simplest form, where if the microhotplate is cooler than a set-point temperature, the heater is turned on at maximum power, and once it is hotter than the set-point temperature, the heater is switched off completely. However, bang–bang control can give rise to instability (unless controlled carefully), which in turn could damage the heater due to very rapid changes in voltage (hence temperature).

Barrettino et al. [8,18] proposed a simple proportional temperature controller circuit as shown in Figure 9.4. The operational amplifier (which contains an integral stabilization capacitor of 8 pF) drives a power transistor that provides current to the polysilicon heater. The inputs of the operation amplifier consist of the control voltage ($V_{control}$) and the voltage drop across the temperature sensor. The same group has also reported an on-chip digital PID controller using a 0.8 μm

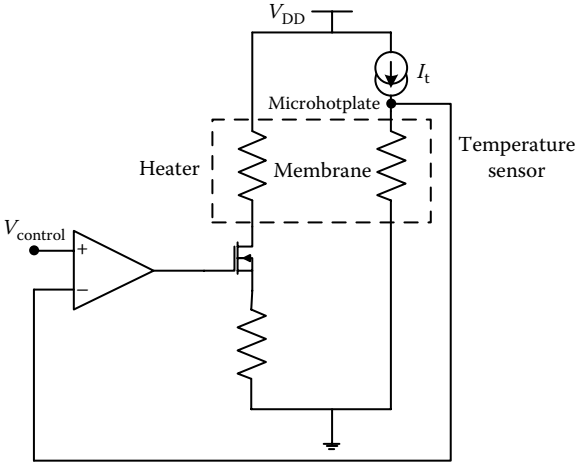

FIGURE 9.4 A simple proportional temperature controller circuit. The operational amplifier drives a power transistor that provides current to the polysilicon heater. commercial CMOS process for controlling heater temperature smoothly and shows a micrograph of the integrated sensor chip with three PIDs and 10 bit ADC [19]:

3. The design of this interfacing circuit is perhaps the most challenging part. This is because
   a. The baseline resistance (baseline resistance means resistance in the absence of any gas) of different sensing materials varies over a very wide range (may be from 1 kΩ to 1 GΩ); this is equivalent to a range of 120 dB.
   b. The baseline resistance of nominally the same material also differs from one gas sensor to another (up to 50%), because resistance depends on grain size, morphology, and many other such parameters; that is, a synthesis mechanism is the key for controlling these factors.
   c. The sensing material resistance changes in the presence of a gas; the amount of change depends on the concentration of the gas, temperature of operation, and sensitivity of the material toward that particular gas.
   d. The sensing material resistance drifts with aging (through poisoning/stability issues) and also due to the incomplete release of analytes at the end of the measurements.

So the interface circuit must handle the precision and wide dynamic range that is demanded by the sensing element. The resolution of the circuit needs to be high so that it can amplify the change in resistance in the presence of a gas at PPM levels or lower. Along with these, a drift cancellation circuit will make the system smarter and more accurate, because drifting gives the impression of change in resistance due to the presence of a gas. The drift control circuit also reduces the possibility of output saturation in the subsequent signal conditioning amplifier stages. The problem here is to know the difference between drift and genuine signal without using calibration gases.

In the literature, there have been reports of several approaches to deal with the aforementioned challenges. However, simple voltage divider or Wheatstone bridge techniques that are popular to determine unknown resistances are not suitable at the CMOS level because of the need for trimming (or variable resistance) and also a large resistor value demands a large silicon area (prohibitively expensive). One of the earlier reports came from the Baltes group of *ETH Zurich*, where they proposed logarithmic interface circuit (shown in Figure 9.5) for the sensing material. Although lacking in resolution (~8 bit) and linearity, this simple circuit was able to cover a wide resistance range of sensing material due to compression [8].

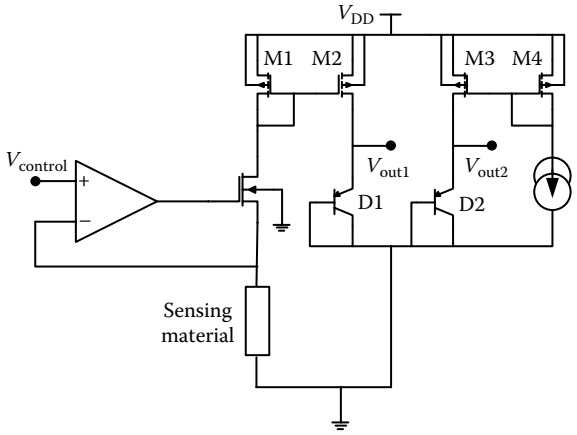

FIGURE 9.5 A logarithmic interface circuit for the sensing material. This simple circuit was able to cover a wide resistance range of sensing material due to compression. V_{DD}, supply voltage; M1, M2, M3, and M4, MOSFETs for current source; D1 and D2, diode temperature sensors. FIGURE 9.6 An array of sensors within the chain of a ring oscillator. This simple scheme can cover a wide resistance range. MUX, multiplexer; C, external capacitor. (Adapted from Merino, J. L. et al., *IEEE Trans. Instrum. Meas*., 53, 1173, 2004.)

The other key scheme found in the literature was resistance-to-frequency conversion. In [20], Merino et al. reported an interfacing circuit (shown in Figure 9.6) where they inserted an array of sensors within the chain of a ring oscillator. This simple scheme can cover a wide resistance range though oscillator accuracy can be affected by parasitic capacitances associated with sensing material. De Marcellis et al. [21,22] came up with a scheme that can also determine parasitic capacitance along with the change in resistance of the sensing material in the presence of a gas. The resistance-to-frequency conversion circuit is shown in Figure 9.7; this contains two comparators, an inverting integrator and an EX-OR digital logic block. The parasitic capacitor role can also be isolated if the resistance of the sensing material is not directly in the oscillating section of the circuit. Such circuit schemes were reported in [23–25]. The circuit structure for this can be achieved by using the sensing material resistor as a voltage-to-current converter or at the reference arm of a current mirror and then using that mirror current to charge and discharge a capacitor (as shown in Figure 9.8). The capacitor voltage is then fed into a Schmitt trigger or through two comparators having threshold voltage V_H and V_L; the resultant square wave then controls the charging and discharging switches. This square wave time period contains information of the value of the sensing material resistor.

There have been some reports to remove/compensate drift of sensing material resistance [26–28]. One popular baseline drift removal approach has been reported by Koickal et al. [27] and is shown in Figure 9.9. In this scheme, during the setup phase, each sensor is driven by a small value current source, and the voltage across the sensor is digitally stored using a simple counting A/D converter. This stored value is converted back to an analog signal (using a D/A converter) and then subtracted from the sensor signal, thus removing the baseline resistance.

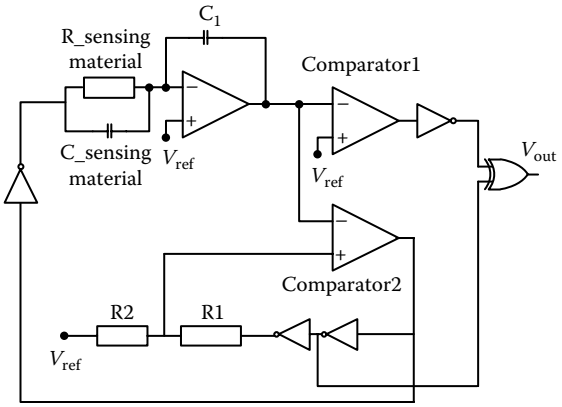

FIGURE 9.7 The resistance-to-frequency conversion circuit contains two comparators, an inverting integrator and an EX-OR digital logic block. V_{ref}, reference voltage generated through voltage divider and buffer; R1 and R2, resistors; V_{out}, output voltage. (Adapted from De Marcellis, A. et al., *Sens. J. et al., *IEEE Trans. Circuits Syst. I Regul. Pap.*, 54, 60, 2007.)

There has been increasing demand to measure multiple gases simultaneously. For example, in a boiler combustion process, there could be a requirement to measure hydrogen or methane as well as CO, CO_2, and even oxygen. Alternatively, in the case of automotive gases, there is a desire to measure CO, NO_2, and unburnt hydrocarbons. In some ways, this is the same requirement faced when developing electronic nose technology. Dickson and Goodman [29] reported an array of 18 × 18 chemical sensors by combining polymer-based chemoresistors with a standard integrated circuit technology to classify different odors. The corresponding circuit scheme consists of row and column selection (M1–M4 transistor switches) to select sensor and readout circuit in the form of a transmission gate (M5–M9 transistor switches)—which passes the sensor voltage to a column output bus for amplification and off-chip processing (as shown in Figure 9.10).

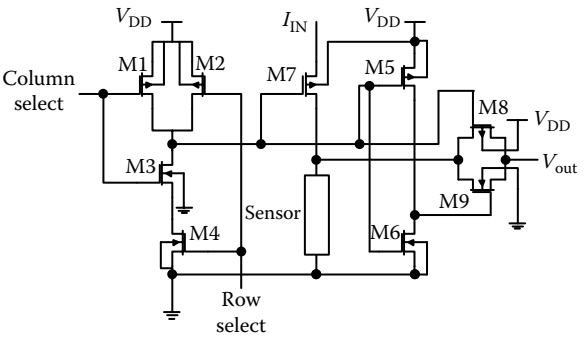

FIGURE 9.10 A typical circuit to measure multiple gases simultaneously. It consists of row and column selection (M1–M4 transistor switches) to select sensor and readout circuit in the form of a transmission gate (M5–M9 transistor switch)—which passes the sensor voltage to a column output bus for amplification and off-chip processing. Goodman, Integrated chemical sensors based on carbon black and polymer films using a standard CMOS process and post-processing, in *Proceedings of the International Symposium on Circuits and Systems*, Presses Polytech. Univ. Romandes, Geneva, Switzerland, pp. 341–344, 2000.)

9.4 Sensing Materials

Modern solid-state resistive gas sensors are generally based on wide-bandgap metal semiconducting oxides (e.g., tin oxide, tungsten oxide, and zinc oxide). The metal oxides are popular as a sensing layer because of their large response in the presence of a gas at part per million (ppm) level or below and their ability to respond to different reactive gases. Resistive sensors commercially available today are usually made of bulk materials (i.e., materials with large grains) as the chemical sensing layer. However, sensors developed on a CMOS platform are miniaturized in size, so large grain materials are not suitable for such sensors (because of their low surface area) to get proper sensitivity. Hence, nanosensing materials (large surface area gives better sensitivity) are the primary contender for a new generation of gas sensors. Researchers have already reported promising performances from various gas detection experiments.

The sensing material growth for CMOS-based gas sensors is very challenging. This is because of the constraints imposed by the CMOS platform, for example:

1. High temperature is often required to synthesize nanomaterials. This can be detrimental for on-chip electronics, particularly for metal tracks (made with aluminum) because of the electromigration issue. However, this metal electromigration effect can be reduced, if one can use metals with higher melting point (e.g., tungsten) rather than aluminum, or voltage switching.
2. Harsh environments (e.g., plasma treatment) and harsh chemicals are also frequently required for nanomaterial synthesis; these can damage semiconductor devices. Particularly, this is detrimental for any fragile structure (e.g., thin membrane-based microhotplates) present in the die.

Hence, novel CMOS friendly methods are being developed for nanomaterial synthesis [30,31]. These new methods use lower temperature (<400 °C) techniques and also less harsh chemicals.

Instead of using conventional techniques (e.g., chemical vapor deposition, aerosol-assisted chemical vapor deposition, atomic layer deposition, flame spray pyrolysis to name a few) to synthesize nanomaterials, techniques like spray coating and even ink-jet printing can be very useful for depositing materials (like metal oxides, CNTs, and nanocomposites) on specified areas. This is usually done with commercially available nanomaterials, so one can avoid a harsh environment that is often necessary to grow nanomaterials. Nowadays, printers are available that can deposit a volume even as low as nanoliters with high precision, and these can be computer controlled [32,33]. Even though these methods are simple and CMOS friendly, it is necessary to dissolve the nanomaterials properly to avoid any clogging at the nozzle.

Although metal oxides are popular as the sensing layer, a well-known problem with these sensing materials is their lack of selectivity. This situation is usually dealt with by using an array of sensors covered with different sensing layers, multicomponent or pattern recognition algorithms (e.g., principal component regression (PCR)), and multiway analysis or by doping the sensing materials (e.g., palladium doping makes metal oxide more selective toward hydrogen). This doping can be done by either physical (e.g., coating through sputtering) or chemical (e.g., with proper chemical solution) means. This functionalization is usually achieved using metal or metal oxide or even with polymer and its composites. Researchers have also been developing mixed metal oxides (two or more metal oxides together) to improve the selectivity. The selectivity can also be improved by the analysis of transient sensor responses to changes in analyte concentration or sensor temperature. The last method that has been extensively investigated [34–37] involves controlling the temperature of the sensing material surface, whether by selecting a fixed temperature to maximize sensitivity to a particular analyte or by programming or modulating the temperature—through these, a single sensor device can provide the type of selectivity that would otherwise require arrays of various doped fixed temperature sensors [15].

Apart from metal oxides, other new-generation materials that have recently been investigated as sensing materials are CNTs (multiwall and single wall) and graphene. As already mentioned, metal oxides react with analytes at elevated temperature (200 °C–500 °C), but CNTs can respond to gases at much lower temperature (even at room temperature). So CNT/graphene-based sensors will be more power efficient compared to their metal-oxide counterpart.

CNTs are usually synthesized using CVD technique at a very high temperature (usually >700 °C). Recently, a unique method of growing CNTs on the CMOS microhotplate was demonstrated by Santra et al. [30] using local growth technique. This is also primarily a CVD technique where instead of heating the whole chip, a microhotplate was used to form small catalytic islands and then to form CNTs by dissociating gas (SEM CNT picture is shown in Figure 9.11). This way, the whole chip will not be exposed to high temperature, and on-chip electronic circuits will remain intact.

The operational principle of graphene as a gas-sensing layer is believed to be similar to that of metal oxides where conductivity changes due to adsorbed gas molecules at the graphene surface (which act as donors or acceptors). However, graphene has extra edge over metal oxides due to its unique properties, for example,

1. As graphene is a 2D material, its whole volume is exposed to the analytes, which increases the sensitivity.
2. It has high conductivity (which implies very low Johnson noise), so even a few extra electrons will give a notable change in carrier concentration.

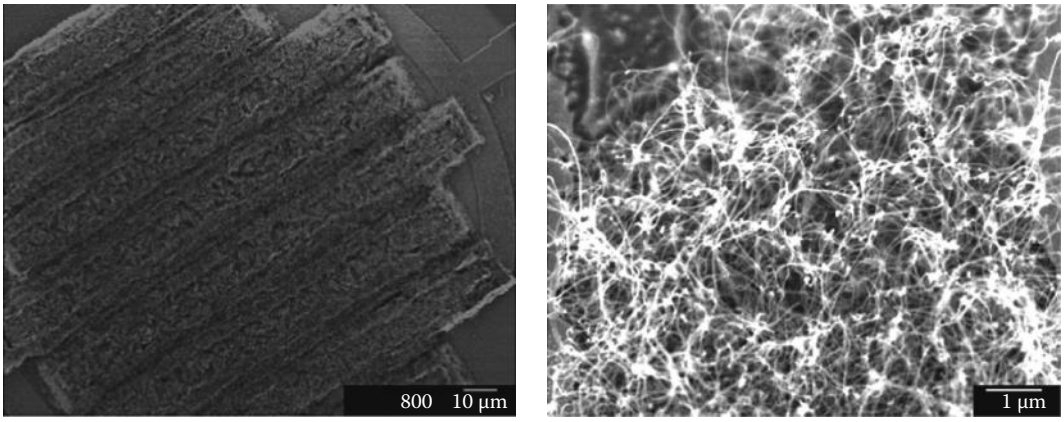

FIGURE 9.11 SEM CNT picture of a CVD technique where instead of heating the whole chip, a microhotplate was used to form small catalytic islands and then to form CNTs by dissociating gas. (Adapted from Santra, S. et al., *Nanotechnology*, 21, 485301, 2010.)

Unfortunately, until now, graphene synthesis is tedious and unreliable; this was usually performed by the mechanical peeling of graphite layers. Recently, researchers have developed chemical methods to generate device quality graphene flakes coated on a wafer scale. Often, this involves the chemical oxidation and exfoliation of graphite to produce graphite oxide and its subsequent reduction to graphene. Recently, Fowler et al. [38] reported the development of chemically converted graphene using spin coating of hydrazine dispersions on interdigitated electrodes, which is integrated on microhotplates. The graphene showed good response in the presence of NH_3 and NO_2. Schedin et al. [39] have demonstrated the ability of detecting individual gas molecule by graphene layer.

Instead of using nanosensing materials in chemoresistive mode, nanomaterials particularly nanowires/nanotubes can be used as FET devices for gas sensor applications [40]. In such devices, the Fermi level within the bandgap of the nanowire can be varied and used to control surface process electronically. The nanowire acts as a conductive channel that joins source and drain electrode. Two methods are common to produce such an FET structure, the first one consisted of nanowire dispersion in ethanol by ultrasonication and drying on a silicon dioxide–silicon substrate and then in electrode deposition by electron beam lithography. The second procedure consisted of deposition of dispersed nanowires on predefined electrode arrays. However, such an approach has to be more automated so that devices on a wafer level are possible to develop.

9.5 Conclusion and Future Outlook

Most commercial gas sensors today are made in a batch process, have an average cost around $25, and are about 1 cm^3 in volume or consume 100 mW of power. Consequently, they are not compatible with the mass market (e.g., 500 million mobile phones that were sold in 2012) that demands a small size (ideally the size of a microSD package) and have low cost (much less than $1). In this chapter, we have discussed the development of CMOS integrated gas sensors that offer the potential to replace existing commercial gas sensors, such as the electrochemical cell, pellistor, NDIR, and Taguchi type. This technology offers the potential not only to make low-cost CMOS gas-sensing elements but also to integrate associated circuitry to make smart sensing modules. The full integration of the sensing element, drive circuitry, and communication interface enables the cost per unit to fall in volume (millions) to a few tens of cents and thus satisfies the emerging market of mobile phones, tablets, and other electronic goods. We believe that the integration of CMOS technology together with a new generation of nanomaterials (such as nanowires, nanotubes, and nanolayers) will ultimately satisfy the mass market and thus make CMOS integrated sensors a ubiquitous commodity just like PCs, mobile phones, and cars!

Nowadays, photovoltaic (PV) panels and thermoelectric generators (TEGs) constitute the most important direct current (dc) energy transducers that can be used to harvest energy from the environment and power an autonomous sensor node. They generate a direct current and voltage for constant operating conditions. A current–voltage (I–V) curve is defined for each operating condition in which an optimum bias point exists where maximum power is achieved. The voltage at the maximum power point (V_{MPP}) depends on the operating conditions and it changes as these conditions vary with time. Several energy conditioners have been proposed and commercialized to transfer the energy to a storage unit or a load. The small magnitudes of the currents and voltages of such transducers constitute the main challenge in the design of these circuits. Ultralow-power consumption energy conditioners have to be designed to make feasible the use of these power sources.

This chapter presents a description of these energy transducers and their associate energy conditioning circuits.

10.1 Photovoltaic Energy Harvesting

PV technology is the most widespread form of energy harvesting because of its availability, low cost, and power density. PV panels generate electric energy when exposed to light irradiance. Consisting of semiconductor junctions (P–N), their operation is based on the photons' impact ionization effect. Each one of these P–N junctions is known as a *PV cell* and can be associated in series and parallel to form a PV panel. The generated current (I) depends on the bias voltage (V), the temperature (T), and the light irradiance (G). Figure 10.1 shows the symbolic representation of a PV panel, its equivalent electrical model, and a couple of graphs showing the current dependency on the bias voltage and on environmental

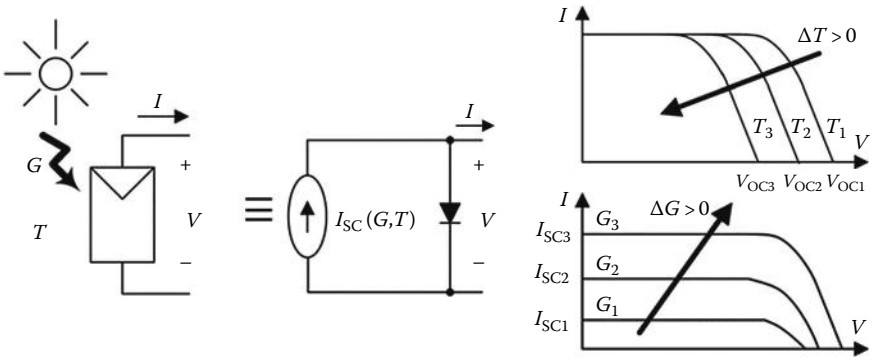

FIGURE 10.1 On the left, the symbolic representation of a PV panel and its equivalent electrical model. On the right, *I*–*V* curves of a PV panel for several temperatures (*T*) and irradiances (*G*) with operating conditions ($G_3 > G_2 > G_1$ and $T_3 > T_2 > T_1$).

conditions (*G* and *T*). For a given *T*, the *short circuit current* (I_{SC}) is proportional to the light irradiance. The current *I* is slightly reduced when the voltage *V* is below a threshold value and is abruptly reduced above it. Considering a single PV cell, this voltage limit corresponds to the diode threshold voltage in the equivalent model of Figure 10.1. The *open-circuit voltage* (V_{OC}) delimits the maximum voltage range in which the PV transducer provides energy and works as a power source.

As shown in Figure 10.1, the values of I_{SC} and V_{OC} depend on the temperature and irradiance operating conditions. PV panel manufacturers conventionally specify the panel parameters under standard test conditions (STCs) ($T = 25$ °C, $G = 1000$ W/m² and light spectrum AM1.5). They usually indicate I_{SC}, V_{OC}, and *the nominal power. Nominal power* is defined as the maximum power achieved from the *I*–*V* curve under STCs.

PV panels can be connected in series or parallel to achieve, respectively, higher voltage or current levels. If all of them have identical operating conditions and performance, the resulting power is scaled to the number of PV panels. Otherwise, for instance, in a shadow projection that produces differences in the light irradiance conditions, the current in a series association is limited by the I_{SC} of the less illuminated PV panel. In the case of a parallel association, the less illuminated PV panel could work as a load reducing the global generated power. To reduce these power losses, a diode can be connected in series with each of the parallel connected PV panels. In the series configuration, an antiparallel diode must be connected instead. Although both solutions can reduce these power losses, identical PV panels and physical orientation are recommended whenever they are connected in series or parallel.

Light efficiency (η_{PV}) indicates how much light energy is converted to electric energy. The efficiency depends on the PV panel technology and on the light spectrum. Although new technologies such as dye-sensitized solar cells are becoming commercially available, silicon PV panels are still the most used because of their low cost and high efficiency. Basically, there are three technologies based on silicon: amorphous, polycrystalline, and monocrystalline PV panels. Each is designed to satisfy a different trade-off between price and efficiency. While amorphous panels have the lowest efficiency (~5%), they are the cheapest ones and are more suited to indoor applications where an artificial light source is used. On the other hand, monocrystalline panels are the most efficient (~20%) for sunlight but they are also the most expensive.

PV energy harvesters can be used to power outdoor or indoor autonomous sensors. Figure 10.2 shows typical irradiance conditions in both environments. In a well-lit office, around 500 lux, the surface of a PV panel would be submitted to a *G* around 2 W/m² (for an incandescent light). When using an amorphous panel, the resulting output power density is about 100 mW/m². These power levels are much lower than the power of an outdoor monocrystalline panel. In this case, the irradiance varies with the time and can reach 1000 W/m². Therefore, the output power density could be as high as 200 W/m². So, the power availability, and thus the design constraints for PV systems, is very different indoors and outdoors.

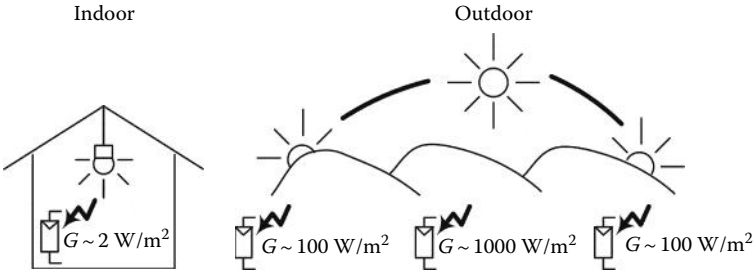

FIGURE 10.2 Typical irradiance (G) conditions in an indoor and an outdoor application.

Design engineers must size PV panels to overcome the average power consumed by the overall sensor node ($\bar{P}_L$), including the energy harvester. If the PV panel works at its maximum power point (MPP), the minimum nominal power under STC (P_{PV}) is determined by

$$P_{PV} > \frac{\bar{P}_L \times 1000\ \text{W/m}^2}{\eta_{Tot} \times \bar{G} \times (1 - \delta_P \times (T_{max} - 25\ °\text{C}))} \tag{10.1}$$

where $\bar{G}$, η_{Tot}, and δ_P are, respectively, the average light irradiance on the surface of the PV panel, the overall efficiency of the energy harvesting system, and the temperature degradation factor of the PV power. The temperature T_{max} is the maximum temperature of the PV panel, which will be higher than the ambient temperature. Both external parameters, such as wind speed, and internal parameters of the PV panels, such as the surface protection material, determine the temperature increment. At G = 800 W/m², 20 °C ambient temperature, and wind speeds of 1 m/s, temperature increases up to 42 °C and 48 °C typically.

The optimal size and orientation of an outdoor PV panel is not evident because the Sun position varies with time. The panel surface must be perpendicular to the light rays to achieve maximum irradiance (G_{Opt}). Figure 10.3 shows the calculation of the irradiance for a surface tilted by angle β. If β is different from the optimum tilt angle (β_{Opt}), the resulting irradiance and generated power is lower. Hence, the sunlight direction must be taken into account to select the panel orientation. On the Earth surface, the sunlight can be split into three components: direct sunlight, diffuse sunlight, and albedo. Diffuse sunlight and albedo are, respectively, the light scattered by molecules and particles in the atmosphere and the light reflected from the Earth surface. Both of them are usually neglected with respect to the direct sunlight to determine the optimal panel orientation. The direction of direct sunlight is described by the Sun position.

The orientation of a PV panel is defined by the azimuth (α) and the tilt (β) angles as shown in Figure 10.4. The azimuth is the angle between the axis of the PV panel and the geographic north direction. The tilt angle is measured between the PV panel surface and the horizontal plane. It can also be defined as the angle between an imaginary line to the center of the Earth and the normal vector of the panel surface.

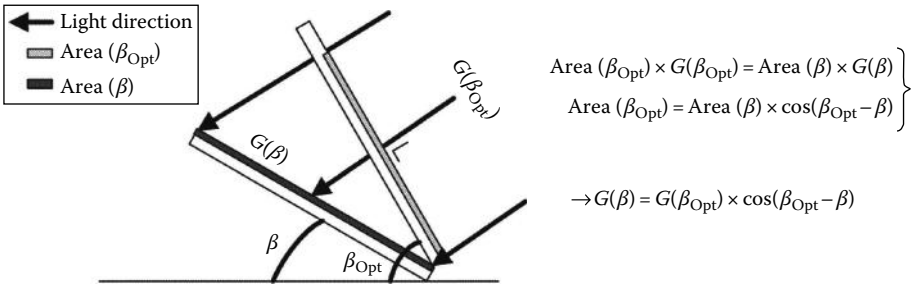

FIGURE 10.3 Calculation of the light irradiance on a surface tilted at angle β.

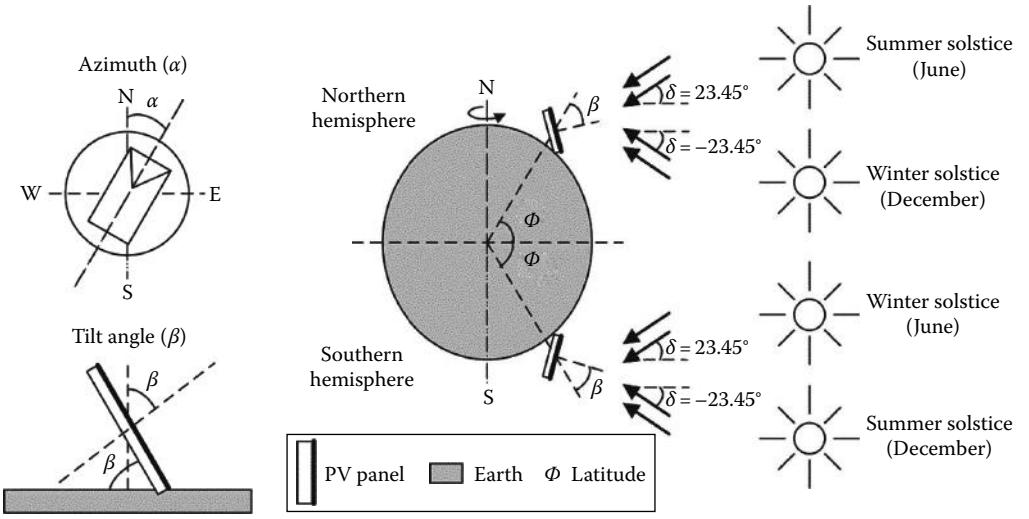

FIGURE 10.4 PV panel orientation and sun declination angle.

The PV system of an autonomous sensor is fixed at a given orientation and tilt because the energy benefit from an automatic orientation system does not compensate for the additional power consumption and cost. The optimal fixed azimuths are respectively 0° (toward the south) and 180° (toward the north) in the northern and southern hemispheres. On the other hand, the optimal fixed tilt angle depends not only on the hemisphere where the PV panel is placed but also on the latitude, the season of the year, and the distribution of the power consumption of the autonomous sensor along the time.

Figure 10.4 shows the variation of the direct sunlight direction during the year, described by the declination angle (δ). δ is the angle between the sun's rays and the equatorial plane. The optimal tilt for the winter solstice is latitude (Φ) minus 23.45° at that solstice (i.e., for the winter solstice and in the northern hemisphere, the optimal tilt will be Φ + 23.45°). Take into account that both the Summer and Winter solstices take place on opposite dates in both hemispheres and thus, δ has a different sign for the same solstice. Φ also has a different sign in both hemispheres.

For long operation periods of the autonomous sensor, the proper tilt angle for the worst-case scenario must be considered. The required P_{PV} for any available tilt angle must be evaluated for each month, using Equation 10.1 and determining the best angle. In this way, an optimum angle and a minimum P_{PV} is determined for each month. The optimum angle for the overall period will be the optimum angle of the month in which maximum P_{PV} is required. In the case of a constant value of $\overline{P_L}$ along the year, the worst case will be the month with the lowest irradiation, which typically is December and June for the northern and southern hemispheres, respectively. Thus, the proper tilt angle will be $\Phi - \delta$ (+23.45° in the northern hemisphere and Φ − 23.45° in the southern hemisphere). Even so, it is not recommended to use tilt angles lower than 15° to let the water from rainfalls slide and avoid the accumulation of dust.

An energy conditioning circuit is used to transfer energy from a PV panel to a storage unit, that is, a battery or a (super) capacitor. Two types of energy conditioners can be distinguished: the *direct coupled* and the *maximum power point trackers* (MPPTs). Figure 10.5 shows these two alternatives by using a battery as the storage unit.

In order to obtain the average light irradiance for a tilt angle and a period of time, meteorological records kept by weather stations all over the world can be used. Although the measurements are mostly limited to a horizontal surface ($G_{0°}$), the irradiance (G_β) on a surface tilted an angle β can be deduced from β_{Opt} and the relationship shown in Figure 10.3. The ratio between G_β and $G_{0°}$ is called the tilt factor and depend on β and on the latitude of the PV panel. Tilt factor tables [1] or interactive databases such as SoDa [2] can be used to estimate the average light irradiance on a PV surface for any tilt angle and period of time.

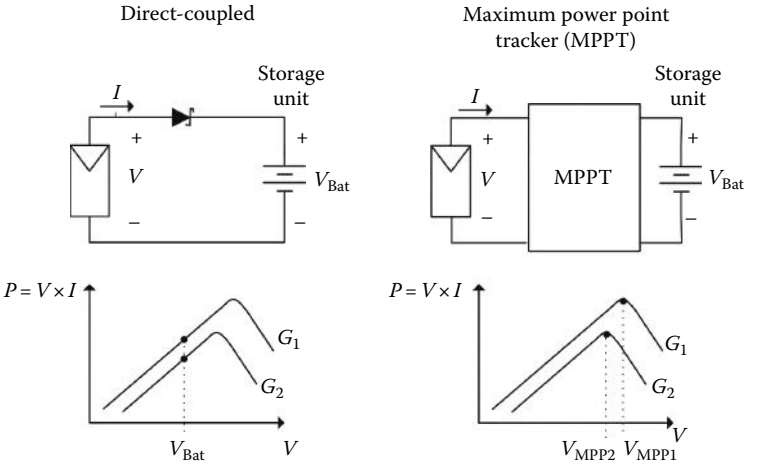

FIGURE 10.5 Energy conditioner schemes.

The *direct coupled* connection is the simplest solution because it simply uses a Schottky diode. The diode permits charging the storage unit from the PV panel and prevents its discharge when V_{OC}, mostly at low irradiance condition, is below the storage unit voltage (V_{Bat}). It is a proper solution for indoor PV panels, where the generated power is very low, because the power loss is limited to that of the diode. Unfortunately, the transducer voltage is fixed by the storage voltage and so, the transducer works outside its MPP. Therefore, Equation 10.1 cannot be used to size the PV panel. Instead, I_{SC} at STC is calculated as:

$$I_{SC} > \frac{\overline{P}_L \times 1000\ \text{W/m}^2}{\eta_{Tot} \times \overline{G} \times V_{Bat} \times (1 - \delta_I \times (T_{min} - 25\ ^\circ\text{C}))} \tag{10.2}$$

where δ_I and T_{min} are, respectively, the temperature degradation factor of the I_{SC} and the minimum temperature of the PV panel. In this design condition, $V_{Bat} < V_{MPP}$ was assumed to approximate the current I by I_{SC}. To account for variations of V_{Bat} with temperature and of V_{MPP} with temperature and irradiance, a conservative (low) value of V_{Bat} ($<V_{MPP}$) is chosen, which leads to oversizing the PV panel. As $V_{Bat} < V_{MPP}$, I_{SC} can be used instead of I in Equation 10.2.

In applications where V_{Bat} is so small that significant power losses are caused by the diode voltage drop, a transistor can be used instead. The SPV1001 of STMicroelectronics is an implementation example of such alternative solution [3].

MPPTs are more sophisticated energy conditioners that bias PV panels at their MPP. Although they have been widely used in high-power PV systems [4], their use in low-power panels is recent. To be feasible, the power benefit caused by following the MPP must outperform the power consumption of the power conditioning circuit. Although this design goal can be easily reached for high-power PV panels, it is more challenging for low-power PV panels (<1 W) used in low-power autonomous sensors. High-performance controllers that were used for high-power PV systems, such as digital signal processors (DSPs), are not feasible for small autonomous sensors because of their high cost and power consumption.

An MPPT is composed of a dc/dc switching converter and a tracking controller (see Figure 10.6). The converter biases the PV panel to a reference voltage given by the tracking controller. The controller measures the appropriate electrical variables of the PV panel (e.g., I and V) to determine the optimal reference voltage that makes the panel work at its MPP.

Switching converters are chosen because of their high efficiencies. Figure 10.7 shows a boost converter that can be used whenever the storage unit voltage is higher than the voltage of the PV panel. The state of

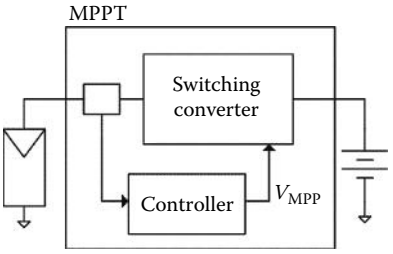

FIGURE 10.6 Block diagram of an MPPT.

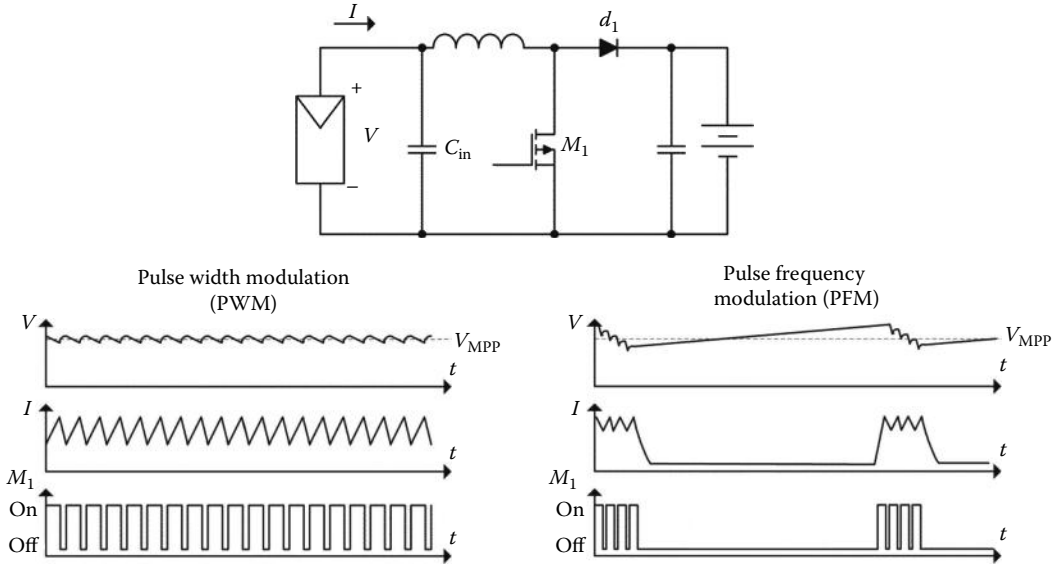

FIGURE 10.7 Switching converter modulation schemes.

the transistor can be controlled by a pulse width modulator (PWM) or by a pulse frequency modulator (PFM). The traditional PWM used in switching converters is not the most suitable solution in low-power applications. A periodic switching sequence holds the transistor in on state during a portion of the sequence period, called *duty cycle*. The voltage of the PV panel is adjusted by means of the *duty cycle*. As the transistor is continuously switching, the resulting power consumption is too high for low-power PV panels (<1 W). Instead, PFM can be used to further reduce power consumption. The converter remains inactive, with low-power consumption, during a long period of time while the capacitor C_{in} is charged by the PV panel. When the voltage V reaches a higher threshold value, the converter is activated to discharge the capacitor to a lower threshold value. In this way, V is held inside a small hysteresis cycle that is centered in V_{MPP}. In [5,6], the authors propose implementations of the PFM switching converter using commercial voltage regulators. There are also commercial MPPT ICs, such as the BQ25504 from Texas Instruments, that uses a PFM switching converter and achieves a current consumption as low as 330 nA [7].

The most popular MPP tracking controllers are *the fractional open-circuit voltage* (FOCV) and the *perturbation and observe* (P&O). The FOCV is an open-loop controller that is based on the empirical relationship between V_{OC} and V_{MPP} of the PV panel. The value of V_{MPP}, which varies with the light irradiance and the temperature, is nearly proportional to V_{OC}. Figure 10.8 shows the functional scheme of this controller and the factor of proportionality, K. The PV panel is periodically disconnected and V_{OC} is captured by a *sample and hold* (S&H) to obtain V_{MPP} through the empirical relationship. This is the most usual MPPT controller for low-power PV panels because of its simplicity [7–9].

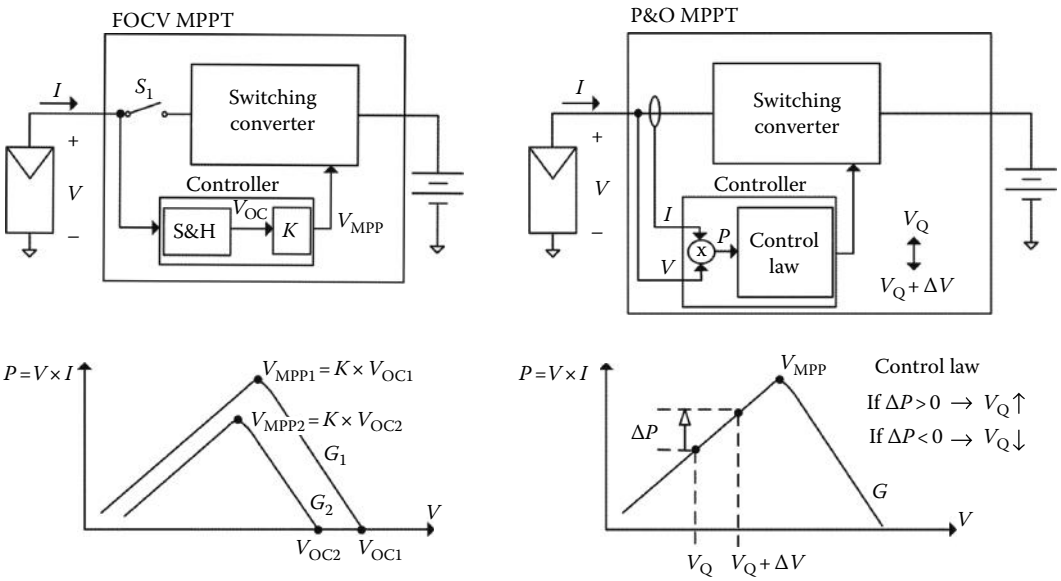

FIGURE 10.8 Low-power MPP tracking controllers.

On the other hand, the P&O is a more sophisticated and accurate tracking controller. It is a closed-loop controller that reaches the MPP by comparing the PV power at two bias points. Figure 10.8 shows the control law that determines if the bias voltage (V_Q) must be increased or decreased to reach the V_{MPP}. The variation of the PV power (ΔP) is measured between one bias voltage (V_Q) and another bias voltage ($V_Q + \Delta V$). Considering a positive perturbation in the voltage (ΔV), the working voltage will be increased if ΔP is higher than zero. Otherwise, it will be decreased. The SPV1040 from STMicroelectronics is an example of a commercial MPPT IC that is based on a P&O and is intended for low-power applications, such as small autonomous sensors [10]. Discrete solutions that implement the control law in a microcontroller [6,11] or using discrete analog circuits [5] can also be found in the literature. In all of them, the main design goal is to reduce the power consumption of the controller. A possible solution consists of reducing the activity of the microcontroller by using an ultralow frequency clock [11]. Nevertheless, such slow microcontrollers cannot be used to implement other tasks of the sensor node. Prediction algorithms, such as those proposed in [6], allow the application of *dynamic power management* techniques that reduce the power consumption, making feasible the use of high-speed microcontrollers.

Another alternative energy conditioning solution is provided by the LT3105 from Linear Technology [12]. The switching converter biases the PV panel to a fixed voltage that is configured in the design process. This is a proper solution if small variations of V_{MPP} are expected.

10.2 Thermoelectric Energy Harvesting

TEGs are used to provide electric energy from a temperature difference between a heat source (hot side) and a cold ambient (cold side). The source can be, for instance, a machine, a warm-blooded animal, or a human being whose temperature is different from the environment. Potential applications could be animal monitoring, fire detection, and cars, ships, and aircrafts industry. Besides its applicability in sensor nodes, it can also power small electronic circuits such as the *Seiko Thermic*, which is a wristwatch driven by body heat [13].

As shown in Figure 10.9, a TEG is implemented with a *Peltier cell*, which is physically based on the *Seebeck effect*. The hot side of TEG is thermally connected to the heat source, and the cold side is held

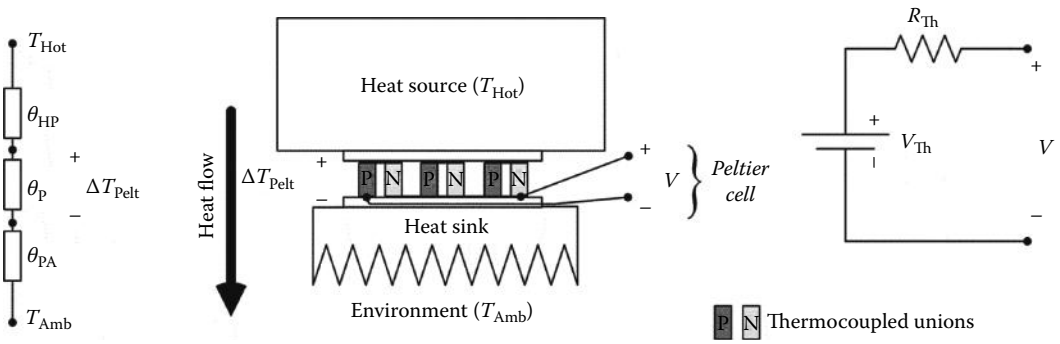

FIGURE 10.9 TEG implemented with a *Peltier cell* connected between a heat source and a heat sink. Equivalent thermal and electrical models are shown, respectively, on the left and on the right.

close to the ambient temperature (T_{Amb}) using a heat sink. The temperature gradient produces a heat flow and a temperature drop (ΔT_{Pelt}) between both faces of the TEG, given by

$$\Delta T_{Pelt} = \frac{\theta_P}{\theta_{HP} + \theta_P + \theta_{PA}} (T_{Hot} - T_{Amb}) \tag{10.3}$$

where θ_{HP}, θ_P, and θ_{PA} are, respectively, the thermal resistances between the heat source and the TEG, between both faces of the TEG, and between the TEG and the environment.

The electrical behavior can be approximated by a Thevenin equivalent circuit. The Thevenin voltage (V_{Th}) is proportional to the TEG temperature drop (ΔT_{Pelt}). The proportionality factor depends on the number (N) of the thermocoupled PN unions of the *Peltier cell* and on the *Seebeck* coefficients of the P-side (S_P) and the N-side (S_N). As the thermocoupled unions are electrically connected in series and thermally in parallel, the value of V_{Th} is

$$V_{Th} = N \times (S_P - S_N) \times \Delta T_{Pelt} \tag{10.4}$$

The Thevenin resistance (R_{Th}) depends on the cross area and length of the thermocoupled unions and on their electrical resistivity.

Nowadays, the thermocoupled unions are built with *bismuth telluride* (BiTe) that has a *Seebeck* coefficient of 0.2 mV/°C ($S_P - S_N$). An example of a commercial *Peltier cell* that could be used as a TEG is the MPG-D751 from Micropelt GmbH [14]. It is formed by 540 thermocoupled unions (N) in an area around 14 mm^2. Despite its small area, the thermal resistance is as small as 12.5 °C/W. The equivalent Thevenin resistance is around 300 Ω and the voltage V_{Th} increases 140 mV/°C at 23 °C. A practical way to increase the generated voltage and power per area consists of using thinner thermocoupled legs. Unfortunately, the industrial technology of BiTe TEG is near its miniaturization limits and it is not possible to decrease the cross section without decreasing their length [15]. An alternative feasible solution consists of using multistage *Peltier cells*. They consist of using two or more stages of *Peltier cells* that are thermally and electrically connected in series. For the same number of thermocoupled unions, the area will be divided by the number of stages and so, higher V_{Th} will be achieved. Figure 10.10 shows the Thevenin voltages for two stages of TEGs thermally connected in series. Considering θ_P much lower than $\theta_{HP} + \theta_{PA}$, the resulting voltage is doubled from a single stage. Nevertheless, the resulting voltage is not doubled if both TEGs are connected thermally in parallel and electrically in series. As the thermal resistances are connected in parallel, the temperature drop is reduced by half and V_{Th} is hardly incremented.

The size and cost design constraints of TEG usually lead to low generated voltages and power levels. In [16], voltages ranging from 150 to 250 mV with a maximum current of 18 mA are achieved with a TEG coupled to a human hand. Such low voltage levels constitute the main challenge when designing a

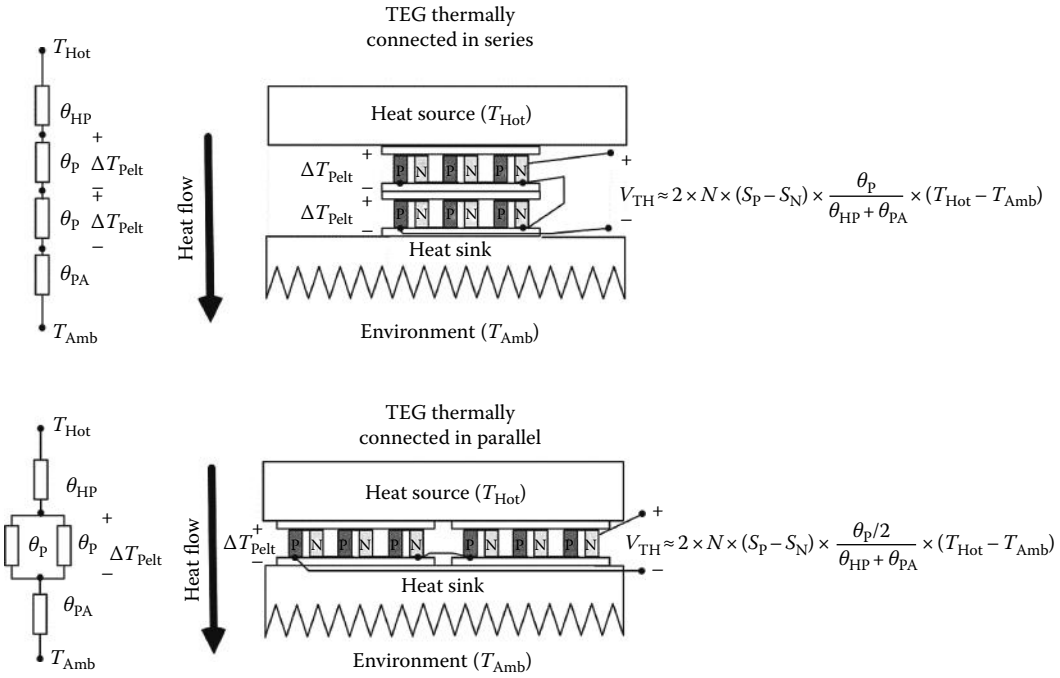

FIGURE 10.10 Comparison between two TEGs thermally connected in series with a parallel connected configuration. To calculate the generated voltage V_{TH}, it was taken into account that both TEGs are electrically series connected and $\theta_P \ll \theta_{HP} + \theta_{PA}$.

power conditioning circuit for the TEG. The minimum start-up voltage of conventional boost (step-up) dc/dc converters is limited to above 0.7 V by the threshold voltage of transistors. If lower input voltages have to be processed, special low-threshold transistors or special power conditioning architectures must be used. An example is the charge pump S-882Z from Seiko that employs silicon on isolation (SOI) transistors with low threshold voltages [17]. The minimum start-up voltage is 300 mV and the quiescent current is 0.6 μA but the power efficiency is below 20%. The manufacturer recommends using S-882Z with a boost switching converter to improve the overall efficiency. The S-882Z is used during the start-up to charge a capacitor until the minimum start-up voltage of the switching converter is reached. The capacitor powers the control circuit of the boost and is charged by the output of the converter through a diode once starts working. Figure 10.11 shows a scheme of the power conditioning circuit and the evolution of the main electrical variables.

An alternative solution to step-up of such low input voltage consists of using an electromagnetic transformer [18]. The induced voltage on the secondary is equal to the voltage in the primary multiplied by the turns ratio. Therefore, the primary voltage will be stepped-up if high turns ratio is selected. Unfortunately, electromagnetic transformers can just step-up an ac voltage source and TEG provides a dc voltage. To overcome this problem, an ac voltage is generated by an oscillator. The oscillator is formed by a JFET transistor that is fed back by a coupled solenoid of the transformer (see Figure 10.12). A JFET transistor is selected instead of bipolar or a MOSFET enhancement-mode channel transistor because it provides a modulated conduction channel from zero input voltage (V_{IN}). Therefore, the oscillator can start working from very low input voltages and a sinusoidal voltage is induced in the secondary (V_S). The output capacitor is charged from V_S through a rectifier diode and powers the control circuit of a boost converter (V_{DD}).

Similar starter circuits are also used by commercial power conditioning ICs such as the LTC3108 from Linear Technology [19]. It is operative from 20 mV input voltage for a 1:100 turns ratio.

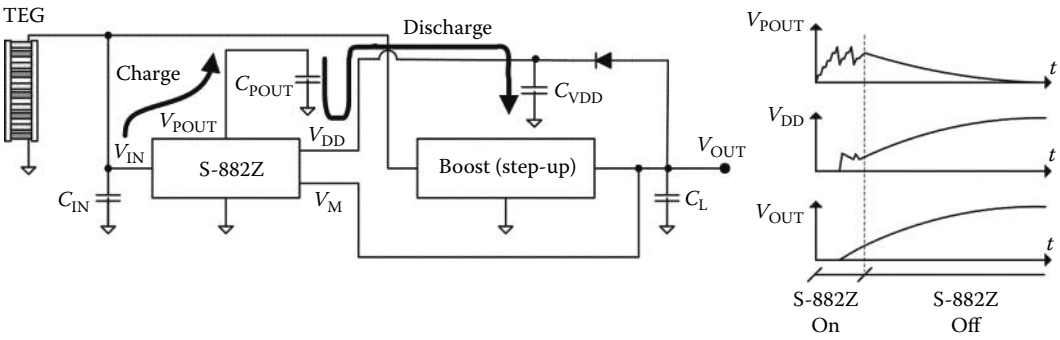

FIGURE 10.11 Scheme of a TEG power conditioner based on the charge pump S-882Z from Seiko.

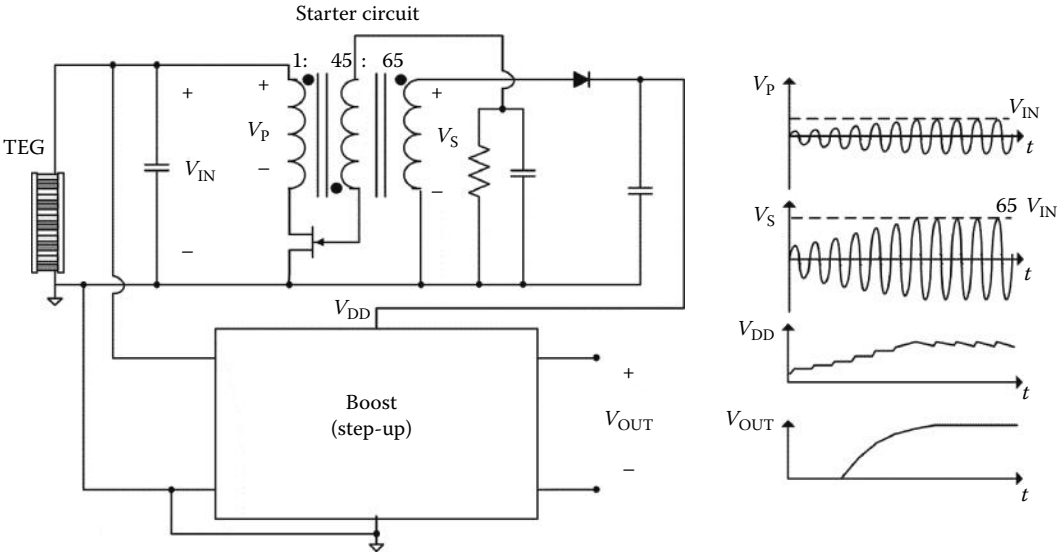

FIGURE 10.12 Scheme of a TEG power conditioner based on a transformer.

Another commercial IC converter, specifically the BQ25504 from Texas Instruments, tracks the MPP of TEGs. As it is based on PFM converter controlled by a simple FOCV, it has an ultralow current consumption that makes feasible to work for such low-power sources. TEGs, as well as PV panels, hold an empirical relationship between the V_{OC} and MPP, and so, the FOCV technique can also be applied. Taking into account that the electrical behavior can be modeled by an equivalent Thevenin source, V_{MPP} will be the half value of V_{OC} ($K = 0.5$).

11.1 Introduction

Radiofrequency (RF) and mechanical energy transducers generate an alternating (ac) voltage and current that is proportional to the available power in the environment. There are other transducers (of different environmental energies) that also generate an ac signal. However, we have chosen these energies as the most representative in terms of the variety of energy conditioning circuits used. Other ac harvesters can use similar circuits and techniques to that presented in this chapter. Indeed, RF and mechanical energy sometimes benefit of the same energy conditioning circuit structures. However, note that each transducer has its own peculiarities that must be accounted for.

Signals generated by these transducers must be rectified in order to charge the battery or the (super) capacitor that powers the load (autonomous sensor). When using just a rectifying stage, the load fixes the working point of the harvester and the system is not optimized under all environmental conditions. Additionally, under some circumstances, the voltage coming from RF or mechanical energy transducers is quite low and needs to be stepped-up. One advantage of having an ac signal is that step-up transformers or rectifiers (among other step-up circuits) can readily be used to obtain the output voltage needed to power the autonomous sensor. Energy transducers and rectifiers can be modeled with a Thevenin equivalent circuit that delivers maximum power to a matched resistive load. Consequently, several works have proposed maximum power point trackers (MPPTs) that bias the transducer, or the rectifier, at its maximum power point (MPP). MPPTs are more complex circuits that, if well designed, can highly improve efficiency at very low input powers.

This chapter describes two important ac energies (RF and mechanical) and the most used energy harvesting circuits.

11.2 Radiofrequency Energy Harvesting

RF signals are present in the environment as they are deliberately radiated by broadcasting stations and cellular phone antennas. The ambient available RF power must be harvested by means of broadband and/or circularly polarized antennas [1], because in most cases, there is either a broad range of frequencies and different polarizations or there is lack of detailed information on the ambient RF waves. Except for locations near transmitters, the available ambient power density (S) is in the nW/cm^2 range, which is too low to be useful. However, near transmitters, the power is much higher, and this is why deliberate RF power transmission on the industrial, scientific, and medical (ISM) application frequency bands has also become an alternative to power autonomous sensors [2]. In this case, S can be obtained from Equation 11.1:

$$S = P_{\text{EIRP}} \frac{1}{4\pi d^2} \tag{11.1}$$

where

P_{EIRP} is the effective radiated power, which is related to that of an isotropic radiator (an ideal antenna)
d is the distance from the transmitter

This formula is for free-space propagation; for other scenarios, the power decays more rapidly with distance, unless the location features a structure that acts as a waveguide (e.g., in corridors). Additionally, there are other factors that affect S, including multipath propagation and reflections; thus, calculating the real S requires accurate simulations or field measurements. Furthermore, the maximum P_{EIRP} for ISM frequency bands is regulated (for European regulations, see Annex 11.1 in [3]). The available power that the antenna can deliver to a matched load (P_{AV}) depends on S and on the effective aperture (area) of the antenna (A_e), as shown in Equation 11.2 (known as the *Friis relation*):

$$P_{\text{AV}} = S \cdot A_e = S \frac{\lambda_{\text{RF}}^2}{4\pi} G_r = P_{\text{EIRP}} G_r \frac{\lambda_{\text{RF}}^2}{(4\pi d)^2} \tag{11.2}$$

where

$A_e = \lambda_{\text{RF}}^2 G_r / 4\pi$
G_r is the antenna gain
λ_{RF} is the wavelength

Equation 11.2 clearly demonstrates that the higher the frequency (λ_{RF} is inversely proportional to frequency), the lower the power range. In Europe, the most popular frequency bands for ISM applications are centered at 433 MHz, 868 MHz, and 2.4 GHz.

Figure 11.1 shows the building blocks of an RF energy harvester, encompassing at least an antenna, an impedance matching block, and a rectifier. In some cases, a low-pass filter can be used between the impedance matching and the rectifier in order to prevent harmonics from flowing back to the antenna and reducing voltage amplitude at the input of the rectifier. If a filter is used, an additional second impedance matching block is needed to match the filter output impedance to the input impedance of the rectifier. However, as these filters are not conventionally used in RF energy harvesters, we will not deal with these two blocks.

An RF transducer (antenna) can be modeled as a voltage ac source in series with an output impedance (Figure 11.1). Antenna shapes and dimensions vary widely, and several distinct antenna designs have been employed in RF and radiofrequency identification (RFID) harvesting applications. The series impedance basically comprises the radiation resistance (R_S), the loss resistance (R_{loss}), and a reactive part (X_{ant}). Depending on the antenna design, X_{ant}, can be positive, thus presenting an inductive behavior

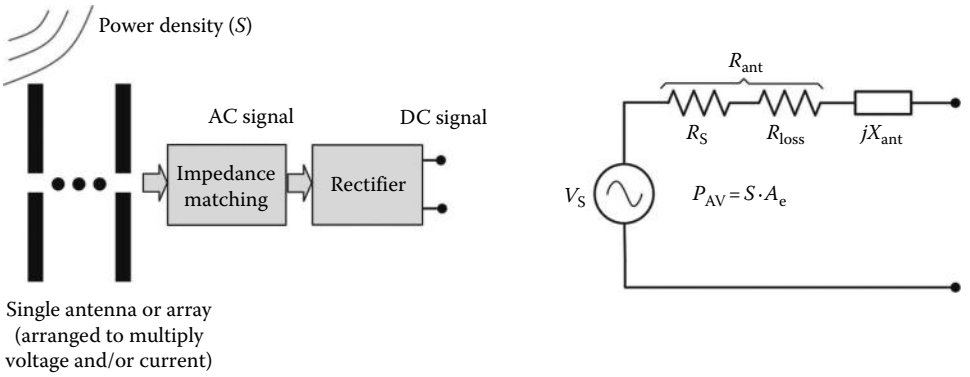

FIGURE 11.1 General block diagram of an RF harvester and the electrical equivalent model for an antenna.

(e.g., in loop-shape antennas) or negative, thus presenting a capacitive behavior (e.g., in patch antennas). The size of the antenna is inversely proportional to the desired resonant frequency. Despite this frequency dependency, some miniaturization techniques, such as high-dielectric substrates or meandered, bent, or tip-loaded structures, can be employed to minimize the final size of the system. The amplitude of the voltage generated on the antenna when matched ($\hat{v}_S$) depends on P_{AV} and R_S as

$$\hat{v}_S = 2\sqrt{2R_S P_{AV}} \tag{11.3}$$

Thus, at a given P_{AV}, $\hat{v}_S$ increases for a larger R_S. $\hat{v}_S$ must be relatively high in order to overcome the voltage drop of the diodes and reduce the losses from the rectifier. P_{AV} depends on A_e and S and, therefore, depends on the antenna characteristics. If greater power is sought, voltages or currents can be added by connecting several antennas (in series and/or in parallel) to form an array; in this case, the antenna's A_e is increased at the expense of a larger physical area [1]. A single rectifying circuit for the whole array reduces the number of rectifying elements but can complicate array design. An antenna with rectifying and matching elements is called a *rectenna. Rectennas* can also be connected in series or parallel in order to add current or voltage; again, at the expense of greater effective area (and physical dimensions). The efficiency of the *rectenna* depends on input power, and for microwatt-level inputs is 20% maximum [1].

The transmitted power reaches its maximum when the antenna sees at its output an impedance that is the conjugate of its own impedance: $Z^*_{ant} = R_S - jX_{ant}$. In Figure 11.2, Z_{in} (R_{in} and C_{in}) is the equivalent input impedance of the rectifier and ensuing load. Z_{in} should be adapted through a matching network (gray components in Figure 11.2) to present Z^*_{ant} at the antenna (point A in Figure 11.2). This procedure is known as *impedance matching*. A properly matched design is as important as a well-designed antenna or rectifier. Numerous matching configurations are available. The choice of the specific configuration depends on the number of elements used for the matching and the way in which they are positioned. Nonetheless, to date, three main circuits have been proposed for RFID or RF harvesting [4]: *a transformer* (Figure 11.2a), *a shunt inductor* (Figure 11.2b), and an *L network* (Figure 11.2c). A shunt inductor matching does not boost the antenna voltage and can be used for high R_S antenna for which $\hat{v}_S$ is relatively high (see Equation 11.3). As this is not always easy, a transformer or an *L* network can be used to boost the voltage generated on the antenna.

Rectifier circuits together with an output low-pass filter (in general a single capacitor) provide a direct current (dc) output voltage at the ensuing load. There are three main options for the rectifier:

1. A diode (which, together with the antenna, forms a rectenna) [1] Figure 11.3a
2. A bridge of diodes (or diode-connected transistors) (Figure 11.3b)
3. A voltage rectifier multiplier [5] (Figure 11.4 left shows a single stage circuit)

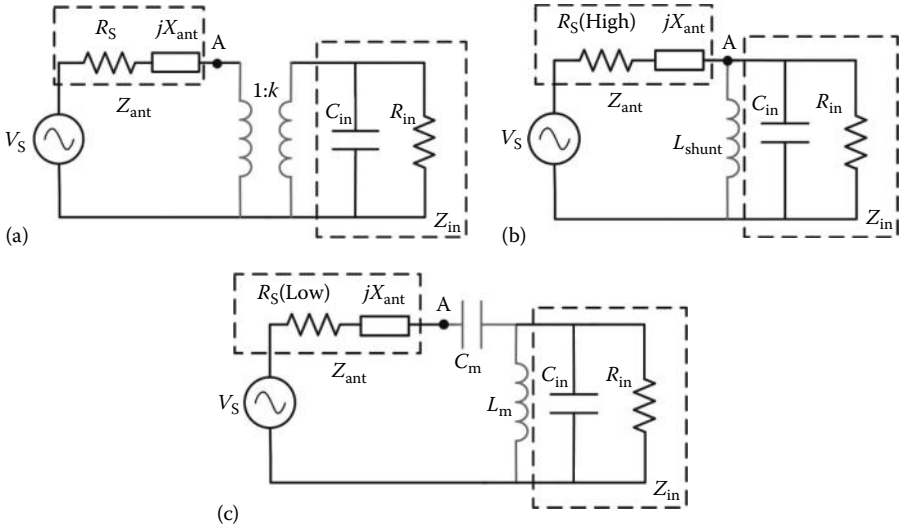

FIGURE 11.2 Typical matching network circuits for RFID or RF harvesting circuits: (a) transformer, (b) shunt inductor, and (c) *L* network. The matching network elements are shown in gray.

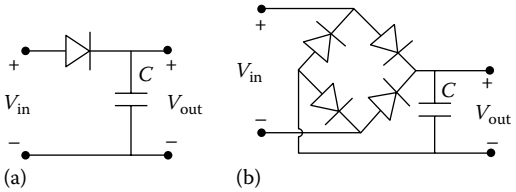

FIGURE 11.3 (a) Single diode and (b) diode bridge rectifiers.

All of these circuits are broadband (i.e., they exhibit the same rectifying characteristics in a broad band of frequencies). For kilohertz or megahertz frequencies, p–n diodes and transistors are used as rectifiers, whereas for microwave frequencies (>1 GHz), Schottky diodes (GaAs or Si type) are preferred, because they have shorter transit times. The rectification performance of the diode depends on its saturation current, its junction capacitance, and its conduction resistance. A large saturation current is sought, because it leads to a low forward voltage drop.

The diode (Figure 11.3a) and the diode bridge (Figure 11.3b) provide an output dc voltage to the load (V_{out}) whose value is lower than the peak value of the incoming signal. The *voltage rectifier multiplier*, as its name indicates, multiplies the peak amplitude of the incoming signal, Figure 11.4. At long distances (low P_{AV} and, consequently, low $\hat{v}_S$; see Equation 11.3), the dc voltage level from diode or diode bridge rectifiers is not high enough to power an electronic circuit, so the voltage rectifier multiplier appears to be the best solution [5]. The output voltage of a *voltage rectifier multiplier* can be further multiplied by cascading several stages as in Figure 11.5.

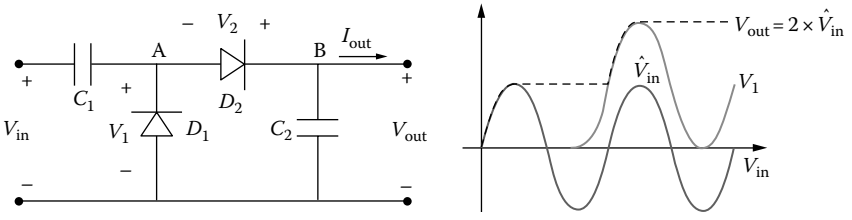

FIGURE 11.4 A single stage of a voltage multiplier rectifier and waveforms during the transient.

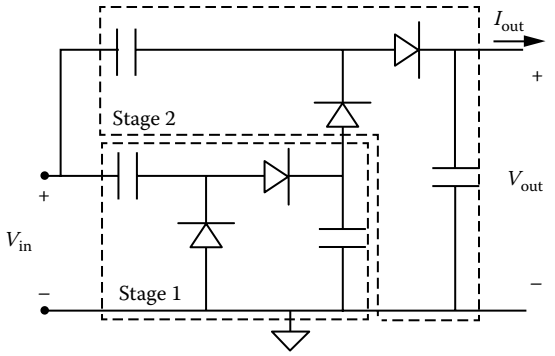

FIGURE 11.5 Two-stage voltage rectifier multiplier.

The diodes of the rectifier can also be implemented using CMOS transistors connected as diodes, which is the case for most RFID tags [5]. Using rectifying elements with low threshold voltage and low reverse current will increase the sensitivity of the rectifier (i.e., the minimum input voltage at which the rectifier can work under given load requirements). To overcome the technological issues of traditional CMOS, researchers have proposed several rectifier designs. For example, to obtain transistors with very low threshold voltage, Curty et al. [6] employed the silicon-on-sapphire (SOS) CMOS process, and Karthaus and Fischer [7] used silicon–titanium Schottky diodes. Others have avoided using these relatively expensive processes by biasing the voltage at the gate of the transistor, which results in almost zero threshold voltage transistors [8,9]. RFID tags usually include the required number of stages that give the desired output voltage at the expected minimum input power, $\bar{P}_{in}$.

P2110 and P1110 from Powercast [2] are two chips that integrate the rectifier and are designed for 50 Ω antennas and for the 850–950 MHz frequency band. The first one can deliver a regulated voltage from 1.8 to 5.25 V at input powers down to –11 dBm. Efficiency is around 10% at this power level and goes up to around 50% at higher power levels. The other circuit can more efficiently harvest input powers from –5 to 20 dBm.

Seen from the load, the rectenna (or the antenna plus any of the previously explained rectifiers) can be modeled with a Thevenin equivalent as a dc voltage source (V_{th}) in series with a Thevenin resistance (R_{th}). V_{th} depends on environmental conditions and R_{th} is constant for a certain range of input powers and generated voltages. Consequently, the system will deliver maximum power to a matched resistive load equal to R_{th}.

To boost the output voltage of the rectifier whenever it is too low, step-up switching converters can be used. Additionally, they can also be used to implement an MPPT [10,11]. Considering the Thevenin equivalent circuit of the *rectenna*, the simplest MPPT technique emulates a fixed resistance equal to R_{Th}. In this way, maximum power is extracted from the *rectenna* for a wide range of environmental conditions. A discontinuous conduction mode boost converter (Figure 11.6) with a simple open-loop controller emulates a resistor (R_{eq}) if its input voltage (V_{in}) is much lower than the output voltage (V_{out}). The average input current is proportional to V_{in} with a proportional constant equal to $1/R_{eq}$ that depends on the duty cycle of the converter's transistor, *D*. *D* depends on the converter timing parameters T_{hf}, t_{on}, *k*, and T_{lf} from Figure 11.6. Using a fixed *D* that leads to $R_{eq} = R_{Th}$, the input voltage the voltage at the maximum power point, reaches V_{MPP} ($V_{Th}/2$). Following this control scheme, the reported overall efficiency in [10] was 16.7% for a power density of 70 μW/cm^2 at the antenna (P_{AV} was around 2.5 mW) when connecting a thin-film lithium battery (4.15 V) at the output of the dc/dc converter.

In addition to the method previously explained, some of the techniques used for photovoltaic energy harvesting, such as the fractional open-circuit voltage (FOCV) MPPT, can also be applied to RF harvesting. In RF energy harvesters, the proportional constant, *k*, of FOCV will be 0.5. In any case, the power consumption of the energy conditioning circuit must be in the microwatt level or below in order to achieve a net power gain.

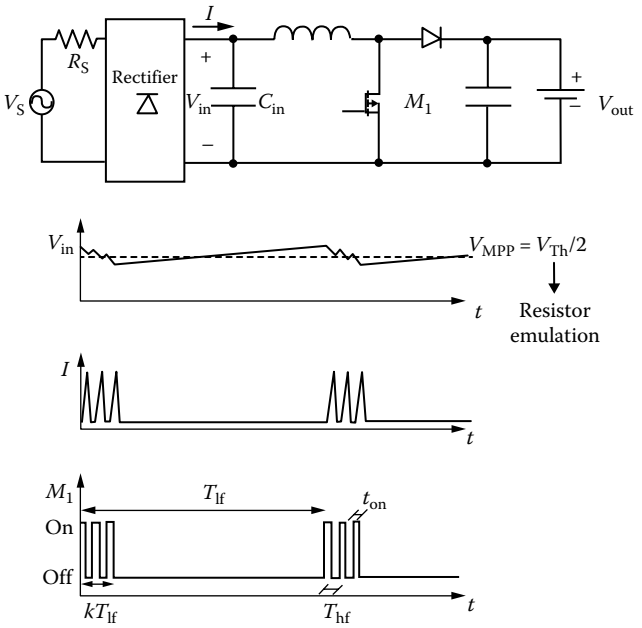

FIGURE 11.6 Boost converter working in discontinuous conduction mode acting as a resistor emulator.

11.3 Mechanical Energy Harvesting

Mechanical energy harvesting is a very active research topic that has spawned numerous reviews (e.g., [12]). It is based on kinetic energy [13], the sources of which include liquid or gas flow, vibrations, human activity, and pressure variations (e.g., acoustic noise and atmospheric pressure). Available power in flow energy increases cubically with an increase in the speed of the liquid or gas. Low-level vibrations occur in machinery, outdoor windows, and transport vehicles; they produce frequencies between 50 and 200 Hz and acceleration amplitudes between 1 and 10 m/s^2. Human activity can actively or passively generate kinetic energy. Active human power requires deliberate movement, whereas passive human power exploits common daily activities (e.g., heel strike while walking).

Mechanical energy can be coupled by one of the following conversion principles [14]: electrostatic, piezoelectric, and electromagnetic. Reported efficiencies are 0.32% [12], 0.5% (for polyvinylidene fluoride [PVDF]) to 20% (for lead zirconate titanate [PZT]) [15], and 6% [12], respectively. The generated signals are ac and must be rectified in order to power autonomous sensors. Figure 11.7 shows a general block diagram for the three types of conversion principles and the equivalent electrical models of the respective harvesters.

Electrostatic converters are based on variable capacitors. One plate is fixed and the other changes with the mechanical force, thereby changing the value of the capacitance. They are IC compatible as microelectric variable capacitors can be fabricated via silicon micromachining techniques. Energy can be extracted via charge-constrained or voltage-constrained approaches. Charge and voltage are related through capacitance ($Q = C \cdot V$); therefore, a change in capacitance produces variations in either voltage (charge constraint [16], Figure 11.8) or charge (voltage constraint [17], Figure 11.9). In both approaches, the extraction cycles are basically divided into three phases. In the first phase, the variable capacitor (C_{VAR}) is charged from an energy reservoir (can be a battery or a capacitor). Then, the harvest phase starts. In the charge-constrained circuit of Figure 11.8, the voltage of C_{VAR} increases as the distance between the plates increases (capacitance decreases) and charges a temporary capacitor (C_S). If the diodes are replaced by transistors, less power will be lost during this phase; however, the control signals will need to be synchronized with the mechanical movement. In the voltage-constrained circuit of Figure 11.9,

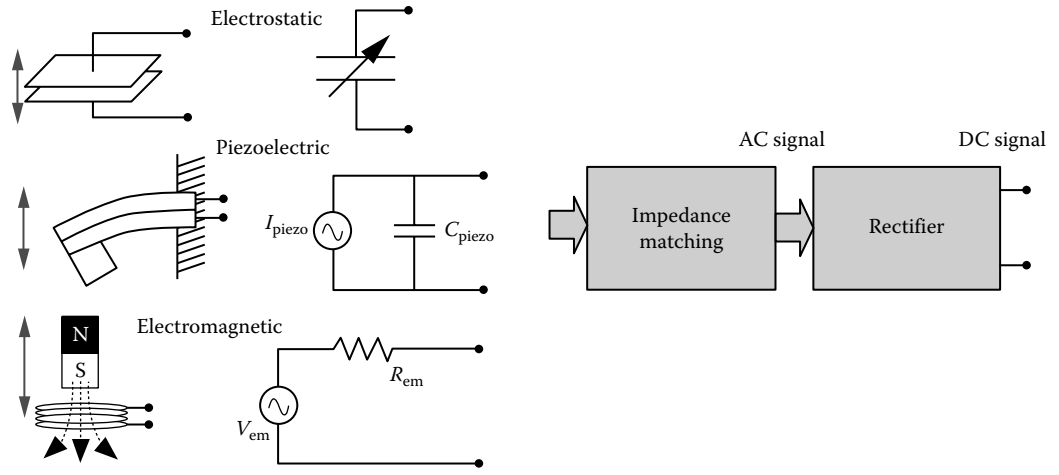

FIGURE 11.7 General block diagram of a mechanical harvester. Includes electrical models of the three different harvesters used for mechanical energy.

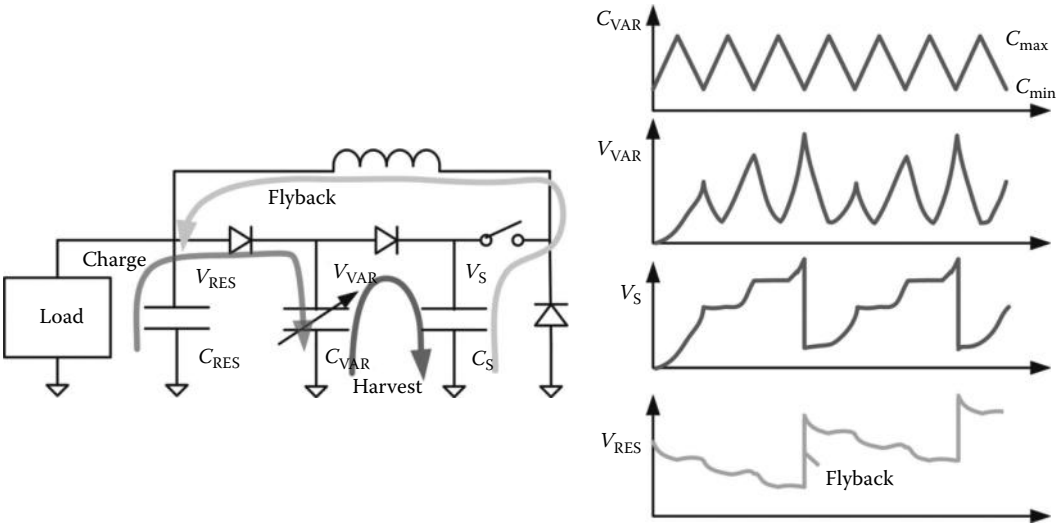

FIGURE 11.8 Charge-constrained energy harvesting circuit for electrostatic mechanical harvesters.

the energy reservoir is directly connected to the harvester and $V_C = V_{BAT}$ during the harvest phase. Thus, current flows to the energy reservoir as the capacity of the harvester decreases (distance between the plates increase). For the charge-constrained scheme, the third phase is performed after several harvest phases. In this phase, the energy in C_S is transferred to the main energy reservoir unit (C_{RES}) through a buck converter (flyback phase), and afterward, the process is started again. In the voltage-constrained scheme, after the harvest phase, the remaining energy in the variable capacitor can be recovered (recovery phase). Nonetheless, this energy is very small and not worthy to extract.

However, these converters have several drawbacks: They need a power source reservoir for starting the extraction cycles, and in the charge constraint scheme, they operate at high voltages, which limit their implementation to more expensive integration processes [18].

Reversible electric polarization in response to strain from mechanical stress is called the *piezoelectric effect*. Piezoelectric materials are anisotropic: their properties vary according to the direction of force and the orientation of the polarization and the electrodes. Several operational modes can be employed

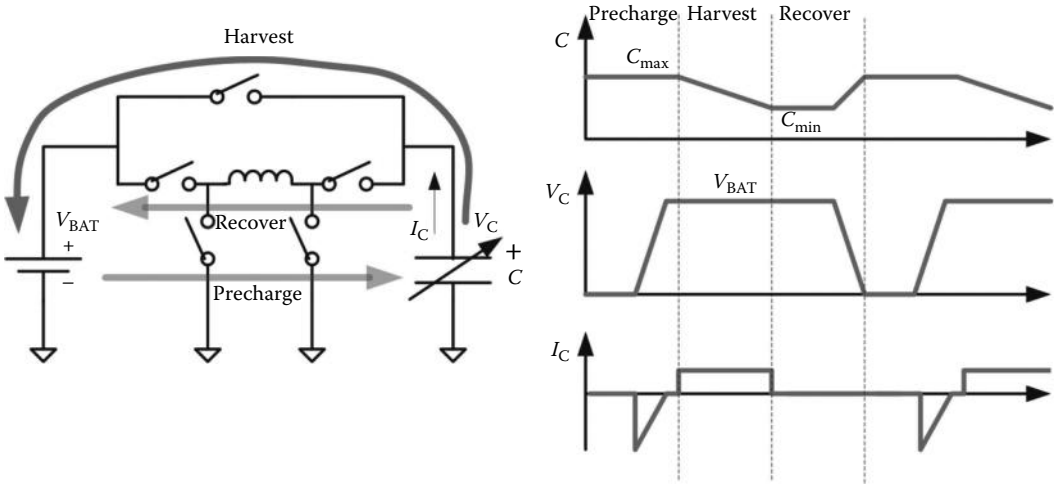

FIGURE 11.9 Voltage-constrained energy harvesting circuit and related curves for electrostatic mechanical harvesters.

for piezoelectric harvesters, the most widely used of which are modes 33 and 31. Mode 33 is used to extract energy from impact or when harvesting energy from passive human power. Mode 31 is more suited for cantilever structures with a proof mass at the free end. Cantilevers are usually bimorphic structures comprising two piezoelectric materials bound together, with a shim in between them. For power extraction, cantilevers typically operate at their resonant frequency. Piezoelectric transducers can be electrically modeled as an ac current source (I_{piezo}) in parallel with a capacitor (C_{piezo}) [19] (Figure 11.7). The main challenge with piezoelectric harvesters is integrating them into an IC.

The maximum voltage at which C_{piezo} will be charged (piezoelectric open-circuit voltage, V_{POC}) is generally in the volt level and can be directly connected to conventional bridge rectifiers (Figure 11.3b) without significant power losses. V_{POC} depends on I_{piezo} (determined by the displacement achieved), the angular frequency ω of the movement, and C_{piezo} (see Equation 11.4). In this case, V_{POC} is usually much higher than the diodes voltage drop (V_D) and must at least be $2V_D$ in order to extract energy from the transducer. For example, a piezoelectric energy harvester such as Volture [20] from Mide (tuned to work at vibrations frequencies between 80 and 175 Hz) can produce several milliwatts at 9.8 m/s^2 vibration with a conventional rectifier. V_{POC} depends on I_{piezo} (determined by the displacement achieved), the angular frequency of the movement and C_{piezo}:

$$V_{POC} = \frac{I_{piezo}}{\omega \cdot C_{piezo}} \tag{11.4}$$

Nonetheless, for microscale implementations or under certain environmental conditions, the output voltages can also be relatively small. Furthermore, more power can be generated if some charge is injected to the piezoelectric element before force is done against it in order to increase the force it posses to the movement. Thus, other circuits have been proposed [21]:

- Synchronous switched extraction circuits that extract all the generated energy from C_{piezo} at lower voltages than the bridge rectifier
- Circuits that inject some charge to the piezoelectric element before force is done against it

In the synchronous switched extraction circuit (Figure 11.10), the charge is accumulated in C_{piezo} until I_{piezo} crosses zero (at the maximum displacement of the piezoelectric transducer), then the switch (S) is closed and charge is extracted with a resonant LC circuit. The switch S is closed for a period that

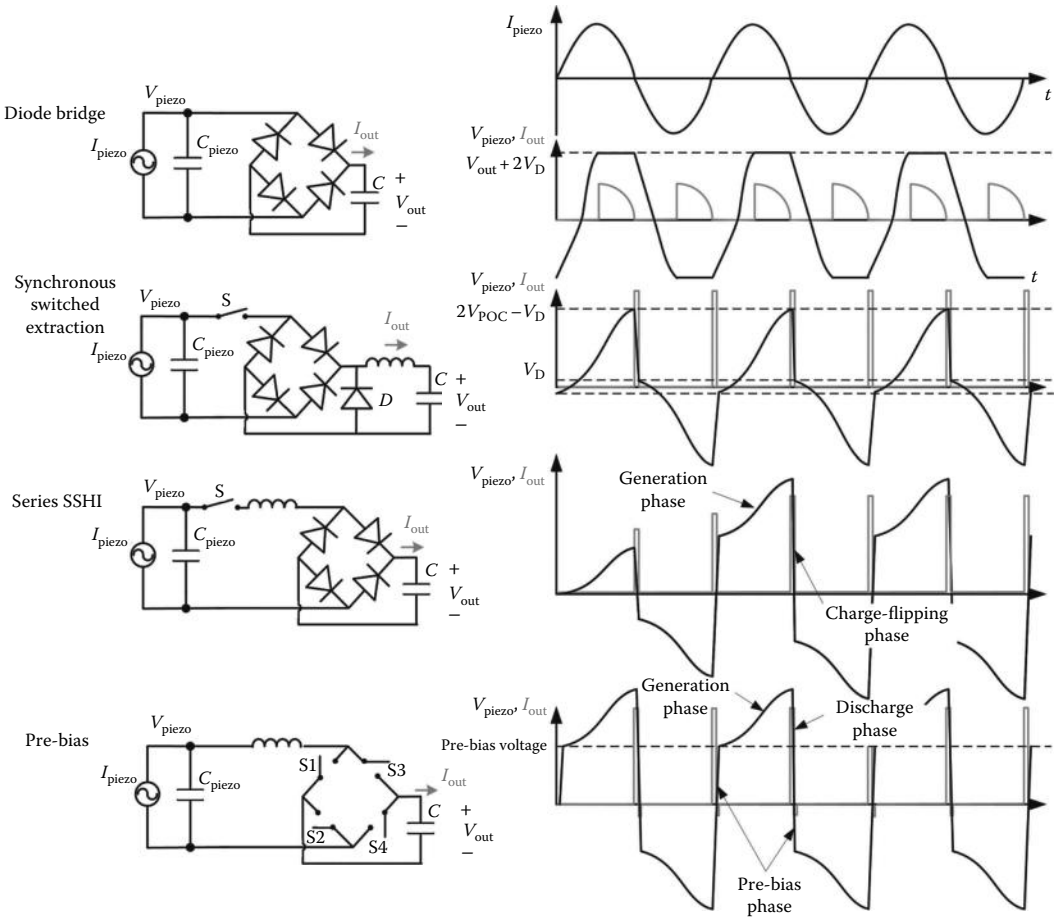

FIGURE 11.10 Different extraction circuits for piezoelectric energy harvesters.

corresponds to half the cycle of the resonant frequency of the *LC* circuit allowing the extraction of all the charge in C_{piezo} whenever the output voltage (V_{out}) is carefully chosen. The discharge time of C_{piezo} should be very small related to the period of the movement. Diode *D* is used to allow the current in *L* (if any) freewheel to *C* once C_{piezo} has been fully discharged. This circuit can handle lower V_{POC}, and contrary to the bridge rectifier circuit, the voltage in C_{piezo} is zero at the end of the charge extraction; thus, more power is harvested. This circuit is feasible whenever $V_{POC} > V_D$.

There are two main types of circuits that inject charge to the piezoelectric element: synchronous, switched harvesting with inductor (SSHI) and prebias circuits.

In SSHI circuits, there is an initial generation phase that stores charge in C_{piezo}, and afterward an inductor, in parallel or series (Figure 11.10) with the piezoelectric transducer, is switched at the zero crosses of I_{piezo} in order to invert the polarity of C_{piezo} (charge flipping phase). In parallel SSHI configuration, V_{POC} can be lower than V_D.

There are several implementations of prebias circuits, the simplest uses switches in an H bridge configuration (Figure 11.10). There are three phases for each semiperiod of I_{piezo}: Firstly, S1 and S4 are closed and C_{piezo} is precharged to the reservoir voltage; then, they are opened and the harvest phase starts; and afterward, when I_{piezo} reaches zero, S1 and S4 are closed again and C_{piezo} is discharged to 0 V through an *LC* resonant circuit. In the other semiperiod, the same phases are repeated with diodes S2 and S3. These circuits allow extracting more power from the harvester than SSHI circuits at the cost of more control overhead because the rectification bridge is implemented with switches.

In any case, there is an MPP at which extracted power is maximal. As happened with RF harvesting circuits, this MPP corresponds to an optimal resistance load in parallel to the output capacitor of the rectifier. Thus, a resistor emulator circuit as that described in Figure 11.6 has also been described for piezoelectric harvesters [22].

In some case, resonant matching networks have also been used to boost the voltage at the input of the rectifier [23]. This work uses a commercial piezoelectric energy harvesting circuit, LTC3588 from Linear Technology, which integrates a full bridge rectifier. Linear has indeed several energy harvesting circuits for piezoelectric energy harvesting that work with input voltages between 2.7 and 20 V and can output voltages between 1.8 and 5 V with current consumptions below one microampere.

Electromagnetic induction, based on Faraday's law (see Equation 11.5), refers to generation of a voltage (V_{em}) in a conductor (typically, a coil) located within a magnetic flux ϕ, usually generated by a permanent magnet. The generated voltage depends on various factors, including the strength of the magnetic field, the velocity of the relative motion between the coil and the magnet, and the number of turns in the coil. Electromagnetic energy transducers can be electrically modeled as low-level ac voltage sources with low series impedance (Figure 11.7):

$$v = -\frac{d\phi}{dt} \tag{11.5}$$

Since magnets are quite difficult to integrate into ICs, integrated prototypes of these transducers show very low output powers. This type of harvester is best suited for high-frequency and low-amplitude vibrations. Some commercially available energy harvesters at macroscale (e.g., the Perpetuum Ltd. [24]) are based on this principle.

Even for macroscale implementations, the generated voltage can usually be around hundreds of millivolts [19]. Bridges or single diodes could be used as the rectifier (Figure 11.3). In that case, the rectifying elements can be implemented with diode-connected transistors that will present lower threshold voltages. However, the output voltage of the rectifier will be lower than the peak value of the input signal (see Equation 11.2), and thus, it will still need to be stepped-up by using, for example, a boost dc/dc converter.

Voltage can also be boosted by using transformer matching circuits before rectification. In Figure 11.11, the voltage of the harvester is boosted by the turns ratio of the transformer, and afterward, each semiperiod of the ac signal is rectified with one of the diodes. One of the major challenges of this circuit is IC integration as transformers are quite difficult to integrate into ICs.

The voltage multiplier rectifier (Figure 11.4) or modified versions of this circuit can also be used to rectify and boost the output voltage of the harvester. The lack of magnetic components makes the voltage multiplier rectifier a good option for IC integration.

More complex circuits such as dual polarity boost converters (Figure 11.12) have also been proposed [19]. There, each converter is used to boost and rectify one of the two semiperiods of the generated

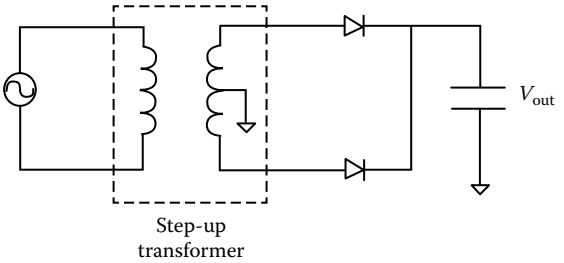

FIGURE 11.11 Circuit to boost the output of an inductive mechanical harvester by using a step-up transformer prior to rectification.

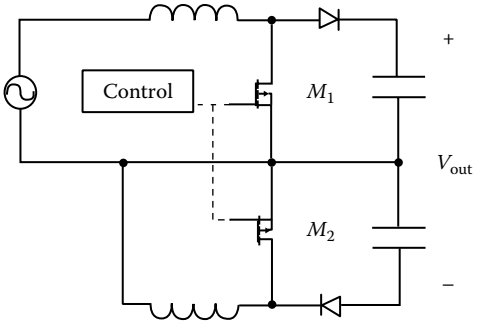

FIGURE 11.12 Dual polarity boost circuit for electromagnetic mechanical energy harvesting.

signal. Rectification is achieved by the alternate activation of one of the two converters. This circuit requires some control overhead.

Finally, MPPT circuits that make the harvester work as if it had an optimal resistor at its output, through resistor emulation as in RF (Figure 11.6) or by setting the working voltage to half the harvester open-circuit voltage (V_{OC}) [25], have also been proposed. In [25], they used switched capacitors to fix the harvester's working voltage at 0.5 V_{OC}, where V_{OC} needs to be periodically sampled.

The trend in energy harvesters is to integrate several energy conditioning circuits into the same chip in order to extract energy from multiple energy sources. Several commercial products and scientific works have recently appeared. Nevertheless, these circuits use the most suitable energy conditioning circuit for each energy source because, as can be deduced from this work, each transducer has its peculiarities. A commercial product from Cymbet, CBC915 [26], can be used indistinctly with different energy harvesters and make them work at their MPP. Furthermore, in [27], they propose a circuit that accepts energy from optical, thermal, and mechanical energy harvesters at the same time and makes all the harvesters work at their MPP for a wide range of environmental conditions. For the mechanical harvester, they used a conventional rectifier and then a buck–boost converter makes this system work at its MPP.

12.1 Introduction

The demand for hydrogen as a process gas and as a renewable energy carrier to reduce dependence on fossil fuels and to mitigate the problems associated with greenhouse gas emissions is increasing [1,2].

Hydrogen has a very low density (0.0899 kg/m^3) and boiling point (20.39 K) and high diffusion coefficient (0.61 cm^2/s in air). It has a low minimum ignition energy (0.017 mJ), high heat of combustion (142 kJ/g H_2), and wide flammable range (4–75 vol% in air), as well as a high burning velocity and an ignition temperature of 560 °C. Hydrogen also acts as a strong reducing agent for many elements and has a high permeability through many materials [3]. In addition, hydrogen is a colorless, odorless, and tasteless flammable gas that makes it undetectable by human senses.

Due to the unique physical and chemical properties of hydrogen, hydrogen-based applications require rigorous safety precautions in comparison to other industrial gases. Since the use of odorants in many hydrogen applications is not possible, dedicated detection devices or sensors are essential to warn of the presence of unwanted hydrogen leaks. Hydrogen sensors play an essential role in ensuring the safety of hydrogen-based applications. As such, sensors boost end user confidence and therefore facilitate the safe use and commercialization of hydrogen as an alternative fuel. Some applications require not only detecting the presence of hydrogen but also measuring the concentration of the gas in the ambient [3].

This chapter reviews the available commercial hydrogen-sensing technologies and their operating principles. The chapter discusses the performance characteristics of these sensor types, such as measuring range, sensitivity, selectivity, and response time. Available emergent technologies and their impact on improved hydrogen gas sensing are also presented.

Hydrogen sensors are transducer devices that detect hydrogen gas and produce an electric signal with a magnitude proportional to the hydrogen gas concentration.

There are several different types of hydrogen sensors and the most common commercial types are catalytic (CAT), electrochemical (EC), thermal conductivity (TCD), semiconductive metal–oxide (MOX), and metal–oxide–semiconductor (MOS) sensors. The following section presents an overview of the main sensor types available on the market.

12.2 Commercial Sensor Technologies and Their Detection Principles of Catalytic Hydrogen Gas Sensor

The detection principle of CAT hydrogen gas sensors is based on heat generation due to hydrogen reaction with oxygen on the surface of a CAT material. There are two types of CAT hydrogen sensors: pellistor type and thermoelectric type.

A pellistor-type sensor is made of two platinum wires embedded in separate beads: a sensing bead and a reference bead. The sensing bead is impregnated with catalyst (usually palladium) to accelerate the oxidation of hydrogen. The reference bead compensates for environmental effects such as changes in humidity or temperature. These two beads are mounted in a Wheatstone bridge as shown in Figure 12.1.

When the target gas is introduced, CAT combustion of the gas occurs on the surface of the sensing bead, releasing heat and causing the temperature of the bead to rise. As a result, the resistance of the embedded platinum wire changes, which imbalances the Wheatstone bridge and provides an output signal that varies with target gas concentration. CAT-type sensors were first suggested by Jonson in 1923 and used in mines for methane detection [4,5]. CAT pellistor-type sensors are well-developed and widely available.

On the other hand, thermoelectric-type CAT sensors use the thermoelectric Seebeck effect to transform the heat generated from the exothermic hydrogen oxidation reaction into an electric signal. The thermoelectric voltage generated is related to the temperature difference by the following expression:

$$U = S\Delta T \tag{12.1}$$

where

U is the thermoelectric voltage generated

S is the Seebeck coefficient

ΔT is the temperature difference due to heat generation

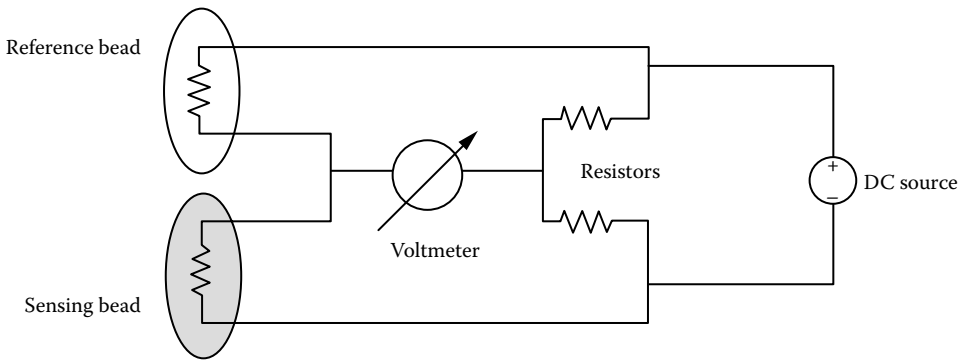

FIGURE 12.1 Wheatstone bridge circuit connected to a CAT hydrogen sensor. The sensing bead represents the variable resistor that imbalances the bridge in the presence of hydrogen.

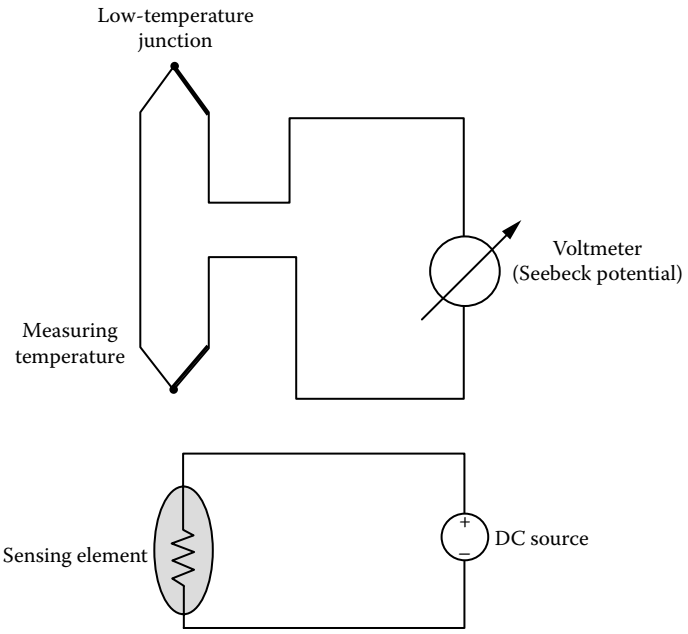

FIGURE 12.2 Schematic diagram representing hydrogen sensing by thermoelectric effect.

Thermoelectric hydrogen gas sensors are fabricated as a film of a thermoelectric material deposited on an insulating substrate material. One-half of the thermoelectric material is coated with a catalyst, and oxidation of hydrogen on the catalyst surface generates heat. This generates a temperature gradient over the thermoelectric film that produces a voltage signal measurable by an electric circuit. One advantage of thermoelectric hydrogen sensors over pellistor sensors is that they can operate at room temperature or slightly elevated temperatures (<100 °C) [6]. Figure 12.2 represents the CAT thermoelectric gas sensor. The thermoelectric effect was first used in sensing application in 1985 and reported by McAleer et al. [7].

12.2.1 Thermal Conductivity Hydrogen Gas Sensor

TCD hydrogen sensors exploit the exceptionally high TCD of hydrogen (0.168 W/m·K at 25 °C), seven times higher than air (0.024 W/m·K at 25 °C). The hydrogen concentration is inferred by the rate at which a sensing thermal element releases heat compared to a reference element. In the classical configuration the two elements are placed into two separate cells connected in a Wheatstone bridge circuit: when the gas is introduced at the sensing element, the difference in thermal conduction from the hot to the cold elements leads to a change in temperature that affects the resistance of the sensor and thus imbalances the bridge. This imbalance can be measured and can be used to indicate the hydrogen concentration. The main difference between the CAT bead sensor and the TCD sensor is the absence of a chemical reaction [8]. Figure 12.3 represents the circuit diagram of the TCD sensor.

12.2.2 Electrochemical Hydrogen Gas Sensor

EC sensors detect the change in charge transport or electrical properties due to EC reactions of hydrogen gas at the sensing electrode. The sensor structure consists of three electrodes stacked parallel and separate by an electrolytic solution as shown in Figure 12.4. There are two types of EC gas detection: amperometric and potentiometric [4].

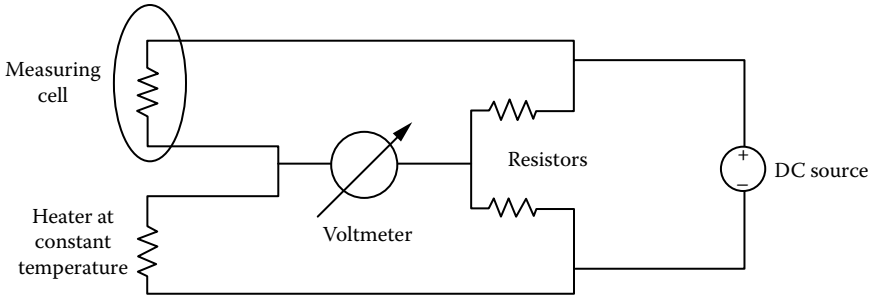

FIGURE 12.3 TCD sensor measuring circuit using a Wheatstone bridge. The measuring cell represents the variable resistor that imbalances the bridge in the presence of hydrogen.

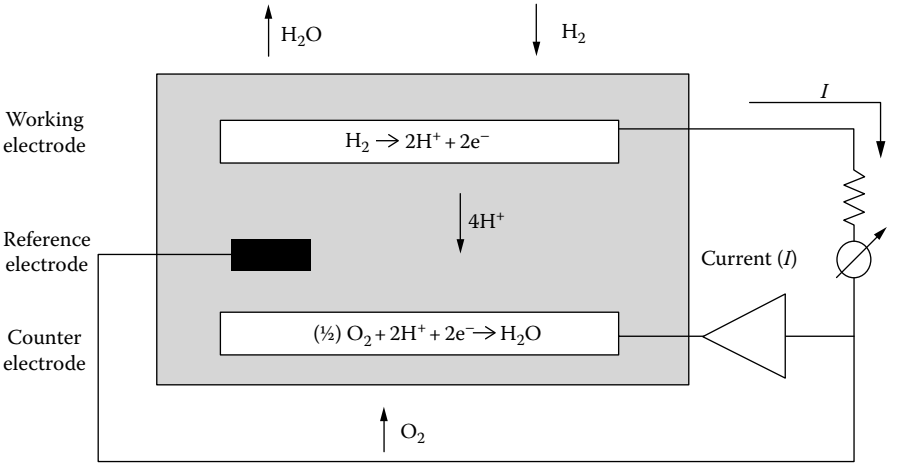

FIGURE 12.4 EC cell for hydrogen detection.

Amperometric sensors work at a constant applied voltage where the sensor signal is a diffusion-limited current. When hydrogen penetrates the gas diffusion barrier, it reaches the surface of the working electrode (anode) where the following oxidation reaction takes place:

$$H_2 \rightarrow 2H^+ + 2e^-$$

The electrons released in this reaction flow to the cathode (counter electrode) via an external circuit; this electric current constitutes the sensor signal. Protons released from the oxidation reaction cross the electrolyte and reach the counter electrode where the reduction of oxygen takes place as follows:

$$(1/2)O_2 + 2H^+ + 2e^- \rightarrow H_2O$$

The flow of electric current is proportional to the hydrogen gas concentration according to Faraday's law:

$$i = zQF$$

where

F is the Faraday constant, 96486.7 A · s/mol
z is the number of exchanged electrons per molecule
Q is the conversion rate of hydrogen in mol/s

The reference electrode maintains a constant voltage at the working electrode.

Potentiometric sensors have the same structure but work at zero current, and the measured quantity is the potential difference or electromotive force between the sensing electrode and the reference electrode. The electrode potential is related to the hydrogen gas concentration and can be written according to the Nernst equation as follows:

$$E = E^0 + \frac{RT}{zF}\ln\left(\frac{a}{a_0}\right) \tag{12.2}$$

where

E is the electrode potential
E^0 is the standard electrode potential
R is the universal gas constant
T is the absolute temperature
F is the Faraday constant
z is the number of electrons taking part in the reaction
a is the chemical activity of the analytes (proportional to hydrogen concentration)
a_0 is the activity of the reference

The processes of diffusion and chemical reaction must be at equilibrium before an accurate signal can be obtained from these sensors [6,9].

12.2.3 Semiconductive Metal–Oxide Hydrogen Sensors

MOX sensors consist of two metal electrodes connected to an active material. The electrodes allow the measurement of the resistance change of the active layer that depends on the target gas concentration. The active material is a semiconducting MOX, such as SnO_2, ZnO, TiO_2, FeO, Fe_2O_3, NiO, Ga_2O_3, In_2O_3, Sb_2O_5, MoO_3, and WO_3, whose electric resistance varies in the presence of hydrogen gas.

When the sensor reaches its operating temperature (generally between 180 °C and 450 °C), oxygen chemisorbs on the surface of the MOX material and forms negatively charged adsorbed oxygen ions that create a surface potential that acts as a barrier to electron flow. Thus, oxygen is necessary to operate this type of sensor. The electric resistance of the active layer is attributed to this barrier potential. In the presence of hydrogen, the surface density of negatively charged oxygen and, consequently, the barrier potential decrease, thus reducing the electric resistance of the active layer. The resistance change can be related to the hydrogen concentration. Typically the MOX film is heated using a resistive metal film [9,10]. Figure 12.5 represents MOX sensor structure.

12.2.4 Metal–Oxide–Semiconductor Hydrogen Sensors

MOS gas sensors are characterized by a three-layer structure: a CAT metal layer is deposited over an oxide layer on a semiconductor substrate. Their operation is based on work function (measured in electron volts) variation due to the presence of hydrogen. For hydrogen detection a hydrogen-sensitive CAT metal, such as platinum or palladium (the gate metal), is deposited on the oxide layer. In the presence of hydrogen, the current–voltage (I–V) characteristics of the MOS transistor change [11]; this change can be detected indicating the presence of the gas as Figure 12.6 illustrates.

In addition to MOS transistor hydrogen sensors, there are metal–semiconductor (MS) Schottky diodes and MOS capacitors structures that can be also used to detect the hydrogen.

In Schottky diodes the CAT metal, typically palladium or platinum for hydrogen detection, is directly in contact with a semiconductive material (Figure 12.7). Hydrogen molecules adsorb onto the surface of the CAT metal and dissociate into hydrogen atoms inducing a change in the work function of the metal

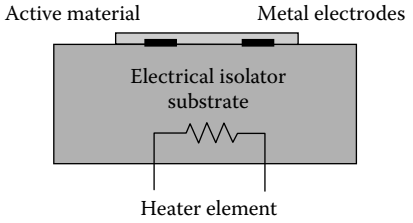

FIGURE 12.5 Typical MOX hydrogen gas sensor structure.

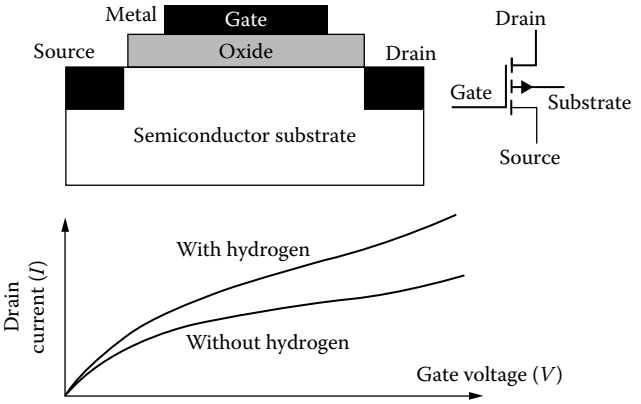

FIGURE 12.6 MOS transistor structure and the *I–V* for hydrogen detection.

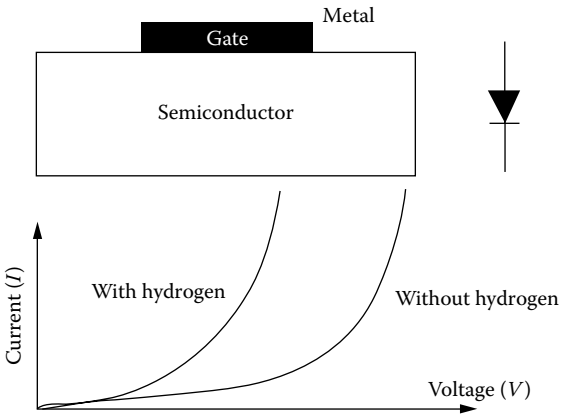

FIGURE 12.7 Schottky diode hydrogen gas sensor structure and the *I–V* curve presenting its principle of operation.

and hence the Schottky barrier height. This change in the Schottky barrier height causes a shift in the *I–V* characteristics. The response can be measured as the change in voltage when the diode is operated at constant bias current [6].

A MOS capacitor is the simplest MOS device and a cross-sectional view of a typical MOS capacitor is shown in Figure 12.8. A thin oxide layer is sandwiched between a metal layer (palladium or platinum) and a silicon substrate layer. The absorption of hydrogen and the chemical reactions at the MOX interface cause a change in the *C–V* characteristics of the capacitor and shift the flat band voltage by an amount proportional to the hydrogen gas concentration [9]. The first MOS capacitor hydrogen sensor was reported by Steele et al. in 1976 [12].

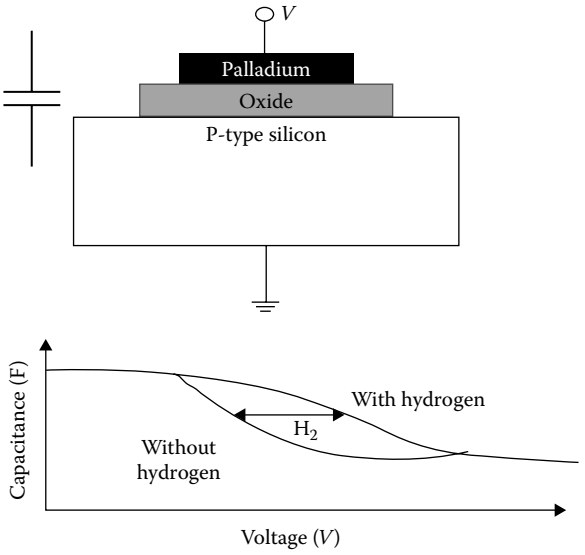

FIGURE 12.8 Typical MOS capacitor for hydrogen detection.

12.2.5 Pd-Based Hydrogen Sensors

Another class of hydrogen sensor is based on the interaction of palladium with hydrogen: the hydrogen molecule is split at the thin palladium film interface and atomic hydrogen can be accommodated in the metal lattice resulting in a change of its physical properties. The hydrogen concentration can be related to the change in the electric resistance (resistance-based sensors), to the change in metal lattice expansion (mechanical sensors), or to the change in dielectric function (optical sensors) of the sensing material. For a review of those sensors, see [6].

12.3 Hydrogen Sensor Specifications

The performance of commercial hydrogen sensors has been evaluated [6,9,13]. Table 12.1 compares the performance specifications of the most common commercial sensor types discussed in the previous sections.

12.3.1 Partial List of Hydrogen Sensor Suppliers and Manufacturers

Tables 12.2 through 12.5 list some known hydrogen sensor suppliers and manufacturers, with links to their websites.

TABLE 12.1 Performance Specifications of Commercial Hydrogen Sensor Types

	Temperature Range (°C)		Humidity (RH%)		Measuring Range (vol%)	Pressure (kPa)		Response	Recovery	Power	Life Time
Sensor	Min	Max	Min	Max	Max	Min	Max	Time (s)	Time (s)	(mW)	(Years)
CAT	−20	70	5	95	4	70	130	<30	10	1000	5
TCD	0	50	0	95	100	80	120	<10	7.5	<500	5

12.4 Requirements of Hydrogen Gas Sensors

To use hydrogen gas sensors in industrial applications, general requirements described in EN IEC 60079-29-1 have to be followed [14]. The previously discussed hydrogen sensors were developed to meet these requirements as it is shown in Table 12.6, and they are suitable for applications such as the production of ammonia or methanol or for safety monitoring in nuclear power plants, where hydrogen is produced via the thermochemical splitting of water as well as stationary systems.

TABLE 12.6 Performance Requirements for Industrial Applications

Parameters	Performance Requirements

TABLE 12.7 Performance Requirements for Automotive Applications

Parameters	Performance Requirements
Measuring range	0%–4% H_2 in air
Response time	<3 s
Recovery time	<3 s
Ambient temperature	−40 °C to +125 °C
Humidity	0%–100% Relative humidity

Source: Boon-Brett, L. et al., *Int. J. Hydrogen Energy*, 35, 371, 2010.

However, for new hydrogen-based applications, the development of new technologies for the detection and measurement of hydrogen concentration requires new performance specifications for which some standards already exist [15].

The use of hydrogen as an automotive fuel represents a new application for which stringent performance specifications have been cited [16]. Table 12.7 reports the requirements for automotive applications in terms of measuring range, response time, recovery time, and operating range of temperature and humidity.

Other requirements for hydrogen sensors in automotive applications are high reliability, long lifetime, high selectivity, and adaptability to the application interface. Low-cost, small dimensions, and

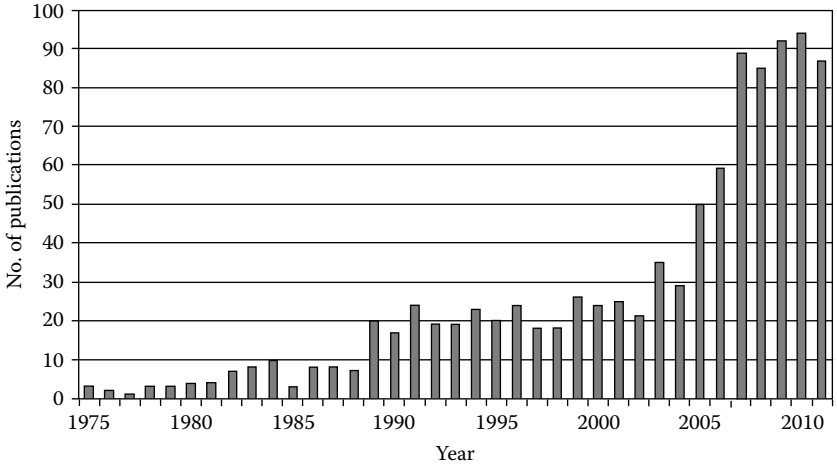

FIGURE 12.9 The number of publications in the area of hydrogen sensing according to an inquiry (June 2012) in SciVerse Scopus (www.scopus.com).

low power consumption are also important concerns for the automotive industry. From the analysis of the performance of hydrogen sensors available on the market (see Table 12.1), it is possible to conclude that there are some weaknesses concerning the performance requirements for automotive industry: although some of the automotive requirements are satisfied by the reported MOS sensor, dimensions, power consumption, and lower detection limit still need to be improved. The use of innovative technologies may enhance hydrogen sensor performance and add extra specifications allowing for integration with different systems/applications [6,7]. In fact research on novel approaches for hydrogen detection is increasing as reflected in the growing number of relevant publications in this area. Figure 12.9 shows the number of publications from 1975 until 2011.

12.5 Emerging Technologies in Hydrogen Gas Sensors

Emerging nanofabrication technologies enable the fabrication of submicron and nanometric devices working according to new hydrogen detection principles that add further performance improvements for gas sensing [17,18].

This section reviews and analyzes various emerging hydrogen-sensing techniques and discusses their advantages and weaknesses. Research and development work being performed to compensate these weaknesses is also presented.

12.5.1 Acoustic Hydrogen Gas Sensors

Acoustic technology offers a novel way of hydrogen sensing since it has the potential for passive wireless gas sensing that facilities the integration in sensor network applications. An acoustic sensor is constructed from two transducers on a piezoelectric substrate such as $LiNbO_3$ or $LiTaO_3$: one of these transducers is responsible to convert the input signal into an acoustic wave, while the second converts the acoustic wave back into an electric output signal as shown in Figure 12.10. This technique claims more robustness under different environment conditions [6].

The operating principle of acoustic gas sensor is based on the propagation of an elastic wave in the device by piezoelectric effect. The gas detection layer (usually palladium) is placed in the path of the acoustic wave between the input and the output transducers. When the sensitive layer absorbs hydrogen, a change in its mechanical (mass density), electrical properties (electric conductivity), or both will occur that produces a detectable change in the frequency of the acoustic wave. The resonant frequency at which the elastic wave propagates depends on the width of the transducer, while the mode of operation depends on elastic wave propagation mode, device geometry, and adopted technology [9]. Figure 12.10 shows a top view of the acoustic gas sensor structure.

Surface acoustic wave (SAW) mode is the most commonly used mode in hydrogen gas detection [19]. In this mode, the use of palladium or a polymer as the gas detection layer permits a mass density change (mass loading) due to the absorption of hydrogen. In this mode, the mass-loading effect dominates since the conductivity of the sensing material is too low to modify the propagation of the

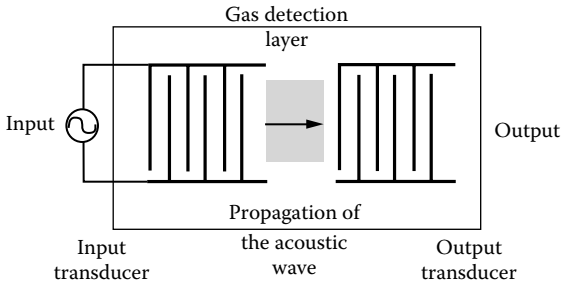

FIGURE 12.10 Top view of an acoustic gas sensor with the input and output transducer.

acoustic wave [20]. To modify the propagation of SAW by changing the electric conductivity, semiconducting MOXs such as WO_3 [21], InO_x [22], and SiN_x [23] are used. In order to improve the sensitivity of the sensitive layer in SAW devices, the gas detection layer is nanostructured to increase the surface-to-volume ratio and hence having more surface contact with the hydrogen that permits a fast response to the gas [24]. Nanostructured ZnO as well as palladium nanowires have been investigated [25,26] showing an enhancement in the sensitivity compared to film structures of the same materials. To improve the selectivity to hydrogen, SAW sensors incorporating a hydrogen catalyst with the semiconducting MOXs have been reported [27].

However, this propagation mode shows some weaknesses, especially a poor stability for temperature and humidity [8]. Therefore, the other propagation modes must be exploited for automotive industry requirements. For example, use of shear horizontal SAW (SH-SAW) sensors instead of SAW sensors reduces the effect of humidity thanks to the absence of vertical component of the wave in the first mode. Other wave propagation modes can be investigated for robustness as well as to facilitate their generation by the transducers [9].

12.5.2 Micromachined Hydrogen Gas Sensors

The advances in the field of microfabrication have permitted fabrication of three dimensional structures from a silicon substrate using micromachining techniques such as bulk micromachining, surface micromachining, dissolved wafer process, LIGA, and electrodischarge machining (EDM) [28]. The available commercial micromachined hydrogen sensors apply the same detection principles discussed previously but with microfabricated sensing elements. MOX, TCD, and CAT micromachined sensors have the advantage of improved performance compared with their conventionally fabricated counterparts.

Silicon wafers coated with silicon dioxide (SiO_2) and silicon nitride (Si_2N_3) are usually used for integration with other components or for micromachining as a sacrificial layer. The structure of the micromachined sensor is almost the same for all these detection principles, which consists of a suspended membrane on which the sensing elements are placed. The membrane is fabricated by either bulk or surface micromachining. Figure 12.11 shows the structure of the micromachined (TCD) gas sensor.

In case of CAT micromachined gas sensor, there are two suspended membranes: one for the active element and the other for the reference element that replace the beads. This can be considered as miniaturization of the classical bead structure that is usually in the order of centimeters [29]. Figure 12.12 is a cross section of a micromachined CAT sensor.

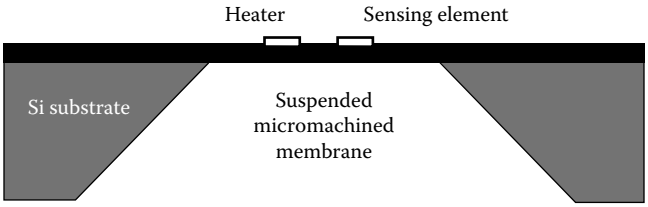

FIGURE 12.11 Micromachined structures for TCD H_2 commercial sensors.

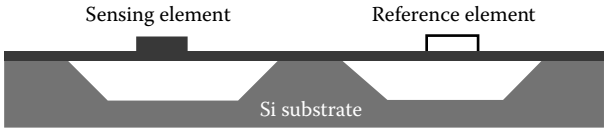

FIGURE 12.12 The structure of micromachined CAT gas sensor on Si substrate.

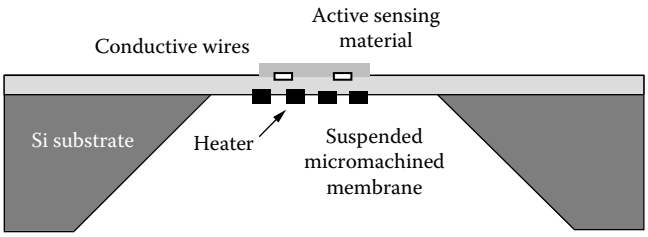

FIGURE 12.13 Micromachined structure of MOX hydrogen gas sensor.

Semiconductive MOX hydrogen sensors can also be fabricated using micromachining techniques whereby the MOX material is deposited on the micromachined suspended membrane. Some MOX structures have the heating element on the same surface as the active material [30], but it is also possible for the heater to be deposited on the underside of the membrane (Figure 12.13).

Micromachined hydrogen sensors show improved performance over conventionally designed and manufactured hydrogen sensors. They are faster and more stable under different environmental conditions. Moreover, they are cheaper and smaller and consume less power. However, there are some challenges facing these sensors and their low cost can only be realized when mass produced.

12.5.3 Nano-/Microelectromechanical System Hydrogen Gas Sensors

Nanolithography allows fabricating nano-/microelectromechanical system (N-MEMS) with high surface-to-volume ratio and with dimensions in the order of a few atomic distances. N-MEMS devices are used in several applications such as mechanical resonators, RF switches, actuators, and sensors. N-MEMS resonators have a quality factor in the order of ~10^3 and an operation frequency in the MHz range. Their functionality is based on the mechanical motion of their components due to an external stimulus. Designing an N-MEMS resonator implies choosing the material and the geometry of the structure. For example, a double-clamped N-MEMS beam resonator has a resonant frequency f_0 given by [31–33]

$$f_0 = 1.03 \frac{w}{L^2} \sqrt{\frac{E}{\rho}} \tag{12.3}$$

where

w is the width

L is the length of the beam

E and ρ are the Young modulus and the density of the material, respectively

The N-MEMS resonator is usually actuated by an external source to reach its mechanical resonance frequency.

NEMS/MEMS resonator devices allow for gas detection by introducing a gas-sensitive layer. For example, N-MEMS can be used for hydrogen sensing in MHz range using gold–palladium alloy as detection material [31]. The sensing mechanism of this sensor is based on resonant frequency shift due to the presence of the hydrogen gas. Another N-MEMS hydrogen sensor has been presented [34], showing the advantage of low power consumption and high sensitivity under ambient conditions [35–37].

12.6 Conclusion

This chapter has reviewed commercially available hydrogen sensor technologies and has discussed the physical principles of hydrogen detection in each of these technologies. The chapter has summarized the performances and operating conditions of each sensor type and compared them to the current industrial

requirements and to the emergent hydrogen applications requirements. Gaps still exist between the sensor performance requirements for emerging applications and the actual performance of commercial hydrogen sensors. Novel hydrogen detection techniques have the potential to enhance hydrogen sensor performance in order to meet the needs of these emerging markets.

Thermal Sensors: Flow

Nam-Trung Nguyen
The University of California, Berkeley

13.1 Introduction

This chapter deals with fundamentals of thermal methods for sensing and measuring mass fluid flows. The flow can be defined as the motion of a continuum (fluid) in a closed structure (channel, orifice), and it is the measured object. The associated physical quantity sensed is the mass flux that flows through a unit cross section. The equation for the volume flow rate Φ_v is given by

$$\Phi_v = \frac{dV}{dt} = vA \tag{13.1}$$

where

V is the volume through in the time t

v is the average velocity over the cross-sectional area A of the channel

with the relation between the volume V, mass M, and the density of fluid ρ

$$V = \frac{M}{\rho} \tag{13.2}$$

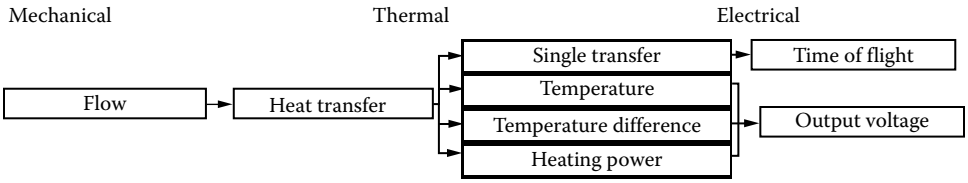

FIGURE 13.1 The three signal domains and the signal transfer process of a thermal flow sensor.

the mass flow rate Φ_m can be derived by using Equations 13.1 and 13.2 to obtain

$$\Phi_m = (\Phi_v \rho) + \left(V \frac{d\rho}{dt} \right) \tag{13.3}$$

For time invariable fluid density, one obtains

$$\Phi_m = \Phi_v \rho = Av\rho \tag{13.4}$$

A thermal mass flow sensor will generally output a signal related to the mass flux

$$\phi_m = \frac{\Phi_m}{A} = v\rho \tag{13.5}$$

and convert the mechanical variable (mass flow) via a thermal variable (heat transfer) into an electrical signal (current or voltage) that can be processed by, for example, a microcontroller. Figure 13.1 illustrates this working principle. The working range for any mass flux sensor is somewhat dependent on the fluid properties, such as thermal conductivity, specific heat, and density, but not on the physical state (gas or liquid) of the fluid.

13.2 Principles of Conventional Thermal Mass Flow Sensors

With two heater control modes and two evaluation modes, there are six operational modes shown in Table 13.1 and three types of thermal mass sensors:

- Thermal mass sensors that sense the effect of the flowing fluid on a hot body (increase of heating power with constant heater temperature, decrease of heater temperature with constant heating power). They are usually called hot-wire, hot-film sensors, or hot-element sensors.
- Thermal mass sensors that respond to the displacement of temperature profile around the heater, which is modulated by the fluid flow. These are called calorimetric sensors.
- Thermal mass sensors that sense the passage time of a heat pulse over a known distance. They are usually called time-of-flight sensors.

TABLE 13.1 Operational Modes of Thermal Mass Flow Sensors

Heater Controls	Constant Heating Power		Constant Heater Temperature	
Evaluation	Heater temperature	Temperature difference	Heating power	Temperature difference
Operational modes	Hot-wire and hot-film types	Calorimetric type	Hot-wire and hot-film types	Calorimetric type
	Time-of-flight type		Time-of-flight type	

13.2.1 Hot-Wire and Hot-Film Sensors

The dependence of the heat loss between a fine wire as well as a thin film and the surrounding fluid has traditionally been the most accepted method for measuring a fluid flow: the hot-wire method. The hot-film method uses film sensors for detecting the flow. The basic elements of this sensor type are discussed.

Flow channel: In contrast to the thermal anemometer described in Chapter 62 of Volume 1 of this book for point measurement, thermal mass flow sensors of the hot-wire and hot-film type have a flow channel defining the mass flow. Figure 13.2 shows two typical arrangements.

Sensor element: Hot-wire sensors are fabricated from platinum, platinum-coated tungsten, or a platinum–iridium alloy. Since the wire sensor is extremely fragile, hot-wire sensors are usually used only for clean air or gas applications. On the other hand, hot-film sensors are extremely rugged; therefore, they can be used in both liquid and contaminated-gas environments. In the hot-film sensor, the high-purity platinum film is bonded to the rod. The thin film is protected by a thin coating of alumina if the sensor will be used in a gas or of quartz if the sensor will be used in a liquid. The alumina coatings have a high abrasion resistance and high thermal conductivity. Quartz coatings are less porous and can be used in heavier layers for electrical insulation. Typical hot-wire and hot-film sensors are shown in Figure 13.3.

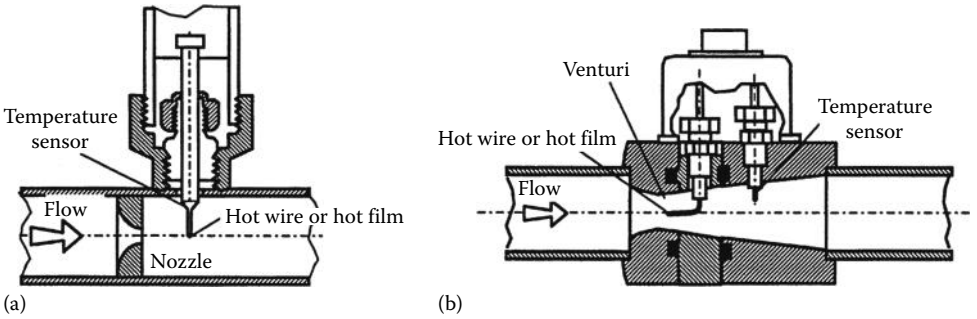

FIGURE 13.2 Typical arrangements of flow channel: (a) nozzle type and (b) venturi type.

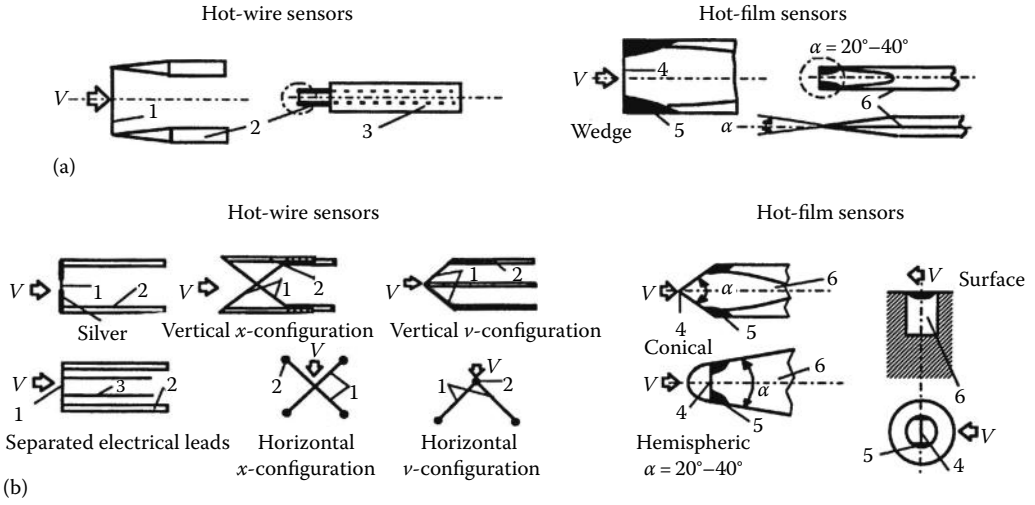

FIGURE 13.3 Typical hot-wire and hot-film sensors: (a) basic shape of the sensor element and (b) further shapes of the sensor element. (1, hot-wire; 2, sensor supports; 3, electric leads; 4, hot-film; 5, contact caps; 6, quartz rod.)

The sensor element, whether it is a wire or a film, should be a resistor that has a resistance with a high temperature coefficient α. For most sensor materials, the temperature dependence can simply be expressed by a first-order function:

$$R = R_r[1 + \alpha(T - T_r)] \tag{13.6}$$

where

R is the resistance at operating temperature T
R_r is the resistance at reference temperature T_r
α is the temperature coefficient

For research applications, cylindrical sensors are most common, either a fine wire (typical diameters from 1 to 15 μm) or a cylindrical film (typical diameters from 25 to 150 μm). Industrial sensors are often a resistance wire wrapped around a ceramic substrate that has typical diameters from 0.02 to 2 mm.

Table 13.2 shows some typical parameters of industrial hot-wire and hot-film sensors.

Control and evaluation circuit: The constant-current and constant-temperature bridge are conventional circuits for control and evaluation of heat-wire or heat-film sensors.

A constant-current Wheatstone bridge with a hot-wire sensor is shown schematically in Figure 13.4a. In this circuit, resistors R_3 and R_4 are much larger than sensor resistor R_1. Therefore, current through R_1 is essentially independent of changes in the sensor resistor R_1. Any flow in the channel cools the hot wire, decreases its resistance as given by Equation 13.6, and unbalances the bridge. The unbalanced bridge produces an output voltage V_o, which is related to the mass flow. Because the output voltage V_o from the bridge is small, it must be amplified before it is recorded. The value of the thermal coefficient α for R_1 and R_2 should be equal in order to eliminate signal errors due to changes in ambient temperature. Similarly, thermal coefficients for R_3 and R_4 should also be equal.

TABLE 13.2 Typical Parameters of Hot-Wire and Hot-Film Sensors

Parameter	Hot Wire	Hot Film
Sensor element	Platinum hot wire (diameter of 70 μm)	Platinum hot film (alumina coated)
Operational mode	Constant heater temperature in air	
Working temperature range	−30°C to 200°C	
Characteristics	Nonlinear	
Accuracy in %	±4	±2
Time response in ms	<5	12
Sensitivity in mV kg^{-1} h^{-1}	1	5

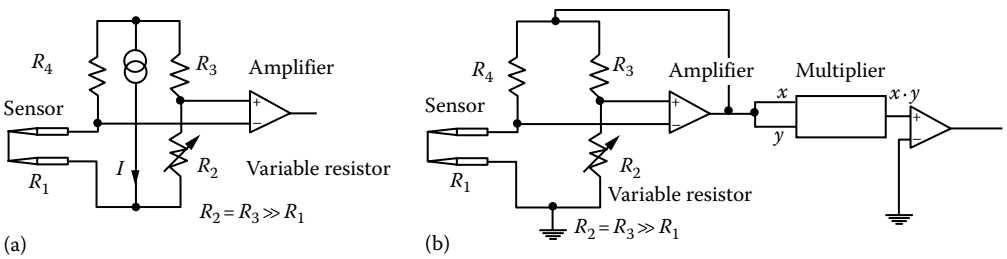

FIGURE 13.4 Control and evaluation circuit of heat-wire and heat-film sensors: (a) constant-current bridge and (b) constant-temperature bridge.

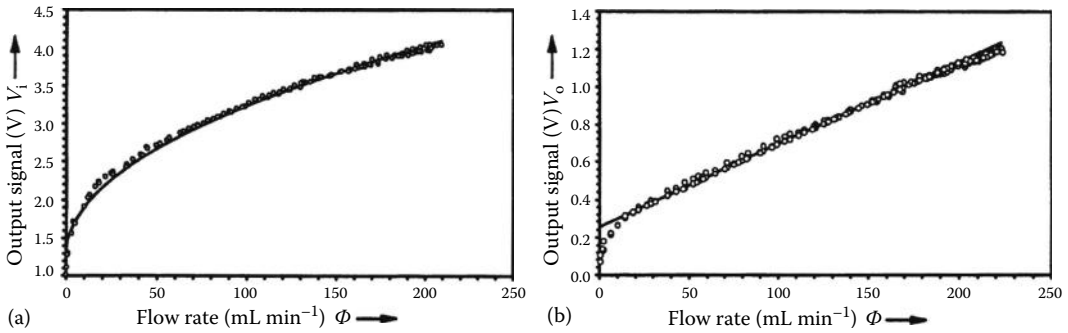

FIGURE 13.5 Sensor characteristics of the constant-temperature mode before (a) and after (b) linearization.

The constant-temperature Wheatstone bridge is shown in Figure 13.4b. The bridge is balanced under no-flow conditions with the variable resistor R_2. The flow cools the hot wire, and its resistance decreases and unbalances the bridge. A differential amplifier balances the bridge with the feedback voltage. The output signal can be linearized before recording.

Because the output signal has a square-root-like characteristic, the linearizer can be realized easily using a multiplier (i.e., AD534 of analog devices) with two equal input signals (a squarer). Figure 13.5 illustrates the results. With this method, there is linearization error in the low-flow range.

13.2.2 Calorimetric Sensors

The displacement of the temperature profile caused by the fluid flow around a heating element can be used for measuring very small mass flow. Depending on the location of the heating and sensing elements, there are two types of calorimetric sensors: the intrusive sensors that lie in the fluid and the nonintrusive sensors that are located outside the flow. Table 13.3 illustrates the two typical calorimetric sensors.

The intrusive type has many limitations. The heater and the temperature sensors must protrude into the fluid. Therefore, corrosion and erosion damage these elements easily. Furthermore, the integrity of the piping is sacrificed by the protrusions into the flow, thus increasing the danger of leakage.

In the nonintrusive sensor type, the heater and the temperature sensors essentially surround the flow by being located on the outside of the tube that contains the flow. The major advantage of this sensor type is the fact that no sensor is exposed to the flowing fluid, which can be very corrosive. This technique is generally applied to flows in the range of 1–500 L min^{-1}. The larger flows are measured using the bypass arrangement. Figure 13.6a shows the measured shift of the temperature distribution around the heater. The asymmetricity of the temperature profile increases with flow.

TABLE 13.3 Typical Parameters of Calorimetric Sensors

Parameter	Gases	Liquids
Working temperature	0 °C–70 °C	0 °C–70 °C
Accuracy in %	±1%	±1%
Linearity	±0.2%	±0.2%
Flow range 1:50	min. 5 mL min^{-1}	min. 5 g h^{-1}
	max. 100 L min^{-1}	max. 1000 g h^{-1}

Source: Mass Flow and Pressure Meters/Controllers, Bronkhorst Hi-Tec B.V., Ruurlo, the Netherlands, 1994.

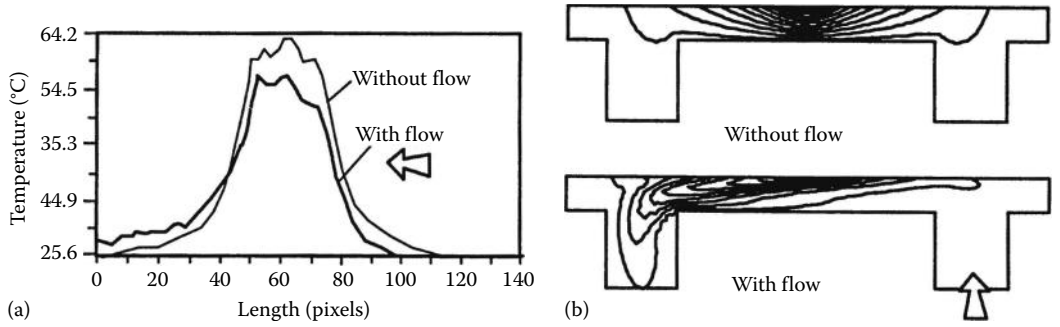

FIGURE 13.6 Temperature distribution around the heater: (a) measurement and (b) numerical simulation.

The measurement was carried out using a thermography system [1]. To understand the working principle, the effect of fluid mechanics and heat transfer should be reviewed. The mathematical theory for this problem is discussed later in this chapter. Figure 13.6b illustrates the influence of the flow over the temperature distribution.

Because the calorimetric mass flow sensors are sensitive in low-flow ranges, bypass designs have been introduced in order to make the sensors suitable for the measurement of larger flow ranges. The sensor element is a small capillary tube (usually less than 3 mm in diameter). They ensure laminar flow over the full measurement range. The laminar flow elements are located parallel to the sensor element as a bypass (Figure 13.7a). They are usually a small tube bundle, a stack of disks with etched capillary channels [2] (Figure 13.7b), or a machined annular channel.

Figure 13.8 shows typical parameters of calorimetric flow sensors. Compared to the hot-wire or hot-film sensors, this sensor type has good linearity and is only limited by signal noise at low flows and saturation at high flows. While the linear range may exceed a 100:1 ratio, the measurable range may be as large as 10,000:1 [3]. The small size of the capillary sensor tube is advantageous in minimizing the electric power requirement and also in increasing the time of response. Because of the small size of the tube, it necessitates the use of upstream filters to protect against plugging of dust particles. With the bypass arrangement, a relatively wide flow range is possible.

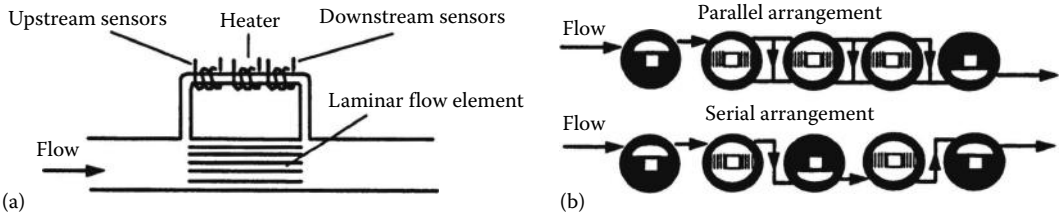

FIGURE 13.7 Bypass arrangement for large flow range: (a) principle and (b) a solution for the laminar flow element. (From *Mass Flow and Pressure Meters/Controllers*, Bronkhorst Hi-Tec B.V., Ruurlo, the Netherlands, 1994.)

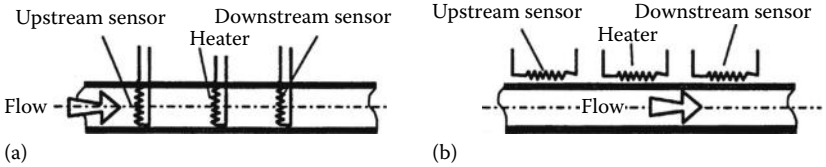

FIGURE 13.8 Typical calorimetric sensors: (a) intrusive type and (b) nonintrusive type.

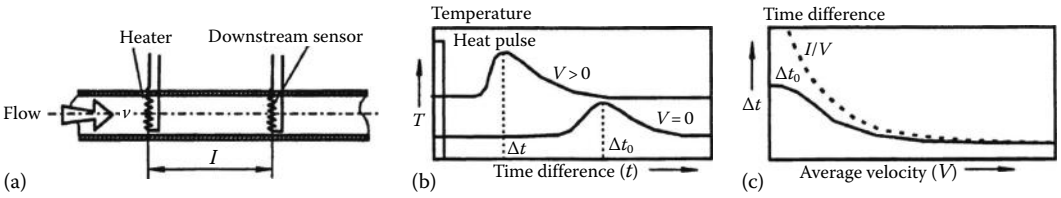

FIGURE 13.9 Time-of-flight sensors: (a) principle, (b) temperature at downstream sensor, and (c) sensor characteristic.

13.2.3 Time-of-Flight Sensors

The time-of-flight sensor consists of a heater and one or more temperature sensors downstream, Figure 13.9a. The heater is activated by a current pulse. The transport of the generated heat is a combination of diffusion and forced convection. The resulting temperature field can be detected by temperature sensors located downstream. The detected temperature output signal of the temperature sensor is a function of time and flow velocity. The sensor output is the time difference between the starting point of the generated heat pulse and the point in time at which a maximum temperature at the downstream sensor is reached, Figure 13.9b. At the relatively low flow rates, the time difference depends mainly on the diffusivity of the fluid medium. At relatively high flow rates, the time difference tends to relate to the ratio of the heater–sensor distance and the average flow velocity [4].

Because of the arrangement shown in Figure 13.9a, the time-of-flight sensors have the same limitations as the intrusive type of calorimetric sensors: corrosion, erosion, and leakage. Since the signal processing needs a while to measure the time difference, this sensor type is not suitable for dynamic measurement. The advantage of this type of volumetric flow sensor is the independence of fluid properties as well as fluid temperature in the higher flow range. The influence of fluid properties on the mass flow sensor output is described in [3], as well as an approach to compensate for changes in these properties, which is valid for both hot-element and calorimetric sensors.

13.2.4 Mass and Heat Transfer

The most important signal of the transfer process shown in Figure 13.1 is the thermal signal. There are different kinds of thermal signals: temperature, heat, heat capacity, and thermal resistance. In the following, the transfer of heat and the interaction between heat and temperature will be explained by three mean heat transfer processes: conduction, convection, and radiation. The first two processes can be described by the general equation of a transfer process. The transfer variables in the equation can be the momentum (momentum equation), the temperature (energy equation), or the mass (mass equation).

A transfer process consists of four elements: accumulation, conduction, induction, and convection. The *accumulation process* describes the time dependence of the transfer variable. The *conduction* presents the molecular transfer. The *convection* is the result of the interaction between the flow field and the field of the transfer variable. The *induction* describes the influence of external fields and sources.

13.2.5 Conduction

When there is a temperature gradient in a substance, the heat will flow from the hotter to the colder region, and this heat flow q (in W m^{-2}) will be directly proportional to the value of the temperature gradient:

$$q = -\lambda \frac{dT}{dx} \tag{13.7}$$

where T is the temperature. The previous expression is called Fourier's law of heat conduction and defines the material constant λ (in W K^{-1} m^{-1}), the thermal conductivity. Figure 13.10 shows the order of the thermal conductivity λ. of different materials.

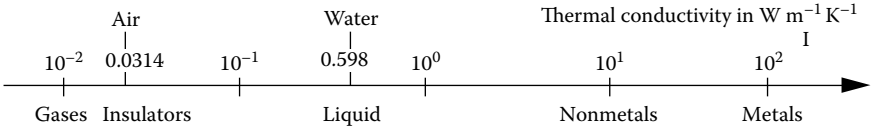

FIGURE 13.10 The order of thermal conductivity of different materials.

The differential form of the heat-conduction equation is a special case of the energy equation (see Section 13.2.6). The transfer equation only consists of the accumulative, conductive, and inductive terms:

$$\frac{\partial T}{\partial t} = \frac{\lambda}{\rho c}\left(\frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2} + \frac{\partial^2 T}{\partial z^2}\right) + \frac{q'}{\rho c} \tag{13.8}$$

where

ρ is the density

c is the specific heat at constant pressure

q' (in W m^{-3}) is the amount of heat (in joules) per unit of volume and time that can be generated inside the material itself, either through the action of a separate heat source or through a change in phase of matter

In the steady state without internal heat sources, the equation of conduction reduces to

$$\frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2} + \frac{\partial^2 T}{\partial z^2} = 0 \tag{13.9}$$

13.2.6 Convection

In general, there are two kinds of convection: forced convection and natural convection. The first one is caused by a fluid flow and the other one by itself because of the temperature dependency of fluid density and the buoyancy forces. To describe convection, three conservation equations are required:

Conservation of mass: continuity equation

$$\frac{\partial \rho}{\partial t} + \nabla(\rho v) = 0 \tag{13.10}$$

Conservation of momentum: Navier–Stokes equation

$$\frac{\rho \partial v}{\partial t} + v\nabla v = -\nabla p + \eta \nabla^2 v + \rho g \tag{13.11}$$

Conservation of energy: energy equation

$$\frac{\partial T}{\partial t} + v\nabla T = \left(\frac{\lambda}{\rho c}\right)\nabla^2 T + \frac{q'}{\rho c} \tag{13.12}$$

where η is the dynamic viscosity of the fluid. The temperature field and the heat power can be found by solving these three equations. For designing and understanding the thermal flow sensor, the convective heat transfer can be expressed in the simplest form:

$$Q = \varepsilon A \Delta T \tag{13.13}$$

where

Q (in W) is the heat transfer rate (or the heat power)
ε is the heat transfer coefficient between the heated surface A and the fluid
ΔT is the temperature difference between the heated body and ambient

The dimensionless Nusselt number describes the heat transfer. The relationship between the heat transfer coefficient ε and the Nusselt number Nu can be expressed as follows:

$$\varepsilon = \mathrm{Nu}\frac{\lambda}{L} \tag{13.14}$$

where L is the characteristic length (the length L of a flat plate, the hydraulic diameter D_h of a tube, and the half of the perimeter of a wire, Figure 13.11). The hydraulic diameter D_h can be calculated using the wetted perimeter U and the cross-sectional area A of the tube:

$$D_h = \frac{4A}{U} \tag{13.15}$$

The relevant dimensionless number that describes the flow is the Reynolds number

$$\mathrm{Re} = \frac{vL}{\nu} \tag{13.16}$$

where

v is the average flow velocity
ν the kinematic viscosity of the fluid, which is defined by the density ρ and the dynamic viscosity η:

$$\nu = \frac{\eta}{\rho} \tag{13.17}$$

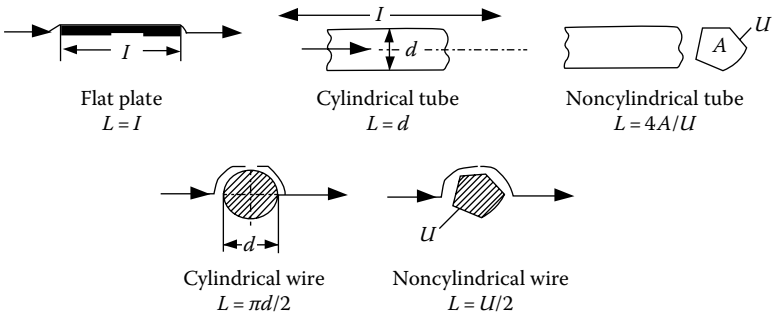

FIGURE 13.11 Definition of the characteristic length of different objects. (From VDI-Wärmeatlas, VDI-Verlag, 1994.)

TABLE 13.4 Nusselt Number (Nu) of Forced Convection

Object	Nu_{lam} for Laminar Regime	Nu_{turb} for Turbulent Regime	Average Nusselt Number Nu
Flat plate	$Nu_{lam} = 0.664\sqrt{Re^3}\sqrt{Pr}$	$Nu_{turb} = \dfrac{0.037\ Re^{0.8}\ Pr}{1 + 2.443\ \ Re^{-0.1}(Pr^{2/3} - 1)}$	$Nu = \sqrt{Nu_{lam}^2 + Nu_{turb}^2}$
	$Re < 10^5$; $0.6 < Pr < 2000$	$5.10^5 < Re < 10^7$; $0.6 < Pr < 2000$	$10 < Re < 10^7$; $0.6 < Pr < 2000$
Cylindrical tube	$Nu_{lam} = 3.65 + \dfrac{0.19(Re\ Pr\ d/l)^{0.8}}{1 + 0.117(Re\ Pr\ d/l)^{0.467}}$	$Nu_{turb} = \dfrac{\xi/8(Re - 1000)\,Pr}{1 + 12.7\sqrt{\xi/8}\,(Pr^{2/3} - 1)}\left[1 + \left(\dfrac{d}{l}\right)^{2/3}\right]$	
	$Re < 2300$; $0.1 < (Re\ Pr\ d/l) < 10^4$	where $\xi = (1.28\ \log_{10}Re - 1.64)^{-2}$	
Short cylindrical tube $0.1 < d/l < 1$	$Nu_{lam} = 0.664^3\sqrt{Pr}\sqrt{Re\,d/l}$	Thermal entrance, fully developed flow, $2300 < Re < 10^4$	
	$Re < 2300$; $0.1 < (Re\ Pr\ d/l) < 10^4$	$Nu_{turb} = \sqrt[3]{3.66^3 + 1.61^3\ Re\,Pr\,d/l}$	
		Thermal entrance, developing flow, $2300 < Re < 10^6$	
Wire	$Nu_{lam} = 0.664\sqrt{Re^3}\sqrt{Pr}$	$Nu_{turb} = \dfrac{0.037\,Re^{0.8}\ Pr}{1 + 2.443\ \ Re^{-0.1}(Pr^{2/3} - 1)}$	$Nu = 0.3 + \sqrt{Nu_{lam}^2 + Nu_{turb}^2}$
	$10 < Re < 10^7$; $0.6 < Pr < 1000$		

Source: VDI-Wärmeatlas, VDI-Verlag, 1994.

TABLE 13.5 Average Nusselt Number of Free Convection in Some Special Cases

Cases	Equation	References
Vertical flat plate or wire	$Nu = 0.55(Gr\ Pr)^{1/4}$	[8]
Horizontal flat plate	For the upper surface: $Nu = 0.76(Gr\ Pr)^{1/4}$	[9]
	For the lower surface: $Nu = 0.38(Gr\ Pr)^{1/4}$	

Table 13.4 shows a collection of formulae for calculating the Nusselt number. The fluid properties (kinematic viscosity ν and Prandtl number Pr) should be chosen at the average temperature T_{av} between the heater temperature $T + \Delta T$ and the fluid temperature T:

$$T_{av} = T + \frac{\Delta T}{2} \tag{13.18}$$

In the case of natural convection, the Nusselt number depends on the Grashof number Gr, which describes the influence of buoyancy forces:

$$Gr = \frac{g\beta L^3 \Delta T}{\nu^2} \tag{13.19}$$

where

g is the acceleration due to the gravity (9.81 m s^{-2})
β the thermal expansion coefficient of the fluid
ΔT is the temperature difference between the hot fluid and the ambient

The average Nusselt number can be calculated for a laminar flow ($10^4 < Gr\ Pr < 10^8$) in Table 13.5.

13.2.7 Radiation

A body can either emit or absorb thermal radiation. Radiation is not important for the operational principle of thermal mass flow because of its relatively low magnitude.

Following, the physical and mathematical backgrounds of these three sensor types are discussed in detail. The working principle and the influence of fluid properties on the sensor signal can be determined using these mathematical models. However, the mathematical models only describe the relationship between thermal variables (heat power, temperature) and the average velocity. Further relationships between mass flow, mass flux, thermal, and electrical variables can be derived using Equations 13.1 through 13.6.

13.3 Analytical Models for Calorimetric Flow Sensing

13.3.1 Model for the Intrusive Type of Calorimetric Sensors

In a quasi-static situation, the incoming heat at a certain point in the fluid must be equal to the outgoing heat. The heat is transported either by conduction in the fluid and/or supporting beams or by convection through the thermal mass of the fluid. Ultimately, the heat is transported to the walls of the tube; see Figures 13.8 and 13.12. A heat balance equation results in a differential equation for T in x. The temperature profile in the y and z directions is assumed to be constant and linear, respectively [5].

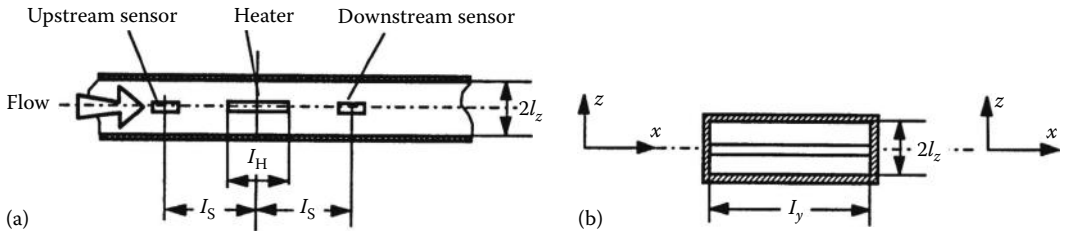

FIGURE 13.12 Analytical model for the intrusive type of calorimetric sensors: (a) length cut and (b) cross section.

Referring to Figure 13.12 and using A as the cross-sectional area of the flow channel ($A = l_y 2l_z$), ρ as the fluid density, c as the fluid heat capacity (at constant pressure), v as the average fluid velocity, and λ as the fluid thermal conductivity, one finds that

$$\frac{\partial^2 T}{\partial x^2} - v\left(\frac{\rho c}{\lambda}\right)\frac{\partial T}{\partial x} - \left(\frac{T}{l_z^2}\right) = 0 \tag{13.20}$$

or

$$\frac{\partial^2 T}{\partial x^2} - \left(\frac{v}{a}\right)\frac{\partial T}{\partial x} - \frac{T}{l_z^2} = 0 \tag{13.21}$$

where $a = \lambda/\rho c$ is the thermal diffusivity of the fluid. Equation 13.21 is linear in T. Solving the differential equation using a heater length l_H, a heater power Q, and the boundary condition

$$\lim_{x \to \pm\infty} T(x) = 0 \tag{13.22}$$

the following temperature distribution results

$$x < \frac{-l_H}{2} \quad \text{for } T(x) = T_0 \exp\left[\gamma_1\left(x + \frac{l_H}{2}\right)\right] \tag{13.23}$$

$$\frac{l_H}{2} < x < \frac{l_H}{2} \quad \text{for } T(x) = T_0 \tag{13.24}$$

$$x > \frac{l_H}{2} \quad \text{for } T(x) = T_0 \exp\left[\gamma_2\left(x - \frac{l_H}{2}\right)\right] \tag{13.25}$$

where

$$\gamma_{1,2} = \frac{\left(v \pm \sqrt{v^2 + 2a^2/l_z^2}\right)}{(2a)} \tag{13.26}$$

$$T_0 = \frac{P}{\left[\left(2\lambda l_y l_H / l_z\right) + A\lambda\left(\gamma_1 - \gamma_2\right)\right]} \tag{13.27}$$

The temperature difference between the two sides, upstream (at $x = l_s$) and downstream (at $x = -l_s$), can be then calculated as

$$\Delta T(v) = T_0\left\{\exp\left[\gamma_2\left(\frac{l_s - l_H}{2}\right)\right] - \exp\left[\gamma_1\left(\frac{-l_s + l_H}{2}\right)\right]\right\} \tag{13.28}$$

13.3.2 Model for the Nonintrusive Type of Calorimetric Sensors

A simple, 1D model is used to show the working principle of the nonintrusive type with capillary-tube and heater wire winding around it. Geometric parameters and assumptions are given in Figure 13.13. Because of the symmetry, only half of the capillary tube will be considered for the calculation model. The conservation of thermal energy in a lumped element (Figure 13.13c) can be given in the following equation:

$$Q_{\text{cond.},x,\text{fluid}} + Q_{\text{conv.},x,\text{fluid}} + Q_{\text{cond.},x,\text{wall}} = Q_{\text{cond.},y,\text{fluid}} \tag{13.29}$$

The indices define the conduction or convection in the *x*- or *y*-axis in the fluid as well as in the heated wall. Defining the temperature along the *x*-axis as $T(x)$, the average flow velocity as v, the thermal conductivities of wall material as λ_w and of fluid as λ, the thermal diffusivity of fluid $a = \lambda/(\rho c)$,and the thickness of the average thermal boundary layer as δ, one finds the heat balance equation:

$$\left[\frac{1}{2} + \left(\frac{\lambda_W d_W}{\lambda \delta}\right)\right]\frac{\partial^2 T}{\partial x^2} - \frac{v}{(2a)}\frac{\partial T}{\partial x} - \frac{T(x)}{\partial^2} = 0 \tag{13.30}$$

The thickness of the average thermal boundary layer δ depends on the flow velocity [6]. For gases with a small Prandtl number (Pr < 1) or liquids with a low Reynolds number, one can assume that

$$\delta = r \tag{13.31}$$

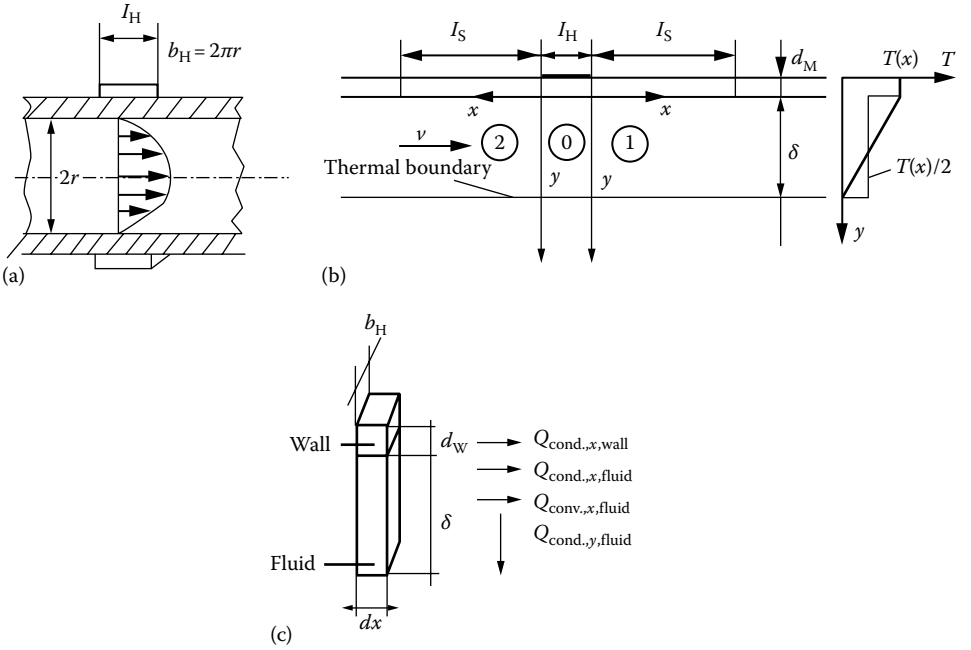

FIGURE 13.13 Analytical model for the nonintrusive type of calorimetric sensors: (a) heater and channel geometry, (b) model geometry, and (c) model of a lumped element.

After solving Equation 13.30 in the local coordinate systems 1 and 2 (Figure 13.13b), one obtains the temperature difference $\Delta T(v)$ between the temperature sensors:

$$\Delta T(v) = \vartheta_0 \left[\exp(\gamma_2 l_s) - \exp(\gamma_1 l_s) \right] \tag{13.32}$$

with

$$\gamma_{1,2} = \frac{\left(v \pm \sqrt{v^2 + 16a^2\kappa/\delta^2} \right)}{(4a\kappa)} \tag{13.33}$$

The dimensionless factor

$$\kappa = \frac{1}{2} + \frac{(\lambda_w d_w)}{(\lambda \delta)} \tag{13.34}$$

describes the influence of the wall on the heat balance. If the wall is neglected, we get $\kappa = 1/2$ as in the similar case of Equation 13.21. The heater temperature T_0 can be calculated for the constant heat power Q:

$$T_0 = \frac{Q}{\left\{ 2\pi r\lambda \left[(l_H/\delta) + \sqrt{(v^2\delta^2)/((4a^2) + 4\kappa)} \right] \right\}} \tag{13.35}$$

13.3.3 Model for the Time-of-Flight Type

The transport of the heat generated in a line source through a fluid is governed by the energy Equation 13.12. The analytical solution of this differential equation for a pulse signal with input strength $q_0' (\mathrm{W\,m^{-1}})$ is given in [7] as

$$T(x,y,t) = \left(\frac{q_0'}{4\pi\lambda t} \right) \exp\left\{ -\frac{[(x - vt)^2 + y^2]}{4at} \right\} \tag{13.36}$$

where a denotes the thermal diffusivity. By measuring the top time τ at which the signal passes the detection element ($y = 0$), in other words differential Equation 13.36 with respect to time, one can obtain the basic equation for the so-called time of flight of the heat pulse:

$$v = \frac{x}{t} \tag{13.37}$$

For Equation 13.36 to be valid, the term $4at$ must be much smaller than the heater–sensor distance x. This assumes that forced convection by the flow is dominating over the diffusive component. In other words, Equation 13.36 is true at high flow velocities. When the diffusive effect is taken into account, the time of flight is given by

$$\Delta t = \tau = \frac{[-2a + (4a^2 + v^2x^2)^{1/2}]}{v^2} \quad v \neq 0 \tag{13.38}$$

$$\tau = \frac{x^2}{4a} \quad v = 0 \tag{13.39}$$

13.3.4 Principles of Microflow Sensors

In research papers, the first reference to thermal mass flow sensor normally cited is that of King in 1914. Since then, microsystems technology has been developed. The development of thermal flow sensor can be realized in micron size using the three current technologies: bulk micromachining, surface micromachining, epimicromachining and LIGA techniques (LIGA: German description of "Lithographie, Galvanoformung, Abformung"). These fabrication techniques (except LIGA) are compatible with conventional microelectronic processing technology. Thermal flow sensors developed using these technologies will be called "microflow sensors" in this section. The operational modes are similar to the conventional thermal flow sensor. In Table 13.6, the microflow sensors are classified after their transducing principle. With these new sensors, very small flows in the nanoliter and microliter range can be measured. Table 13.7 shows some realized examples of microflow sensors.

TABLE 13.6 Transducing Principle of Microflow Sensors

Transducing Principle	Realization	Application
Thermoresistive	Metal film (platinum), polycrystalline silicon, single crystalline silicon or metal alloys	Measurement of temperature, temperature difference, and heat power
Thermoelectric	*p*Si–Al (bipolar technology), polySi–Al (CMOS technology), or *p*PolySi–*n*PolySi thermopiles	Measurement of temperature and temperature difference
Thermoelectronic	Transistors, diodes	Measurement of temperature and temperature difference
Pyroelectric	Pyroelectric materials ($LiTaO_3$) with metal or silicon resistors as heater and electrodes	Measurement of heat power
Frequency analog	SAW oscillators	Measurement of temperature

TABLE 13.7 Examples of Microthermal Mass Flow Sensors

13.3.5 Smart Thermal Flow Sensors and Advanced Evaluation Circuits

Conventional sensors usually have separate electronics, which causes high cost and prevents large serial production. An integrated smart thermal flow sensor is defined as a chip that contains one or more sensors, signal conditioning, A/D conversion, and a bus output [6]. Therefore, there is a need for advanced evaluation methods that convert the thermal signal directly into a frequency and duty-cycle output.

13.3.6 Duty-Cycle Modulation for the Hot-Wire Sensors

The constant heater temperature can be controlled by modulation of the amplitude of the heat voltage (conventional principle) or by modulation of the duty cycle. The heater is activated when the output signal is high. This heater controlling output goes low when the temperature level $T_0 + \Delta T$ is reached. During low output, the heating temperature decreases to the temperature level $T_0 + \Delta T$, where the output goes high again and restarts the heating cycle. The temperature level is determined by a reference resistor and a variable resistor. An increase in the flow rate increases the convective cooling of the heater, and it needs a longer time to reach the temperature level. That results in the higher output time t_H. Figure 13.14 shows the working principle of the duty-cycle modulation, where t_d is the time delay in the switching action. Defining the maximum heating power as Q_{max} (the output signal is always high), one obtains the relation:

$$Q = Q_{max}\left(\frac{t_H}{t_{total}}\right) \tag{13.40}$$

13.3.7 Electrical Sigma–Delta Modulation for Calorimetric Sensors

Conventional signal-conditioning circuits use an analog-to-digital converter (ADC) to get digital sensor readout, which can be regarded as an amplifier or a voltmeter. They read the information signal from the sensor, but do not interact with the sensor. In contrast, sigma–delta converters are a part of the sensor function since they act as a feedback amplifier for the sensor output. Hence, sigma–delta conversion normally results in a much more robust sensor signal than is provided by conventional ADCs. Following, the principle of sigma–delta conversion applied to calorimetric flow sensors is explained.

The transistors T_1 and T_2 represent two switchers that feed the constant current I_0 into the *RC* network. It is assumed in this example that the temperature on the resistor R_{s2} is higher than the

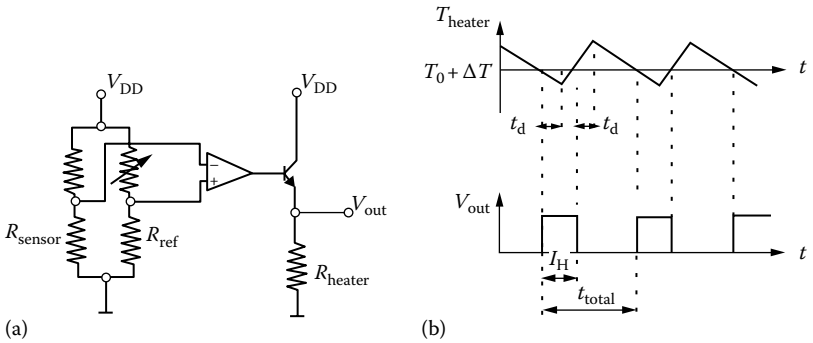

FIGURE 13.14 The duty-cycle modulation for hot-wire sensors: (a) basic circuit and (b) the heater temperature detected by R_{sensor} and the output voltage V_{out} vs. the time.

temperature on R_{s1}. Therefore, the resistance of R_{s2} is larger than R_{s1}. It results in a larger time constant for the charging of C_2. With the help of the comparators and the D flip-flop, the constant current I_0 can be switched on and off. The switching signals $f1$ and $f2$ have, in the same time period, different pulse numbers $N + S$ and N:

$$\frac{R_{s2}}{R_{s1}} = \frac{(N+S)}{N} = 1 + \frac{\Delta R}{R_{s1}} \tag{13.41}$$

Thus

$$\frac{\Delta R}{R_{s1}} = \frac{S}{N} \tag{13.42}$$

with

$$R_{s1} = \frac{(V_{ref} N)}{(I_0 G)} \tag{13.43}$$

The resistance difference as well as the temperature difference can be calculated:

$$\Delta R = \frac{(S V_{ref})}{G I_0} \tag{13.44}$$

The counting and recording of S and G are shown in Figure 13.15.

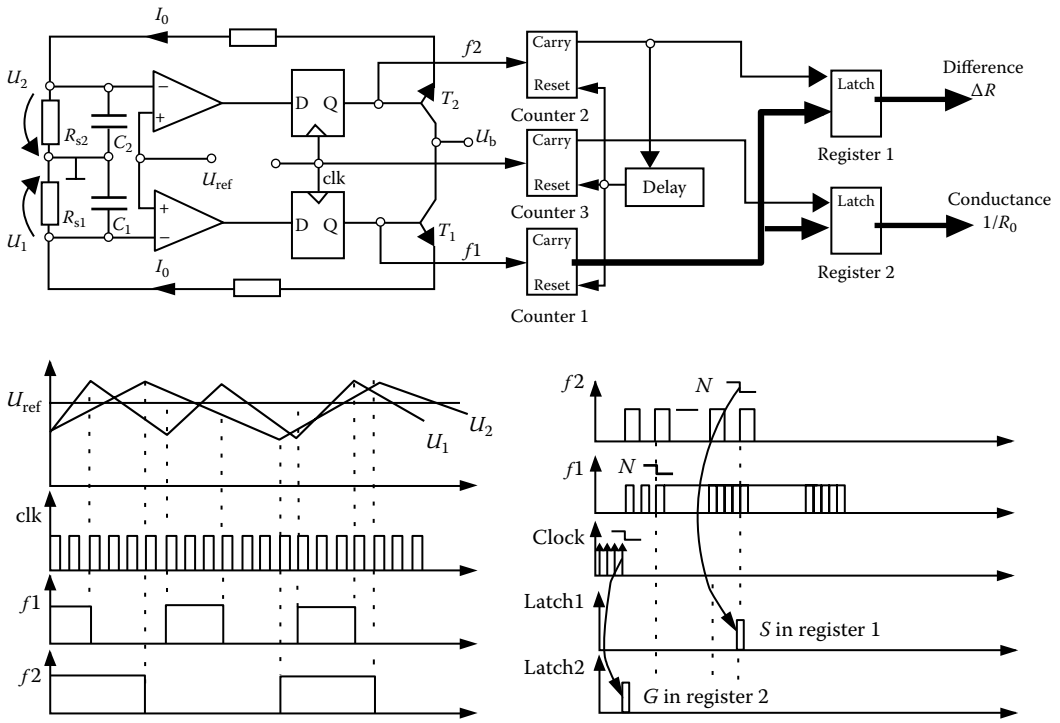

FIGURE 13.15 Sigma–delta conversions for calorimetric sensors.

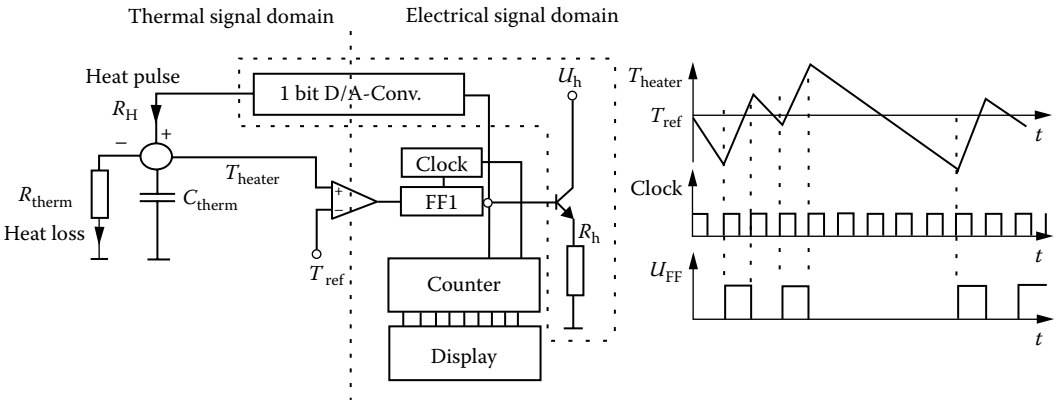

FIGURE 13.16 Principle of thermal sigma–delta modulation.

13.3.8 Thermal Sigma–Delta Modulation

The principle of thermal sigma–delta modulation is based on the conventional electrical sigma–delta: the thermal sigma–delta converter uses a thermal integrator (thermal *R*/*C* network) instead of an electric integrator (electric *R*/*C* network). Figure 13.16 shows the principle of thermal sigma–delta modulation. The comparator output modulates the flip-flop. The flip-flop synchronizes the heating signal by its clock. Therefore, the heating periods are chopped into further small pulses that depend on the clock frequency. The heater is actuated step by step until the comparator switches again, and one obtains a frequency analog output at the flip-flop [10].

13.4 Calibration Conditions

13.4.1 Calibration of Hot-Wire and Hot-Film Sensors

The hot-wire and hot-film sensors are based on the point velocity measurement (see Figure 13.2). Therefore, the measurement results depend on the velocity distribution inside the flow channel. Achieving a high signal-to-noise ratio can thus require spatial arrays of hot-wire and hot-film sensors that give more information about the velocity field and thus more accurate results of the mass flow in channel. With the use of a nozzle, a Venturi, or a flow conditioner, the flow profile is preconditioned, which leads to an acceptable accuracy.

13.4.2 Temperature Dependence of Fluid Properties

Most fluid properties depend on the working temperature. The heat transfer process depends on the fluid properties. The measurement of fluid temperature (see Figure 13.2) keeps the heater on a constant temperature difference to the fluid and can also be used for compensation of variations in temperature. For these reasons, accurate thermal mass flow sensors require both flow calibration and calibration for temperature compensation. Furthermore, the influence of temperature and/or fluid composition can be derived utilizing the relationships developed in the sections on modeling (Equations 13.20 through 13.35).

13.4.3 Instrumentation and Components

Table 13.8 lists some companies that manufacture and market thermal mass flowmeters.

TABLE 13.8 Manufactures of Thermal Mass Flow Sensors

Manufacturers	Data
KOBOLD Instruments Inc. 1801 Parkway View Drive Pittsburg, PA 15205	Calorimetric type: MAS-Series; air; min. range 0–10 mL min; max. range 0–40 L min. T_{max}. 50 °C; max. pressure 10 bar; accuracy ±2% Hot-wire type: ANE-Series; air; range 0–20 m/s; working temperature 20 °C–70 °C
Hontzsch GmbH Box 1324, Robert-Bosch Str. 8 D-7050 Waiblingen, Germany	Hot-wire type: range 0.05–20 m/s
Bronkhorst Hi-Tech Nijverheidstraat 1A 7261 AK Ruurlo, Netherlands	Calorimetric type: gases and liquids; min. range (gas) 0–5 mL min; max. range (liquid) 0–1000 mL/min; max. pressure 400 bar
Honeywell MicroSwitch, Freeport, IL	Calorimetric type: gases; range 0–1000 mL min^{-1}; max. pressure 1.75 bar
Sierra Instruments Inc. 5 Harris Ct., Bldg. L Monterey, CA 93924	Calorimetric type: all gases from 1 mL/min to 10,000 L/min; –40 °C to 100 °C; 30 bar max.; 1% accuracy Hot-wire type in stainless-steel sheath: gases from 0 to 100 m/s; –40 °C to 400 °C; 100 bar max.; 2% accuracy
Brooks Instrument Division Emerson Electric Co. 407 W. Vine Street Hatfield, PA 19440	Calorimetric type: all gases from 1 mL/min to 10,000 L/min; –40 °C to 100 °C; 100 bar max.; 1% accuracy

SQUID Magnetometers

Robert L. Fagaly
Quasar Federal Systems

Superconducting quantum interference devices (SQUIDs) have been a key factor in the development and commercialization of ultrasensitive magnetic measurement systems [1]. In many cases, SQUID magnetometers offer the ability to make measurements where no other methodology is possible.

Because of their superconducting nature, SQUID sensors operate at cryogenic temperatures. Although SQUID electronics have the capability to operate well above 1 MHz, most applications tend to be at lower frequencies. The ability of a SQUID sensor to measure changes in magnetic fields and currents is based on four effects: superconductivity, the Meissner effect, flux quantization, and the Josephson effect. Magnetic flux penetrating a superconducting loop containing one or more Josephson junctions (the SQUID loop) results in an output voltage that is proportional to the magnetic flux.

Typical SQUID input circuits may include (Figure 14.1) superconducting detection coils with superconducting connections and an "input coil" that is inductively coupled to the SQUID loop. Input circuits with such "flux transformers" have applications for measuring magnetic fields and for the sensitive measurement of magnetic properties in physics, chemistry, geology, biology, and medicine as well as numerous other applications.

SQUID sensors are normally fabricated from two types of materials: The first, commonly referred to as a low-temperature superconductor (LTS), is based on niobium metal, whose ductility can allow the winding of small-diameter loops. The second, referred to as a high-temperature superconductor (HTS), uses $YBa_2Cu_3O_{7-\delta}$, which is a brittle ceramic material produced as a 2-D structure.

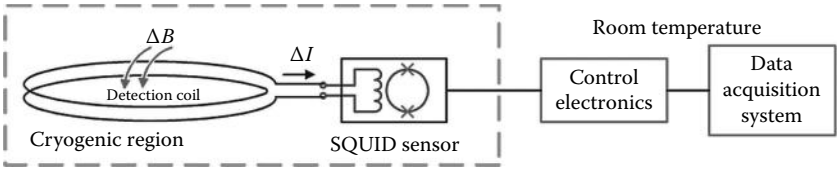

FIGURE 14.1 Schematic diagram of a typical SQUID input circuit.

14.1 Cryogenic Requirements

The superconducting nature of SQUIDs requires them to operate well below their superconducting transition temperature (9.3 K for niobium and 93 K for $YBa_2Cu_3O_{7-\delta}$). The thermal environment for the SQUID sensor and detection coil has typically been, respectively, liquid helium or liquid nitrogen contained in a vacuum-insulated vessel known as a dewar.

If the measurement is of an external field, the dewar must be magnetically transparent and metallic construction is not appropriate. Dewars for external field measurements (e.g., geophysical or biomagnetic) are normally constructed of nonmetallic, low-susceptibility materials to minimize their magnetic interactions with the SQUID sensors and detection coils. Materials used are typically fiberglass/epoxy composites such as G-10 (see Figure 14.2).

To get the detection coil(s) as close as possible to the object being measured, a "tailed" design is often used. This decreases the forces on the bottom of the dewar and allows the use of thinner end pieces (closer tail spacing). Dewars for biomagnetic measurements often have curved tails to get closer to the head, chest, or abdomen. Some SQUID magnetometers (primarily those for rock magnetometry) use metallic dewars cooled by closed cycle refrigeration [2].

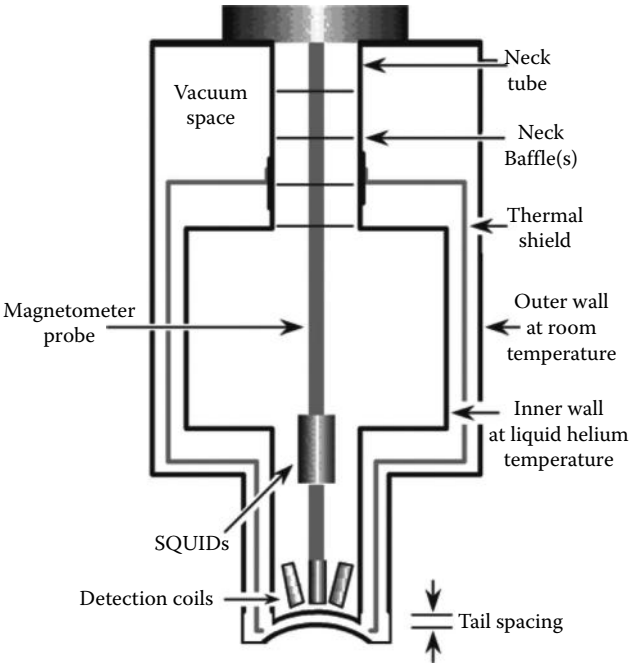

FIGURE 14.2 Typical design of a fiberglass dewar used for biomagnetic measurements.

14.2 Magnetic Field Sensing

The SQUID can act as a magnetometer by allowing flux to directly penetrate the SQUID loop. Because of the small diameter (~50 μm) of the SQUID loop, this results in field sensitivities at the 50 pT/√Hz level. LTS SQUID loops are shielded to isolate the Josephson junctions from such interference, and the input signal is inductively coupled via an input coil for greater sensitivity (Figure 14.1).

Because HTS materials are planar devices and suffer from the inability to make zero-resistance superconducting joints, complex coil geometries (e.g., Figure 14.3b, f, and e) cannot be fabricated. Instead, HTS magnetometers use bare SQUID loops (for magnetic microscopy), integral detection coils, or inductively coupled (e.g., flip chip [3]) detection coils.

The most common input circuit used with LTS SQUIDs is a simple superconducting detection coil that is used to detect changes in magnetic fields. This circuit is connected to the SQUID input terminals as shown in Figure 14.1. Since the total flux in a superconducting loop is conserved, any change in external field through the detection coil will induce a current in the SQUID, which must satisfy

$$\Delta\Phi = NA\Delta B = (L_{\text{coil}} + L_{\text{input}})\Delta I \tag{14.1}$$

where

ΔB is the change in applied field
N, A, and L_{coil} are the number of turns, area, and inductance of the pickup coil
ΔI is the change in current

To calculate the sensitivity and noise levels of a simple detection coil system, the inductance of the detection coil must be known. The inductance of a flat, tightly wound, circular multiturn loop of superconducting wire is given (in MKS units) by [4]

$$L = \mu_0 N^2 r\left[\log_e\left(\frac{8r_{\text{coil}}}{r_{\text{wire}}}\right) - 2\right] \tag{14.2}$$

where

μ_0 is the magnetic permeability of free space
r_{coil} is the radius of the detection coil
r_{wire} is the radius of the (superconducting) wire

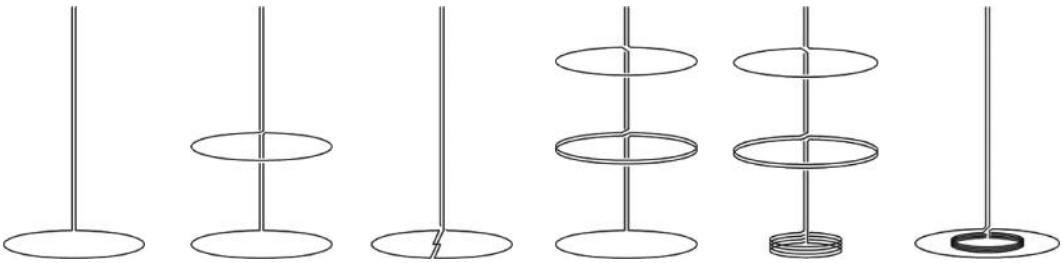

FIGURE 14.3 (a) Magnetometer [B_z], (b) first-derivative axial gradiometer [dB_z/dz], (c) first-derivative planar gradiometer [dB_z/dx], (d) second-derivative axial gradiometer [d^2B_z/dz^2], (e) second-derivative asymmetric axial gradiometer [d^2B_z/dz^2], and (f) first-derivative radial gradiometer [dB_z/dr].

Knowing the coil inductance L_{coil}, we can rewrite Equation 14.3 as

$$\Delta B = (L_{coil} + L_{input})\frac{\Delta I}{NA} \tag{14.3}$$

Since the SQUID system has an output proportional to the input current, maximum sensitivity is obtained by using the input circuit that provides the maximum current into the SQUID and satisfies all other constraints of the experimental apparatus. For a pure magnetometer of a given diameter, the maximum sensitivity will occur when the impedance of the detection coil matches that of the SQUID sensor ($L_{coil} = L_{input}$).

As an example, a single turn coil of 0.13 mm superconducting wire with a diameter of 4 cm when used with commercially available SQUIDs can have a sensitivity better than 20 fT/√Hz (1 fT = 10^{-15} T = 10^{-11} Gauss). For maximum sensitivity, L_{coil} and L_{input} should be matched.

Much higher sensitivity (10^{-17} T/√Hz) in a limited bandwidth (100 Hz in this case) has been achieved by incorporating rf SQUID into a parametric amplifier circuit [5]. Substituting a present-day direct current (dc) SQUID sensor could yield a sensitivity of $<3 \times 10^{-18}$ T/√Hz. The highest sensitivity reported for a commercially available HTS SQUID magnetometer is 3.5×10^{-15} T/√Hz [6].

14.2.1 Environmental Noise

One problem with pure magnetometers (and virtually all HTS SQUIDs) is that they are extremely sensitive to the outside world (Figure 14.5). This may be acceptable if one is measuring external fields, but if what is needed to be measured is very close to the detection coil and very weak, outside interference, for example, the Earth's magnetic field, 50 or 60 Hz power line frequencies and/or radio-frequency interference (rfi), may prevent measurements at SQUID sensitivities. If the experiment is the measurement of a magnetic field due to an object a few cm away from the detection coil, a gradiometer may offer a solution.

Since the magnetic field of a dipole source is proportional to the cube of the distance,

$$B_{dipole} \propto \frac{1}{z^3} \tag{14.4}$$

where z is the distance beneath the coil, it follows that the field from a distant source is relatively uniform in direction and magnitude at the sensor. If we connect in series two identical and exactly parallel loops wound in opposite senses, separated by a distance b (the baseline), we obtain a coil (Figure 14.3b) that will reject uniform fields.

Using the previous example, with two 4 cm diameter coils separated by 10 cm (the baseline), one obtains a gradient sensitivity of 2 fT/cm·√Hz. For objects that are less than a few baselines away from a gradiometer, this coil system will act as a magnetometer for the source of interest ($\propto z^{-3}$) and as a (Nth order) gradiometer for distant sources ($\propto z^{-3-N}$) [7]. Figure 14.4 shows the relative response of first- and second-order gradiometers to distant sources. As can be seen, for sources relatively close to the signal coil, the effective response is that of a pure magnetometer, while distant sources have significantly reduced signal strengths.

14.2.2 Gradiometer Balance

If the gradiometer is perfectly made with the area turns of both coils being identical (i.e., balanced), it will reject uniform fields. However, should one coil have a larger effective diameter than the other, the

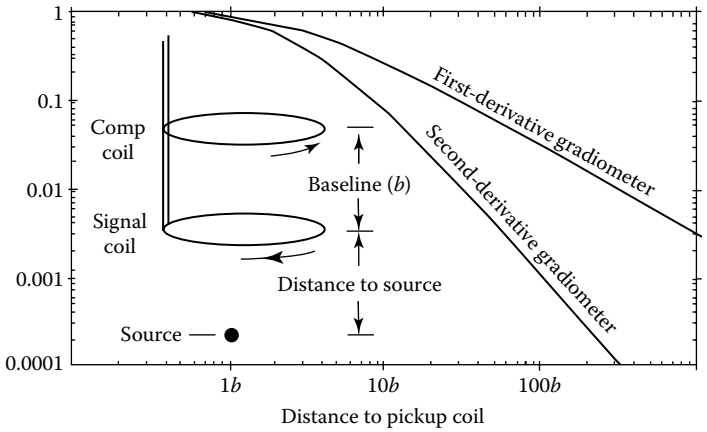

FIGURE 14.4 Response of gradient coils relative to magnetometer response ($1/z^3$ suppressed).

response of the coil will not be that of a perfect gradiometer but that of a gradiometer in series with a magnetometer. Mathematically, the balance, β, can be defined as

$$V_{\text{out}} \propto \mathbf{G} + \beta \cdot \mathbf{H} \tag{14.5}$$

where

V_{out} is the system response
G is the coil's response to a gradient field
H is the applied uniform field

Second-derivative coils ($N = 2$) have been constructed with balances better than one part per million [8]. That is, the effects of uniform magnetic fields on the detection coils are reduced by more than a million. This can allow a SQUID gradiometer to operate in relatively large (mT) ambient fields while maintaining sensitivities in the tens of fT. This has importance in measurements of magnetic fields of biological origin and nondestructive test and evaluation.

While nearly all HTS gradiometers are planar devices, it is possible to use a thick-film-patterned (as a planar gradiometer) HTS tape and bend it to form an axial gradiometer [9]. Note that there will be substantial gradiometer imbalance.

14.2.3 Magnetic Shields and Shielding Rooms [10]

To reduce the effect of environmental noise—assuming that the measurement is not of external fields and size permitting—the experiment can be placed in a magnetic shield (e.g., magnetic microscopy) or a magnetically shielded room (MSR) (e.g., biomagnetism). Attenuation of external magnetic fields can be accomplished by induced current shielding or flux shunting. Faraday's law ($\nabla \times \mathrm{E} = -\partial B/\partial t$) states that an electric field is induced in a material when it is exposed to a time-dependent magnetic field. If the shielding material is conducting ($\rho \ll \infty$), the electric field induces a current that generates a magnetic flux to oppose the externally applied field. This effect, which is frequency dependent, can be used to create an eddy current shield to attenuate electromagnetic interference. Eddy current shields can be constructed from sheet metal (e.g., aluminum) or wire (e.g., copper screen). While not capable of attenuating dc fields, the shielding factor of eddy current shields increases with frequency. Screened rooms are relatively inexpensive and properly constructed and are good at attenuating MHz and GHz noise sources.

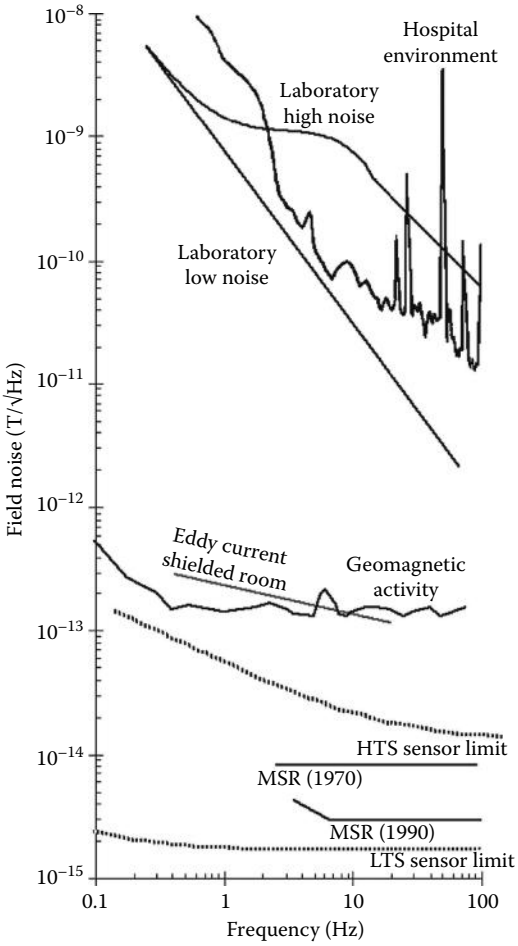

FIGURE 14.5 rms field noise spectra in various environments as a function of frequency.

The need for shielding at lower frequencies down to dc has led to the use of high-permeability materials (e.g., mu-metal) for shunting magnetic fields external to the experimental region. For biomagnetic measurements, it may be necessary to enclose not only the sensing device but also the subject in an MSR with large interior dimensions (e.g., 4 m × 3 m × 2 m). The use of multiple shields can act to further shield the interior of an MSR with commercial MSRs offering shielding factors >40 dB at dc, increasing to 100+ dB above 100 Hz.

The effective use of magnetic shields can reduce the background magnetic noise to levels that allow measurements below pT/√Hz levels (Figure 14.5).

A unique advantage of SQUIDs is that they can be used to make magnetic field sensors with dc response and sensitivities well below environmental noise levels. This has allowed noninvasive measurements of electrophysiological activity and a number of other magnetic sensing methodologies not possible with conventional electromagnetic sensing systems.

14.3 Geophysical Applications

The geomagnetic field at the surface of the Earth (Figure 14.6) is generated by a number of sources. There exists a background field of ~50 μT with a daily variation of ±0.1 μT. In addition, there is a $1/f^{3/2}$ contribution (below 1 Hz) from ultralow electromagnetic energy reaching the Earth from solar-generated

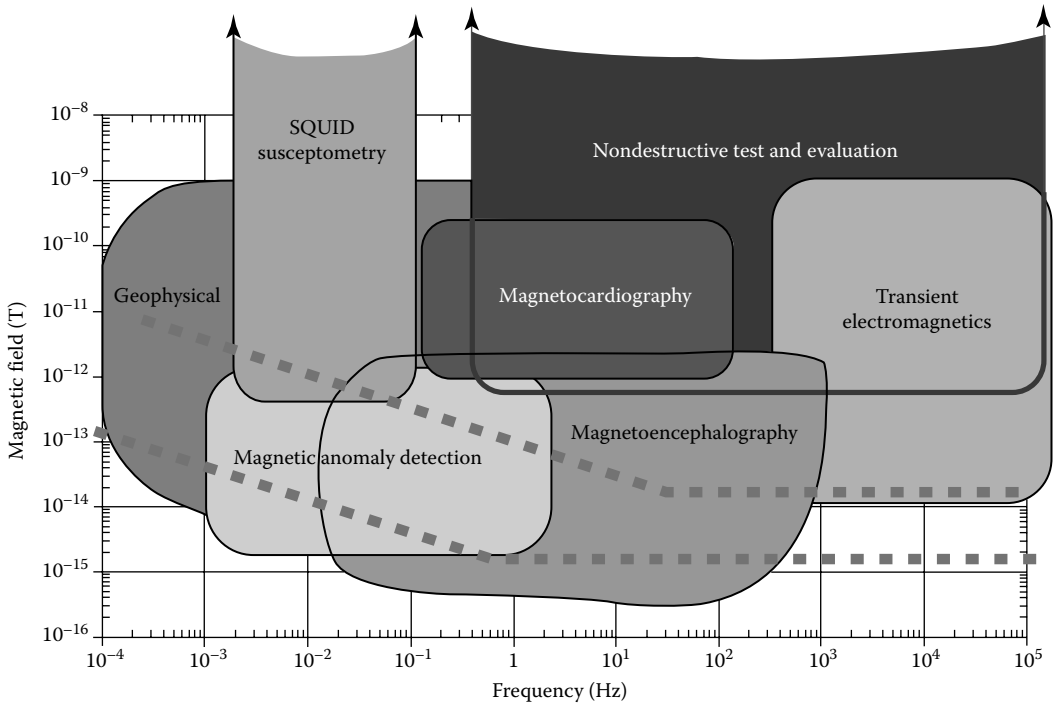

FIGURE 14.6 Field sensitivities and bandwidths typical of various applications. The dashed lines indicate the sensitivity of commercially available SQUIDs (the lower line is a typical LTS SQUID, and the upper line is a typical LTS SQUID).

disturbances in the ionosphere [10]. Other contributions include lightning strikes and man-made contributions such as structural steel and other localized magnetic materials such as furniture and instruments that distort the Earth's field and result in field gradients; moving vehicles that generate transient fields; electric motors; elevators; radio, television, and microwave transmitters; and the ever-present power line electromagnetic field and its harmonics.

A technique known as magnetotellurics (MT) [11] can be used to determine the electric conductivity distribution of the Earth's crust by measuring the Earth's electric and magnetic field. Because the Earth is a good electrical conductor compared to the air, the electric field generated in the ionosphere (due to the solar wind) is reflected at the Earth's surface, with components of both the electric and magnetic field decaying as they penetrate into the Earth. The decay length or skin depth (δ) can be expressed as

$$\delta \approx 0.5\sqrt{\rho\tau} \text{ (km)} \tag{14.6}$$

where

ρ is the electrical resistivity of the Earth
τ is the period of the electromagnetic wave

In magnetotellurics, the electric field (as a function of frequency) is related to the magnetic field via an impedance tensor where $\mathbf{E}(\omega) = \mathbb{Z}\mathbf{H}(\omega)$. The impedance tensor ($\mathbb{Z}$) contains four complex elements Z_{xx}, Z_{xy}, Z_{yx}, and Z_{yy} and is related to the resistivity ρ by the relation $\rho_{ij} \approx 0.2|Z_{ij}(\omega)|^2\tau$ where τ is the period in seconds and ρ is measured in $\Omega \cdot$m and $\mathbb{Z}$ in mV/km $\cdot$ nT.

SQUID magnetometers have been used to measure the Earth's magnetic field at frequencies ranging between 1 kHz and 10^{-4} Hz. MT has been effective in areas of thick sediments and on near-surface

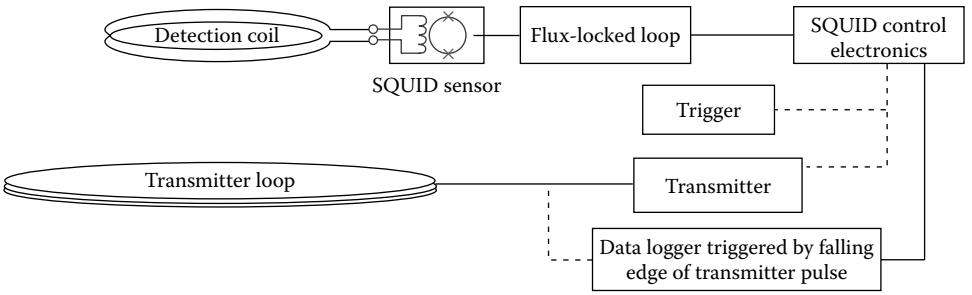

FIGURE 14.7 Block diagram of controlled source electromagnetic system.

metamorphic or volcanic rocks. The increased conductivity of hot saline regions associated with geothermal sites makes it well suited for location of hydrothermal reservoirs.

Rather than using the electromagnetic field generated by the solar wind, active methods create a time-dependent magnetic field generated by a loop driven by an electric current, with the magnetometer detecting the induced field. Measurements can be in either the time (e.g., transient electromagnetics [TEM]) or frequency (e.g., controlled source audio magnetotelluric [CSAMT]) domains. Figure 14.7 shows the key elements of a TEM measurement using relatively small field excitation coils [12]. Targets were centered beneath the transmitter coil, which had three turns with a current of 0.01 A (65 nT effective field).

14.3.1 Rock Magnetometers

Geophysical rock magnetometers [13] for paleomagnetism typically use three orthogonal detection coils to measure all three components of the remnant magnetic moment of rock and core samples with sensitivities approaching 10^{-10} emu/√Hz levels. They do not use a bias field magnet; in fact, the detection coil region is magnetically shielded to reduce the ambient magnetic fields in the detection coil region to well below the Earth's magnetic field. Another difference between rock magnetometers and SQUID susceptometers is that the sample tubes are made from fiberglass/epoxy rather than stainless steel primarily because metallic tubes conduct rfi into the pickup coil region and can cause SQUID noise. This also allows for time constants that approach microseconds. Typically, the sample chamber of rock magnetometers does not have variable temperature capabilities but are fixed at room (300 K) temperature. SQUID microscopes have also been used for paleomagnetic investigations.

A variation on the traditional rock magnetometer is the spinner magnetometer. In this case, the sample is rotated beneath a SQUID magnetometer. In this situation, the sample is not tightly coupled to the sensing magnetometer; thus, sensitivity will be significantly reduced. Rotating the sample on two axes permits the orientation and magnitude of the rock's magnetization to be determined. Sensitivities of 4×10^{-5} A/m have been achieved [14] using 100 fT/√Hz HTS SQUID magnetometers.

SQUIDs can also be used for magnetic anomaly detection (MAD) [15]. Knowledge of the total magnetic field gradient ($\nabla\mathbf{B}$) of an object can allow determination of its magnitude and direction [16]. From Maxwell's equations, four of the gradients are redundant (e.g., $\partial B_y/\partial x = -\partial B_x/\partial y$). Thus, only five gradient components (dB_x/dx, dB_y/dy, dB_x/dz, dB_y/dz, dB_z/dz) are necessary to determine $\nabla\mathbf{B}$. The three field (B_x, B_y, B_z) components are normally used to construct an 8-element array for MAD HTS tensor arrays. An 8-element vector/tensor array can also be made from pure (e.g., HTS) magnetometer elements [1].

14.4 Nondestructive Test and Evaluation

Magnetic sensing techniques such as eddy current testing (Figure 14.8e) have been used for many years to detect flaws in structures. A major limitation on their sensitivity is the skin depth, λ (the distance where the field is attenuated by a factor $1/e$) of metallic materials. For a sinusoidal varying wave,

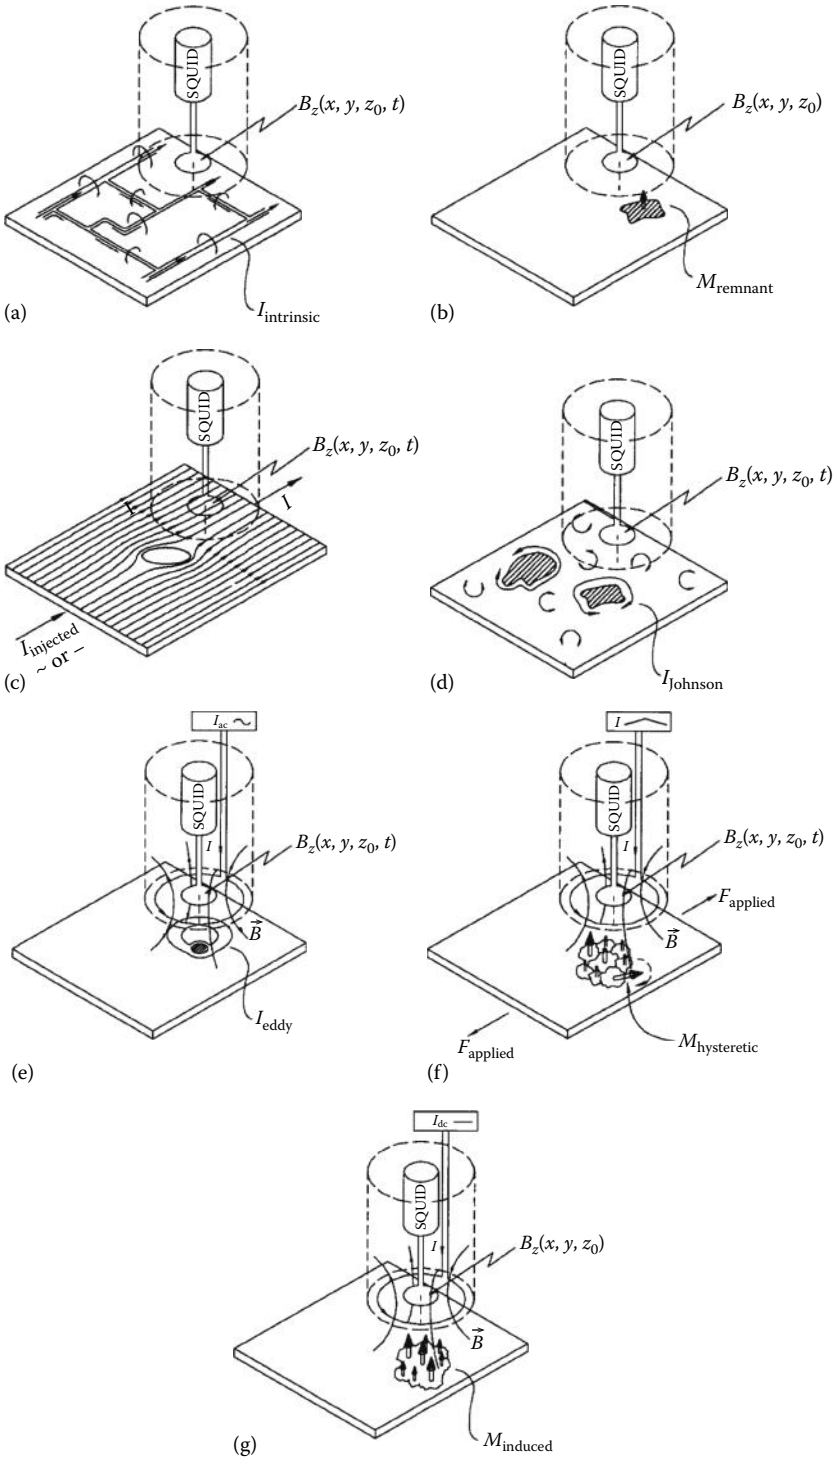

FIGURE 14.8 Measurement configurations for SQUID NDE: (a) intrinsic currents, (b) remnant magnetization, (c) flaw-induced perturbations in applied currents, (d) Johnson noise or corrosion activity in conductors, (e) eddy currents induced by an applied ac magnetic field, (f) hysteretic magnetization by application of stress or an applied field, and (g) diamagnetic and/or paramagnetic materials in an applied field. (Photo courtesy of J. P. Wikswo.)

$\lambda = \sqrt{\rho/\pi\mu_0 f}$ where f is the frequency of the applied field, ρ is the electrical resistivity, and μ_o is the magnetic permeability of free space. Because SQUID sensors have true dc response and superior sensitivity, they can see "deeper" into metallic structures. DC response also means that they can detect remnant magnetization—without the need for externally applied magnetic fields. Their flat frequency response and zero-phase distortion allow for a wide range of applications. Reference [17] gives an excellent overview of SQUID NDE research.

Magnetic susceptibility (Figure 14.8g) can be measured by applying an external magnetic field in the same orientation as the detection coil(s). If the material being studied is isotropic, the response of the material to the applied field will be sufficient to determine the material's magnetic properties.

A particular advantage of magnetic sensing is in examining defects beneath insulating barriers. For example, a cladded pipe with asbestos lagging can be quickly examined because the insulating barriers are virtually invisible to magnetic detection—the asbestos need not be removed or cut into. A similar use would be to detect corrosion underneath paint or other opaque coverings. Unlike eddy current measurements, which have a skin depth that is frequency dependent, the true dc response of a SQUID magnetometer allows measurements with little, if any, effect from intervening materials. This is true even if the intervening material is metallic.

14.4.1 SQUID Microscopes

Since electric currents create magnetic fields, the ability to measure small magnetic fields offers the potential to locate the causes of semiconductor failures. In failed integrated circuits (ICs), a short circuit would appear as a small area of intense magnetic flux. By overlaying a magnetic map (created by scanning a SQUID sensor over an IC—Figure 14.8a) onto a computer-aided design (CAD) map of an IC's features, it is possible to locate where faults occur in a device. SQUID microscopes have been used to make noncontact measurements of electronic circuits [18]—one instrument has better than 10 μm resolution [19]. Another [20] can detect 10 nA currents flowing in a conductor 100 μm from the sensor.

14.5 Medical Applications of SQUID

As mentioned, SQUID magnetometers may provide diagnostic capabilities in areas where there is no present measurement technique. The use of bioelectric signals as a diagnostic tool is well known in medicine, for example, the electrocardiogram (ECG) for the heart and the electroencephalogram (EEG) for the brain. The electrical activity that produces the surface electrical activity that is measured by EEG and ECG also produces magnetic fields [21]. The analogous magnetic measurements are known as the magnetocardiogram (MCG) and the magnetoencephalogram (MEG).

Magnetic fields of biological origin (Figure 14.9) are quite small compared to the Earth's magnetic field. The heart produces the strongest magnetic field with a strength on the order of 100 pT [22]. Brain activity can be ten thousand times weaker (ten billion times weaker than the Earth's magnetic field) [23]. In addition, magnetic measurements can be made for which there are no electrical analogs. These are measurements of static magnetic fields produced by ferromagnetic materials inhaled, injected, or ingested into the body and measurements of the magnetic susceptibility of materials in the body. Examples of these are magnetic dusts inhaled and retained in the lungs and the paramagnetic iron storage compounds ferritin and hemosiderin that occur naturally in the body.

The relative strengths of these various biomagnetic fields vary by more than 10,000. The strongest is associated with magnetic contaminants in the lung. An example would be dust inhaled by a machinist or an arc welder. The external magnetic field after exposure to a magnetizing field of a 0.3 mT (the equivalent of a toy magnet) can be as great as 1 nT. Evoked neurological responses, such as the response to visual or auditory stimuli, have field strengths at the surface of the skull of a few tens of fT. The sources of these fields vary from localized groups of neurons in the brain to the more dispersed muscle tissues in the heart, to magnetic particles distributed through the lungs.

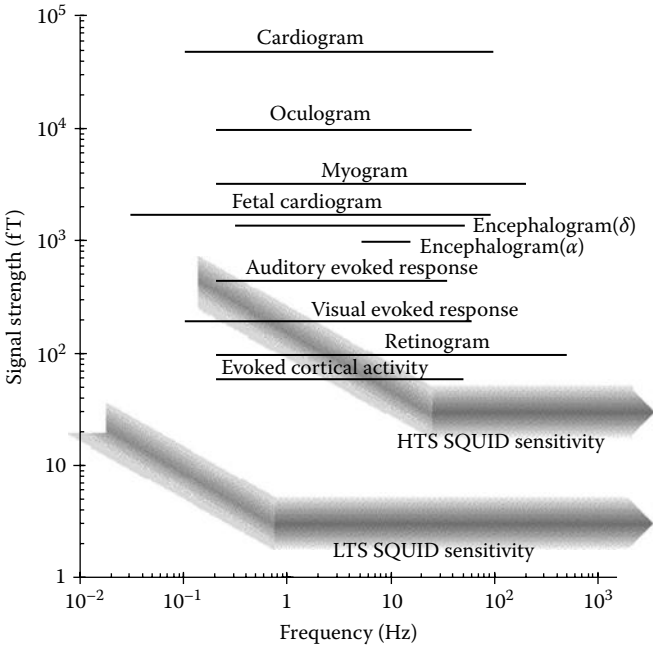

FIGURE 14.9 Typical amplitudes and frequency ranges for various biomagnetic effects.

Magnetic fields from active electrical sources in the body can be measured passively and externally to the body (i.e., noninvasively) by placing the magnetometer (actually first- or second-order gradiometers) in close proximity to the body's surface. As mentioned, the use of gradiometers can allow measurements to be made in unshielded environments at sensitivities below 5 fT/√Hz. This technique is applicable to measurement of the heart, brain, and skeletal muscles.

14.5.1 Magnetoencephalography

The magnetic analog to electroencephalography (EEG), MEG, has the advantage of being (in the case of depth electrodes) noninvasive and unambiguous in its ability to locate neurological activity. Within the brain, a population of neurons can be modeled as an equivalent current dipole (Figure 14.10) that generates well-defined magnetic field profile. Mapping of these field profiles can be used to infer the location

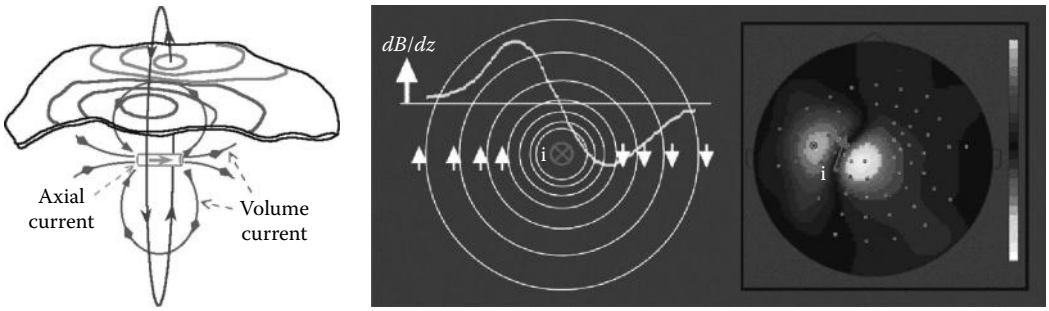

FIGURE 14.10 (a) Magnetic field generated by a current dipole. For a sphere, the dipole is located at midpoint of the maxima and minima, and (b) at a depth = distance $D/\sqrt{2}$, where D is the separation between the maxima and minima on the surface of the sphere.

of the equivalent active dipole site region to within millimeters [24]. Using evoked response techniques, the location of signal pathways and information processing centers in the brain can be mapped at different delay times (latencies) following the stimulus. MEG systems for clinical use can have channel counts in the hundreds [25].

14.5.2 Magnetocardiography

Measurement of the heart's conduction system is important in the diagnosis of diseases in which the heart has an abnormal rhythm, reduced mechanical performance, and higher susceptibility to sudden failure. DC MCG measurements have shown that a "current of injury" flows in the heart as a result of myocardial infarction. Although a current of injury signal can also be seen in the alternating current (ac)-coupled ECG, the magnitude of the injury and the location of the injured region cannot be determined with precision. Using MCG, it may be possible to determine both the location and extent of the injured heart tissue. Clinical studies are underway to test this hypothesis [26].

The SQUID magnetometer is sensitive enough to noninvasively detect the fetal MCG (fMCG). The fetal ECG (fECG) is often used by physicians as a measure of fetal distress, but detection of this fetal heart beat is often unreliable, especially between 25 and 34 weeks of gestation. Unlike fECG, it is possible to monitor the fetal heart (via fMCG) through all phases of gestation. Another advantage of magnetic (as compared to electrical) methods is that the spatial resolution of MCG allows it to better isolate the fetal heart in the presence of the maternal heartbeat [27].

14.5.3 Other Biomagnetic Applications

The location and quantity of ferrimagnetic materials in the body, typically due to contaminants in the lungs, can be determined by measuring the magnetic field of the body before and after a low-intensity (~10 mT) field is applied to magnetize the ferrimagnetic materials. The distribution of these materials can be determined by applying the field to only a small region of the body at a time [28].

Fields from paramagnetic or diamagnetic materials (such as iron stored in the liver) can also be measured. By comparing measurements made while a low-intensity magnetic field (~0.3 mT) is applied to a local region of the body with those of the background field when the subject is lowered beneath the detection coil(s), actual quantities of the (paramagnetic or diamagnetic) materials can be determined. Information on the depth of these materials can be obtained by using magnetization and detection coils of differing sizes in the same instrument or by measuring the field as a function of distance from the body. This technique is already being used to monitor patients suffering from iron overload diseases such as thalassemia and hemochromatosis [29].

It is only since the development of the SQUID that measurements of biomagnetic fields have become a reality. Current SQUID magnetometers for MEG utilize hundreds of channels to provide whole-head coverage, sensitivities at the 5 fT/√Hz level, and bandwidths up to 5 kHz.

Defining Terms

Josephson junction critical current (I_c): The current at which a Josephson junction transitions from superconducting to normal (resistive) behavior.

Magnetic flux (Φ): The product of the magnetic field (B) penetrating an area times the area ($\Phi = BA$). Flux is quantized in units of $h/2e = 2.068 \times 10^{-15}$ Wb (T · m^2).

SQUID: Superconducting quantum interference device that acts as a current- or flux-to-voltage amplifier that operates at cryogenic temperatures. The principles of SQUIDs are discussed in Chapter 5.

Transition temperature (T_c): The temperature in which a superconductor transitions from superconducting ($R = 0$) to normal ($R > 0$) behavior.

Sensor Networks and Communication

Robert M. Crovella
NVIDIA Corporation

15.1 Introduction

15.1.1 What Is a Communication Network?

A communication network provides a system by which multiple users may share a single communication path (or medium) to exchange information. The telephone system is an example of a system containing many communication networks, which can be considered to be a single communication network as an abstract example. Communication networks are commonly used in various industries and applications to provide an economical means to allow multiple, geographically separated users to exchange information.

15.1.2 Ordinary Sensors versus Networked Sensors

A definition of the function of a sensor is to map or convert one measured variable (e.g., spatial, mechanical, electromagnetic) into another—usually electric—variable or signal. This signal may then be passed to a measurement or processing system for capture and analysis, or as a direct input to some controlled process. In this case, the measured variable is represented as an electric signal. This signal must be handled individually by the measurement system, and it may also be subject to corruption from a variety of sources, such as electromagnetic interference (EMI) in the case of an electric signal.

In applications where a number of sensing devices are needed, and/or where the sensing devices are distributed geographically (or are distant from the measurement and analysis system), the application designer may wish to use a communication network to transmit sensor data from the measurement point to the measurement and analysis system. Such applications typically involve some sort of digital computing machinery at the measurement and analysis point, or as part of the control system. Figure 15.1 depicts a representative block diagram of a sensor/network system showing the relationship of the various components.

Networked sensors can be distinguished into two components: those performing the measurement function and those components performing the communication function. In some cases, these two functions may be designed as a single unit, such that the "sensor" intrinsically includes communication capability. In other cases, an ordinary sensor may be connected to a conversion unit, which converts the output signal of the ordinary sensor into a form suitable for the network and manages the delivery of this information on the network.

15.1.3 Why Use Networked Sensors?

Network communication combined with sensor technology can provide several benefits to an application, as well as to the sensor designer. The most obvious benefit of a network is the simplification of the wiring for the transmission of the signals from one place to another. For system containing N users, the number of wires or cables T required to individually connect each user with each other user is given by Equation 15.1:

$$T = 2^{(N-1)} - 1 \tag{15.1}$$

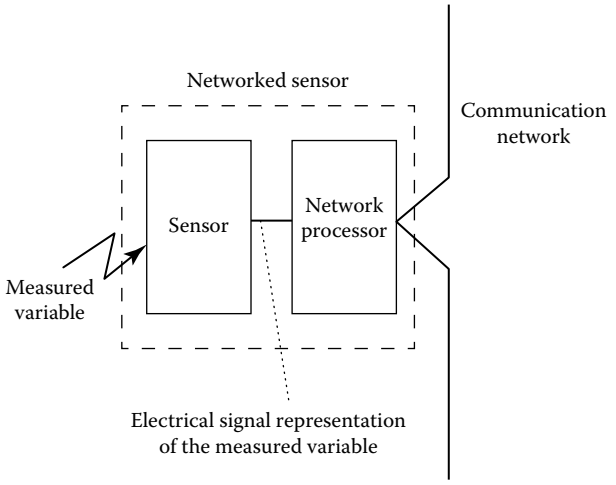

FIGURE 15.1 A networked sensor is an ordinary sensor with network communication components added.

assuming each wire or cable can carry information in both directions between the two users connected by that cable. For more than a few users, the number of cables required (T) to provide an individual connection between each pair of users is large. Sensors are often connected to a central measurement and analysis system and may only need to communicate with the central system. In this case, the number of individual wires or cables needed is equal to the number of sensors ($N - 1$). Even with this smaller number of cables, the wiring for a large number of sensors in some applications can be quite complex. A network may be able to reduce the total number of cables required to a much smaller number. In fact, in a sensor network, all of the sensors and the central measurement and analysis system can be connected to a single cable.

An indirect benefit of networking may be in its handling of the sensor signal. Because most modern networks are digital in nature, an analog sensor signal typically must be digitized before it can be transmitted on a network. With a networked sensor, the digitization will typically be carried out by circuitry in relatively close proximity to the sensor. As a result, the analog signal will have traveled a short distance before being converted to a digital signal. This can be a benefit in two ways. The first is that the analog signal will not suffer as much attenuation or degradation due to electric losses associated with carrying a signal over a great distance. The second is that once in digital form, the "signal" can be made relatively immune to the effects of distortion or degradation due to EMI. Although digital transmission of signals is still subject to EMI, modern protocols and transmission systems can be designed to be very robust, using signaling that is resistant to EMI as well as using error control techniques. As a result, the effect of attenuation and disturbances can be essentially eliminated by digital transmission of the signal.

Another benefit of networking is the ability to communicate a much wider range of information—in both directions—when compared with a single cable carrying a sensor signal. With many modern networks suitable for networked sensing applications, a microprocessor is used at the sensor to manage the handling of the sensor signal and its transmission on the network. But there is generally no need to limit the microprocessor to this one function alone. The combination of the network and the microprocessor provides a platform upon which many additional functions and features can be incorporated into the networked sensor. For example, the signal of a sensor may need a certain calibration or correction function applied to it before it can be used in calculations. It may be beneficial to load into the networked sensor (through the network) a set of correction parameters or coefficients and then have the microprocessor correct or calibrate the output of the sensor before transmitting it to the network. Sensors can be easily designed to have multiple sensing functions, such as temperature and pressure. Each signal can be handled separately and transmitted separately on the network, with no need for additional connections. Sensors may be designed to store certain types of information, such as the name of the manufacturer, or certain calibration parameters determined by the manufacturer at the time of manufacture. This information can then be read out over the network and used for a variety of purposes. A sensor can even be designed to have "intelligent" functions, such as the ability to sense its environment and determine when certain parameters have been exceeded (such as operating temperature range) or report a special message containing an "alarm" when the sensor signal level exceeds a certain threshold. The combination of the network and the microprocessor leads to an endless variety of functions and features that can be added to the basic sensor technology.

15.1.4 Potential Problems with Networked Sensors

Networked sensors will generally require more complex circuitry than equivalent, nonnetworked sensors. A drawback of analog-to-digital (A/D) conversion and digital transmission of signals is the time and level quantization effect that A/D conversion can have on the analog signal. These effects can be mitigated with modern, high-speed A/D converters (to minimize the effect of time quantization or the sampling effect) with the ability to convert in high resolution (i.e., using a large number of digital bits to represent the analog signal level). These drawbacks are not unique to networked sensors but rather to digitized sensor values and digital control whether or not it uses a network. Finally, the

capacity of the network to carry information (the bandwidth) must be considered in any communication system. Putting a large number of sensors on a single network may overload the information-carrying capability of the network, resulting in queuing delays in the reception of sensor signals and, in some cases, lost data.

15.2 Communication and Networking Concepts

In order to be able to select an appropriate network technology, it is necessary to understand some basic terminology so that the features and capabilities of various networks and technologies can be categorized and compared.

15.2.1 Station

A station represents a single communicating element on a network system. Each user of the network must access the communication capability of the network via a station. Each station will typically have some implementation of the open systems interconnection (OSI) network reference model as the means of utilizing the network system.

15.2.2 Media Access

Media access is the method by which individual stations determine when they are permitted to transmit or "use" the media. Media access control (MAC) is a function that is usually performed in the data link layer of the OSI reference model. Some well-known methods of MAC include carrier sense multiple access with collision detection (CSMA/CD) and token passing. CSMA/CD systems (such as Ethernet) allow all stations on a network equal access. Each station must "listen" to the network to determine periods of inactivity before transmitting. Any station wishing to use the network may begin transmitting provided that the network is not busy when it checks the network status. If multiple stations attempt to transmit simultaneously, a collision occurs. This is detected by all transmitting stations, which all must immediately stop transmitting and each wait a randomly determined period of time, before attempting to use the network again. Controller area network (CAN), for example, uses a variant of CSMA/CD for media access. Token-passing systems have a logical "token" that is exchanged among stations via network messaging. The station that holds the token has permission to transmit. All other stations are only permitted to receive messages. Stations wishing to transmit but not having the token must wait until the station holding the token passes it on. Another commonly used method of MAC is master–slave. In this method, one station on the network (designated the master) is generally in charge of, and originates, all communications. Slaves only respond to the master and only respond when the master initiates communications with them via sending a message to the slave. Profibus fieldbus messaging specification (FMS) (see later) is an example of a protocol that uses both token passing (in some cases) and master–slave (in some cases) to control media access.

15.2.3 Bandwidth

Bandwidth may have several different definitions. For digital communication systems, bandwidth describes the capacity of the system to transport digital data from one place to another. This term may be applied to the raw capability of the physical and data link layers to transport message data (*raw bandwidth*, closely related to the bit rate concept), or it may be applied to the effective rate at which user-meaningful information is transported (*effective bandwidth*). The bandwidth of a given system is generally inversely proportional to the worst-case node-to-node distance. The smaller the network span, the higher its bandwidth can be.

15.2.4 Addressing

Addressing is a concept that assigns generally unique identifiers to each station in a network system. This identifier (the address) can then be used by the network for a variety of purposes, including identifying the origin and/or destination of messages, or arbitrating access to a shared communications medium. Another addressing or identifier concept assigns unique identifiers not to stations but to unique pieces of data or signals that will be carried by the network. Stations then use an identifier according to what type of data they will be transmitting. Many but not all networking methods require establishment of an explicit address for each network station.

15.2.5 Arbitration

Arbitration is a function closely related to MAC. Arbitration is used by some networks to define the procedure followed when multiple stations wish to use the network simultaneously.

15.2.6 Signaling

Signaling refers to the actual physical (e.g., electrical, optical, or other) representation of data as they are carried on the media. For example, in some networks, data elements may be represented by certain voltage levels or waveforms in the media. In other networks, data elements may be represented by the presence of certain wavelengths of light in the media. The association of all the representable data elements (e.g., 0/1 or on/off) with the corresponding signal representations in the media is the signaling scheme or method. An important signaling method where electric wires are used as the medium is differential signaling. Differential signaling represents a particular data element (1 or 0) as two different states on a pair of wires. Determining the data element requires measuring the voltage difference between the two wires, not the absolute level of the voltage on either wire. Different data elements are then represented by the (signed) voltage difference between the two wires. For example, RS-485 represents a digital 1 data element as a 5 V signal level on the first wire and a 0 V signal level on the second wire, and a digital 0 as a 0 V signal level on the first wire and 5 V signal level on the second wire. One of the principal benefits of differential signaling is that it is possible to determine the data being transmitted without knowing the ground reference potential of the transmitter. This allows the transmitter and receiver to operate reliably, even when they have different ground potentials (within limits), which is a common occurrence in communication systems.

15.2.7 Encoding

Encoding refers to the process of translating user-meaningful information into data elements or groups of data elements to be transported by the network system. A code book refers to the set of all relationships between user-meaningful information and data carried by the network. Encoding may occur at several levels within the OSI reference model, as user-meaningful information is transformed successively until it becomes an actual network message, produced by the data link layer. Decoding is the reverse process, whereby a network message is successively translated back into user-meaningful information.

15.2.8 Modulation

Modulation in a classical sense refers to a signaling technique by which data or information is used to control some combination of the frequency, phase, and/or amplitude of a carrier signal. The carrier signal carries the information to a remote receiver where it will be demodulated to retrieve the information. Modulated network systems will briefly be explained in this chapter.

15.2.9 Message

A message is the fundamental, indivisible unit of information that is exchanged between stations. User-meaningful information will be grouped into one or more messages by the OSI network reference model.

15.2.10 Multiplexing

Multiplexing refers to the ability to use the media in a network to carry multiple messages or information streams "simultaneously." Multiplexed systems allow several communication channels to use the same physical wire or media. Each message or information stream may have different sources and destinations. Multiplexing may be accomplished using a variety of means. Time division multiplexing (TDM) involves breaking access to the media into a series of time quanta. During each time quantum, the media carries a separate message or information stream. The close arrangement of time quanta allows the network media to carry multiple messages "simultaneously." Code division multiplexing (CDM) involves the separation of the code book (see Section 15.2.7) into sections. Each section of the code book provides all of the messages that will be used for a particular information stream. Therefore, a particular information stream within the network media is distinguished by all of the messages that belong to the section of the code book for that stream. Frequency division multiplexing (FDM) divides an available bandwidth of a communication channel into several frequency ranges and assigns one information stream to each frequency range.

15.2.11 Protocols

A protocol is a defined method of information exchange. Protocols typically are defined at several levels within the OSI network reference model, such as at the application layer and at the data link layer. Protocols are used to define how the services provided by a particular layer are to be exercised, and how the results of these services are to be interpreted.

15.2.12 Service

A service represents a specific function or operation that is supported by a particular layer in the OSI network reference model. For example, an application layer service might be provided for the reading of or writing to a data element contained in another device (or station) on the network. This service might make use of a data link layer service that might be provided for supporting the exchange of a message with another device (or station) on the network.

15.2.13 Topology

Topology refers to the physical or geographic layout or arrangement of a network. Certain types of canonical topologies are commonly discussed in the context of networks, such as trunk line–branchline, star (or hub), ring, and daisy chain.

15.2.14 Bit Rate

Bit rate refers to the speed at which binary pieces of information (bits) are transmitted on a particular network. The raw bit rate of a network generally refers to the actual speed of transmission of bits on the network. The effective bit rate—or throughput—generally refers to the speed at which user information is transmitted. This number is less than or equal to the raw bit rate, depending on what percentage of the bits transmitted is used for carrying user information. The bits not carrying user information are overhead, used to carry protocol, timing, or other network information.

15.2.15 Duplex (Half and Full Duplex)

Half duplex refers to a communication system in which a station can either transmit information or receive information but not both simultaneously. A full-duplex network allows a station to transmit information and receive information simultaneously.

15.2.16 Error Control

Many network systems provide mechanisms to control errors. Error control has four aspects: prevention, detection, correction, and isolation. Error prevention may simply be shielding for the media to minimize electromagnetic disturbances, or it may be more complicated, such as signal sampling control to optimize the probability that a signal will be in the correct state when sampled. Error detection generally depends on detecting violations of protocol rules at various network levels or violations of computed data added to a message for error control purposes. Some examples of error detection techniques are parity and cyclic redundancy check (CRC). Both methods involve the computation of additional bits of information based on the data that are contained in a message and appending these bits to the message. For example, a particular protocol may require that the data link layer compute and append a CRC to a message prior to transmission. The receiver of the message may then also compute the CRC and compare it to the CRC that has been appended to the message. If a mismatch exists, then it is assumed an error has occurred. Error correction may take on a variety of forms. One of the simplest methods of error correction is to require that the data link layer of the transmitter retransmits a message that has been detected to have an error during transmission. This method is based on the assumption that the error was caused by a disturbance that is unlikely to occur again. Another method of error correction involves transmission of additional bits of information along with the user information in a message. These additional bits of information are computed by the transmitter to provide redundant information in the message. When fewer than a certain number of bit-level errors have occurred during the transmission of the message, the receiver is able to reconstruct the original user information accurately using the redundant information (bits) supplied within the message. Error isolation is a capability of some networks to localize the source of errors and isolate the sections of the network or the stations at which the errors have been localized. Error isolation allows the fault-free portions of the network to continue communicating even when other portions of the network have degraded to the point of generating errors.

15.2.17 Internetworking

There are occasions when communications between two or more points are best handled by multiple networks. This may be the case when a single network has limitations that prevent it from tying the points together (e.g., distance limits) or when multiple networks are required for other reasons (e.g., to carry different types of data). When multiple networks are used to provide communications, there may be a need to pass messages or information directly from one network to another.

A repeater may be used when the networks to be joined are logically identical, and the purpose is simply to extend the length of the network or extend its capabilities in some way. A repeater generally has no effect on messages and simply carries all messages from one cable or port to another (i.e., a change of physical media). A repeater allows for connection of networks at the physical layer level.

A bridge is similar to a repeater but allows for connection of networks at the data link layer level. Generally, a bridge will pass all messages from one network to another, by passing messages at the data link layer level.

A router usually has the function of partitioning similar networks. Two networks may be based on the same technologies and protocol but may not be logically identical. In these cases, some, but not all, of the messages on one network may need to be carried or transported to the other network. The router has

the function of determining which messages to pass back and forth based on certain rules. Functions to enable efficient, automatic routing of messages may be included in layer 3 (the network layer) of the OSI network reference model, and a router allows for connection of networks at the network layer level.

A gateway may have a function similar to a router, or it may have the function of joining dissimilar networks, that is, networks based on dissimilar technologies and/or protocols. When functioning like a router, a gateway usually performs its discrimination at a higher protocol level than a router. When a gateway joins dissimilar networks, generally a more complex set of rules must be designed into the gateway so that message translation, mapping, and routing can occur within the gateway as it determines which messages to pass from one network to the other.

15.2.18 ISO/OSI Network Reference Model

The explosion in the use and types of communication networks over the last several decades has led to more precise descriptions and treatment of communication networks in general. The International Organization for Standardization (ISO) has recognized one such method of precise description of networks, called the OSI reference model [1]. As shown in Figure 15.2, this model decomposes an arbitrary communication network into a "stack" of seven "layers." At each layer, certain types of network communication functions are described. The user of the communication system—usually another system that needs to communicate on the network—interacts with layer 7, the highest layer. The actual transmission medium (e.g., copper cable, fiber optic, free space) is connected to layer 1, the lowest layer. Most communication networks do not implement all of the layers in the reference model. In this case, formal definition, treatment, or inclusion of certain layers of the model in the actual network design is omitted. Layers 1, 2, and 7 are typically present in all networks, but the other layers may only be explicitly

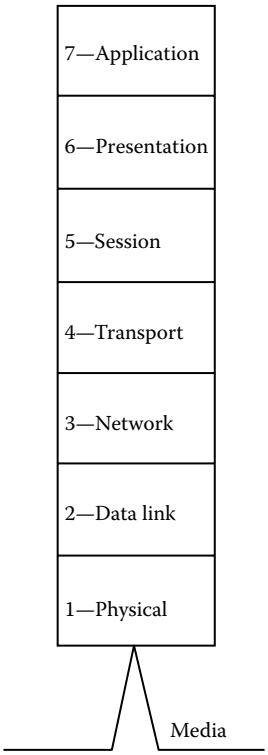

FIGURE 15.2 The ISO/OSI seven-layer model provides a method for segmenting communication functions.

included or identifiable when their function is an important part of the network communications. In many sensor communication networks, the functions performed by layers 3, 4, 5, and 6 are "collapsed" into vestigial additions to the functions of layer 7, the application layer.

15.2.19 Physical Layer

The physical layer is the lowest layer of the model. This layer is responsible for converting between the symbolic or data representation of the network messages and the actual physical representation of data in the network medium. This layer specifies the behavior of the electric circuits referred to as the transmitter and the receiver. It also defines physical structures for connectors.

15.2.20 Data Link Layer

The data link layer, or layer 2, is responsible for several functions. This layer manages access to the network medium (MAC), structures the bits of information into well-defined groups identified as "frames" or messages, handles identification of source and destination stations on the network, and provides for error-free transmission of a message from source to destination stations, all according to the data link layer protocol. A number of standard data link layer protocols exist, which act as the basis for many of the communication networks in wide use. Ethernet, or IEEE 802.3, for example, specifies a MAC sublayer that works with the IEEE 802.2 Logical Link Control layer to form the data link layer protocol used in the majority of office information networks [2].

15.2.21 Network Layer

The network layer encapsulates functions related to routing of messages, both within a single network and among multiple networks. This layer typically uses addressing in a variety of forms as a key part of the functions of directing and routing messages and the search and usage of the available communication paths.

15.2.22 Transport Layer

The transport layer provides any additional data transfer functions not directly provided by the data link layer for end-to-end reliable messaging. For example, some data transfer functions between stations may require the use of multiple data link layer messages to accomplish a reliable message transfer. The generation of multiple messages and the sequential disassembly, delivery, and assembly of data are accomplished by the transport layer. The transport layer also recovers from lost, duplicated, and misordered messages.

15.2.23 Session Layer

The session layer provides for a higher level of control and management of network usage and data flow than that provided at lower layers, including opening or building up a communication channel, maintaining the channel, and closing the channel. This layer is infrequently implemented in contemporary systems.

15.2.24 Presentation Layer

The presentation layer provides functions to transform data from formats that are transportable by the network to the user-accessible formats that are defined in the application layer and understood in the local station.

15.2.25 Application Layer

The application layer, or layer 7, provides communication services directly to the user application. The usage and formatting of these services is summarized in the application layer protocol. The user interacts with the network by invoking functions and services provided by the application layer and passing data to and from the network through these services.

15.3 Network Technologies

There is a wide range of technologies in various stages of development and standardization, which address virtually all levels or layers of the ISO/OSI network reference model. One or more of the available technologies will probably suit almost any networking need. An analysis of the available technologies and their limitations will also be beneficial if it is deemed that a networking method must be designed to meet a particular application. The selection and description of technologies is by no means complete or exhaustive. The technologies presented are selected from several industries that make common use of networking to communicate sensor data. Table 15.1 provides a comparison of selected parameters for a set of networks.

15.3.1 RS-232

RS-232 (ANSI/EIA/TIA-232-E-91) is a widely used method of communication, which has been standardized in a variety of places including the Electronics Industry Association [3]. RS-232 represents elements of layer 1 of the OSI model, for communicating between two (and only two) stations. RS-232 provides a separate wire for transmission of data in each direction between the two stations and gives the two stations different designations—data terminal equipment (DTE) and data communications equipment (DCE)—so that a method exists to distinguish which station will use which wire to transmit and receive. The signal levels for RS-232 represent a digital 1 bit as a voltage in the range of 5–12 V on the wire and a digital 0 bit as a voltage of negative 5–12 V on the wire. RS-232 is typically implemented in a full-duplex fashion, since each station can transmit to the other simultaneously using separate wires. RS-232 can be made to operate at a variety of bit rates but typically is used at bit rates from 300 bit/s up to 115,200 bit/s.

TABLE 15.1 Comparison of Selected Parameters (Maximum Values) for Various Network technologies[a]

	Length	Stations	Bit Rate	Wires	Media	Topology
RS-232	30 m	2	115 kb/s	2	TP	P–P
RS-485	1200 m	32	10 Mb/s	2	TP	D-C
Seriplex	1500 m	256	200 kb/s	4	2STP	D-C, Free
AS-i	100 m	32	167 kb/s	2	UP	T–B
Interbus-S	25.6 km[b]	64	500 kb/s	6	3STP	Ring
CAN	450 m	64	1 Mb/s	4	2STP	T–B
4-20 mA	1000 m	2	—	2	STP	P–P
HART	1000 m	2(15)	1200 b/s	2	STP	P–P (D-C)
Profibus	9600 m	126	12 Mb/s	2	STP	D-C
Found. Fieldbus	1900 m	32	2.5 Mb/s	2	STP	D-C
LonWorks	1400 m	64	1.2 Mb/s	2	STP	D-C, Free

Notes: P–P, point to point; D-C, daisy chain; T–B, trunk line–branchline; TP, twisted pair; STP, shielded twisted pair; UP, unshielded pair.

[a] Maximum parameters for networks are not achievable simultaneously and do not include repeaters, routers, or gateways. Maximum parameters are estimates based on available information.

[b] Maximum 400 m between stations.

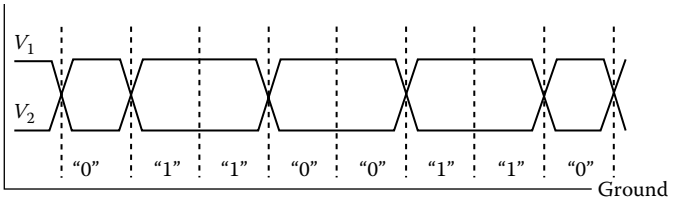

FIGURE 15.3 A sample RS-485 waveform showing voltages on differential wire pair (V_1, V_2) and superimposed bit intervals showing 0 and 1 bits. The ground reference is arbitrary within the defined signaling range.

15.3.2 RS-485

EIA RS-485 was made a standard in 1983, derived from the RS-422 standard. RS-485 provides for differential transmission of data on a pair of wires among 32 or more stations. Like RS-232, the standard is a layer 1 specification. RS-485 provides for half-duplex communication, since a station cannot simultaneously transmit and receive independent data streams. Each station in an RS-485 system can have either a transmitter or a receiver, or both (commonly called a transceiver). Most implementations provide a transceiver. When one transceiver is transmitting, all others should be receiving (i.e., not transmitting). Which station is allowed to transmit at which time is not specified in the standard and must be covered by a higher layer protocol (e.g., Interbus-S, Profibus distributed periphery [DP]). Figure 15.3 shows a sample RS-485 waveform, indicating the differential nature of the signaling.

15.3.3 Seriplex*

Seriplex® is a digital, serial multiplexing system developed by Automated Process Control, Inc., in Jackson, MS. Square D Corporation purchased Automated Process Control and the rights to Seriplex in 1995, and subsequently launched Seriplex Technology Organization (STO) to manage the protocol. Seriplex is designed to be particularly efficient at handling large numbers of digital or on/off input and output points. Seriplex provides three communication wires, one for a clock signal, one for a data signal, and a ground reference. The system can be operated in two different modes (peer-to-peer and master–slave). In master–slave mode, one station is designated the master. The master synchronizes all data transmission among stations by driving a digital waveform on the clock line that all stations listen to and use for timing of transmit and receive operations. The master generates a repetitive pattern on the clock line that causes all stations to transmit and/or receive data on each cycle or "scan" of the network. Each station is given an address and uses the address along with the clock signal to determine when to drive the data line (in the case of an input point) or when to monitor the data line for valid output data (in the case of an output point). There are variations possible in implementation that allow for various clock speeds and bit rates (16, 100, and 200 kHz). Other protocol details allow for the handling of analog or multibit input and output points (by combining several bits on sequential scans together), bus fault detection, input redundancy, and communication error control using multiple scans of the network. Implementing the protocol in a sensor or other device typically requires using a Seriplex application-specific integrated circuit (ASIC), which must be licensed from the STO [4].

15.3.4 AS-i

Actuator Sensor Interface (AS-i) was developed by a consortium of primarily European companies interested in developing a low-cost, flexible method for connecting sensors and actuators at the lowest levels of industrial control systems. The system is managed by an independent worldwide organization [5].

* Seriplex is a trademark of the STO.

The AS-i system provides a two-wire, nontwisted cable for interconnection of devices. Devices may draw current from the two wires (nominally at 24 V dc) for powering circuitry, and the data communications are modulated on top of the nominal dc level at a bit rate of 167 kHz, under the control of the master. A single parity bit per station is used for error detection. Similar to Seriplex, an AS-i device is typically implemented using a special ASIC that handles the communication.

15.3.5 Interbus-S

Interbus-S was developed by Phoenix Contact [6] and is controlled by the Interbus-S Club. The topology of the network is a ring, with data being sequentially shifted from point to point on the ring under the control of a network master. Each device in the ring acts as a shift register, transmitting and receiving data simultaneously at 500 kHz. The actual serial data transmission between stations conforms to RS-485. Interbus-S transmissions include a CRC for error detection. Interbus-S (Interbus-S remote bus) has also been extended to include a subprotocol called Interbus sensor loop (or Interbus-S local bus). This subprotocol provides an alternate physical layer, with a single twisted pair carrying power and data on the same lines and a reduction in the minimum size of the shift register in each station from 16 to 4 bits. Each Interbus sensor loop system can act as a single station on an Interbus-S network, or the sensor loop can be connected directly to a controller or master. Interbus-S devices are usually implemented with a special ASIC.

15.3.6 CAN

CAN is a data link layer (layer 2) network technology developed by Robert Bosch Corporation [7], with an application target of onboard automotive networking. The technology is standardized in ISO 11898 [8], licensed to all major integrated circuit manufacturers, and is widely available—both as separate CAN controllers and CAN controllers integrated with microprocessors. As a result, CAN has been used in a variety of industries. As a data link layer technology, it is not a complete network definition. A number of physical layer options are usable with CAN (e.g., twisted pair, fiber optic, radio-frequency [RF] wireless) and some have been subject to standardization (e.g., ISO 11898). Also, a number of application layer protocols have been developed for use with CAN, such as DeviceNet, Smart Distributed System (SDS), CANOpen [9], and SAE J1939 [10]. Both DeviceNet [11] and SDS [12] have developed systems for creating networks of industrial field devices for the factory floor, including sensors and actuators. SDS was originally developed by Honeywell, now it is a part of IEC 62062 Standards Part 5 Ed 1.0 B:2000 [12].

15.3.7 4–20 mA Current Loop

The 4–20 mA current loop is a widely used method for transferring information from one station (the transmitter) to another station (the receiver). Therefore, this system allows for only two stations. A typical current loop system assigns a sensing range (e.g., 0 °C–100 °C) to the current range between 4 and 20 mA. A loop exists (i.e., two wires) between the transmitter and receiver. The transmitter can impress a certain current in the loop (using a controlled current source) so that the receiver can measure the current in the loop (e.g., by placing a small resistor in series with the loop and measuring the voltage drop across the resistor). After measuring the current, the receiver can then determine the present level of the sensed signal within the defined sensing range. This method uses current signaling, instead of voltage signaling, and therefore is relatively unaffected by potential differences between the transmitter and the receiver. This is similar to the benefit of differential (voltage) signaling, which also requires two wires. Another characteristic of this method is that it is not primarily digital in nature, as many other sensor communication systems are. The measured value can vary continuously in the range of 4–20 mA and therefore can easily represent an analog sensing range, rather than a set of digital signals. Also, the signal is continuously variable and available. Another characteristic of this method is that the integrity of the loop can be verified. As long as the loop is unbroken and the transmitter is in good working order,

the current in the loop should never fall below 4 mA. If the current approaches 0 mA, then the receiver can determine that a fault exists—perhaps a broken cable. These systems are widely used in various process control industries (e.g., oil refining) for connecting sensors (transmitters) with control computers. Because one station is always the transmitter and one station is always the receiver, this is a unidirectional, half-duplex communication system.

15.3.8 HART*

HART® is a protocol that builds upon 4–20 mA communication systems. The basic idea is that additional data (beyond the basic sensor signal being carried in the current loop) can be transmitted by modulating a signal on top of the current flowing in the loop. The actual modulation method conforms closely to the Bell 202 standard for analog modem communications on telephone lines at 1200 bit/s. Because a 4–20 mA current loop carries a relatively slowly varying signal, it is easy to separate the 4–20 mA signal from the digital signal using filters. The Bell 202 standard uses continuous-phase frequency shift keying between two frequencies at up to 1200 shifts/s to modulate digital ones and zeros onto the 4–20 mA current loop. This method allows for bidirectional, full-duplex communication between the two stations, on top of the 4–20 mA signal. It is also possible to configure HART communications on a network that is not carrying a 4–20 mA signal, in which case up to 15 devices can be connected together on the network. HART was developed by Fisher-Rosemount Corporation and has been transferred to an independent foundation for management [13]. Because HART is compatible with US telephone systems, it can theoretically be run over the telephone line and is therefore capable of running over arbitrarily long distances.

15.3.9 Profibus

Profibus (PROcess FIeld BUS) is one of three networks standardized by a European standard [14]. Profibus is under the control of a global organization, PNO [15]. Profibus is an umbrella network standard that encompasses three subnetworks within the Profibus family. Profibus DP is the variant that is designed specifically for communication with field devices (sensors and actuators) at the device I/O level. Profibus process automation (PA) is a variant that has more capabilities designed to support the needs of device-level networking for process industries, such as oil refining. One of the capabilities of Profibus PA is its ability to be installed in an intrinsically safe (IS) way, thus providing a higher degree of safety in environments that may be explosive or otherwise hazardous. Profibus PA typically uses a special physical layer specification standardized under IEC 61158-2, which is used by several network systems for process automation applications. IEC 61158-2 specifies a two-wire twisted pair implementation carrying both power and data on the same two wires at 31.25 kbit/s. Profibus FMS represents the highest level implementation, which is used to link together controllers (not field or I/O devices) in a factory.

Profibus DP systems are typically master–slave systems, where usually a single network master (the host controller) communicates with a number of slave devices (remote I/O blocks and other I/O devices). The protocol provides for cyclic exchange of I/O information as well as on-demand exchange of other types of information. Profibus DP can be implemented on several different physical layers, including RS-485 and fiber optics, at various bit rates up to 12 Mbit/s. Profibus messages include a CRC for error detection.

15.3.10 Foundation Fieldbus

Foundation fieldbus (FF) is a networking standard that has grown out of an effort within industry standards organizations, especially ISA-SP50 [16] and IEC SC65C/WG6 [17], to provide a replacement for the 4–20 mA analog sensor communication standard. FF provides two basic levels of networking: H1 and H2. H1 is a

* HART is a trademark of the HART Communications Foundation.

lower-speed system that can provide IS operation and uses a single twisted pair to deliver both power and data communications to field devices, according to IEC 1158-2. Running at a bit rate of 31.25 kbit/s, H1 is very similar to Profibus PA, when run on the IEC 1158-2 physical layer standard. The H1 system is designed to be able to connect hierarchically "upward" to an H2 system, which acts as the host. FF H2 can be run at either 1 or 2.5 Mbit/s on twisted pair wires and also provides an IS option at the 1 Mbit/s rate. The H2 system can act as a network backbone in a factory environment, carrying data among various H1 systems.

15.3.11 WorldFIP

WorldFIP [18] is another technology of the three that were standardized in the European standard EN 50 170, running on the IEC 1158-2 physical layer. Many of the proponents of WorldFIP have embraced FF and contributed to the development of that standard. WorldFIP is a member of the FF, and FF has incorporated many of the capabilities of WorldFIP as a result. When run on the IEC 1158-2 physical layer, WorldFIP has similar capabilities to FF.

15.3.12 LonWorks*

LonWorks® is a networking technology developed and controlled by the Echelon Corporation [19]. LonWorks is designed to be a general-purpose networking technology suitable for a variety of industries. LonWorks has been applied extensively in the building automation and control industry, as well as a variety of other industries. The core LonWorks technology for devices is contained in special integrated circuits—called Neuron® chips—which combine several microprocessors to manage the network and communications and provide a general-purpose control environment. These chips are available from Motorola, Inc., and the Toshiba Corporation, which are licensees of the LonWorks technology. Echelon has also announced the possibility to license the LonTalk® protocol to other manufacturers for implementation in other microprocessors. LonWorks networks can be implemented on a variety of physical layers, including twisted pair at several bit rates and wireless options at 4800 bit/s, but the most common is a differential twisted pair system running at 78 kbit/s. Most of the networking details (the LonTalk protocol) are hidden from the user and are encapsulated as functions within the general-purpose control environment. The user programs (using a language like the C programming language) the Neuron chip for each station to behave in a certain way and communicate various data items to other stations. Then, specialized tools are used to tie all of the stations together (handling addressing and other network details) to yield a functioning network. The system combines flexibility with a certain amount of ease of implementation and can easily be applied to a variety of applications.

15.4 Applying Network Communications

15.4.1 Shielding

Many communication networks require shielding of the media (the cable). Shielding constitutes an electric conductor that completely encases the communication media (e.g., twisted pair) to provide protection against EMI. Shielding provides an electric conductive barrier to attenuate electromagnetic waves external to the shield and provides a conduction path by which induced currents can be circulated and returned to the source, typically via a ground reference connection. Shields in communication systems are often grounded at only a single point. This single point of ground prevents the shield from participating in a "ground loop," which is an alternative path for current to flow between two points of potential difference connected to a common ground. Ground loops can lead to noise problems and can be destructive if the stray currents are large enough, since a shield ground is usually not constructed to carry heavy currents.

* LonWorks, LonTalk, and Neuron are trademarks of the Echelon Corporation.

15.4.2 Media

The most common media types for network systems fall into three categories: electric, optical, and electromagnetic. Electric media are based on conductors (e.g., copper wire), whereas optical media are based on optical waveguides or fiber optics. Electromagnetic media consists of free space, or general electromagnetic wave-permeable materials, and are referred to as wireless systems. Within the category of electric media are a large variety of conductor configurations. The most common are unshielded pair, unshielded twisted pair (UTP), shielded twisted pair (STP), and coaxial (COAX). These conductor configurations have various properties that are significant for the transmission of electric signals, as well as varying degrees of immunity to EMI. As a rule of thumb, the quality of the transmission line characteristics (signal transmission and immunity to EMI) improves in the order listed. Twisted pair systems are generally easier to install, whereas coaxial and fiber-optic systems generally require more specialized tools and termination methods. Of course, wireless systems are easy to install, but attention must still be paid to the media. The characteristics of the free space such as distance and amount of EMI present must be considered for reliable operation of the network.

15.4.3 Bit Rate

Some networks provide only one choice of bit rate, whereas others provide user-selectable options for bit rate. Bit-rate options may be dependent on the type of media that is installed. As a rule of thumb, the bit rate chosen should be the lowest possible bit rate that still supports the application requirements for speed of data transfer and overall bandwidth. This generally results in more reliable operation and generally gives the network more immunity to minor degradations, specification violations, and EMI.

15.4.4 Topologies

There are a variety of network topologies that are commonly used. Topology refers to the physical arrangement and interconnection of stations by the media. Some networks can be run using several different topologies; some can only be run with a certain topology (e.g., Interbus-S requires a ring topology). The most common topologies are daisy chain, trunk line–branchline, ring, and star. Variations on these exist, and networks that incorporate or can be run on highly varied topologies are sometimes called free-form, tree, or free topology networks. Figure 15.4 depicts graphically several different types of topologies. In some cases, networks require certain topologies. Deviating from these can cause degradation in network behavior (e.g., corruption of messages) or network failure.

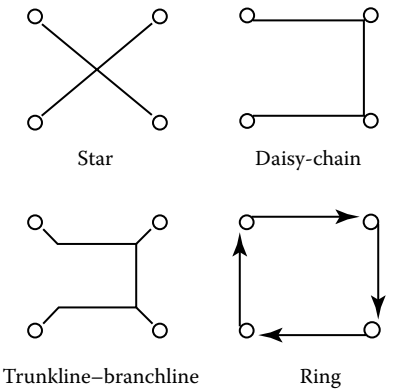

FIGURE 15.4 Some examples of the many possible network topologies using four stations.

15.4.5 Configuration

Most networks involve some sort of configuration. Configuration is the process of connecting stations together and assigning certain programmable parameters to each station required for proper operation of the network. The most common configurable parameter in many networks is the station address. Some networks may require other parameters to be preset, such as the communication speed or bit rate. Some networks have the capability to autoconfigure, which means to assign parameters automatically to stations as part of the network start-up process, without explicit user intervention (e.g., Interbus-S). Many networks define various tools, which may be computer based, to assign parameters to each station in order to configure the network. In other cases, the stations may incorporate switches or other manual means to configure the necessary parameters for network operation.

15.5 Recent Advances

15.5.1 Wireless Technologies

The need for networking is present even in environments where an electrical or optical cable cannot be easily distributed. This may be due to various limitations, such as difficulty in running a new cable from one building to another or connecting to sensors in motion or on vehicles. There are two general categories of wireless communications, based on electromagnetic frequency spectra. Various wireless technologies employ the infrared spectrum. These technologies generally have transmission limited to applications that have a direct line of sight between stations. Also, the distances are generally limited to 100 m or less. Because of these limitations, there are generally no legal restrictions in employing these frequency spectra, and infrared transceivers are now becoming available from a variety of manufacturers.

The other general category of wireless communications is based on RF communications. In most countries, the use of these spectra is tightly controlled by governmental agencies. As a result, employing wireless networking in most of these frequency ranges requires special licensing. However, a number of frequency ranges are reserved for low-power public communications. Within these frequency ranges, devices are allowed to communicate in an unlicensed fashion as long as they transmit according to certain rules about transmitted power output. RF-based wireless systems are generally not limited to line-of-sight applications and can be designed to cover greater distances than infrared-based systems.

Wireless technologies can be viewed as simply another choice for the physical layer media, that is, free space. As such, it is possible to consider, in some cases, a wireless media for implementation of a variety of protocols. For example, both CAN and LonWorks systems could be candidates for wireless networking.

15.5.2 Fiber Optics

Another physical layer media choice is fiber-optic media. Fiber-optic media employs pulses of light delivered along a tubular waveguide (glass or plastic fiber) to transmit information from one station to another. Fiber optics enjoy some benefits over traditional copper wiring. First, attenuation of light within fiber optics is generally about an order of magnitude less than attenuation of an electric signal within a copper wire. Second, fiber-optic transmission systems can be modulated (or pulsed) at much higher frequencies, yielding greater potential bandwidths and bit rates than copper media. Finally, fiber-optic systems are generally immune to the traditional sources of EMI that can cause trouble for copper media systems. There are also limitations in present implementations of fiber-optic systems. One of the limitations is that special tools and termination techniques must be used to connect a fiber-optic cable to a sensor or field device. Second, fiber-optic "taps" are not easily created. Therefore, most fiber-optic systems are implemented in a point-to-point fashion. When multiple devices are involved in a network, each device usually acts as an optical repeater, with a fiber-optic input and a fiber-optic output port.

15.5.3 Network Design Considerations

Designing a network communication system from the ground up can be a lengthy undertaking and should not be considered unless a careful review of available technologies has yielded no solutions to the particular requirements of the application. The designers must take into account a number of fundamental questions to shape the capability of the network. One topic mentioned frequently in the area of networking for control applications is the subject of determinism. This refers to the ability of the network to behave in a predictable fashion under any given set of stimuli or external conditions. Many networks do not exhibit this characteristic. Another question to be resolved is the subject of priority and media access. The designers must determine the conditions under which any particular station is allowed to transmit, and if multiple stations are attempting to transmit, how it will be determined which station will be given priority to transmit first. Media access methods often impact the ability of a network to behave in a deterministic fashion.

15.5.4 Integrating Sensors with Communications: IEEE P1451

A recent interesting development in the area of sensor networks is an effort being sponsored by the IEEE [20] out of its TC-9 committee, called IEEE P1451. This activity is working toward the development of a standard to define sensor (or transducer) interfaces to networks generically. The first part of the proposed standard, IEEE P1451.1, includes definitions for the interface between the device and the network (refer to Figure 15.1). The second part, IEEE P1451.2, includes definitions for the interface between the transducer (or sensor) and the network interface block within the device. P1451.2 includes a definition for a transducer electronic data sheet (TEDS), which defines a summary set of information pertinent to the sensor, allowing for standardized exchange of data on the network. The proposed standard has the potential benefits to make it easier to connect a sensor to a variety of networks and to allow similar sensors from different manufacturers to be handled in a similar fashion on the network.

Electrical Variables

16

Electric Current Sensors*

Pavel Ripka
Czech Technical University in Prague

16.1 Introduction

Current sensors are required for numerous applications, including

- Industrial applications—large ac and dc currents
- Car applications: special requirements for hybrid cars
- Energy production, conversion, storage, and consumption
- Current leakage monitoring
- House automation
- Motor drives, power converters, and power modules
- Current sensors embedded in ICs

The basic literature on current sensors is a book by Iwansson [2] and comprehensive review articles [1,3]. Contactless current sensors are based on magnetic sensors that are covered by [4].

* This chapter is based on an abbreviated paper [1] with kind permission of IOP.

16.2 Basic Current-Sensing Parameters

The basic parameters of any sensor are *linearity*, *offset* (for dc sensors) and *sensitivity*, and also stability of offset and sensitivity with temperature and time. Also important is the sensor bandwidth (or frequency characteristics), as current waveforms often contain high-frequency component. Current sensors with ferromagnetic yoke or field concentrators also suffer from *hysteresis* and *perming* (change in offset after the sensor is overloaded).

Wide bandwidth: a large frequency range from dc to several MHz is required for applications in switching power converters.

High dynamic range and resistance against overload is another important parameter. Accuracy is often required even for a small fraction of the full scale. One example is the requirement to measure the current consumption of the house in the standby mode and during full operation.

Immunity against dV/dt is critical for use in modern power modules. Current sensors located close to fast-switching transistors can be subjected to transients of 10 kV/μs. Such transients can be coupled by parasitic capacitances to the output of the current sensor. Proper electrostatic shielding can efficiently suppress this effect, but it complicates the design of the sensor.

Low cost and high environmental resistance is a must for industrial sensors.

16.3 Geometrical Selectivity

Also important for contactless sensors is *geometrical selectivity*—the reading should be independent of the position of the measured conductor and the sensor should be resistant to external currents and magnetic fields [5].

The most common way to achieve geometrical selectivity is to use a closed magnetic circuit with a measured conductor inside. This is used in current transformers (CTs), fluxgate current sensors, and in most Hall current sensors. The high-permeability magnetic circuit (the yoke is often in the shape of a ring) concentrates all field lines from the measured current, so that the measured flux in the magnetic circuit does not depend on the actual position of the conductor. In this case, H in the yoke central line l is constant, and we can write

$$H \times l = N \times I \tag{16.1}$$

where

I is the measured current
N is the number of turns

The magnetic circuit also shields against external fields.

The best magnetic circuit for a current sensor is a toroid made from high-permeability material without an air gap. This is used in CTs and in some residual current sensors.

It is important to use a high cross-sectional area of the magnetic material to keep a high demagnetization factor against external fields.

The magnetic yoke should not be saturated, that is, $l > NI/H_{sat}$. This means that the magnetic circuit becomes very large for high measured currents. Air gaps can be introduced to avoid saturation, but these degrade the geometrical selectivity. Another approach is to compensate the measured current using a multiturn coil. However, generating the compensation current requires power.

Magnetic gradient techniques can be used if the power or space limitations do not allow the use of a yoke. Simple integrated current sensors use a folded conductor and a gradient field sensor. This suppresses the response from distant sources, giving a low gradient. For large currents,

the current bar should be kept straight, and circular arrays of typically four to eight sensors are used [6]. More complex weight sum field decoupling method allows using sensor arrays of different shapes [7].

16.4 Overview of Electric Current Measurement

16.4.1 Definitions and Standards

Electric current is caused by movement of charge, and in the older MKS system it was therefore naturally defined as a derived unit. In the present SI unit system, the Ampere is the fundamental unit that is realized using the current balance. A much more practical realization of the Ampere is via Ohm's law from the volt and the Ohm, which are easily reproducible using the Josephson junction and the quantum Hall effect.

The proposed new definition of the Ampere is a return to the natural concept based on elementary charge and time.

National metrology institutes offer calibration of current sensors with minimum expanded uncertainty of typically 10 μA/A for dc currents and 100 μA/A for ac currents. The ac current ratio is calibrated with minimum expanded uncertainty of 5 ppm in ratio error and 5 μrad in phase displacement.

16.4.2 Current Shunts and Other Contact Methods

The disadvantages of current shunts are obvious: the measured current has to be interrupted to introduce the sensor, shunts for large currents are bulky, they dissipate heat, and the output is galvanically connected with the measured circuit. However, current-sensing resistors are a robust and cheap solution for many applications. Self-made coaxial current shunt with minimum inductance and wide frequency bandwidth can easily be made from a set of metal resistors in parallel [8].

If precision is not a critical consideration, the current can be measured even through the voltage drop across a current-carrying copper trace or bus bar. In power converters, the current is often measured as a voltage drop across the inductance or less precisely using a voltage drop across the power switch or more precisely using a sensing MOSFET, which is matched with the power MOSFET, but has much lower channel width [9].

In order to measure very small currents, the value of the current-sensing resistor should be increased so that the measured drop is measurable. For measuring picoamps and lower currents, a current-to-voltage converter (Figure 16.1) with op-amp is preferred. The range is changed by output divider R_A, R_B rather than by changing the feedback resistor R_F.

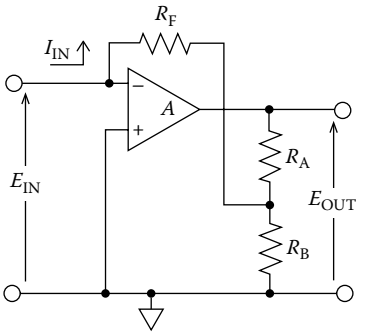

FIGURE 16.1 Current-to-voltage converter. (From Keithley, Inc., Low current measurements, AN 100, 2007, www.keithley.com.)

16.5 Contactless Sensor Principles

Current measurement using a shunt resistor is impractical or impossible in some cases. Contactless current sensors keep galvanic insulation between the measured current and their output voltage. A wide range of ac and dc contactless current sensors are produced by LEM, F.W. Bell, VAC, Honeywell, Telcon, and many other manufacturers. Magnetic field sensors can be used to measure currents in remote conductors at high potentials, in underground cables, and in building structures.

16.5.1 Instrument Current Transformers

A CT (or ICT) usually has a bulk ring core made of high-permeability material. For currents higher than 50 A, the primary winding is a single conductor through the core opening. The secondary winding should ideally be short-circuited; however, for most applications, it is connected to a small "burden" resistor, which serves for sensing the secondary current. The core is wound with high-permeability tape (for low-frequency devices) or is made from ferrite (for high-frequency current probes). In some devices, the secondary current is measured by active current-to-voltage converter in such a way that the burden is virtually zero. This leads to smaller error, as the transformer core works at lower flux density.

CTs are also made with an openable core, most often as ac current clamps for oscilloscopes or multimeters.

CTs are very popular devices:

- They are very simple and robust.
- They do not require external power.
- They have high galvanic insulation.
- They are cheap.
- They have a long lifetime with invariant parameters.

Figure 16.2 shows the equivalent circuit of the CT.

At low frequencies (such as 50/60 Hz), the dominant source of error is the magnetizing current I_L, which is inversely proportional to the frequency. To make this current small, one should make L_m large. This can be achieved by

- Using a core material with high permeability
- Increasing the core area
- Increasing the number of turns
- Virtually increasing the core permeability by a feedback [11]

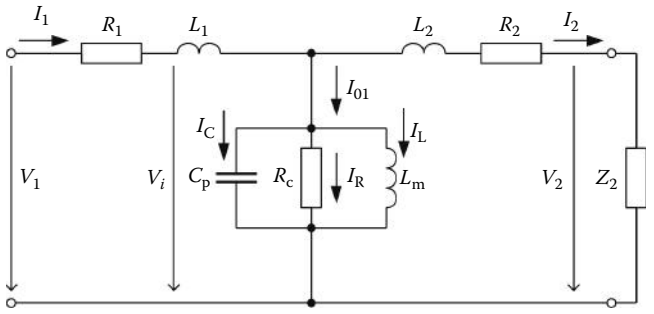

FIGURE 16.2 Equivalent circuit of the CT. R_1, R_2, L_1, and L_2 represent resistances and leakage inductances of primary and secondary windings; R_c is the resistance representing losses in the ferromagnetic core; L_m is the magnetizing inductance; C_p represents the parasitic capacitances of the winding; Z_2 is the burden; $I_L + I_R$ is the magnetization current. (From Ripka, P., *Meas. Sci. Technol.*, 21(11), 1, 2010.)

The magnetizing inductance L_m, together with secondary resistance R_2 and burden resistance R, forms a high-pass filter circuit. Simple approach to improve transformer accuracy at low frequencies is therefore to eliminate the burden resistance R by using a current-to-voltage converter [12].

Some CTs have almost a constant ratio error for a wide range of measured currents. In this case, the error can be compensated for by adding extra turns to the secondary winding. This is called turn error compensation. Transformers with such compensation show anomalous behavior—their error increases when the burden decreases. Magnetization of the CT core (e.g., due to a lightning strike) may also lead to increased errors when the measured current is small so that the CT core is not demagnetized [13].

At higher frequencies, parasitic capacitances between the turns and layers of the winding are the dominant source of error. Here, increasing the number of turns increases the error. For precise fast-CTs, amorphous cobalt-based cores or ferrite cores are used, which give high permeability at MHz frequencies. Such transformers are used to observe short beam pulses in particle accelerators. Bergoz manufactures transformers with cutoff frequencies up to 2 GHz.

CTs are often used in electronic watt and energy meters. For this application, it is very important to make them resistant against saturation—either from a strong permanent magnet or due to a dc component in the measured current [14]. Possible methods for avoiding such saturation are as follows:

1. Use flat-loop magnetic material, which has a very high saturation field H.
2. Use composite cores, consisting of a high-permeability ring for precision and a low-permeability ring for saturation immunity.
3. Detect saturation by other means.
4. Use a Rogowski coil instead of a CT, which has no magnetic core.

The composite high-permeability core gives low angular and amplitude error for most applications, but this is not guaranteed for all types of loads. Flat-loop materials do a better job, but these materials are expensive. It was recently shown that some cheap low-permeability rings can also be used for this application: they have a relatively large phase shift, but it is constant over the wide range of measured currents and can therefore be compensated [14].

Fe-based nanocrystalline alloys are promising materials for very precise small-size CTs.

16.5.2 Rogowski Coil

The Rogowski coil for measuring current is an air coil wound around the measured current conductor (Figure 16.3). The basic operating principle is given by the mutual inductance M between the primary (single turn) and the secondary (many turns). The output voltage is proportional to the derivative of the current:

$$V(t) = M\left(\frac{dI}{dt}\right) \tag{16.2}$$

The coil should be precisely manufactured with constant winding density and diameter. Ideally, a homogeneous coil has excellent geometrical selectivity, that is, it is insensitive to external fields and to the position of the measured conductor, as it follows Ampere's law in the open air:

$$\oint_C \vec{B} \cdot d\vec{l} = \mu_0 i_C \tag{16.3}$$

where the integration path C is the central line of the coil (usually a circle).

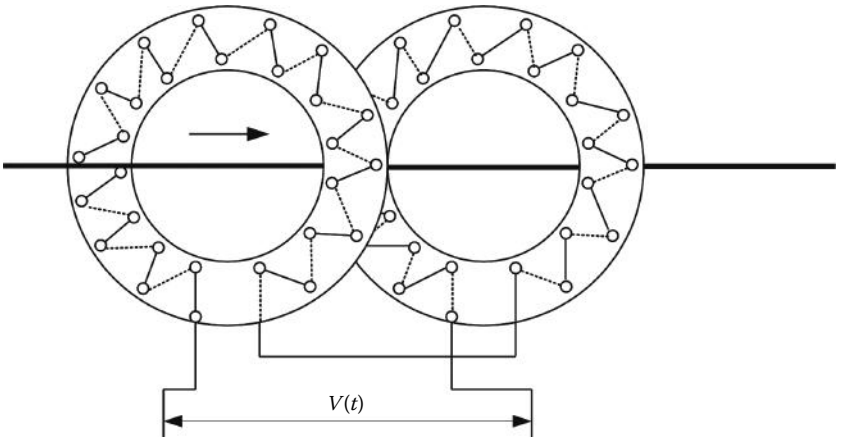

FIGURE 16.3 A Rogowski coil in PCB technology. Each layer is wound in the opposite direction to compensate for the loop created by turn advancement. (From Kojovic, L., High-precision Rogowski coils for improved relay protection, control and measurements, *The Line*, 7–8, 2002, http://www.cooperpower.com/Library/pdf/02049.pdf.)

In order to obtain the ac current waveform, a Rogowski coil is used together with an integrator. Single-chip digital integrators have been developed to process the signal of Rogowski coils (also known as *dI*/*dt* sensors) for energy meters. The use of an AD 7759 signal processor with built-in sigma–delta A/D converters gives 0.1% error from the measured value in the 1000:1 dynamic range [15].

The Rogowski coil contains no ferromagnetic material, and thus it has excellent linearity and an extremely large dynamic range. Users often rely on their linearity and use them to measure currents that are much higher than the currents used for calibration. Care should be taken with the geometry of the connecting bus bars and the return conductor to reduce the effect of magnetic coupling.

The Rogowski coil can be very simply temperature compensated [16].

Stationary Rogowski coils are used to measure ac or transient currents or changes in dc currents. For long-term measurements, the limiting factor is the offset drift of the integrator. It is also possible to measure dc current with an openable Rogowski coil: the output voltage is integrated while the coil is closed around the measured conductor.

Flexible Rogowski coils can be easily wound on top of a plastic cable with thick insulation, such as a coaxial cable with removed shielding. The inside conductor is used as a return loop, which compensates the perpendicular virtual loop created by the winding advance [17].

Rogowski coils are useful for measuring transient currents. The coil self-inductance and the parasitic capacitance form a resonant circuit. In order to increase the resonant frequency of this circuit, a lower number of turns should be used, which decreases the sensitivity. 1–3 MHz resonant frequency is typical for flexible coils, while multiturn solid coils may have resonance as low as 50 kHz.

Printed circuit board (PCB) technology was used to produce Rogowski coils with a more precise geometry and improved temperature stability. To compensate the virtual perpendicular loop, two PCB coils with opposite winding directions are connected in series. In order to achieve perfect compensation, it is important to design these two coils with the same diameter, as in Figure 16.3.

An improved twin-loop PCB Rogowski coil with a transfer ratio of 4 V/400 kA was used to measure the plasma current in the tokamak [19]. In this design, both coils are made in the same place, which means that one of them has a smaller diameter and thus the sensitivity to axial fields is not perfectly compensated.

High-frequency inductive current sensors are similar to Rogowski coils, but they use only a single turn as a secondary coil [20]. These sensors do not suppress external fields.

16.5.3 DC Current Transformers and Current Comparators

Classical CTs naturally measure only ac currents. DC CTs and dc current comparators use the fluxgate effect in a core that is periodically saturated by the excitation field. If no dc current is present, the core flux and also the voltage induced into the detection winding contain only odd harmonics. DC current shifts the magnetization characteristics, and the flux waveform is no longer symmetrical. This induces even harmonics proportional to the measured dc current. Usually phase-sensitive detectors are used to extract the second harmonics from the induced voltage. Dual core minimizes feedthrough of the excitation voltage into the measured circuit [21].

The accuracy of a typical commercial 40 A DC CT is 0.5%, linearity 0.1%, and current temperature drift <30 mA (–25 °C to 70 °C). Because of their low offset drift, fluxgate-based "DC CTs" are superior to current sensors that have a Hall sensor in the air gap. A disadvantage is the large power consumption of these devices. Top sensors of this type achieved linearity error of 10 ppm of FS, zero temperature drift of ±5 μA/°C, and resolution ±0.3 ppm of FS ±0.4 μA. Their frequency band is dc up to 100 kHz.

16.5.4 Hall Effect Current Sensors

Hall effect sensors are also known as Hall sensors. Many dc current sensors use a Hall element mounted in the air gap of a magnetic core (Figure 16.4). The yoke has two important effects: (1) increasing the sensitivity and (2) increasing the geometrical selectivity, that is, shielding the external fields and decreasing the influence of the position of the measured current.

Even when using a magnetic yoke, Hall current sensors are sensitive to external magnetic fields and nearby currents and also to the position of the measured conductor, due to the nonhomogeneity associated with the air gap.

A serious dc offset can be caused by the remanence of the magnetic core—only a few Hall current meters have an ac demagnetization circuit to erase perming after the sensor has been exposed to a large dc current or external field.

In general, the yoke material should have large saturation induction B_s and low coercivity H_c. A widely used material is a cheap grain-oriented FeSi, and for precise applications 50% Ni–Fe alloy is used. By proper annealing, the coercivity of 50% Ni–Fe can be decreased below 2 A/m. The nonhomogeneity of magnetic materials has an influence on the linearity of open-loop current sensors. By increasing the air gap, the influence of this nonlinearity is decreased, as is the influence of the remanence. The hysteresis error is approximately 0.2%–0.5% for a 1 mm air gap and different

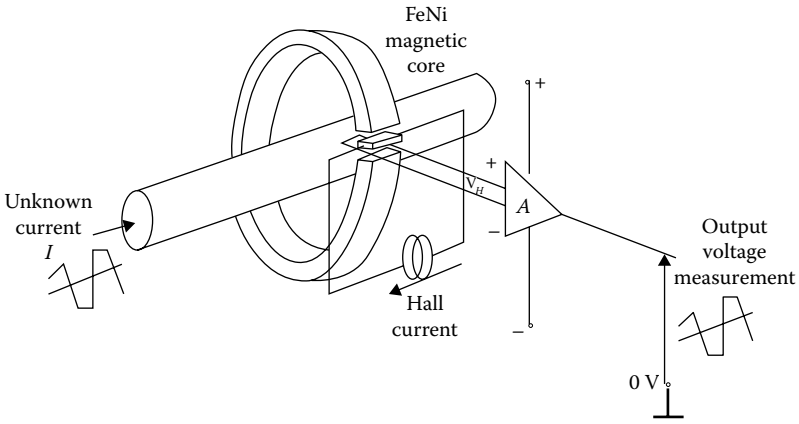

FIGURE 16.4 A Hall dc current sensor in open-loop configuration. (From *J. Magnet. Magnet. Mater.,* 304(2), Waeckerlé, T., Fraisse, H., Furnemont, Q., and Bloch, F., Upgrade Fe-50%Ni alloys for open-loop dc current sensor: Design and alloy-potential characteristics, e850, Copyright 2006. With permission from Elsevier.)

grades of 50% Ni–Fe [22]. However, a larger air gap leads to unwanted sensitivity to the position of the measured conductor within the core and also reduces the suppression of external currents and fields.

The sensor linearity can be increased by using the feedback principle. Feedback-compensated devices cancel the field in the yoke by using multiturn compensation winding. These sensors can achieve 0.02% error and a temperature coefficient of sensitivity of only 50 ppm/K. However, the main weak point is still the limited zero stability due to the Hall sensor offset: the typical offset drift of a 50 A sensor is 600 mA in the (0 °C–70 °C) range. This parameter is 20 times worse than that of fluxgate-type current sensor modules.

Some Hall current sensors use *field concentrators*, which increase the measured field but do not completely surround the measured current. In this case the danger of saturation is much lower, but the position of the measured conductor should be fixed, and suppression of the external fields and currents should be achieved by other means. A low-cost current sensor based on a highly sensitive Hall sensor with simple integrated flux concentrators is described in [23] (Figure 16.5). The field concentrators transform a lateral field locally into the vertical direction (Figure 16.6). The sensor is manufactured by

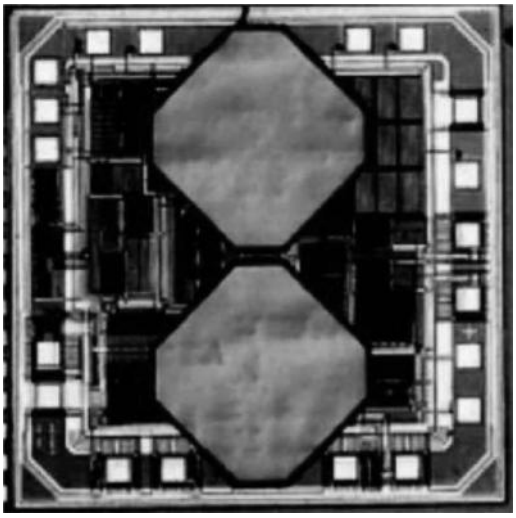

FIGURE 16.5 Internal structure of the CMOS integrated Hall magnetic sensor with twin integrated magnetic concentrators. (Courtesy of Sentron AG, Zug, Switzerland.)

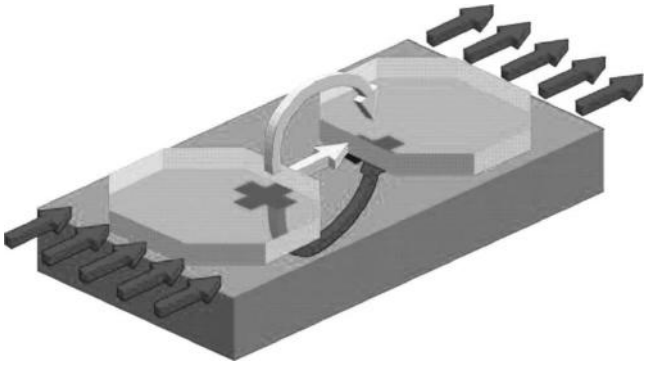

FIGURE 16.6 Field concentrators deflect the flux into the vertical direction. The two small crosses under the concentrators are Hall sensors. (Courtesy of Sentron AG, Zug, Switzerland.)

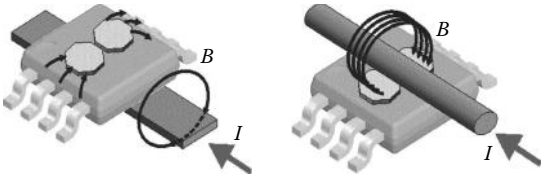

FIGURE 16.7 Current-sensing application of the CMOS integrated Hall magnetic sensor for a PCB conductor and a free-standing conductor. (Courtesy of Sentron AG, Zug, Switzerland.)

Sentron (Melexis group) with 1% accuracy in the ±12 A range. It can be used to measure the currents in both PCB conductors and free-standing conductors (Figure 16.7).

A *yokeless current transducer* with six Hall probes around the rectangular bus bar achieves 0.5% linearity and 0.2% temperature stability in the 100 kA range. Close conductors are typically suppressed by a factor of 100. An integrated current sensor based on two Hall sensors placed on both sides of the current strip was developed by Frick et al. [24]. The differentially connected Hall sensors reject the common-mode interference from the external magnetic fields. Proper autobalancing is achieved using built-in calibration coils. The achieved accuracy was 0.5% in the 5 A range with 1.5 kHz bandwidth.

Some current sensors use a combination of a Hall sensor (for the dc and low-frequency component) and a CT (for the high-frequency component), using a gapped ferrite core. A frequency range of 30 MHz was achieved for 40 A range [25].

The background calibration using integrated coils together with the spinning current technique can reduce the temperature sensitivity drift of the Hall sensor to less than 50 ppm/°C, while the bandwidth can be still as high as 500 kHz. Sensitivity variations due to mechanical stresses and ageing are also compensated [26]. This technique can significantly improve the performance of current sensors, even if feedback compensation is not possible.

16.5.5 AMR Current Sensors

These sensors employ anisotropic magnetoresistance effect. They have higher resolution than Hall sensors, but their sensing direction is in the chip plane, so they cannot be built into the narrow air gap in the magnetic yoke. Yokes with a large air gap suffer from field leakage sensitivity to external currents and magnetic fields. Thus, most current sensors based on AMR magnetoresistors are yokeless. The popular configuration is again a bridge measuring the magnetic gradient from the current, since it is resistant against homogeneous external magnetic fields (e.g., from distant currents). The bridge also suppresses the temperature variation of the electric resistivity of the magnetoresistive material (Figure 16.8). This type of sensor usually has the current conductor integrated with the sensors in a single device to ensure stable geometry. The bridge has all the barber poles in the same direction, which means it is made insensitive to a homogeneous external field but sensitive to measured current through the bus bar. The measured current can be compensated by a feedback current through a compensation conductor. A typical application is a galvanically isolated current sensing in a pulse width modulation (PWM) regulated brushless motor. These sensors are manufactured by Sensitec (also under the F.W. Bell label) with ranges from 5 to 220 A. The achieved linearity is 0.1%, temperature coefficient of sensitivity is 100 ppm/K, and the offset drift in the (−45 °C to +85 °C) range is 1.4% FS.

Similar sensors were developed with a giant magnetoresistance (GMR) detector (which employs GMR) and other types of magnetoresistors such as TMR, but they did not achieved the precision of AMR current sensors. The main obstacle is even characteristics of these sensors, which requires bias field and also hysteresis and nonlinearity of these sensors.

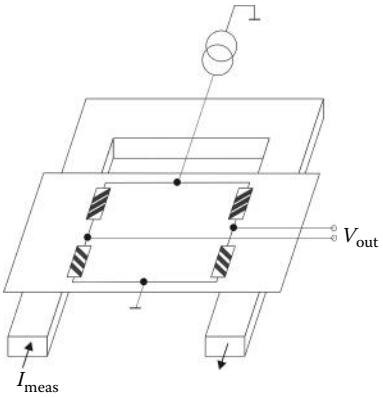

FIGURE 16.8 An AMR current sensor. (From Ripka, P., *Meas. Sci. Technol.*, 21(11), 1, 2010.)

16.5.6 Magneto-Optical Current Sensors (Including Fiber-Optic)

Optical current sensors have several advantages that are very attractive for power distribution applications:

1. Effective isolation from high potentials
2. Immunity against electromagnetic interferences
3. High dynamic range, no saturation effects
4. High bandwidth
5. Compact and lightweight design

These features offer a significant cost reduction in comparison to conventional high-voltage CTs. A good review of these sensors is [27].

Most optical current sensors are based on the Faraday effect—either in bulk material or in an optical fiber. The polarization plane of a linearly polarized light that travels through the magneto-optical material is rotated by angle α, which depends on magnetic field along the optical path. If the optical path is closed around the current I, α depends linearly on I and the sensor is insensitive to other currents.

16.5.6.1 Bulk Magneto-Optical Sensors

Magneto-optical point sensors (or unlinked sensors) use a piece of glass or a crystal rod placed in the neighborhood of the electric conductor [28]. The sensor is usually interrogated by optical fibers. These devices are robust, cheap, and sensitive. They belong to the class of "extrinsic fiber sensors," that is, sensors that use optical fibers for transmission, not for sensing. These sensors are employed in the first generation of the ABB magneto-optic current transducer (MOCT), which serves since 1995 in industrial applications. The ABB sensor achieves an accuracy class of 0.2 A in the 3000 A range.

The triangular prism bulk magneto-optical sensor has a closed sensing optical path around the measured conductor. This provides independence of the sensor output from the position of the measured conductor within the closed path and also resistance to external conductors and external homogeneous magnetic fields.

16.5.6.2 All-Fiber Sensors (or Intrinsic Fiber Sensors)

In wound fiber devices, too, the magneto-optical material encloses the electric conductor, and thus these sensors are not sensitive to external currents and magnetic fields.

Optical fiber is made from materials that have much lower sensitivity than the magneto-optic crystals used for bulk sensors, but their sensitivity can be increased by using a higher number of turns of the fiber wound around the measured conductor. Fiber-optic sensors are simple devices; they suffer from the spurious birefringence induced in bent fibers [29].

Commercially available all-fiber current sensors are manufactured by ABB since 2005. These devices also use two circularly polarized light waves travelling in the same direction. The phase difference caused by the magnetic field is measured by the interferometer. This configuration effectively suppresses the bending-induced linear birefringence in the fiber. The measuring range is 600 kA, corresponding to 360° phase difference, while the resolution is 0.25 A. The sensitivity can be increased by using multiple turns of the optical fiber around the measured conductor. Great care was taken to insulate the measuring fiber from mechanical stress and vibrations, as this is a major source of temperature sensitivity drift.

Similar sensors were developed for measuring large dc currents: the achieved accuracy is 0.1% for currents up to 600 kA [30].

16.5.6.3 Other Types of Extrinsic Fiber-Optic Current Sensors

These sensors utilize optical fibers for galvanically isolated connection to a nonoptical current sensor such as Rogowski coil [31]. The required electric supply energy can be converted from the incoming light.

16.6 Other Types of Current Sensors

16.6.1 Superconducting Current Sensors

Superconducting quantum interference detector (SQUID) magnetoencephalographs measure the fT fields produced by neural currents in the brain. SQUIDs can also be used to measure the small currents that pass through a coil inductively coupled to the SQUID loop. The SQUID should be shielded against external magnetic fields or made as a gradiometer with a very short baseline. SQUIDs normally measure only flux changes, but an array of SQUIDs can be used to build an absolute current sensor with 1 nA resolution. As the SQUID is a nonlinear device (the voltage-flux characteristic is similar to a sine wave), the flux should be compensated by a flux-locked loop. This is a technical problem at higher frequencies. A noise level of 7.4 pA/√Hz up to 10 MHz was achieved using a two-stage SQUID instead of an external op-amp [32].

16.6.2 Magnetometric Location and Measurement Hidden Currents

The field from a long straight conductor decreases with $1/r$, assuming that the return conductor is at a large distance. If this is not the case, the magnetic field is lower, and it should be calculated from the actual geometry. The other extreme is a small current loop, which creates a field decreasing with $1/r^3$ distance. Underground electric conductors can be located and their current can be remotely monitored by measuring their magnetic field at several points. In the case that the cable contains both forward and return currents, it can be detected only from a small distance, and the current value cannot be measured.

Sensitive magnetic sensors such as fluxgates should be used. It is an advantage if the sensor is vectorial.

16.7 Current Clamps

Current clamps usually have an openable magnetic yoke, so they can be mounted without interrupting the measured conductor. The role of the yoke is again to concentrate the field lines so that the sensor reading is not dependent on the actual position of the clamped conductor and the device is insensitive to unclamped conductors.

AC clamps are usually based on CT principles. The measured conductor forms the primary winding, and the multiturn secondary winding is terminated by a small frequency-independent resistor.

DC clamps are usually based on a Hall sensor in the air gap. These devices may have 10 mA resolution, but the maximum achieved accuracy is typically 30 mA, even if they are of the compensated type. Their main disadvantage is unwanted sensitivity to external fields, due to the air gap in the magnetic circuit that is necessary for the Hall sensor. Even the change of position with respect to the Earth's field causes significant error, and the offset should be manually nulled.

Not only traditional clamps but also flexible sensors can form an openable magnetic circuit. The most popular are flexible Rogowski coils as discussed earlier.

16.8 Discussion and Conclusions

Shunt resistors are still widely used, but they are very large and power consuming for high currents.

Traditional dc and ac contactless current sensors are available for ranges from mA to kA with precision from 3% (uncompensated Hall current sensors) to 0.1% (compensated Hall devices and magnetic amplifiers). Higher precision is easily achievable with current comparators. Current sensors based on the AMR effect are very promising. If the measured current does not have a dc component, CTs and *di*/*dt* sensors (Rogowski coils) are the best choice.

For kA and larger currents, Faraday effect current sensors are attractive, as they are smaller and lighter than traditional sensors and they also have significantly lower power consumption. For smaller currents, optical sensors are not competitive with other sensor types: they are expensive, and they would require many turns of the fiber cable to achieve the required sensitivity.

Nonlinear System Modeling with Invariance to Fourier Transform for Fault Diagnosis: Application to Power Transformers

Gerasimos Rigatos
Harper Adams University College

Pierluigi Siano
University of Salerno

17.1 Introduction

A neural network with basis functions that remain invariant under the Fourier transform is proposed for fault diagnosis of nonlinear systems. The considered neural network is of the feedforward type and uses Gauss–Hermite polynomial basis functions. This neural model follows the concept of wavelet networks [1–3] and employs basis functions that are localized both in space and frequency, thus allowing better approximation of the multifrequency characteristics of monitored nonlinear system [4–8]. Gauss–Hermite basis functions have some interesting properties [9,10]: (1) They remain almost unchanged by the Fourier transform and satisfy an orthogonality property, which

means that the weights of the associated neural network demonstrate the energy that is distributed to the various eigenmodes of the nonlinear system's dynamics, and (2) unlike wavelet basis functions, the Gauss–Hermite basis functions have a clear physical meaning since they represent the solutions of differential equations describing stochastic oscillators (see [11]) and each neuron can be regarded as the frequency filter of the respective eigenfrequency.

The concept of the proposed fault detection and isolation (FDI) technique is as follows: The neural network with Gauss–Hermite polynomial activation functions is used for approximating the nonlinear system's dynamics out of a set of input–output data. Thus, the output of the neural network provides a series expansion that takes the form of a weighted sum of Gauss–Hermite basis functions. Knowing that the Gauss–Hermite basis functions remain unchanged under the Fourier transform, subjected only to a change of scale, one has that the considered neural network provides the spectral analysis of the output of the monitored system. Actually, the squares of the weights of the output layer of the neural network denote the distribution of the energy of the monitored signal from the nonlinear system into the associated spectral components. Moreover, since Gauss–Hermite basis functions satisfy an orthogonality property, the sum of the square of the output layer weights of these neural networks stands for a measure of the energy contained in the output of the monitored system. By observing changes in the amplitude of the aforementioned spectral components of the nonlinear system's dynamics, one can have also an indication about malfunctioning of the monitored system and can detect the existence of failures. Moreover, since specific faults are associated with amplitude changes of specific spectral components of the system, fault isolation can be also performed.

The proposed FDI method can be applied to several electromechanical systems, for example, vehicles, electric motors, and power generators. In this chapter, as a case study, the problem of fault diagnosis of electric power transformers is considered. Significant information about the thermal condition of oil-immersed power transformer and about their ageing and failure risks can be obtained through monitoring of the transformer's hot-spot temperature (HST). The HST can be measured with the placement of sensors at a specific point of the mineral oil volume that serves as both the insulating and cooling material for the transformer's functioning. A deviation of HST from the anticipated temperature profile is probably an indication of ageing of the transformer or in some cases of prefailure situations. Analytical and numerical (neural/fuzzy) models for HST have been developed [12–15]. These models associate the HST to inputs such as the ambient temperature, the top-oil temperature (TOT) rise over the ambient temperature, and the maximum winding hot-spot rise over the TOT. By modeling the HST variations with the use of neural network that contains Gauss–Hermite polynomial basis functions, one obtains (1) a numerical model that associates the HST with other parameters of the power transformer such as ambient temperature, TOT, and load current and (2) indications about the spectral characteristics of the HST signal and the distribution of its energy content to various spectral components associated with the basis functions. By recording changes in the amplitude of these spectral components, one can detect the existence of failures in the power transformer and can identify which are the components of the transformer that are responsible for malfunctioning.

The structure of the chapter is as follows: In Section 17.2 FNNs are analyzed and their use in nonlinear systems modeling is explained. In Section 17.3 FNNs with Gauss–Hermite activation functions are introduced and their distinctive properties are explained such as orthogonality of the basis functions and invariance to Fourier transform. In Section 17.4 basic principles of signals spectral analysis are presented and the use of Fourier transform in calculating a signal's energy content and power spectral density is explained. In Section 17.5 modeling issues for condition monitoring of electric power transformers are analyzed. In Section 17.6 the use of neural networks with Gauss–Hermite basis functions in modeling the thermal dynamics of electric power transformers is explained. It is shown how these neural networks enable spectral analysis of the HST signal and how based on this signal's spectral content one can perform FDI for the power transformer. Finally, in Section 17.7 concluding remarks are stated.

17.2 Feedforward Neural Networks for Nonlinear Systems Modeling

The proposed fault diagnosis approach for nonlinear dynamical systems can be substantiated with the use of FNNs. FNNs serve as powerful computational tools in a diversity of applications including function approximation, classification, and pattern recognition. When equipped with procedures for learning from measurement data, they can generate models of unknown systems. FNNs are the most popular neural architectures due to their structural flexibility, good representational capabilities, and availability of a large number of training algorithms.

The idea of function approximation with the use of FNNs comes from generalized Fourier series [16]. It is known that any function $\psi(x)$ in an L^2 space can be expanded, using generalized Fourier series in a given orthonormal basis, that is,

$$\psi(x) = \sum_{k=1}^{\infty} c_k \psi_k(x) \quad \alpha \le x \le \beta \tag{17.1}$$

Truncation of the series yields in the sum

$$S_M(x) = \sum_{k=1}^{M} a_k \psi_k(x) \tag{17.2}$$

If the coefficients a_k are taken to be equal to the generalized Fourier coefficients, that is, when $a_k = c_k = \int_a^b \psi(x)\psi_k(x)dx$, then Equation 17.2 is a mean square optimal approximation of $\psi(x)$.

Unlike generalized Fourier series, in FNN the basis functions are not necessarily orthogonal. The hidden units in an FNN usually have the same activation functions and are often selected as sigmoidal functions or Gaussians. A typical FNN consists of n inputs x_i, $i = 1, 2, \ldots, n$, a hidden layer of m neurons with activation function $h{:}R \to R$, and a single output unit (see Figure 17.1a). The FNN's output is given by

$$\psi(x) = \sum_{j=1}^{n} c_j h\left(\sum_{i=1}^{n} w_{ji} x_i + b_j\right) \tag{17.3}$$

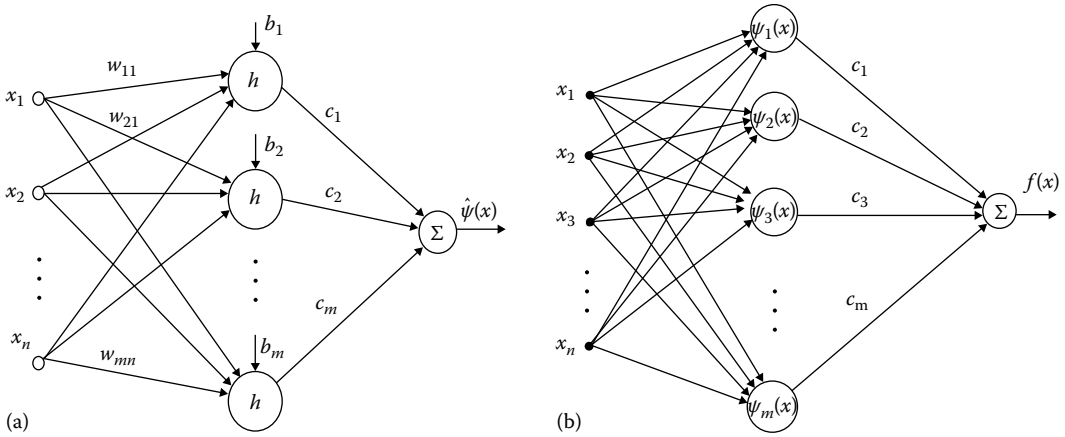

FIGURE 17.1 (a) FNN and (b) neural network with Gauss–Hermite basis functions.

The root mean square error (RMSE) in the approximation of function $\psi(x)$ by the FNN is given by

$$E_{\text{RMS}} = \sqrt{\frac{1}{N}\sum_{k=1}^{N}(\psi(x^k) - \hat{\psi}(x^k))^2} \tag{17.4}$$

where $x^k = [x_1^k, x_2^k, \ldots, x_n^k]$ is the kth input vector of the neural network. The activation function is usually a sigmoidal function $h = 1/(1 + e^{-x})$, while in the case of radial basis functions networks, it is a Gaussian [17]. Several learning algorithms for neural networks have been studied. The objective of all these algorithms is to find numerical values for the network's weights so as to minimize the mean square error, E_{RMS}, of Equation 17.4. The algorithms are usually based on first- and second-order gradient techniques. These algorithms belong to (1) batch-mode learning, where, to perform parameters update, the outputs of a large training set are accumulated and the mean square error is calculated (backpropagation algorithm, Gauss–Newton method, Levenberg–Marquardt method, etc.) and, (2) pattern-mode learning, in which training examples are run in cycles and the parameters' update is carried out each time a new datum appears (extended Kalman filter algorithm) [18].

Unlike conventional FNN with sigmoidal or Gaussian basis functions, Hermite polynomial-based FNNs remain closer to Fourier series expansions by employing activation functions that satisfy the property of orthogonality [16]. Other basis functions with the property of orthogonality are Legendre, Chebyshev, and Volterra polynomials [9–12].

17.3 Neural Networks Using Gauss–Hermite Activation Functions

17.3.1 Gauss–Hermite Series Expansion

Next, as orthogonal basis functions of the FNN, Gauss–Hermite activation functions are considered. These are the spatial components $X_k(x)$ of the solution of Schrödinger's differential equation and describe a stochastic oscillation:

$$X_k(x) = H_k(x)e^{-x^2/2}, \quad k = 0, 1, 2, \ldots \tag{17.5}$$

where $H_k(x)$ are the Hermite orthogonal functions (Figure 17.2). The Hermite functions $H_k(x)$ are the eigenstates of the quantum harmonic oscillator. The general relation for the Hermite polynomials is

$$H_k(x) = (-1)^k e^{x^2} \frac{d^{(k)}}{dx^{(k)}} e^{-x^2} \tag{17.6}$$

According to Equation 17.6, the first five Hermite polynomials are

$$H_0(x) = 1, \quad H_1(x) = 2x, \quad H_2(x) = 4x^2 - 2, \quad H_3(x) = 8x^3 - 12x, \quad H_4(x) = 16x^4 - 48x^2 + 12$$

It is known that Hermite polynomials are orthogonal, that is, it holds

$$\int_{-\infty}^{+\infty} e^{-x^2} H_m(x)H_k(x)dx = \begin{cases} 2^k k!\sqrt{\pi} & \text{if } m = k \\ 0 & \text{if } m \neq k \end{cases} \tag{17.7}$$

Using now Equation 17.7, the following basis functions can be defined [9]:

$$\psi_k(x) = [2^k \pi^{1/2} k!]^{-1/2} H_k(x)e^{-x^2/2} \tag{17.8}$$

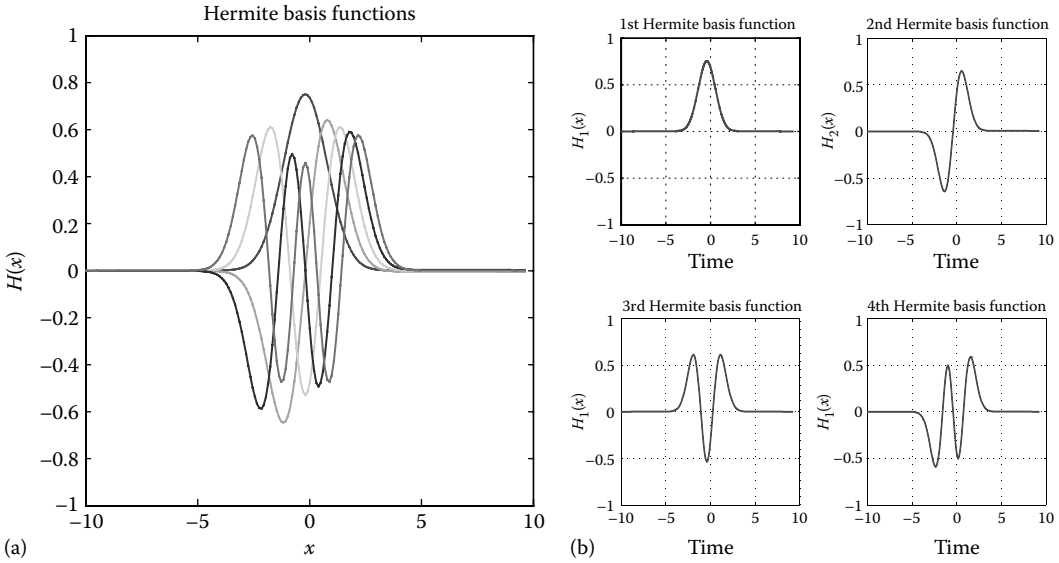

FIGURE 17.2 (a) First five 1D Hermite basis functions and (b) analytical representation of the 1D Hermite basis function.

where $H_k(x)$ is the associated Hermite polynomial. From Equation 17.7, the orthogonality of basis functions of Equation 17.8 can be concluded, which means

$$\int_{-\infty}^{+\infty} \psi_m(x)\,\psi_k(x)dx = \begin{cases} 1 & \text{if } m = k \\ 0 & \text{if } m \neq k \end{cases} \tag{17.9}$$

Moreover, to succeed multiresolution analysis, Gauss–Hermite basis functions of Equation 17.8 are multiplied with the scale coefficient α. Thus, the following basis functions are derived:

$$\beta_k(x, \alpha) = a^{-1/2}\psi_k(a^{-1}x) \tag{17.10}$$

which also satisfy orthogonality condition

$$\int_{-\infty}^{+\infty} \beta_m(x, \alpha)\beta_k(x, \alpha)dx = \begin{cases} 1 & \text{if } m \neq k \\ 0 & \text{if } m = k \end{cases} \tag{17.11}$$

Any function $f(x)$, $x \in R$, can be written as a weighted sum of the previous orthogonal basis functions, that is,

$$f(x) = \sum_{k=0}^{\infty} c_k \beta_k(x, a) \tag{17.12}$$

where coefficients c_k are calculated using the orthogonality condition

$$c_k = \int_{-\infty}^{+\infty} f(x)\beta_k(x, a)dx \tag{17.13}$$

Assuming now that instead of infinite terms in the expansion of Equation 17.12 M terms are maintained, then an approximation of $f(x)$ is succeeded. The expansion of $f(x)$ using Equation 17.12 is a Gauss–Hermite series. Equation 17.12 is a form of Fourier expansion for $f(x)$ and can be considered as the Fourier transform of $f(x)$ subject only to a scale change. Indeed, the Fourier transform of $f(x)$ is given by

$$F(s) = \frac{1}{2\pi}\int_{-\infty}^{+\infty} f(x)e^{-jsx}dx \Rightarrow f(x) = \frac{1}{2\pi}\int_{-\infty}^{+\infty} F(s)e^{jsx}ds \tag{17.14}$$

The Fourier transform of the basis function $\psi_k(x)$ of Equation 17.8 satisfies [9]

$$\Psi_k(s) = j^k\psi_k(s) \tag{17.15}$$

while for the basis functions $\beta_k(x, a)$ using scale coefficient α, it holds that

$$B_k(s, a) = j^k\beta_k(s, a^{-1}) \tag{17.16}$$

Therefore, it holds

$$f(x) = \sum_{k=0}^{\infty} c_k\beta_k(x, a) \xrightarrow{F} F(s) = \sum_{k=0}^{\infty} c_k j^k\beta_k(s, a^{-1}) \tag{17.17}$$

which means that the Fourier transform of Equation 17.12 is the same as the initial function, subject only to a change of scale. The structure of an FNN with Hermite basis functions is depicted in Figure 17.1b.

17.3.2 Neural Networks Using 2D Hermite Activation Functions

2D Hermite polynomial-based neural networks can be constructed by taking products of the 1D basis functions $B_k(x, a)$ [9]. Thus, setting $x = [x_1 \quad x_2]^T$, one can define the following basis functions:

$$B_k(x, a) = \frac{1}{a}B_{k_1}(x_1, a)B_{k_2}(x_2, a) \tag{17.18}$$

These 2D basis functions are again orthonormal, that is, it holds

$$\int d^2xB_n(x, a)B_m(x, a) = \delta_{n_1m_1}\delta_{n_2m_2} \tag{17.19}$$

The basis functions $B_k(x)$ are the eigenstates of the 2D harmonic oscillator and form a complete basis for integrable functions of two variables. A 2D function $f(x)$ can thus be written in the series expansion

$$f(x) = \sum_{k_1,k_2}^{\infty} c_kB_k(x, a) \tag{17.20}$$

The choice of an appropriate scale coefficient a and maximum order $k_{\max}$ is of practical interest. The coefficients c_k are given by

$$c_k = \int dx^2 f(x) B_k(x, a) \tag{17.21}$$

Indicative basis functions $B_2(x, a)$, $B_6(x, a)$, $B_9(x, a)$, $B_{11}(x, a)$, $B_{13}(x, a)$, and $B_{15}(x, a)$ of a 2D FNN with Hermite basis functions are depicted in Figures 17.3 through 17.5. Following the same method, N-dimensional Hermite polynomial-based neural networks ($N > 2$) can be constructed. The associated high-dimensional Gauss–Hermite activation functions preserve the properties of orthogonality and invariance to Fourier transform.

17.4 Signal Power Spectrum and the Fourier Transform

17.4.1 Parseval's Theorem

To find the spectral density of a signal $\psi(t)$ with the use of its Fourier transform, the following definition of the signal's energy is used:

$$E_\psi = \int_{-\infty}^{+\infty} (\psi(t))^2 dt = \frac{1}{2\pi} \int_{-\infty}^{+\infty} \psi(t) \left(\int_{-\infty}^{+\infty} \Psi(j\omega) e^{j\omega t} d\omega \right) dt, \quad \text{i.e.}$$
$$E_\psi = \frac{1}{2\pi} \int_{-\infty}^{+\infty} \Psi(j\omega) \left(\int_{-\infty}^{+\infty} \psi(t) e^{j\omega t} d\omega \right) dt = \frac{1}{2\pi} \int_{-\infty}^{+\infty} \Psi(j\omega)\Psi(-j\omega) d\omega \tag{17.22}$$

Taking that $\psi(t)$ is a real signal, it holds that $\Psi(-j\omega) = \Psi^*(j\omega)$, which is the signal's complex conjugate. Using this in Equation 17.22, one obtains

$$E_\psi = \frac{1}{2\pi} \int_{-\infty}^{+\infty} \Psi(j\omega)\Psi^*(j\omega) d\omega \quad \text{or}$$
$$E_\psi = \frac{1}{2\pi} \int_{-\infty}^{+\infty} |\Psi(j\omega)|^2 \, d\omega \tag{17.23}$$

This means that the energy of the signal is equal to $1/2\pi$ times the integral over frequency of the square of the magnitude of the signal's Fourier transform. This is *Parseval's theorem*. The integrated term $|\Psi(j\omega)|^2$ is the energy density per unit of frequency and has units of magnitude square per hertz.

17.4.2 Power Spectrum of Infinite Energy Signals

The concept of Fourier transform is also applied to infinite time extent and energy signals. The ordinary Fourier transform is defined for signals that are absolutely integrable, that is, $\int_{-T}^{+T} |\psi(t)| \, dt < \infty$, so it cannot be directly used for infinite energy signals. Some of these signals can be handled by allowing the Fourier transform to contain impulses. The average power of a signal is defined as

$$P_\psi = \lim_{T \to \infty} \frac{1}{2T} \int_{-T}^{T} |\psi(t)|^2 \, dt \tag{17.24}$$

and a *power signal* is one for which $0 < P_\psi < \infty$, which means that the power is finite (but not necessarily the energy). The Fourier transform is redefined to handle also the case of signals of infinite energy. One approach for power signals is to take a time-limited sample of an infinite duration signal, where the time window is allowed to approach infinity. For example, such a time-limited sample can be of the form

$$\psi_T(t) = \psi(t) \quad |t| \le T < \infty$$
$$\psi_T(t) = 0 \quad |t| > T \tag{17.25}$$

and the corresponding Fourier transform is

$$\Psi_T(j\omega) = \int_{-\infty}^{+\infty} \psi_T(t) e^{-j\omega t} dt = \int_{-T}^{T} \psi(t) e^{-j\omega t} dt \tag{17.26}$$

Using a generalization of Parseval's theorem, the average power of a real-valued power signal $\psi_T(t)$ is computed from the Fourier transform as

$$P_\psi = \lim_{T\to\infty} \frac{1}{2T} \int_{-T}^{T} |\psi(t)|^2 dt \quad \text{or}$$

$$P_\psi = \lim_{T\to\infty} \frac{1}{4\pi T} \int_{-\infty}^{\infty} |\Psi_T(j\omega)\Psi_T(-j\omega) d\omega \quad \text{or} \tag{17.27}$$

$$P_\psi = \lim_{T\to\infty} \frac{1}{4\pi T} \int_{-\infty}^{\infty} |\Psi(j\omega)|^2 \, d\omega$$

The power spectral density of the signal is computed from the Fourier transform as

$$S_\psi(\omega) = \lim_{T\to\infty} \frac{|\Psi_T(j\omega)|^2}{2T} \tag{17.28}$$

17.4.3 Power Spectrum of Stochastic Signals

The power spectral density is a stationary stochastic signal (its statistical characteristics do not change in time) that converges and that is defined as an expected (mean) value. As with the case of power signals, one can consider first a time-limited sample of an infinite duration signal and then extend the duration to infinity. The average power of a signal over a finite time window $|t| < T$ is

$$\frac{1}{2T} \int_{-\infty}^{+\infty} |\psi_T(t)|^2 dt = \frac{1}{4\pi T} \int_{-\infty}^{+\infty} |\Psi_T(j\omega)|^2 \, d\omega \tag{17.29}$$

From Equation 17.29 and using the statistical expectation, it holds

$$E\left[\frac{1}{2T} \int_{-\infty}^{+\infty} [\psi_T(t)]^2 dt\right] = E\left[\frac{1}{4\pi T} \int_{-\infty}^{+\infty} [\Psi_T(j\omega)]^2 d\omega\right] \quad \text{i.e.} \tag{17.30}$$

and consequently one obtains

$$\lim_{T\to\infty} E\left[\frac{1}{2T} \int_{-\infty}^{+\infty} [\psi_T(t)]^2 dt\right] \quad \text{i.e.}$$

$$\lim_{T\to\infty} E\left[\frac{1}{4\pi T} \int_{-\infty}^{+\infty} [\Psi_T(j\omega)]^2 dt\right] \quad \text{i.e.} \tag{17.31}$$

$$\frac{1}{2\pi} \int_{-\infty}^{+\infty} \lim_{T\to\infty} E\left[\frac{[\Psi_T(j\omega)]^2}{2T}\right] d\omega$$

The integrand of the last row of Equation 17.31 is the power spectral density of the signal:

$$S_{\psi}(\omega) = \lim_{T\to\infty} E\left[\frac{|\Psi_T(j\omega)|^2}{2T}\right] \tag{17.32}$$

17.4.4 Power Spectrum of the Signal Using the Gauss–Hermite Expansion

It has been shown that the Gauss–Hermite basis functions satisfy the orthogonality property, that is, according to Equation 17.9 for these functions, it holds

$$\int_{-\infty}^{+\infty} \psi_m(x)\psi_k(x)dx = \begin{cases} 1 & \text{if } m = k \\ 0 & \text{if } m \neq k \end{cases}$$

Therefore, using the definition of the signal's energy, one has

$$E = \int_{-\infty}^{+\infty} (\psi(t))^2 dt = \int_{-\infty}^{+\infty} \left[\sum_{k=1}^{N} c_k \psi_k(t)\right]^2 \tag{17.33}$$

and exploiting the orthogonality property one obtains

$$E = \sum_{k=1}^{N} c_k^2 \tag{17.34}$$

Therefore, the square of the coefficients c_k provides an indication of the distribution of the signal's energy to the associated basis functions. One could arrive at the same results using the Fourier-transformed description of the signal and Parseval's theorem. It has been shown that the Gauss–Hermite basis functions remain invariant under the Fourier transform subject only to a change of scale. Denoting by $\Psi(j\omega)$ the Fourier-transformed signal of and by $\Psi_k(j\omega)$ the Fourier transform of the kth Gauss–Hermite basis function, one obtains

$$\Psi(j\omega) = \sum_{k=1}^{N} c_k \Psi_k(j\omega) \tag{17.35}$$

and the energy of the signal is computed as

$$E_{\psi} = \frac{1}{2\pi} \int_{-\infty}^{+\infty} |\Psi(j\omega)|^2 \, d\omega \tag{17.36}$$

Substituting Equation 17.35 into Equation 17.36, one obtains

$$E_{\psi} = \frac{1}{2\pi} \int_{-\infty}^{+\infty} \left|\sum_{k=1}^{N} c_k \Psi_k(j\omega)\right|^2 d\omega \tag{17.37}$$

and using the invariance of the Gauss–Hermite basis functions under Fourier transform, as well as their orthogonality property, one gets that the signal's energy is proportional to the sum of the squares of the coefficients c_k that are associated with the Gauss–Hermite basis functions, that is, a relation of the form of Equation 17.34.

17.5 Application for Condition Monitoring of Electric Power Transformers

17.5.1 Failures in Electric Power Transformers

It will be shown that the proposed method for modeling nonlinear systems, which is characterized by invariance to Fourier transform, is suitable for performing FDI in several electromechanical systems such as vehicles, electric motors and power generators, or components of the electric power transmission and distribution system. As a case study the problem of fault diagnosis for electric power transformers will be presented.

One can distinguish between several classes of power transformers using two major classification criteria. The first criterion has to do with the insulating material used in the transformer (e.g., oil-immersed, gas-immersed, and dry-type transformers). The second criterion has to do with the incoming and outgoing voltage levels of the power transformers and their role in the electric power grid (e.g., power transformers in generation stations, power transformers in the transmission system, power transformers in the distribution system, distribution substation transformers, or distribution network transformers).

The minimization of the risk of failures in power transformers is important for improving the operation of the power grid. FDI for power transformers aims at continuously assessing the transformer's state through the monitoring of associated critical parameters and at determining if the transformer is on the verge of a failure (this can be due to an internal fault or due to ageing) [19–21]. Common failures in electric power transformers are (1) insulation breakdown in windings, (2) the on-load tap changer (OLTC) failures, and (3) bushing failures (see Figure 17.6).

Among other condition monitoring methods for power transformers, *thermal analysis* aims at monitoring of the evolution in time of the transformer's HST, which can be an indication of the ageing and degradation of the windings or of operating the transformer under overload conditions [22,23]. Most of the faults cause change in the thermal behavior of the transformer. Such abnormal conditions can be detected by analyzing the HST [24,25]. The most common abnormal condition of the transformer that can be detected with the use of thermal analysis is the overload. Transformer life is severely affected if the HST remains for long time intervals more than 110 °C. In this chapter a method for preventive maintenance of power transformers based on HST monitoring (thermal analysis) will be investigated.

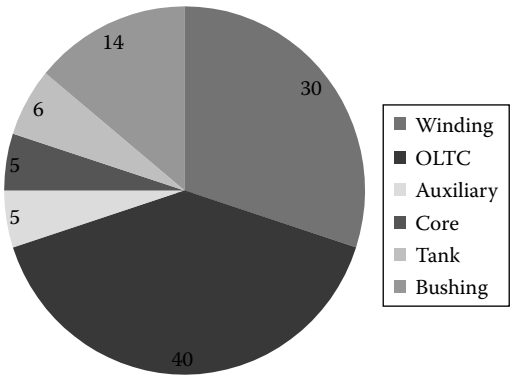

FIGURE 17.6 Frequency of faults in components of electric power transformers.

17.5.2 Analytical Thermal Model of Power Transformers

The stages for obtaining an analytical model of the power transformer's thermal behavior are as follows [14]:

- Calculate at each time step the ultimate top oil temperature (TOT) rise in the transformer from the load current at that instant, using

$$\Delta\Theta_{TO,U} = \Delta\Theta_{TO,R}\left[\frac{I_L^2 R + 1}{R + 1}\right]^q \tag{17.38}$$

  where
  $\Delta\Theta_{TO,U}$ is the ultimate TOT rise, °C
  $\Delta\Theta_{TO,R}$ is the rated TOT rise over ambient, °C
  I_L is the load current normalized to rated current, p.u.
  q is an empirically derived exponent to approximately account for effects of change of resistance with change in load
  R is the ratio of rated-load loss to no-load loss at applicable tap position

- Calculate the increment in the TOT from the ultimate top-oil rise and the ambient temperature at each time step using the following differential equation:

$$\tau_{TO}\frac{d\Theta_{TO}}{dt} = [\Delta\Theta_{TO,U} + \Theta_A] - \Theta_{TO} \tag{17.39}$$

  where
  Θ_{TO} is the TOT, °C
  τ_{TO} is the top-oil rise time constant
  Θ_A is the ambient temperature, °C

- Calculate the ultimate HST rise using

$$\Delta\Theta_{HS,U} = \Delta\Theta_{HS,R} I_L^{2\beta} \tag{17.40}$$

  where
  β is an empirically derived exponent, dependent on the cooling method
  $\Delta\Theta_{HS,U}$ is the ultimate HST rise over top oil (for a given load current), °C
  $\Delta\Theta_{HS,R}$ is the rated HST rise over top oil (for rated-load current), °C

- Calculate the increment in the HST rise, using the following differential equation:

$$\tau_{HS}\left\{\frac{d\Delta\Theta_{HS}}{dt}\right\} = \Delta\Theta_{HS,U} - \Delta\Theta_{HS} \tag{17.41}$$

  where
  Θ_{HS} is the hot-spot winding temperature, °C
  $\Delta\Theta_{HS}$ is the HST rise above top oil, °C
  τ_{HS} is the hot-spot rise time constant, h

- Finally, add the TOT to the HST rise to get the HST, using

$$\Theta_{HS} = \Theta_{TO} + \Delta\Theta_{HS} \tag{17.42}$$

The model of Equations 17.38 through 17.42 named top-oil rise model is based on some simplifying assumptions, and its accuracy can deteriorate due to parameter variations. As a result, in order to protect power transformers, conservative safety factors have been introduced that prevent the transformer's overheating. Consequently, the calculated maximum power transfer may be 20%–30% less or worse than the real transformer capability.

17.6 Gauss–Hermite Neural Modeling of Power Transformers Thermal Condition

The previously described methodology was employed to identify a neural model able to estimate with high accuracy the winding HST of a laboratory prototype mineral-oil-immersed power transformer. A measurement station has been set up consisting of thermocouples that were monitoring (a) the HST of the medium and voltage windings and (b) the TOT. The HST could have been also measured with optical fiber sensors. The manufacturer's specifications give the most probable hot-spot position. A Hall effect current transducer has been used in order to measure the load current.

Neural modeling of the power transformer has been carried out. The electric power transformer was modeled with the use of a neural network, having as output the estimated HST (k) and as inputs past values of the TOT, for example, $\Theta_{TO}(k-1)$, $\Theta_{TO}(k-2)$, and past values of the load current, for example, $I_L(k-1)$. Neural models with the same output, such as HST (k) and a larger number of inputs, that is, including more past values of the TOT and of the load current, could be also considered.

The transformer's model has been identified considering the previously analyzed neural network with Gauss–Hermite basis functions. The neural network was used to model the variations of the power transformer HST. The *inputs/outputs* configuration of the neural model of the power transformer thermal dynamics is shown in Figure 17.7. The RMSE of training the Gauss–Hermite neural model was of the order of 4×10^{-3}.

RMSE, defined as $\text{RMSE} = \sqrt{1/N \sum_{k=1}^{N} \left(y_k - y_k^d \right)^2}$, gives a measure of the performance of the neural network with Gauss–Hermite basis functions. It is noted that training affects only the output weights and can be performed with second-order gradient algorithms. However, since the speed of convergence is not the primary objective of this study, the least mean squares (LSM) algorithm is sufficient for training. Thus, the update of the output layer weights of the neural network is given by a gradient-type equation of the form

$$w^i(k+1) = w^i(k) - \eta e(k) \phi^T(k) \tag{17.43}$$

where

$e(k) = y(k) - y_d(k)$ is the output estimation error at time instant k

$\phi^T(k)$ is the regressor vector at time instant k having as elements the values $\phi(x(k))$ of the Gauss–Hermite basis functions for input vector $x(k)$

Training with the *data set* of dimension N is repeated in successive cycles (epochs) until no further drop of the approximation error (RMSE) can be observed. Diagrams depicting the approximation of the HST signal provided by the neural network with Gauss–Hermite polynomial basis functions, in comparison to the real HST signal, are given in Figures 17.8 and 17.9. Four different HST profiles have been considered, each one associated with different operating conditions for the transformer. As shown in Figures 17.8 and 17.9, thanks to the inherent multifrequency characteristics of the Hermite polynomial basis functions, such a neural model can capture with increased accuracy spikes and abrupt changes in the HST profile [1,11,18].

In Figures 17.8 and 17.9, diagrams are provided about the approximation of the HST signal by the neural network with Gauss–Hermite basis functions, and the estimated HST variations are compared

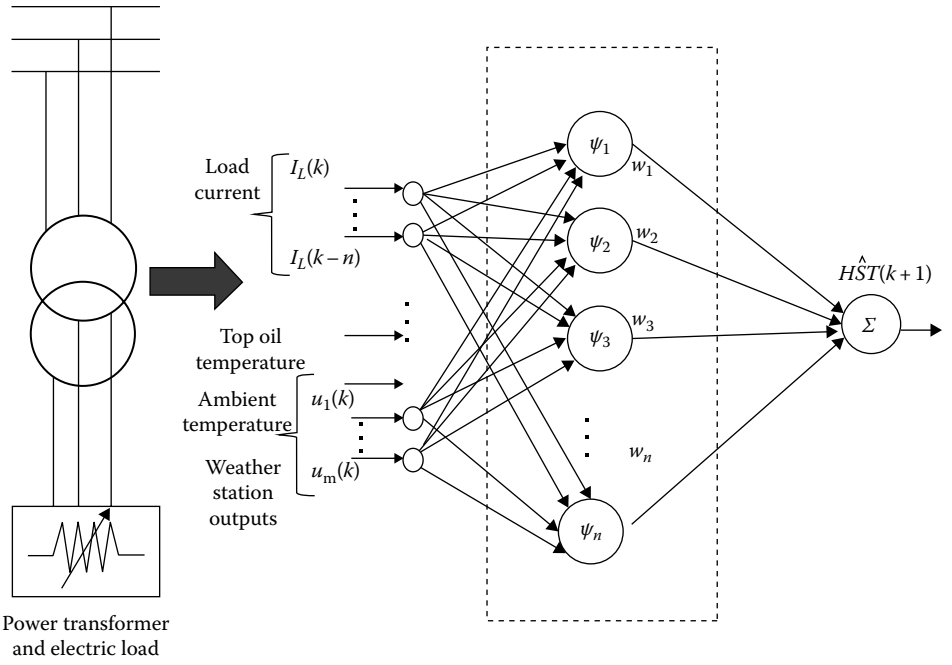

FIGURE 17.7 Inputs/outputs configuration of the neural model of the power transformer thermal dynamics.

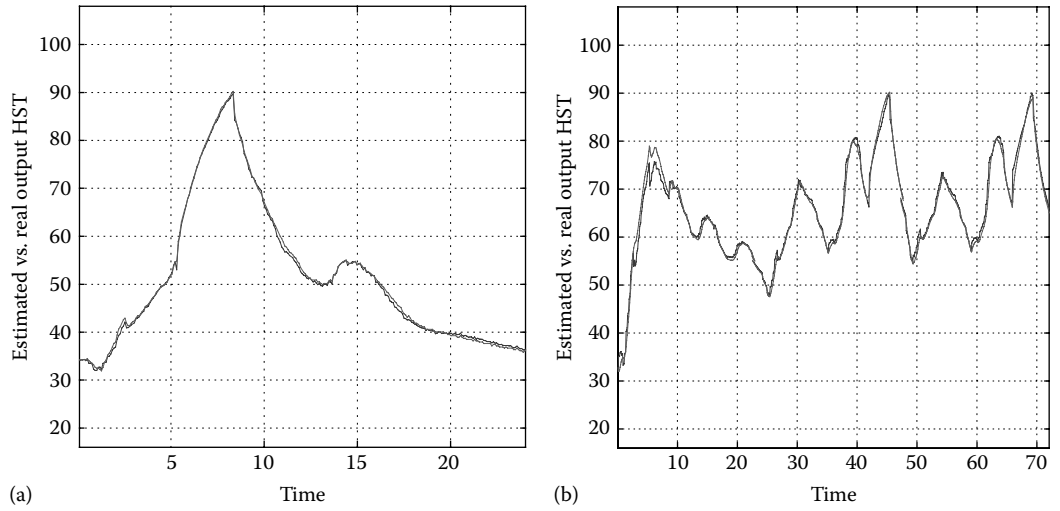

FIGURE 17.8 Approximation of the HST of the electric power transformer; by a neural network with Hermite polynomial basis functions: (a) HST time variation (profile 1) and (b) HST time variation (profile 2).

against the real HST measurements. Four different HST profiles have been considered, each one associated with different operating conditions of the power transformer.

To approximate the HST variations described in a data set consisting of 870 quadruplets of the form $[\Theta_{TO}(k-1), \Theta_{TO}(k-2), I_L(k-1)|HST(k)]$, an FNN with 3D Gauss–Hermite basis functions has been used, containing 64 nodes in its hidden layer. The spectral components of the HST signal for both the fault-free and the under-fault operation of the power transformer have been shown in Figures 17.10a through 17.13a. Note that after a fault has taken place in the power transformer, the amplitude of the

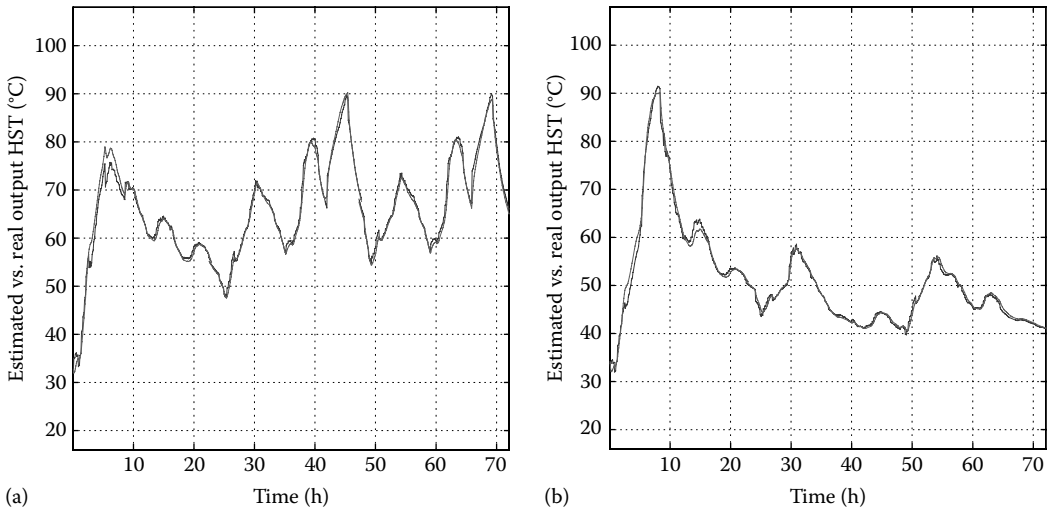

FIGURE 17.9 Approximation of the HST of the electric power transformer; by a neural network with Hermite polynomial basis functions: (a) HST time variation (profile 3) and (b) HST time variation (profile 4).

aforementioned spectral components changes, and this can be a strong indication about failure of the monitored transformer.

Obviously, the proposed spectral decomposition of the monitored signal, using the series expansion in Gauss–Hermite basis functions, can be used for fault detection tasks. As it can be seen in Figures 17.10b through 17.13b, in case of failure the spectral components of the monitored signal differ from the ones that are obtained when the system is free of fault. Moreover, the fact that certain spectral components exhibit greater sensitivity to the fault and change value in a more abrupt manner is a feature that can be exploited for fault isolation. Specific failures can be associated with variations of specific spectral components of the monitored signal. Therefore, they can provide indication about the appearance of specific types of failures and specific malfunctioning components.

It is noted that the problem of thermal condition monitoring is apparent in several systems and devices. For example, through thermal condition monitoring, one can draw conclusions about the existence of

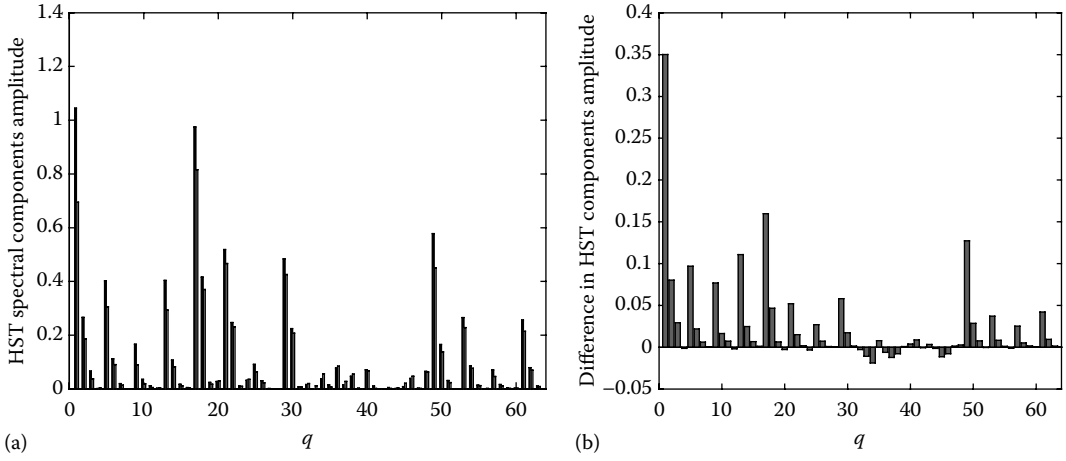

FIGURE 17.10 HST time variation (profile 1): (a) amplitude of the spectral components of the HST signal measured from the electric power transformer in the fault-free case (black line) and when a fault had taken place (gray line) and (b) differences in the amplitudes of the spectral components between the fault-free and the faulty case.

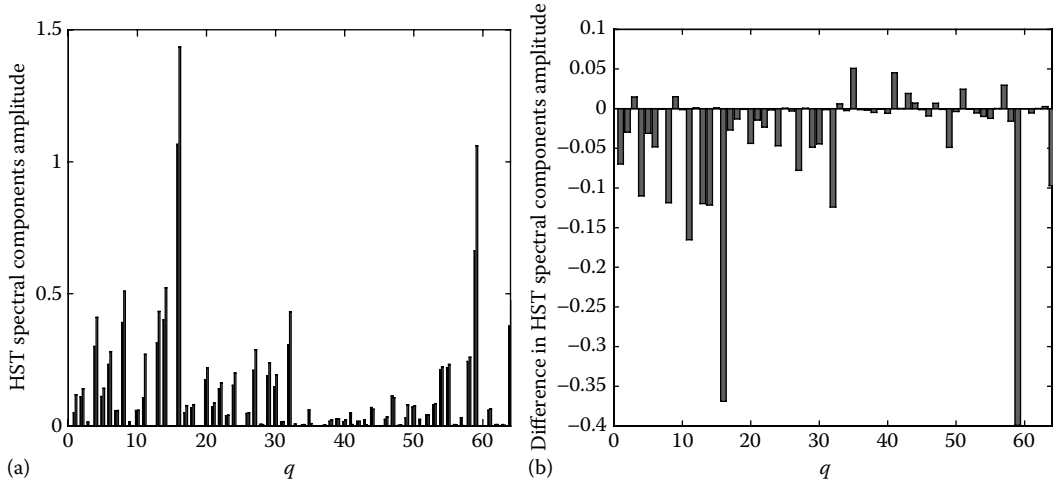

FIGURE 17.11 HST time variation (profile 2): (a) amplitude of the spectral components of the HST signal measured from the electric power transformer in the fault-free case (black line) and when a fault had taken place (gray line) and (b) differences in the amplitudes of the spectral components between the fault-free and the faulty case.

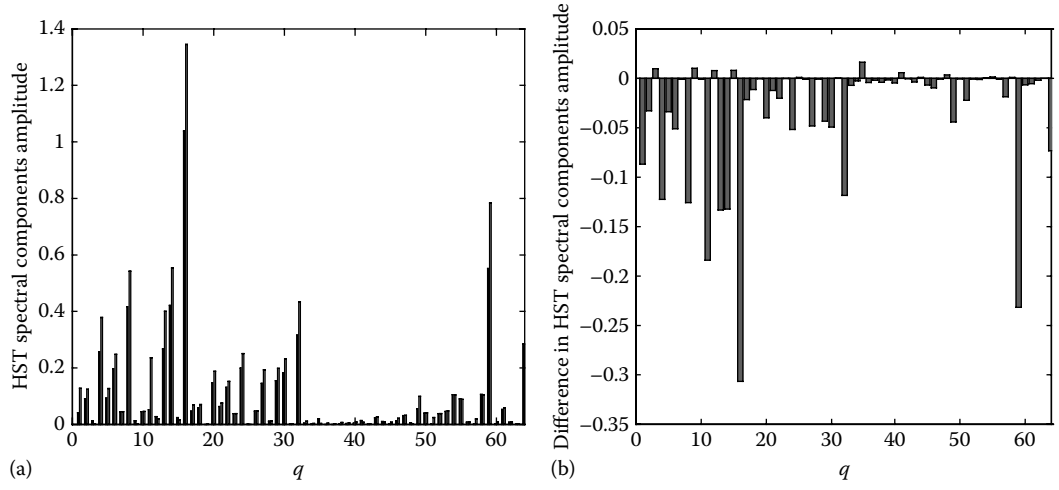

FIGURE 17.12 HST time variation (profile 3): (a) amplitude of the spectral components of the HST signal measured from the electric power transformer in the fault-free case (black line) and when a fault had taken place (gray line) and (b) differences in the amplitudes of the spectral components between the fault-free and the faulty case.

failures not only in power transformers but also in transmission lines and in electric machines such as motors and generators. Temperature histories strongly influence an electric machine's condition and future capability. High temperatures inside an electric machine, especially the winding temperatures, affect the functioning of the machine. For instance, winding insulation materials suffer irreversible damage when thermal stresses exceed their permissible limits. These temperature-dependent changes affect the machine's performance, can shorten its useful life, and may lead to failure. Therefore, the previously analyzed approach for nonlinear dynamics modeling under invariance to Fourier transform can be a useful method for performing systematic condition monitoring of dynamical systems subject to thermal stresses or other harsh operating conditions.

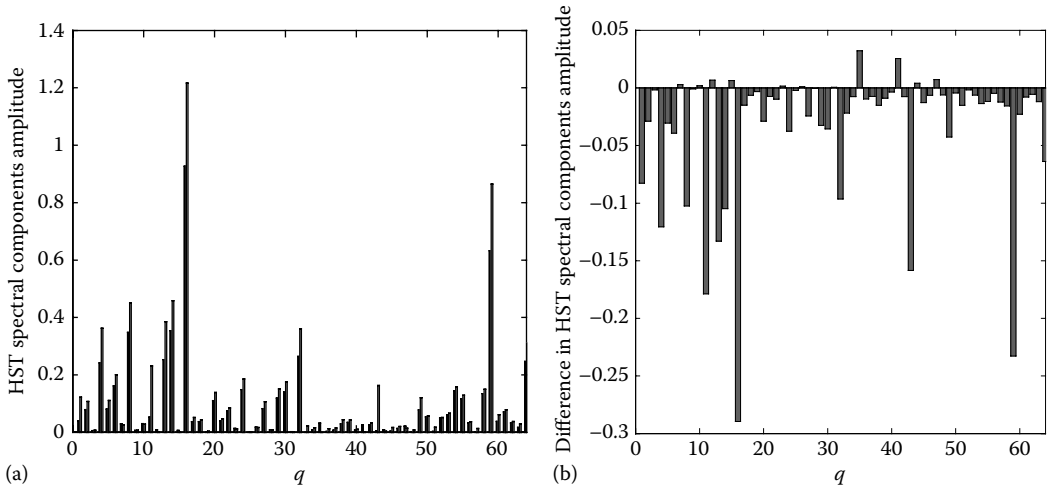

FIGURE 17.13 HST time variation (profile 4): (a) amplitude of the spectral components of the HST signal measured from the electric power transformer in the fault-free case (black line) and when a fault had taken place (gray line) and (b) differences in the amplitudes of the spectral components between the fault-free and the faulty case.

17.7 Conclusions

A new method for fault diagnosis of nonlinear systems has been proposed based on the modeling of the system's dynamics with FNNs that use orthogonal basis functions exhibiting invariance to Fourier transform. A neural network with Gauss–Hermite polynomial activation functions has been used for approximating the nonlinear system's dynamics out of a set of input–output data. The output of the neural network has taken the form of a series expansion that was written as a weighted sum of Gauss–Hermite basis functions. Using the Fourier transform property of the Gauss–Hermite basis functions, it was shown that the considered neural network could provide spectral analysis of the output of the monitored system. Moreover, using the orthogonality property of the Gauss–Hermite basis functions, it was shown that the sum of the square of the output layer weights of these neural networks stands for a measure of the energy contained in the output of the monitored system.

The monitoring of changes in the amplitude of the aforementioned spectral components provides an indication about malfunctioning of the monitored system and a tool for detecting the existence of failures. Additionally, since specific faults are associated with amplitude changes of specific spectral components of the system, fault isolation can be also performed. The proposed FDI method can be applied to several electromechanical systems, for example, vehicles, electric motors, and power generators. As a case study, the problem of fault diagnosis of electric power transformers has been examined. The considered neural network with Gauss–Hermite polynomial activation functions enabled to obtain information about the thermal condition of oil-immersed power transformers and about their ageing and failure risks through the approximation and spectral decomposition of a critical variable of the transformer known as HST. Evaluation tests have confirmed the efficiency of the proposed fault diagnosis method.

Meter Voltage Measurement

Alessandro Ferrero
Politecnico di Milano

Instruments for the measurement of electric voltage are called *voltmeters*. Correct insertion of a voltmeter requires the connection of its terminals to the points of an electric circuit across which the voltage has to be measured, as shown in Figure 18.1. To a first approximation, the electric equivalent circuit of a voltmeter can be represented by resistive impedance Z_v (or a pure resistance R_v for dc voltmeters). This means that any voltmeter, once connected to an electric circuit, draws a current I_v given by

$$I_v = \frac{V}{Z_v} \tag{18.1}$$

where V is the measured voltage. The higher the value of the internal impedance, the higher the quality of the voltmeter, since it does not significantly modify the status of the electric circuit under test.

Different operating principles are used to measure an electric voltage. The mechanical interaction between currents, between a current and a magnetic field, or between electrified conductors was widely adopted in the past to generate a mechanical torque proportional to the voltage or the squared voltage to be measured. This torque, balanced by a restraining torque, usually generated by a spring, causes the instrument pointer, which can be a mechanical or a virtual optical pointer, to be displaced by an angle proportional to the driving torque and hence to the voltage or the squared voltage to be measured. The value of the input voltage is therefore given by the reading of the pointer displacement on a graduated scale. The thermal effects of a current flowing in a conductor are also used for measuring electric voltages, although they have not been adopted as widely as the previous ones. More recently, the widespread diffusion of semiconductor devices led to the development of a completely different class of voltmeters: *electronic* voltmeters. They basically attain the required measurement by processing the input signal by means of electronic semiconductor devices. According to the method, analog or digital, the input signal is processed; the electronic voltmeters can be divided into *analog*

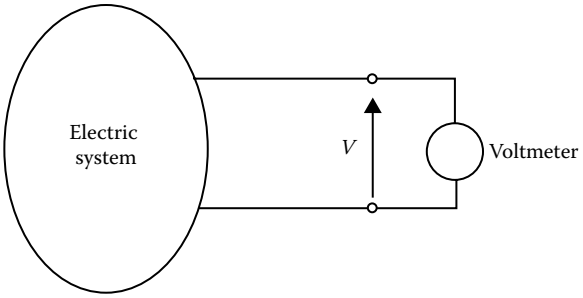

FIGURE 18.1 Voltmeter insertion.

TABLE 18.1 Classification of Voltage Meters

Class	Operating Principle	Subclass	Application Field
Electromagnetic	Interaction between currents and magnetic fields	Moving magnet	dc voltage
		Moving coil	dc voltage
		Moving iron	dc and ac voltage
Electrodynamic	Interactions between currents	—	dc and ac voltage
Electrostatic	Electrostatic interactions	—	dc and ac voltage
Thermal	Current's thermal effects	Direct action	dc and ac voltage
		Indirect action	dc and ac voltage
Induction	Magnetic induction	—	ac voltage
Electronic	Signal processing	Analog	dc and ac voltage
		Digital	dc and ac voltage

electronic voltmeters and *digital* electronic voltmeters. Table 18.1 shows a rough classification of the most commonly employed voltmeters, according to their operating principle and their typical application field.

This chapter section briefly describes the most commonly employed voltmeters, both electromechanical and electronic.

18.1 Electromechanical Voltmeters

Electromechanical voltmeters measure the applied voltage by transducing it into a mechanical torque. This can be accomplished in different ways, basically because of the interactions between currents (*electrodynamic voltmeters*), between a current and a magnetic field (*electromagnetic voltmeters*), between electrified conductors (*electrostatic voltmeters* or *electrometers*), and between currents induced in a conducting vane (*induction voltmeters*). According to the different kinds of interactions, different families of instruments can be described, with different application fields. Moving-coil electromagnetic voltmeters are restricted to the measurement of dc voltages; moving-iron electromagnetic, electrodynamic, and electrostatic voltmeters can be used to measure both dc and ac voltages, while induction voltmeters are restricted to ac voltages.

The most commonly employed electromechanical voltmeters are the electromagnetic and electrodynamic ones. Electrostatic voltmeters have been widely employed in the past (and are still employed) for the measurement of high voltages, both dc and ac, up to a frequency on the order of several megahertz. Induction voltmeters have never been widely employed, and their present use is restricted to ac voltages.

Therefore, only the electromagnetic, electrodynamic, and electrostatic voltmeters will be described in the following sections.

18.2 Electromagnetic Voltmeters

18.2.1 DC Moving-Coil Voltmeters

The structure of a dc moving-coil meter is shown in Figure 18.2. A small rectangular pivoted coil is wrapped around an iron cylinder and placed between the poles of a permanent magnet. Because of the shape of the poles of the permanent magnet, the induction magnetic field B in the air gap is radial and constant.

Suppose that a dc current I is flowing in the coil, the coil has N turns, and that the length of the sides that cut the magnetic flux (active sides) is l; the current interacts with the magnetic field B, and a force F is exerted on the conductors of the active sides. The value of this force is given by

$$F = NBlI \tag{18.2}$$

Its direction is given by the right-hand rule. Since the two forces applied to the two active sides of the coil are directed in opposite directions, a torque arises in the coil, given by

$$T_i = Fd = NBldI \tag{18.3}$$

where d is the coil width. Since N, B, l, and d are constant, Equation 18.3 leads to

$$T_i = k_i I \tag{18.4}$$

showing that the mechanical torque exerted on the coil is directly proportional to the current flowing in the coil itself.

Because of T_i, the coil rotates around its axis. Two little control springs, with k_r constant, provide a restraining torque T_r. The two torques balance when the coil is rotated by an angle δ so that

$$k_i I = k_r \delta \tag{18.5}$$

that leads to

$$\delta = \frac{k_i}{k_r} I \tag{18.6}$$

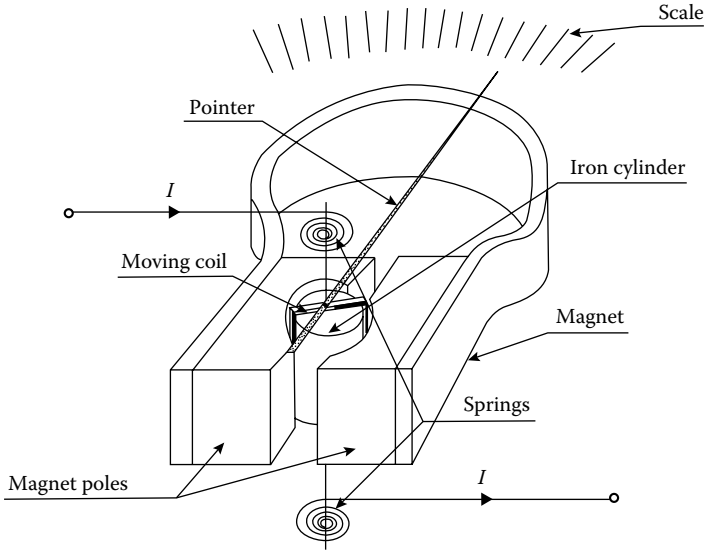

FIGURE 18.2 DC moving-coil meter.

Equation 18.6 shows that the rotation angle of the coil is directly proportional to the dc current flowing in the coil. If a pointer with length h is keyed on the coil axes, a displacement $\lambda = h\delta$ can be read on the instrument scale. Therefore, the pointer displacement is proportional to the current flowing in the coil, according to the following relationship:

$$\lambda = h\frac{k_i}{k_r}I \tag{18.7}$$

This instrument is hence intrinsically a current meter. A voltmeter can be obtained by connecting an additional resistor in series with the coil. If the coil resistance is R_c and the resistance of the additional resistor is R_a, the current flowing in the coil when the voltage V is applied is given by

$$I = \frac{V}{R_a + R_c} \tag{18.8}$$

and therefore the pointer displacement is given by

$$\lambda = h\delta = h\frac{k_i}{k_r}I = h\frac{k_i}{k_r(R_a + R_c)}V \tag{18.9}$$

and is proportional to the applied voltage. Because of this proportionality, moving-coil dc meters show a proportional-law scale, where the applied voltage causes a proportional angular deflection of the pointer.

Because of the operating principle expressed by Equation 18.3, these voltmeters can measure only dc voltages. Due to the inertia of the mechanical part, ac components typically do not cause any coil rotation, and hence these meters can be also employed to measure the dc component of a variable voltage. They have been widely employed in the past for the measurement of dc voltages up to some thousands volts with a relative measurement uncertainty as low as 0.1% of the full-scale value. At present, they are being replaced by electronic voltmeters that feature the same or better accuracy at a lower cost.

18.2.2 DC Galvanometer

18.2.2.1 General Characteristics

A galvanometer is used to measure low currents and low voltages. Because of the high sensitivity that this kind of measurement requires, galvanometers are widely employed as null indicators in all dc balance measurement methods (like the bridge and potentiometer methods) [1,2].

A dc galvanometer is, basically, a dc moving-coil meter, and the relationship between the index displacement and the current flowing in the moving coil is given by Equation 18.7. The instrument constant

$$k_a = h\frac{k_i}{k_r} \tag{18.10}$$

is usually called the galvanometer *current constant* and is expressed in mm μA^{-1}. The galvanometer *current sensitivity* is defined as $1/k_a$ and is expressed in $\mu A\ mm^{-1}$.

According to their particular application field, galvanometers must be chosen with particular care. If k_a is taken into account, note that once the full-scale current and the corresponding maximum pointer displacement are given, the value of the ratio hk_i/k_r is also known. However, the single values of h, k_i, and k_r can assume any value and are usually set in order to reduce the friction effects. In fact, if the restraining friction torque T_f is taken into account in the balance equation, Equation 18.5 becomes

$$k_i I = k_r\frac{\lambda}{h} \pm T_f \tag{18.11}$$

where the ± sign shows that the friction torque does not have its own sign but always opposes the rotation.

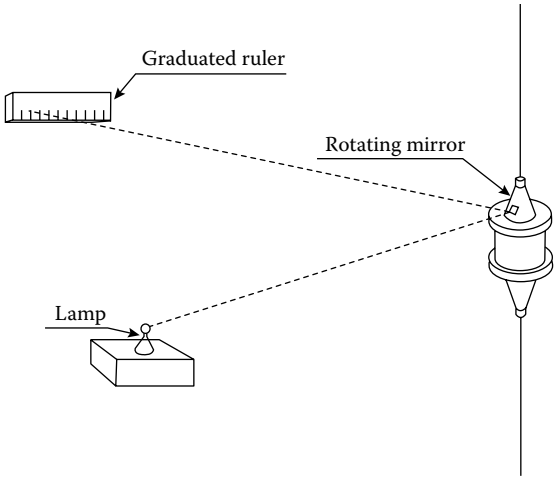

FIGURE 18.3 Virtual optical pointer structure in a dc galvanometer.

The effects of T_f can be neglected if the driving torque hk_iI and the restraining torque $k_r\lambda$ are sufficiently greater than T_f. Moreover, since the galvanometer is employed as a null indicator, a high sensitivity is needed; hence, k_a must be as high as possible. According to Equations 18.10 and 18.11, this requires high values of hk_i and low values of k_r. A high value of h means a long pointer; a high value of k_i means a high driving torque, while a low value of k_r means that the inertia of the whole moving system must be low.

The pointer length can be increased without increasing the moving system inertia by employing virtual optical pointers: a little, light concave mirror is fixed on the moving-coil axis and is lit by an external lamp. The reflected light hits a translucid, graduated ruler, so that the mirror rotation can be observed (Figure 18.3). In this way, a virtual pointer is obtained, whose length equals the distance between the mirror and the graduated ruler.

The reduction of the moving system inertia is obtained by reducing the weight and dimension of the moving coil and reducing the spring constant. This is usually done by suspending the moving coil with a thin fiber of conducting material (usually bronze). Thus, the friction torque is practically removed, and the restraining spring action is given by the fiber torsion.

According to Equations 18.3 and 18.4, the driving torque can be increased by increasing the coil flux linkage. Three parameters can be modified to attain this increase: the induction field B, the coil section ld, and the number of turns N of the coil winding.

The induction field B can be increased by employing high-quality permanent magnets, with high coercive force, and minimizing the air gap between the magnet's poles. This minimization prevents the use of moving coils with a large section. Moreover, large coil sections lead to heavier coils with greater inertia, which opposes the previous requirement of reduced inertia. For this reason, the coil section is usually rectangular (although a square section maximizes the flux linkage) and with $l > d$.

If the galvanometer is used to measure a low-voltage V, the *voltage sensitivity*, expressed in μV mm^{-1}, is the inverse of

$$k_v = \frac{\lambda}{V} \tag{18.12}$$

where k_v is called the galvanometer's *voltage constant* and is expressed in mm μV^{-1}.

18.2.2.2 Mechanical Characteristics

Due to the low inertia and low friction, the galvanometer moving system behaves as an oscillating mechanical system. The oscillations around the balance position are damped by the electromagnetic

forces that the oscillations of the coil in the magnetic field exert on the coil active sides. It can be proved [1] that the oscillation damping is a function of the coil circuit resistance, that is, the coil resistance r plus the equivalent resistance of the external circuit connected to the galvanometer. In particular, the damping effect is nil if the coil circuit is open and maximum if the coil is short-circuited.

In practical situations, a resistor is connected in series with the moving coil, whose resistance is selected in such a way to realize a critical damping of the coil movement. When this situation is obtained, the galvanometer is said to be *critically damped* and reaches its balance position in the shortest time, without oscillations around this position.

18.2.2.3 Actual Trends

Moving-coil dc galvanometers have been widely employed in the past when they represented the most important instrument for high-sensitivity measurements. In more recent years, due to the development of the electronic devices and particularly high-gain, low-noise amplifiers, the moving-coil galvanometers are being replaced by electronic galvanometers, which feature the same, or even better, performance than the electromagnetic ones.

18.3 Electrodynamic Voltmeters

18.3.1 AC Moving-Coil Voltmeters

The structure of an ac moving-coil meter is shown in Figure 18.4. It basically consists of a pivoted moving coil, two stationary field coils, control springs, a pointer, and a calibrated scale. The stationary coils are series connected, and when a current i_f is applied, a magnetic field B_f is generated

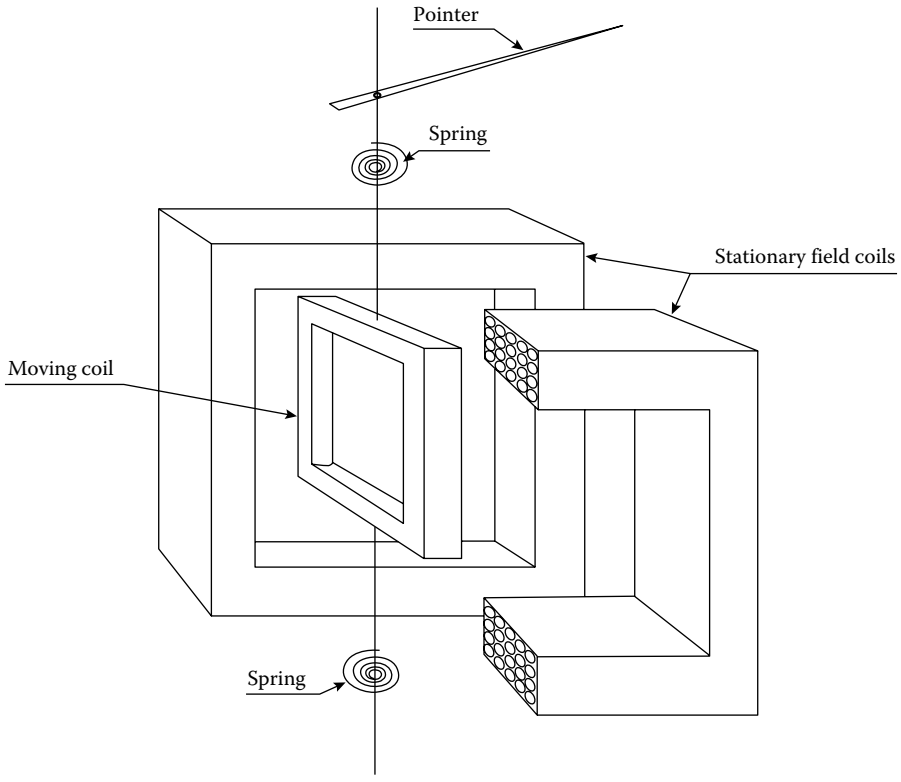

FIGURE 18.4 AC moving-coil meter.

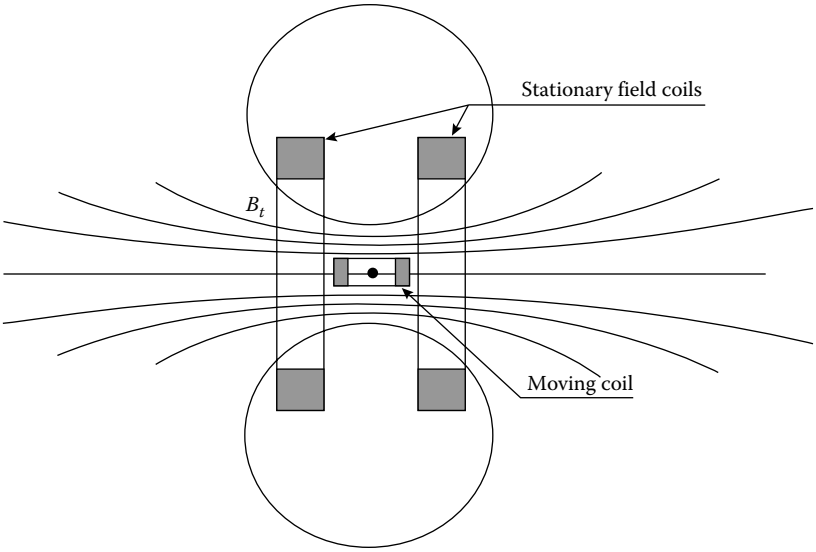

FIGURE 18.5 Magnetic field generated by the field coils in an ac moving-coil meter.

along the axis of the stationary coils, as shown in Figure 18.5. A magnetic flux is therefore generated, whose instantaneous values are given by

$$\varphi_f(t) = k' m_f i_f(t) \tag{18.13}$$

where

m_f is the number of turns of the stationary coil
k' is a proportionality factor

When a current i_m is applied to the moving coil, a torque arises, whose instantaneous values are proportional to the product of φ_f and i_m instantaneous values:

$$T_i(t) = k''\varphi_f(t) i_m(t) = k i_f(t) i_m(t) \tag{18.14}$$

The driving torque is therefore proportional to the instantaneous product of the currents flowing in the two coils. Due to this driving torque, the moving element is displaced by an angle (δt), until the spring restraining torque $T_s(t) = k_s\delta(t)$ balances the driving torque. The moving element rotation is thus given by

$$\delta(t) = \frac{k}{k_s} i_f(t) i_m(t) \tag{18.15}$$

and, if the pointer length is h, the following pointer displacement can be read on the scale:

$$\lambda(t) = h\frac{k}{k_s} i_f(t) i_m(t) \tag{18.16}$$

The proportionality factor k is generally not constant, since it depends on the mutual inductance between the two coils and thus on their number of turns, shape, and relative position. However, if the two coils are carefully designed and placed, the magnetic field can be assumed to be constant and radial in the rotation area of the moving coil. Under this condition, k is virtually constant.

Because the bandwidth of the moving element is limited to a few hertz, due to its inertia, the balance position is proportional to the average value of the driving torque when the signal bandwidth exceeds

this limit. If i_f and i_m currents are sinusoidal, with I_f and I_m rms values, respectively, and with a relative phase displacement β, the driving torque average value is given by

$$\overline{T_i} = kI_f I_m \cos\beta \tag{18.17}$$

and, thus, the pointer displacement in Equation 18.16 becomes

$$\lambda = h\frac{k}{k_s} I_f I_m \cos\beta \tag{18.18}$$

In order to realize a voltmeter, the stationary and moving coils are series connected, and a resistor, with resistance R, is also connected in series to the coils. If R is far greater than the resistance of the two coils and if it is also far greater than the coil inductance, in the frequency operating range of the voltmeter, the rms value of the coils' currents is given by

$$I_f = I_m = \frac{V}{R} \tag{18.19}$$

V being the applied voltage rms value. From Equation 18.18, the pointer displacement is therefore given by

$$\lambda = h\frac{k}{k_s}\frac{V^2}{R^2} = k_v V^2 \tag{18.20}$$

Because of Equation 18.20, the voltmeter features a square-law scale, with k_v constant, provided that the coils are carefully designed and that the coils' inductance can be neglected with respect to the resistance of the coils themselves and the series resistor. This last condition determines the upper limit of the input voltage frequency.

These voltmeters feature good accuracy (their uncertainty can be as low as 0.2% of the full-scale value), with full-scale values up to a few hundred volts, in a frequency range up to 2 kHz.

18.4 Electrostatic Voltmeters

The action of electrostatic instruments is based on the force exerted between two charged conductors. The conductors behave as a variable plate air capacitor, as shown in Figure 18.6. The moving plate, when charged, tends to move so as to increase the capacitance between the plates. The energy stored in the capacitor, when the applied voltage is V and the capacitance is C, is given by

$$W = \frac{1}{2}CV^2 \tag{18.21}$$

This relationship is valid under both dc and ac conditions, provided that the voltage rms value V is considered for ac voltage.

When the moving plate is displaced horizontally by ds, while the voltage is held constant, the capacitor energy changes in order to equal the work done in moving the plate. The resulting force is

$$F = \frac{\mathrm{d}W}{\mathrm{d}s} = \frac{V^2}{2}\frac{\mathrm{d}C}{\mathrm{d}s} \tag{18.22}$$

For a rotable system, Equation 18.21 leads similarly to a resulting torque:

$$T = \frac{\mathrm{d}W}{\mathrm{d}\vartheta} = \frac{V^2}{2}\frac{\mathrm{d}C}{\mathrm{d}\vartheta} \tag{18.23}$$

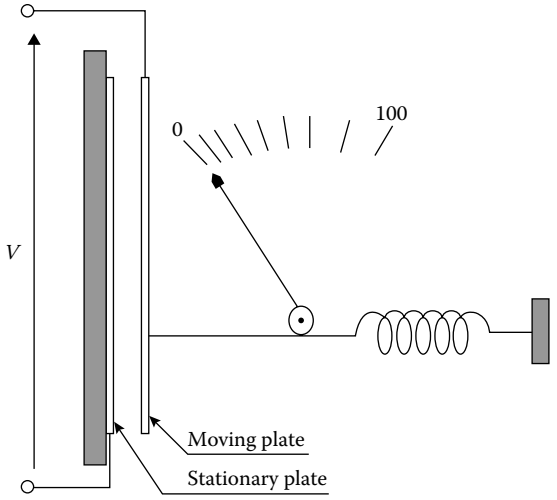

FIGURE 18.6 Basic structure of an electrostatic voltmeter.

If the action of a control spring is also considered, both Equations 18.22 and 18.23 show that the balance position of the moving plate is proportional to the square of the applied voltage, and hence electrostatic voltmeters have a square-law scale. These equations, along with Equation 18.21, show that these instruments can be used for the measurement of both dc and ac rms voltages. However, the force (or torque) supplied by the instrument schematically represented in Figure 18.6 is generally very weak [2], so that its use is very impractical.

18.4.1 Electrometer

A more useful configuration is the quadrant electrometer, shown in Figure 18.7. Four fixed plates realize four quadrants and surround a movable vane suspended by a torsion fiber at the center of the system. The opposite quadrants are electrically connected together, and the potential difference $(V_1 - V_2)$ is applied. The moving vane can be either connected to potential V_1 or V_2, or energized by an independent potential V_3.

Let the zero torque position of the suspension coincide with the symmetrical $X - X$ position of the vane. If $V_1 = V_2$, the vane does not leave this position; otherwise, the vane will rotate.

Let C_1 and C_2 be the capacitances of quadrants 1 and 2, respectively, relative to the vane. They both are functions of ϑ, and according to Equation 18.23, the torque applied to the vane is given by

$$T = \frac{(V_3 - V_1)^2}{2}\frac{\mathrm{d}C_1}{\mathrm{d}\vartheta} + \frac{(V_3 - V_2)^2}{2}\frac{\mathrm{d}C_2}{\mathrm{d}\vartheta} \tag{18.24}$$

Since the vane turns out of one pair of quadrants as much as it turns into the other, the variations of C_1 and C_2 can be related by

$$-\frac{\mathrm{d}C_1}{\mathrm{d}\vartheta} = \frac{\mathrm{d}C_2}{\mathrm{d}\vartheta} = k_1 \tag{18.25}$$

Taking into account the suspension restraining torque $T_r = k_2\vartheta$, the balance position can be obtained by Equations 18.24 and 18.25 as

$$\vartheta = \frac{k_1}{2k_2}[(V_3 - V_2)^2 - (V_3 - V_1)^2] \tag{18.26}$$

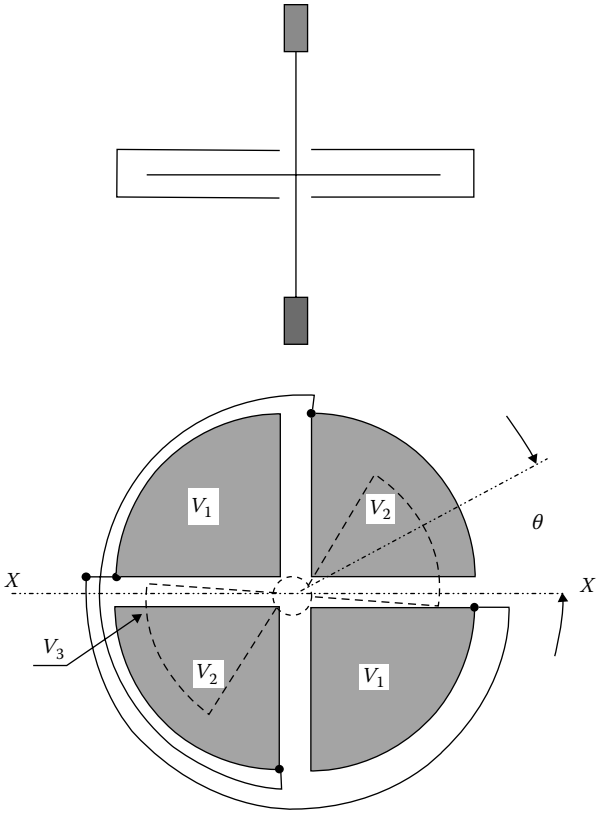

FIGURE 18.7 Quadrant electrometer structure.

If the vane potential V_3 is held constant and is large compared to the quadrant potentials V_1 and V_2, Equation 18.26 can be simplified as follows:

$$\vartheta = \frac{k_1}{k_2} V_3 (V_1 - V_2) \tag{18.27}$$

Equation 18.27 shows that the deflection of the vane is directly proportional to the voltage difference applied to the quadrants. This method of use is called the *heterostatic* method.

If the vane is connected to quadrant 1, $V_3 = V_1$ follows, and Equation 18.26 becomes

$$\vartheta = \frac{k_1}{2k_2} (V_1 - V_2)^2 \tag{18.28}$$

Equation 18.28 shows that the deflection of the vane is proportional to the square of the voltage difference applied to the quadrants, and hence this voltmeter has a square-law scale. This method of use is called the *idiostatic* method and is suitable for the direct measurement of dc and ac voltages without an auxiliary power source.

The driving torque of the electrometer is extremely weak, as in all electrostatic instruments. The major advantage of using this kind of meter is that it allows for the measurement of dc voltages without drawing current by the voltage source under test. Now, due to the availability of operational amplifiers with extremely high input impedance, they have been almost completely replaced by electronic meters with high input impedance.

18.5 Electronic Voltmeters

Electronic meters process the input signal by means of semiconductor devices in order to extract the information related to the required measurement [3,4]. An electronic meter can be basically represented as a three-port element, as shown in Figure 18.8.

The input signal port is an input port characterized by high impedance, so that the signal source has very little load. The measurement result port is an output port that provides the measurement result (in either an analog or digital form, depending on the way the input signal is processed) along with the power needed to energize the device used to display the measurement result. The power supply port is an input port that the electric power required to energize the meter internal devices and the display device flows through.

One of the main characteristics of an electronic meter is that it requires an external power supply. Although this may appear as a drawback of electronic meters, especially where portable meters are concerned, note that, this way, the energy required for the measurement is no longer drawn from the signal source.

The high-level performance of modern electronic devices yields meters that are as accurate (and sometime even more accurate) as the most accurate electromechanical meters. Because they do not require the extensive use of precision mechanics, they are presently less expensive than electromechanical meters and are slowly, but constantly, replacing them in almost all applications.

Depending on the way the input signal is processed, electronic meters are divided into *analog* and *digital* meters. Analog meters attain the required measurement by analog, continuous-time processing of the input signal. The measurement result can be displayed both in analog form using, for example, an electromechanical meter, and in digital form by converting the analog output signal into digital form. Digital meters attain the required measurement by digital processing of the input signal. The measurement result is usually displayed in digital form. Note that the distinction between analog and digital meters is not due to the way the measurement result is displayed but to the way the input signal is processed.

18.5.1 Analog Voltmeters

An electronic analog voltmeter is based on an electronic amplifier and an electromechanical meter to measure the amplifier output signal. The amplifier operates to make a dc current, proportional to the input quantity to be measured, flow into the meter. This meter is hence a dc moving-coil milliammeter.

Different full-scale values can be obtained using a selectable-ratio voltage divider if the input voltage is higher than the amplifier dynamic range or by selecting the proper amplifier gain if the input voltage stays within the amplifier dynamic range.

The main features of analog voltmeters are high input impedance, high possible gain, and wide possible bandwidth for ac measurements. The relative measurement uncertainty can be lower than 1% of full-scale value. Because of these features, electronic analog voltmeters can have better performance than the electromechanical ones.

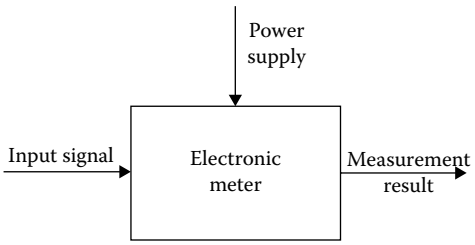

FIGURE 18.8 Electronic meter.

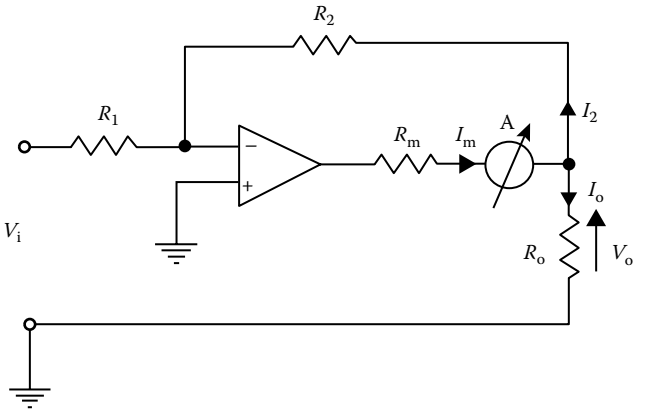

FIGURE 18.9 Electronic dc analog voltmeter schematics.

18.5.1.1 DC Analog Voltmeters

Figure 18.9 shows the circuit for an electronic dc analog voltmeter. Assuming that the operational amplifier exhibits ideal behavior, current I_m flowing in the milliammeter A is given by

$$I_m = I_o + I_2 = \frac{V_o}{R_o} + \frac{V_o}{R_2} = -V_i \frac{R_2}{R_1} \frac{R_2 + R_o}{R_2 R_o} = -\frac{V_i}{R_1}\left(1 + \frac{R_2}{R_o}\right) \tag{18.29}$$

If $R_1 = R_2$ and the same resistances are far greater than R_o, Equation 18.29 can be simplified to

$$I_m = -\frac{V_i}{R_o} \tag{18.30}$$

Equation 18.30 shows that the milliammeter reading is directly proportional to the input voltage through resistance R_o only. This means that, once the milliammeter full-scale value is set, the voltmeter full-scale value can be changed, within the dynamic range of the amplifier, by changing the R_o value. This way, the meter full-scale value can be changed without changing its input impedance.

18.5.1.2 Rectifier-Based AC Analog Voltmeters

Analog meters for ac voltages can be obtained starting from the dc analog voltmeters, with a rectifying input stage. Figure 18.10 shows how the structure in Figure 18.9 can be modified in order to realize an ac voltmeter.

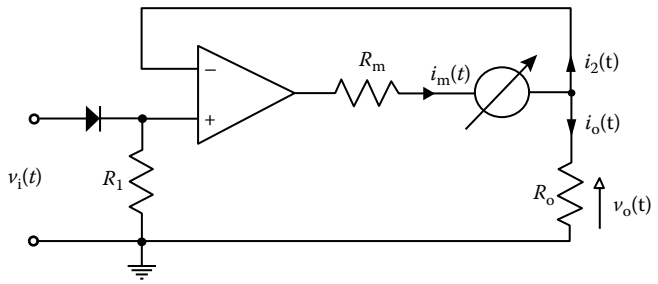

FIGURE 18.10 Electronic, rectifier-based ac analog voltmeter schematics.

Because of the high input impedance of the electronic amplifier, $i_2(t) = 0$, and the current $i_m(t)$ flowing in the milliammeter A is the same as current $i_o(t)$ flowing in the load resistance. Since the amplifier is connected in a voltage-follower configuration, the output voltage is given by

$$v_o(t) = v_i(t) \tag{18.31}$$

Due to the presence of the input diode, current $i_m(t)$ is given by

$$i_m(t) = \frac{v_i(t)}{R_o} \tag{18.32}$$

when $v_i(t) > 0$, and

$$i_m(t) = 0 \tag{18.33}$$

when $v_i(t) \leq 0$. If $v_i(t)$ is supposed to be a sine wave, the waveform of $i_m(t)$ is shown in Figure 18.11.

The dc moving-coil milliammeter measures the average value $\overline{I}_m$ of $i_m(t)$, which, under the assumption of sinusoidal signals, is related to the rms value V_i of $v_i(t)$ by

$$\overline{I}_m = \frac{2\sqrt{2}}{\pi R_o} V_i \tag{18.34}$$

The performance of the structure in Figure 18.10 can be substantially improved by considering the structure in Figure 18.12, which realizes a full-wave rectifier. Because of the presence of diodes D_1 and D_2, the output of amplifier A_1 is given by

$$v_1(t) = \begin{cases} -v_i(t) & \text{for } v_i(t) \geq 0 \\ 0 & \text{for } v_i(t) < 0 \end{cases} \tag{18.35}$$

where $v_i(t)$ is the circuit input voltage.

If capacitor C is supposed to be not connected, amplifier A_2 output voltage is

$$v_o(t) = -\left[v_i(t) + 2v_1(t)\right] \tag{18.36}$$

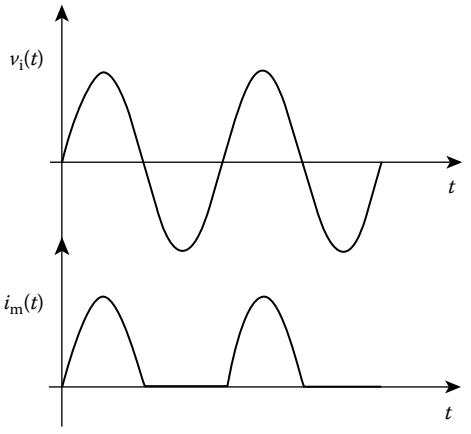

FIGURE 18.11 Signal waveforms in a rectifier-based ac analog voltmeter when the input voltage is sinusoidal.

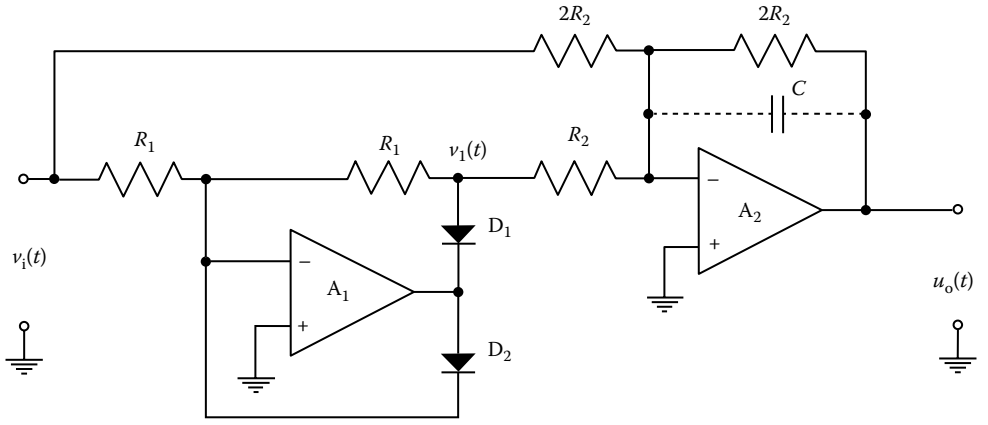

FIGURE 18.12 Electronic, full-wave rectifier-based ac analog voltmeter schematics.

that gives

$$v_o(t) = \begin{cases} v_i(t) & \text{for } v_i(t) \geq 0 \\ -v_i(t) & \text{for } v_i(t) < 0 \end{cases} \tag{18.37}$$

thus proving that the circuit in Figure 18.12 realizes a full-wave rectifier.

If $v_i(t)$ is a sine wave, the waveforms of $v_i(t)$, $v_1(t)$, and $v_o(t)$ are shown in Figure 18.13. Connecting capacitor C in the feedback loop of amplifier A_2 turns it into a first-order low-pass filter, so that the circuit output voltage equals the average value of $v_o(t)$:

$$\overline{V}_o = \overline{|v_i(t)|} \tag{18.38}$$

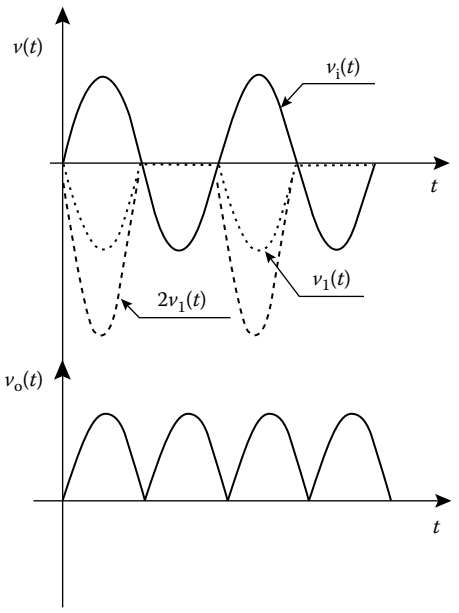

FIGURE 18.13 Signal waveforms in a full-wave rectifier-based ac analog voltmeter when the input voltage is sinusoidal.

In the case of sinusoidal input voltage with rms value V_i, the output voltage is related to this rms value by

$$\bar{V}_o = \frac{2\sqrt{2}}{\pi} V_i \tag{18.39}$$

$\bar{V}_o$ can be measured by a dc voltmeter.

Both meters in Figures 18.10 and 18.12 are actually average detectors. However, due to Equations 18.34 and 18.39, their scale can be labeled in such a way that the instrument reading gives the rms value of the input voltage, provided it is sinusoidal. When the input voltage is no longer sinusoidal, an error arises that depends on the signal form factor.

18.5.1.3 True rms Analog Voltmeters

The rms value V_i, of a periodic input voltage signal $v_i(t)$, with period T, is given by

$$V_i = \sqrt{\frac{1}{T}\int_0^T v_i^2(t)\,dt} \tag{18.40}$$

The electronic circuit shown in Figure 18.14 provides an output signal V_o proportional to the squared rms value of the input signal $v_i(t)$. The circuit section between nodes 1 and 2 is a full-wave rectifier. Hence, node 2 potential is given by

$$v_2(t) = \left|v_i(t)\right| \tag{18.41}$$

The circuit section between nodes 2 and 4 is a log multiplier. Because of the logarithmic characteristic of the feedback path due to the presence of T_1 and T_2, node 3 potential is given by

$$v_3(t) = 2k_1 \log[v_2(t)] = k_1 \log[v_2^2(t)] = k_1 \log\left[\left|v_i(t)\right|^2\right] = k_1 \log[v_i^2(t)] \tag{18.42}$$

and, due to the presence of T_3, the current flowing in node 4 is given by

$$i_4(t) = k_2 \exp\left[v_3(t)\right] = k_3 v_i^2(t) \tag{18.43}$$

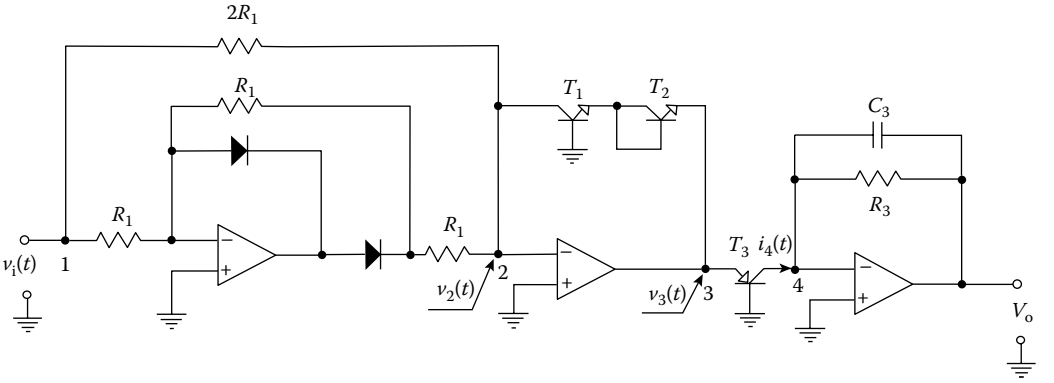

FIGURE 18.14 True rms electronic ac voltmeter schematics.

The circuit section after node 4 is a low-pass filter that extracts the dc component of the input signal. Therefore, the circuit output voltage is given by

$$V_o = \frac{k}{T}\int_0^T v_i^2(t)\mathrm{d}t = kV_i^2 \tag{18.44}$$

thus providing an output signal proportional to the squared rms value of the input signal $v_i(t)$ in accordance with Equation 18.40. Quantities k_1, k_2, and k depend on the values of the elements in the circuit in Figure 18.14. Under circuit operating conditions, their values can be considered constant, so that k_1, k_2, and k can be considered constant also.

If carefully designed, this circuit can feature an uncertainty in the range of ±1% of full scale, for signal frequencies up to 100 kHz.

18.5.2 Digital Voltmeters

A digital voltmeter (DVM) attains the required measurement by converting the analog input signal into digital and, when necessary, by discrete-time processing of the converted values. The measurement result is presented in a digital form that can take the form of a digital front-panel display or a digital output signal. The digital output signal can be coded as a decimal BCD code or a binary code.

The main factors that characterize DVMs are speed, automatic operation, and programmability. In particular, they presently offer the best combination of speed and accuracy if compared with other available voltage-measuring instruments. Moreover, the capability of automatic operations and programmability make DVMs very useful in applications where flexibility, high speed, and computer controllability are required. A typical application field is therefore that of automatically operated systems.

When a DVM is directly interfaced to a digital signal processing system and used to convert the analog input voltage into a sequence of sampled values, it is usually called an analog-to-digital converter (ADC).

DVMs basically differ in the following ways: (1) number of measurement ranges, (2) number of digits, (3) accuracy, (4) speed of reading, and (5) operating principle.

The basic measurement ranges of most DVMs are either 1 or 10 V. It is however possible, with an appropriate preamplifier stage, to obtain full-scale values as low as 0.1 V. If an appropriate voltage divider is used, it is also possible to obtain full-scale values as high as 1000 V.

If the digital presentation takes the form of a digital front-panel display, the measurement result is presented as a decimal number, with a number of digits that typically range from 3 to 6. If the digital representation takes the form of a binary-coded output signal, the number of bits of this representation typically ranges from 8 to 16, though 18 to 24 bit ADCs are now available.

The accuracy of a DVM is usually correlated to its resolution. Indeed, assigning an uncertainty lower than 0.1% of the range to a three-digit DVM makes no sense, since this is the displayed resolution of the instrument. Similarly, a poorer accuracy makes the three-digit resolution quite useless. Presently, a six-digit DVM can feature an uncertainty range, for short periods of time in controlled environments, as low as 0.0015% of reading or 0.0002% of full range.

The speed of a DVM can be as high as 1000 readings per second. When the ADC is considered, the conversion rate is taken into account instead of the speed of reading. Presently, the conversion rate for 12 bit, successive approximation ADCs can be on the order of 10 MHz. It can be in the order of 100 MHz to 1 GHz for lower resolution, flash ADCs [5].

DVMs can be divided into two main operating principle classes: the *integrating* types and the *nonintegrating* types [3]. The following sections give an example for both types.

18.5.2.1 Dual-Slope DVM

Dual-slope DVMs use a counter and an integrator to convert an unknown analog input voltage into a ratio of time periods multiplied by a reference voltage. The block diagram in Figure 18.15 shows this operating principle. The switch S1 connects the input signal to the integrator for a fixed period of time t_f. If the input voltage is positive and constant, $v_i(t) = V_i > 0$, the integrator output represents a negative-slope ramp signal (Figure 18.16). At the end of t_f, S1 switches and connects the output of the voltage reference V_R to the integrator input. The voltage reference output is negative for a positive input voltage. The integrator output starts to increase, following a positive-slope ramp (Figure 18.16). The process stops when the ramp attains the 0 V level, and the comparator allows the control logic to switch S1 again. The period of time t_v the ramp takes to increase to 0 V is variable and depends on the ramp peak value attained during period t_f.

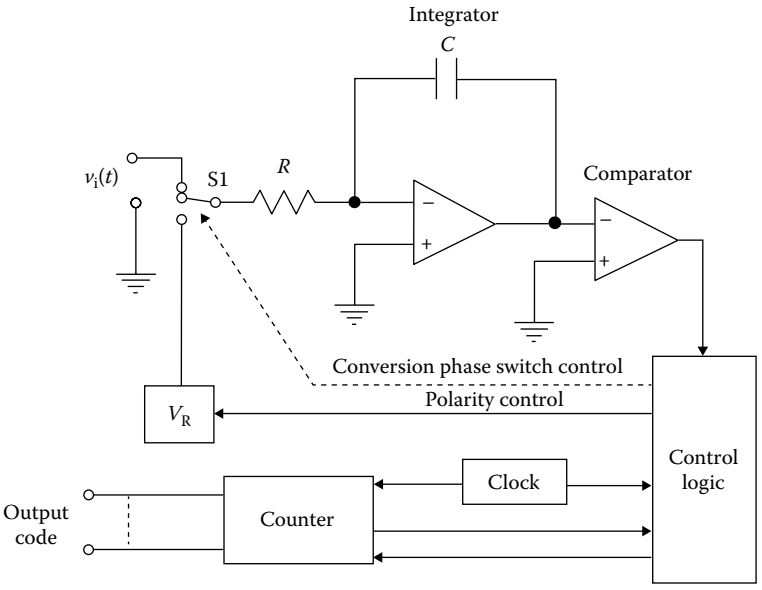

FIGURE 18.15 Dual-slope DVM schematics.

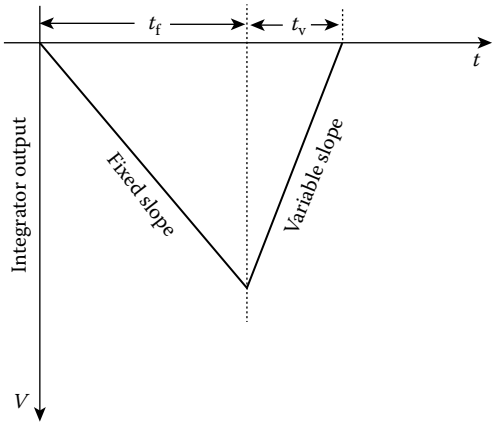

FIGURE 18.16 Integrator output signal in a dual-slope DVM.

The relationship between the input voltage V_i and the time periods t_v and t_f is given by

$$\frac{1}{RC}\int_0^{t_f} V_i \, dt = \frac{t_v}{RC} V_R \tag{18.45}$$

that, for a constant input voltage V_i, leads to

$$V_i = V_R \frac{t_v}{t_f} \tag{18.46}$$

Since the same integrating circuit is used, errors due to comparator offset, capacitor tolerances, long-term counter clock drifts, and integrator nonlinearities are eliminated. High resolutions are therefore possible, although the speed of reading is low (in the order of milliseconds).

Slowly varying voltages can be also measured by dual-slope DVMs. However, this requires that the input signal does not vary for a quantity greater than the DVM resolution during the reading time. For high-resolution DVMs, this limits the DVM bandwidth to a few hertz.

18.5.2.2 Successive Approximation ADC

The successive approximation technique represents the most popular technique for the realization of ADCs. Figure 18.17 shows the block diagram of this type of converter. The input voltage is assumed to have a constant value V_i and drives one input of the comparator. The other comparator's input is driven by the output of the digital-to-analog converter (DAC), which converts the binary code provided by the successive approximation register (SAR) into an analog voltage. Let n be the number of bits of the converter, V_R the voltage reference output, and C the code provided by the SAR. The DAC output voltage is then given by

$$V_c = \frac{C}{2^n} V_R \tag{18.47}$$

When the conversion process starts, the SAR most significant bit (MSB) is set to logic 1. The DAC output, according to Equation 18.47, is set to half the reference value and hence half the analog input full-scale range. The comparator determines whether the DAC output is above or below the input signal. The comparator output controls the SAR in such a way that, if the input signal is above the DAC output, as shown in Figure 18.18, the SAR MSB is retained and the next bit is set to logic 1.

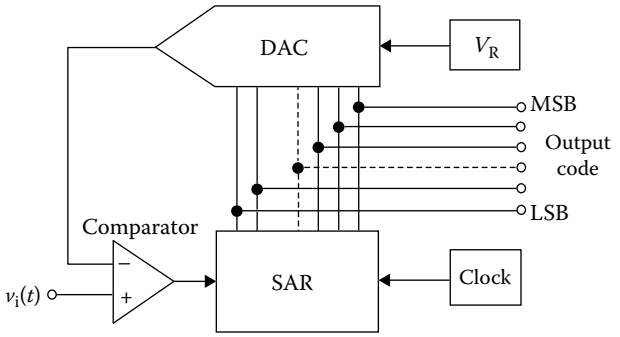

FIGURE 18.17 Successive approximation ADC schematics.

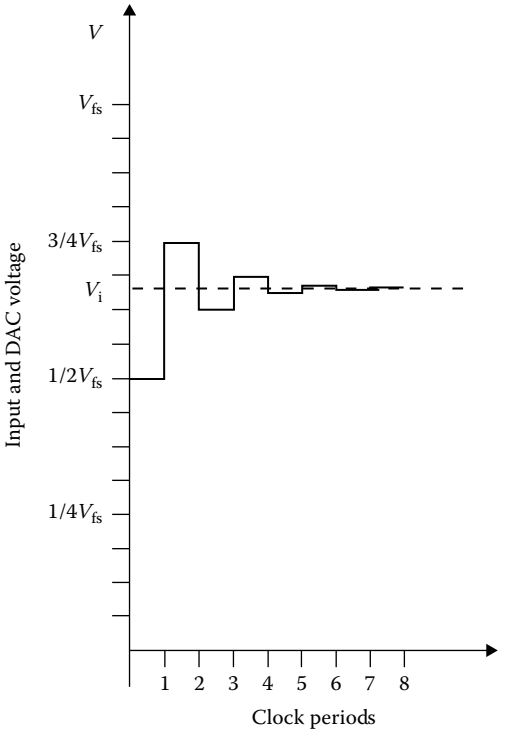

FIGURE 18.18 DAC output signal in a successive approximation ADC.

If now the input signal is below the DAC output (Figure 18.18), the last SAR bit set to logic 1 is reset to logic 0, and the next one is set to logic 1. The process goes on until the SAR least significant bit (LSB) has been set. The entire conversion process takes time $t_c = nT_c$, where T_c is the clock period. At the end of conversion, the SAR output code represents the digitally converted value of the input analog voltage V_i.

According to Equation 18.47, the ADC resolution is $V_R/2^n$, which corresponds to 1 LSB. The conversion error can be kept in the range ±½ LSB. Presently, a wide range of devices is available, with resolution from 8 to 16 bits and conversion rates from 100 μs to below 1 μs.

Varying voltages can be sampled and converted into digital by the ADC, provided the input signal does not vary by a quantity greater than $V_R/2^n$ during the conversion period t_c. The maximum frequency of an input sine wave that satisfies this condition can be readily determined starting from given values of n and t_c.

Let the input voltage of the ADC be an input sine wave with peak-to-peak voltage $V_{pp} = V_R$ and frequency f. Its maximum variation occurs at the zero-crossing time and, due to the short conversion period t_c, is given by $2\pi f t_c V_{pp}$. To avoid conversion errors, it must be

$$2\pi f t_c V_{pp} \leq \frac{V_R}{2^n} \tag{18.48}$$

Since $V_{pp} = V_R$ is assumed, this leads to

$$f \leq \frac{1}{2^n 2\pi t_c} \tag{18.49}$$

If $t_c = 1$ μs and $n = 12$, Equation 18.49 leads to $f \leq 38.86$ Hz. However, ADCs can still be employed with input signals whose frequency exceeds the value given by Equation 18.49, provided that a *sample and hold* circuit is used to keep the input voltage constant during the conversion period.

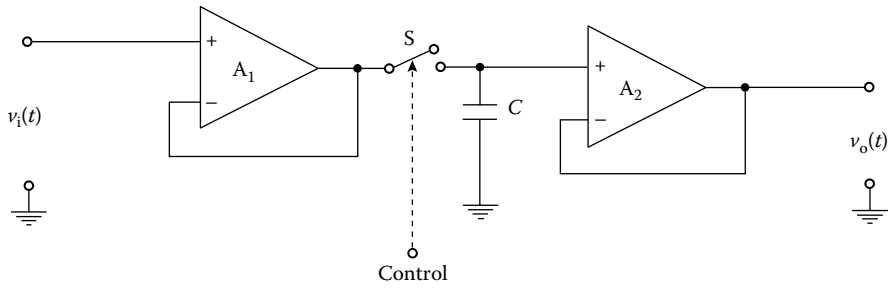

FIGURE 18.19 Sample and hold schematics.

The *sample and hold* circuit is shown in Figure 18.19. When the electronic switch S is closed, the output voltage $v_o(t)$ follows the input voltage $v_i(t)$. When switch S is open, the output voltage is the same as the voltage across capacitor *C*, which is charged at the value assumed by the input voltage at the time the switch was opened. Due to the high input impedance of the operational amplifier A_2, if a suitable value is chosen for capacitor *C*, its discharge transient is slow enough to keep the variation of the output voltage below the ADC resolution.

18.5.2.3 Delta–Sigma ADC

The modern delta–sigma (Δ–Σ) ADC combines the dual-slope technique with a DSP technique to attain the good accuracy and linearity of the dual-slope DVM with a much shorter conversion time.

The block diagram of a Δ–Σ ADC is shown in Figure 18.20. Two main blocks can be recognized: an analog modulator and a digital filter. The operations of both devices are synchronized by a high-frequency clock.

The analog modulator can be schematically represented with an integrator, a comparator, and a single-bit DAC. The comparator provides the modulator digital, single-bit output signal, called *bit stream*. The DAC provides a two-level, bipolar voltage V_{DA} that acts as the feedback signal of the modulator closed-loop structure. The absolute value of V_{DA} must be greater than the converter full-scale input voltage. It can be recognized that the modulator structure is similar, in principle, to that of the dual-slope converter of Figure 18.15.

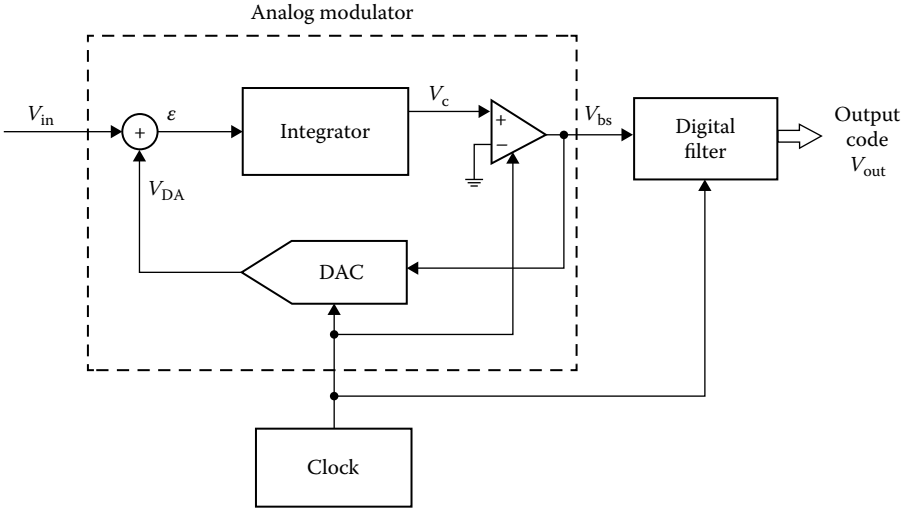

FIGURE 18.20 Δ–Σ ADC schematics.

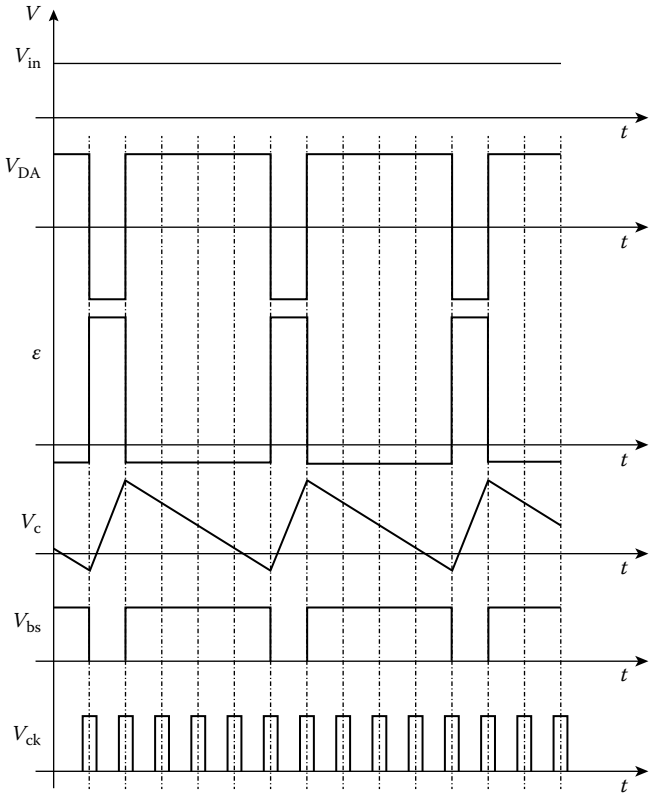

FIGURE 18.21 Operating principle of a Δ–Σ modulator.

The modulator operating principle is shown, in the time domain, in Figure 18.21. Let us suppose that the input voltage V_{in} is positive and constant and the integrator output is negative at the first clock pulse. Consequently, the comparator output V_{bs} is switched to the low level by the clock pulse. The DAC output voltage is switched to the negative $-V_{DA}$ value and subtracted to V_{in}, so that the input signal ε to the integrator is positive and high enough to force the integrator output V_c to become positive before the next clock pulse.

Consequently, the comparator output is switched to the high value at the next clock pulse, thus driving the DAC value to its positive V_{DA} value. Signal ε becomes now negative, with an absolute value that is inversely proportional to V_{in}. Therefore, the integrator output signal decreases to zero with a negative, slower slope than the positive one. Positive and negative slopes are equal only if $V_{in} = 0$. At the first clock pulse after V_c becomes negative, the whole process restarts.

For constant input signals V_{in}, the modulator output V_{bs} and comparator output V_c are periodic (Figure 18.21), with period NT_{ck}, T_{ck} being the clock period.

The relationship between V_{in} and the V_{bs} period can be obtained in a similar way as that followed to study the dual-slope DVM. It is

$$\int_0^{T_{ck}} \left(V_{in} + V_{DA}\right) dt = \int_{T_{ck}}^{(N-1)T_{ck}} \left(V_{DA} - V_{in}\right) dt \tag{18.50}$$

that leads to

$$V_{in} = \frac{N-2}{N} V_{DA} \tag{18.51}$$

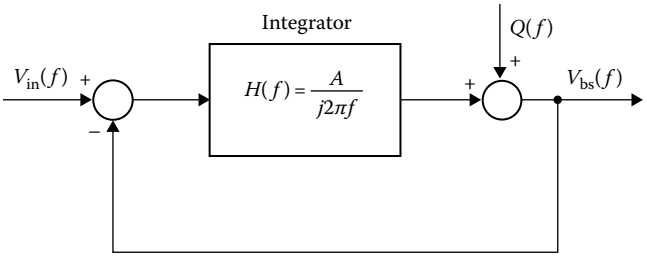

FIGURE 18.22 Linearized, frequency-domain model of a Δ–Σ modulator.

Therefore, the value of the input voltage V_{in} is related to the succession of 1 and 0 bits in the bit stream obtained as output signal V_{bs} by the comparator.

A better insight on the way the modulator works can be obtained by considering variable input signals and analyzing the modulator in the frequency domain. Figure 18.22 shows the linearized, frequency-domain model of the modulator, where the comparator effect is modeled as a quantization noise $q(t)$.

The Fourier transform $V_{bs}(f)$ of the modulator output signal is related to the Fourier transforms $V_{in}(f)$ and $Q(f)$ of the input signal and quantization noise, respectively, by the following relationship:

$$V_{bs}(f) = \frac{A}{A + j2\pi f} \cdot V_{in}(f) + \frac{j2\pi f}{A + j2\pi f} \cdot Q(f) \tag{18.52}$$

where A is the integrator constant and depends on the modulator parameters.

It can be easily recognized that the input signal and the quantization noise are processed in a quite different way by the modulator. Indeed, the first term in Equation 18.52 represents a low-pass filter, with cutoff frequency $f_c = A/2\pi$, applied to the input signal. On the other hand, the second term in Equation 18.52 represents a high-pass filter, with the same cutoff frequency f_c, applied to the quantization noise.

Therefore, the signal spectral components are separated by the quantization noise components, as shown in Figure 18.23. If the modulator parameters are such that $f_0 < f_c$, f_0 being the upper limit of the input signal band, and the clock frequency f_{ck} is significantly higher than the Nyquist frequency $2 \cdot f_0$, the input signal is not modified by the modulator, while most part of the quantization noise is moved outside the signal band, thus improving the signal-to-noise ratio inside the signal band. Because of this result, the modulator of a Δ–Σ ADC is often called *noise-shaping filter*, and its frequency response is shown in Figure 18.23.

In order to extract the input signal components from the V_{bs} bit stream modulator output, this signal has to be low-pass filtered, with cutoff frequency f_c' in the range: $f_0 < f_c' < f_c$. This is done by the digital filter in Figure 18.20. The digital filter is a finite impulse response (FIR) filter [6,7] that provides the output code as a linear combination of M previous samples of V_{bs}:

$$V_{out}(n) = \sum_{k=0}^{M} a_k \cdot V_{bs}(n-k) \tag{18.53}$$

where the filter order M and the M a_k coefficients are defined according to the desired frequency response [6,7]. Equation 18.53 shows also that, being V_{bs} coded on a single bit, the number of bits on which V_{out} is coded depends on the number of bits employed to code the a_k coefficients.

Therefore, a Δ–Σ ADC can feature a virtually unlimited number of bits. The actual limit is set by the residual noise left in the signal band by the noise-shaping filter. This residual noise can be further reduced by increasing the modulator order or, if the signal bandwidth is much lower than

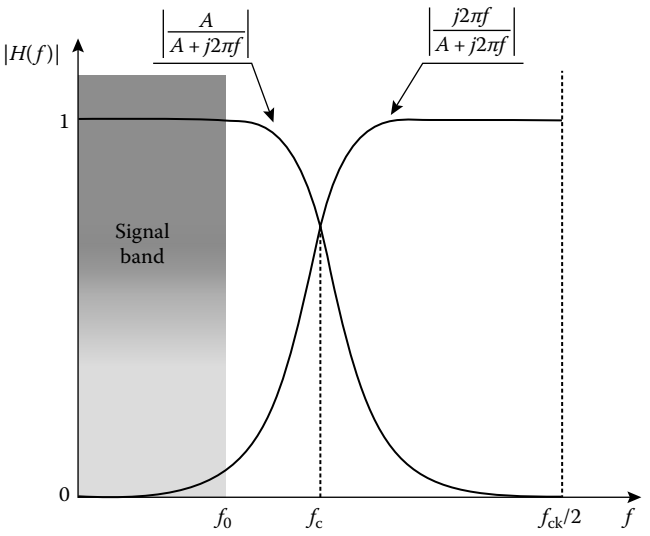

FIGURE 18.23 Frequency response of the noise-shaping filter.

half the clock frequency (which represents the actual sampling frequency), by applying decimation techniques on the V_{out} sequence.

Nowadays, 24 bit Δ–Σ ADCs are available, with sampling frequency up to 200 kHz. Higher sampling frequencies can be obtained with a lower resolution.

18.5.2.4 AC Digital Voltmeters

True rms ac voltmeters with digital reading can be obtained using an electronic circuit like the one in Figure 18.14 to convert the rms value into a dc voltage signal and measuring it by means of a DVM.

However, this structure cannot actually be called a digital structure, because the measurement is attained by means of analog processing of the input signal.

A more modern approach, totally digital, is shown in Figure 18.24. The input signal $u_i(t)$ is sampled at constant sampling rate f_s and converted into digital by the ADC. The digital samples are stored in the memory of the digital signal processor (DSP) and then processed in order to evaluate Equation 18.40 in a numerical way. Assuming that the input signal is periodic, with period T, and its frequency spectrum is upper limited by harmonic component of order N, the sampling theorem is satisfied if at least $(2N + 1)$ samples are taken over period T in such a way that $(2N + 1)T_s = T$, $T_s = 1/f_s$ being the sampling period [6,7]. If $u_i(kT_s)$ is the kth sample, the rms value of the input signal is given by, according to Equation 18.40,

$$V^2 = \sqrt{\frac{1}{2N+1}\sum_{k=0}^{2N} v_i^2(kT_s)} \tag{18.54}$$

This approach can feature a relative uncertainty as low as ±0.1% of full scale, with an ADC resolution of 12 bits. The instrument bandwidth is limited to half the sampling frequency, according to the

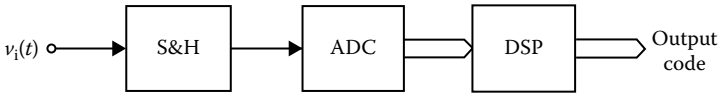

FIGURE 18.24 Block diagram of a modern digital meter.

sampling theorem. When modern ADCs and DSPs are employed, a 500 kHz to 1 MHz bandwidth can be obtained. Wider bandwidths can be obtained but with a lower ADC resolution and hence with a lower accuracy.

18.5.2.5 Frequency Response of AC Voltmeters

When the frequency response of ac voltmeters is taken into account, a distinction must be made between the analog voltmeters (both electromechanical and electronic) and DVMs, based on DSP techniques.

The frequency response of the analog meters is basically a low-pass response, well below 1 kHz for most electromechanical instruments and up to hundreds of kilohertz for electronic instruments.

When digital, DSP-based meters are concerned, the sampling theorem and aliasing effects must be considered. To a first approximation, the frequency response of a digital meter can be considered flat as long as the frequency-domain components of the input signal are limited to a frequency band narrower than half the sampling rate. If the signal components exceed this limit (the so-called Nyquist frequency), the aliasing phenomenon occurs [6]. Because of this phenomenon, the signal components at frequencies higher than half the sampling rate are folded over the lower-frequency components, changing them. Large measurement errors occur under this situation.

To prevent the aliasing, a low-pass filter must be placed at the input stage of any digital meter. The filter cutoff frequency must ensure that all frequency components above half the sampling rate are negligible. If the low-pass, antialiasing filter is used, the digital DSP-based meters feature a low-pass frequency response also.

Oscilloscope Voltage Measurement

Jerry Murphy
Hewlett-Packard

19.1 Introduction

Engineers, scientists, and other technical professionals around the world depend on oscilloscopes as one of the primary voltage measuring instruments. This is an unusual situation because the oscilloscope is not the most accurate voltage measuring instrument usually available in the lab. It is the graphical nature of the oscilloscope that makes it so valued as a measurement instrument—not its measurement accuracy.

The oscilloscope is an instrument that presents a graphical display of its input voltage as a function of time. It displays voltage waveforms that cannot easily be described by numerical methods. For example, the output of a battery can be completely described by its output voltage and current. However, the output of more complex signal source needs additional information such as frequency, duty cycle, peak-to-peak amplitude, overshoot, preshoot, rise time, fall time, and more to be completely described. The oscilloscope, with its graphical presentation of complex waveforms, is ideally suited to this task. It is often described as the "screwdriver of the electronic engineer" because the oscilloscope is the most fundamental tool that technical professionals apply to the problem of trying to understand the details of the operation of their electronic circuit or device. So, what is an oscilloscope?

The oscilloscope is an electronic instrument that presents a high-fidelity graphical display of the rapidly changing voltage at its input terminals.

The most frequently used display mode is voltage versus time. This is not the only display that could be used, nor is it the display that is best suited for all situations. For example, the oscilloscope could be called on to produce a display of two changing voltages plotted one against the other, such as a Lissajous display. To accurately display rapidly changing signals, the oscilloscope is a high-bandwidth device. This means that it must be capable of displaying the high-order harmonics of the signal being applied to its input terminals in order to correctly display that signal.

19.2 Oscilloscope Block Diagram

The oscilloscope contains four basic circuit blocks: the vertical amplifier, the time base, the trigger, and the display. This section treats each of these in a high-level overview. Many textbooks exist that cover the details of the design and construction of each of these blocks in detail [1]. This discussion will cover these blocks in enough detail so that readers can construct their own mental model of how their operation affects the application of the oscilloscope for their voltage measurement application. Most readers of this book have a mental model of the operation of the automatic transmission of an automobile that is sufficient for its successful operation but not sufficient for the overhaul or redesign of that component. It is the goal of this section to instill that level of understanding in the operation of the oscilloscope. Those readers who desire a deeper understanding will get their needs met in later sections.

Of the four basic blocks of the oscilloscope, the most visible of these blocks is the display with its *cathode-ray tube* (CRT). This is the component in the oscilloscope that produces the graphical display of the input voltage, and it is the component with which the user has the most contact. Figure 19.1 shows that the input signal is applied to the vertical axis of a CRT. This is the correct model for an analog oscilloscope, but it is overly simplified in the case of the digital oscilloscope. The important thing to learn from this diagram is that the input signal will be operated on by the oscilloscope's vertical axis circuits so that it can be displayed by the CRT. The differences between the analog and digital oscilloscope are covered in sections to follow.

The *vertical amplifier* conditions the input signal so that it can be displayed on the CRT. The vertical amplifier provides controls of volts per division, position, and coupling, allowing the user to obtain the desired display. This amplifier must have a high enough bandwidth to ensure that all of the significant frequency components of the input signal reach the CRT.

The *trigger* is responsible for starting the display at the same point on the input signal every time the display is refreshed. It is the stable display of a complex waveform that allows the user of an oscilloscope to make judgments about that waveform and its implications as to the operation of the device under test.

The final piece of the simplified block diagram is the *time base*. This circuit block is also known as the horizontal system in some literature. The time base is the part of the oscilloscope that causes the input signal

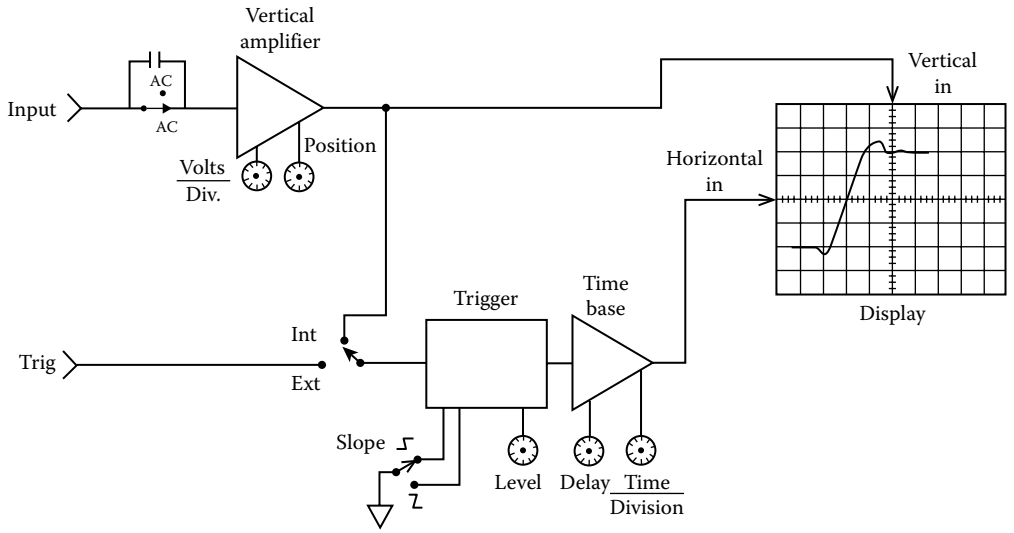

FIGURE 19.1 Simplified oscilloscope block diagram that applies to either analog or digital oscilloscopes. In the case of the digital oscilloscope, the vertical amplifier block will include the ADC and high-speed waveform memory. For the analog scope, the vertical block will include delay lines with their associated drivers and a power amplifier to drive the CRT plates.

to be displayed as a function of time. The circuitry in this block causes the CRT beam to be deflected from left to right as the input signal is being applied to the vertical deflection section of the CRT. Controls for time per division and position (or delay) allow the user of the oscilloscope to adjust the display for the most useful display of the input signal. The time-per-division controls of most oscilloscopes provide a wide range of values, ranging from a few nanoseconds (10^{-9} s) to seconds per division. To get a feeling for the magnitude of the dynamic range of the oscilloscope's time base settings, keep in mind that light travels about 1 m in 3 ns.

19.3 Oscilloscope as a Voltage Measurement Instrument

That the oscilloscope's vertical axis requires a wide-bandwidth amplifier and its time base is capable of displaying events that are as short as a few nanoseconds apart indicates that the oscilloscope can display rapidly changing voltages. Voltmeters, on the other hand, are designed to give their operator a numeric readout of steady-state or slowly changing voltages. Voltmeters are not well suited for displaying voltages that are changing levels very quickly. This can be better understood by the examination of the operation of a voltmeter as compared to that of an oscilloscope. The analog voltmeter uses the magnetic field produced by current flowing through a coil to move the pointer against the force of a spring. This nearly linear deflection of the voltmeter pointer is calibrated by applying known standard voltages to its input. Therefore, if a constant voltage is applied to the coil, the pointer will move to a point where the magnetic force being produced by the current flowing in its coil is balanced by the force of the spring. If the input voltage is slowly changing, the pointer will follow the changing voltage. This mechanical deflection system limits the ability of this measurement device to the measurement of steady-state or very low-frequency changes in the voltage at its input terminals. Higher frequency voltmeters depend on some type of conversion technique to change higher frequencies to a dc signal that can be applied to the meter's deflection coil. For example, a diode is used to rectify ac voltages to produce a dc voltage that corresponds to the average value of the ac voltage at the input terminals in average responding ac voltmeters.

The digital voltmeter is very much like the analog meter except that the mechanical displacement of the pointer is replaced with a digital readout of the input signal. In the case of the digital voltmeter, the input signal is applied to an analog-to-digital converter (ADC) where it is compared to a reference voltage and digitized. This digital value of the input signal is then displayed in a numerical display. The ADC techniques applied to voltmeters are designed to produce very accurate displays of the same signals that were previously measured with analog meters. The value of a digital voltmeter is its improved measurement accuracy as compared to that of its analog predecessors.

The oscilloscope will display a horizontal line displaced vertically from its zero-voltage level when a constant or dc voltage is applied to its input terminals. The magnitude of this deflection of the oscilloscope's beam vertically from the point where it was operating with no input being applied is how the oscilloscope indicates the magnitude of the dc level at its input terminals. Most oscilloscopes have a graticule as a part of their display, and the vertical axis of the scope is calibrated in volts per division of the graticule. As one can imagine, this is not a very informative display of a dc level, and perhaps a voltmeter with its numeric readout is better suited for such applications.

There is more to the scope–voltmeter comparison than is obvious from the previous discussion. That the oscilloscope is based on a wide-bandwidth data-acquisition system is the major difference between these two measurement instruments. The oscilloscope is designed to produce a high-fidelity display of rapidly changing signals. This puts additional constraints on the design of the oscilloscope's vertical system that are not required in the voltmeter. The most significant of these constraints is that of a constant group delay. This is a rather complex topic that is usually covered in network analysis texts. It can be easily understood if one realizes the effect of group delay on a complex input signal.

Figure 19.2 shows such a signal. The amplitude of this signal is a dc level, and the rising edge is made up of a series of high-frequency components. Each of these high-frequency components is a sine wave of specific amplitude and frequency. Another example of a complex signal is a square wave with a frequency of 10 MHz. This signal is made up of a series of odd harmonics of that fundamental frequency. These harmonics are sine

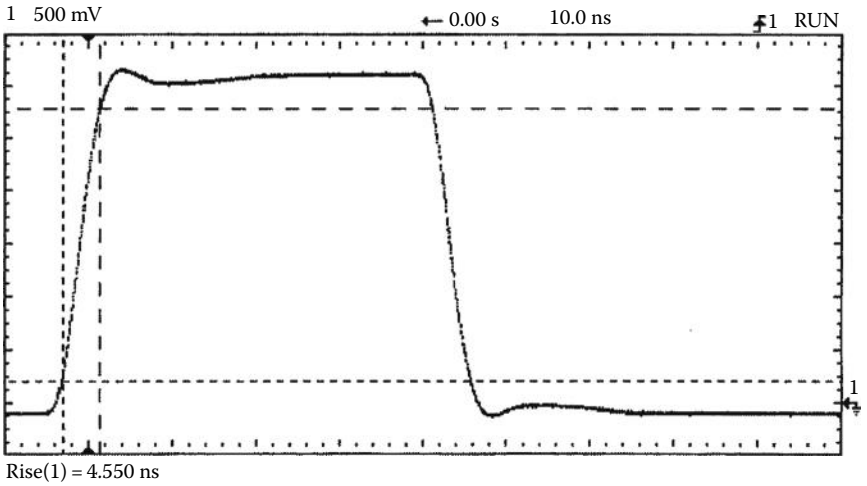

FIGURE 19.2 A typical complex waveform. This waveform is described by measurements of its amplitude, offset, rise time, fall time, overshoot, preshoot, and droop.

waves of frequencies of 10, 30, 50, 70 MHz, etc. So, the oscilloscope must pass all of these high-frequency components to the display with little or no distortion. Group delay is the measure of the propagation time of each component through the vertical system. A constant group delay means that each of these components will take the same amount of time to propagate through the vertical system to the CRT, independent of their frequencies. If the higher order harmonics take more or less time to reach the scope's deflection system than the lower harmonics, the resulting display will be a distorted representation of the input signal. Group delay (in seconds) is calculated by taking the first derivative of phase-versus-frequency response (in radians/(l/s) of an amplifier). If the amplifier has a linearly increasing phase shift with frequency, the first derivative of its phase response will be a horizontal line corresponding to the slope of the phase plot (in seconds). Amplifier systems that have a constant group delay are known as Gaussian amplifiers. They have this name because their pass band shape resembles that of the bell curve of a Gaussian distribution function (Figure 19.3). One would think that the oscilloscope's vertical amplifier should have a flat frequency response, but this is not the case because such amplifiers have nonconstant group delay [1].

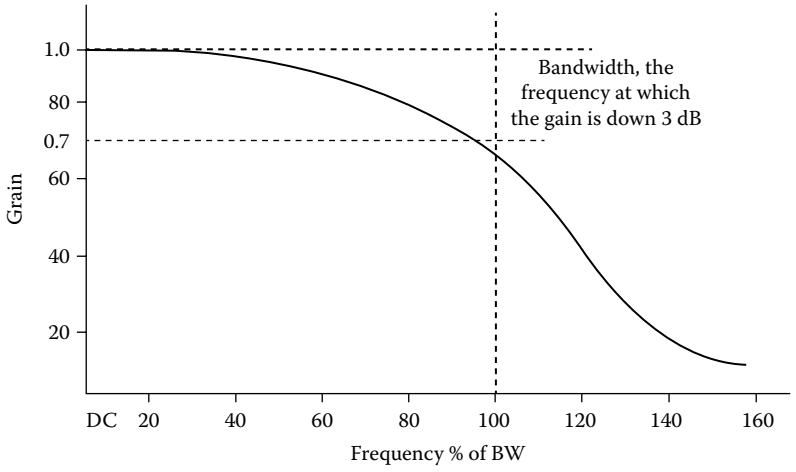

FIGURE 19.3 The Gaussian frequency response of the oscilloscope's vertical system, which is not flat in its pass band. Amplitude measurements made at frequencies greater than 20% of the scope's bandwidth will be in error.

The oscilloscope's bandwidth specification is based on the frequency where the vertical deflection will be –3 dB (0.707) of the input signal. This means that if a constant 1 V sine wave is applied to the oscilloscope's input and the signal's frequency is adjusted to higher and higher frequencies, the oscilloscope's bandwidth will be that frequency where its display of the input signal has been reduced to be 0.707 V. Noticeable errors in amplitude measurements will start at 20% of the scope's bandwidth. The oscilloscope's error-free display of complex waveforms gives it poor voltage accuracy. For the measurement of dc and single-frequency signals such as sine waves, other instruments can produce more accurate measurements.

Conclusion: The voltmeter makes the most accurate measurements of voltages that are dc, slowly changing, or can be converted to a dc analog of their ac content. The oscilloscope is not the most accurate voltage measurement instrument, but it is well suited to measurements of voltages that are changing very rapidly as a function of time. Oscilloscopes are the instrument of choice for observing and characterizing these complex voltages.

19.3.1 Analog or Digital

The world of oscilloscopes is divided into two general categories: analog and digital. The first oscilloscopes were analog. These products are based on the direct-view vector cathode-ray tube (DVVCRT or CRT for short). The analog oscilloscope applies the input signal to the vertical deflection plates of the CRT where it causes the deflection of a beam of high-energy electrons moving toward the phosphor-coated faceplate. The electron beam generates a lighted spot where it strikes the phosphor. The intensity of the light is directly related to the density of the electrons hitting a given area of the phosphor. Because this analog operation is not based on any digitizing techniques, most people have little trouble creating a very accurate and simple mental model in their minds of its operation.

The analog oscilloscope produces a display of the input signal that is bright and easy to see under most conditions. It can also contain as many as 16 shades of gray-scale information. This means that an event that occurs less frequently will appear at a lower intensity in the display than another event that occurs more frequently. This oscilloscope does not produce a continuous display of the input signal. It is blind during retrace and trigger hold-off times. Because the display depends on the production of visible light from the phosphor being excited by an electron beam, the display must be refreshed frequently. This makes the analog oscilloscope a low-dead-time display system that can follow rapidly changing signals. Also, there is little lag time in front-panel control settings.

The analog oscilloscope is not without its shortcomings. The strength of the analog oscilloscope is its CRT, but this is also the source of its weaknesses. The biggest problem with analog scopes is their dependence on a display that is constantly being refreshed. This means that these scopes do not have any waveform storage. If the input signal fails to repeat frequently, the display will simply be a flash of light when the beam sweeps by the phosphor. If the signal's repetition rate falls below 100 Hz, the display will flicker annoyingly. Figure 19.4 shows a plot of the range of an input signal's repetition frequency range from a single-shot event to the full bandwidth of a scope versus the scope's sweep speeds. The result is a map of the scope's operational area. Figure 19.4 shows that the analog oscilloscope fails to map onto the full range of possible input signals and sweep speeds.

Another problem of the analog oscilloscope is its inability to display information ahead of its trigger. This is a problem in applications where the only suitable trigger is at the end of the event of interest. Another limitation of analog scopes is their timing accuracy. The time base of the analog scope is based on the linearity of a voltage ramp. There are other sources of errors in the analog oscilloscope's horizontal axis, but the sweep nonlinearity is the major contributor. This results in these scopes having a timing accuracy of typically ±3% of their full-scale setting. Therefore, if the time base is set to 100 ns/div, in order to view a 100 ns wide pulse, the full scale will be 1000 ns or 1 μs. The accuracy of this pulse width measurement will be ±30 ns or ±30% of the pulse width!

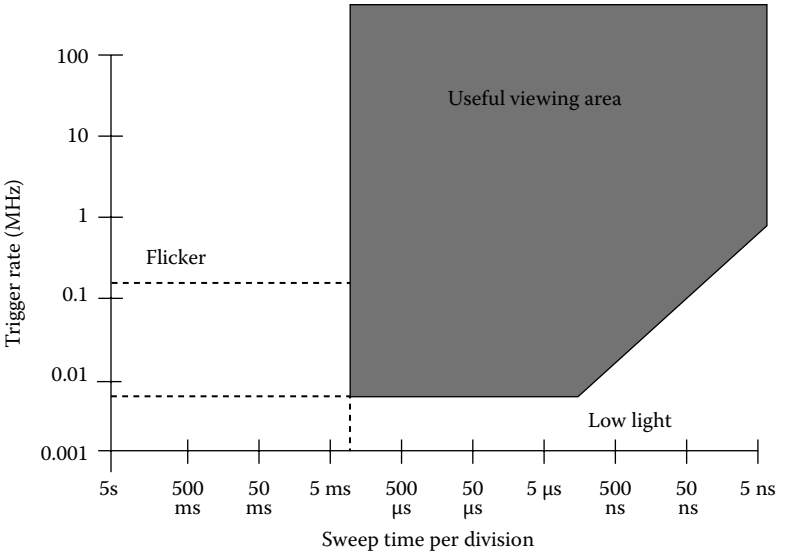

FIGURE 19.4 The operating range of the analog oscilloscope. This is a plot of input signal repetition rate from the lower limit of single shot to the full bandwidth of the scope plotted against sweep speed. The shaded area is the area where the analog oscilloscope will produce a usable display.

The digital oscilloscope or digital storage oscilloscope (DSO) differs from its analog counterpart in that the input signal is converted to digital data and therefore it can be managed by an embedded microprocessor. The waveform data can have correction factors applied to remove errors in the scope's acquisition system and can then be stored, measured, and/or displayed. That the input signal is converted from analog to digital and manipulations are performed on it by a microprocessor results in people not having a good mental model of the digital oscilloscope's operation. This would not be a problem except for the fact that the waveform digitizing process is not totally free from errors, and a lack of a correct mental model of the scope's operation on the part of its user can increase the odds of a measurement error. To make matters worse, various manufacturers of these products make conflicting claims, making it easy to propagate incorrect mental models of the digital scope's operation. It is the intention of this presentation to give the information needed to create a mental model of the operation of these devices that enable the user to perform error-free measurements with ease.

The DSO offers many advantages over its analog counterpart. The first is accuracy. The voltage measurement accuracy of the digital oscilloscope is better than that of an analog scope because the microprocessor can apply correction factors to the data to correct for errors in the calibration of the scope's vertical system. The timing accuracy of a digital oscilloscope is an order of magnitude better than that of an analog scope. The digital scope can store the waveform data for comparison to other test results or uploading to a computer for analysis or project documentation. The digital oscilloscope does not depend on the input signal being continuously updated to produce an easily viewable display. A single-shot event is displayed at the same brightness level as a signal that repeats in time periods corresponding to the full bandwidth of the scope.

The disadvantages of the digital oscilloscope are its more complex operation, aliasing, and display performance. The analog-to-digital conversion process [1] is used to convert the input signal into a series of discrete values, or samples, uniformly spaced in time, which can be stored in memory. Voltage resolution is determined by the total number of codes that can be produced. A larger number permit a smoother and more accurate reproduction of the input waveform but increase both the cost and difficulty in achieving a high sample frequency. Most digital oscilloscopes provide 8-bit resolution in their ADC. As the ADC's sampling speed is increased, the samples will be closer together, resulting in smaller gaps in the waveform record.

All digital scopes are capable of producing an aliased display. Some models are more prone to this problem than others, but even the best will alias under the right conditions. An alias is a lower-frequency false reproduction of the input signal resulting from undersampling, that is, sampling less than the Nyquist frequency. The display of the digital scope is based on computer display technology. This results in a display that is very bright and easy to see, even under conditions where an analog scope would have difficulty in producing a viewable display. The disadvantage of the digital scope's display is its lower horizontal resolution. Most of the scopes on the market have a raster scan display with a resolution of 500 lines, less than half the resolution of an analog scope's display. This is not a problem in most applications. It could become a factor where very complex waveforms, such as those found in TV systems, are being analyzed. Many digital scopes have display systems that exhibit large dead or blind times. Scopes based on a single CPU will be able to display their waveform data only after the CPU has finished all of its operations. This can result in a display that is unresponsive to front-panel control inputs as well as not being able to follow changes in the input signal.

Table 19.1 shows that both analog and digital oscilloscopes have relative advantages and disadvantages. All the major producers of oscilloscopes are pushing the development of digital scopes in an attempt to overcome their disadvantages. A few manufacturers produce scopes that are both analog and digital. These products appear to have the best of both worlds; however, they have penalties with respect to both cost and complexity of operation.

Digital systems place additional demands on the oscilloscope that exceed the capabilities of the analog scope. For example, often, in digital electronic systems, there is a need to view fast events that occur at very slow or infrequent rates. Figure 19.4 shows that these events fail to be viewable on analog scopes. Another common problem with digital systems is the location of trigger events. Often, the only usable trigger is available at the end of the event being viewed. Analog scopes can only display events that occur after a trigger event. The rapid growth of digital electronics in the late 1990s is being attributed to the lowering of the cost of single-chip microcontrollers. These devices, which contain a complete microprocessor on one integrated circuit, are responsible for the "electronics everywhere" phenomenon, where mechanical devices are becoming electronic as well as those devices that were previously electrical in nature. In 1996, Hewlett-Packard introduced a class of oscilloscope designed to meet the unique needs of the microcontroller-based applications. This class of oscilloscope is known as the mixed-signal oscilloscope or MSO [2].

TABLE 19.1 Comparison of Analog and Digital Oscilloscopes

	Analog Oscilloscope	Digital Oscilloscope
Operation	Simple	Complex
Front-panel controls	Direct access knobs	Knobs and menus
Display	Real-time vector	Digital raster scan
Gray scales	>16	>4
Horizontal resolution	>1000 lines	500 lines
Dead time	Short	Can be long
Aliasing	No	Yes
Voltage accuracy	±3% of full scale	±3% of full scale
Timing accuracy	±3% of full scale	±0.01% of full scale
Single-shot capture	None	Yes
Glitch capture	Limited	Yes
Waveform storage	None	Yes
Pretrigger viewing	None	Yes
Data out to a computer	No	Yes

19.4 Voltage Measurements

Voltage measurements are usually based on comparisons of the waveform display to the oscilloscope's graticule. Measurements are made by counting the number of graticule lines between the end points of the desired measurement and then multiplying that number by the sensitivity setting. This was the only measurement available to most analog scope users, and it is still used by those performing troubleshooting with their digital scope as a time-saving step. (Some late-model analog oscilloscopes incorporate cursors to enhance their measurement ability.) For example, a waveform that is 4.5 divisions high at a vertical sensitivity of 100 mV/div would be 450 mV high.

Switching the scope's coupling between ac and dc modes will produce a vertical shift in the waveform's position that is a measurement of its dc component. This technique can be applied to either analog or digital scopes. Simply note the magnitude of the change in waveform position and multiply by the channel's sensitivity.

Additional measurements can be performed with an analog oscilloscope, but they usually require more skill on the part of the operator. For example, if the operator can determine the location of the top and base of a complex waveform, its amplitude can be measured. Measurements based on percentages can be made using the scope's vernier to scale the waveform so that its top and bottom are five divisions apart. Then, each division represents 20% of the amplitude of the waveform being studied. The use of the vernier, which results in the channel being uncalibrated, prevents performance of voltage measurements. Many analog scopes have a red light to warn the operator that the scope is uncalibrated when in vernier mode.

The digital oscilloscope contains an embedded microprocessor that automates the measurement. This measurement automation is based on a histogramming technique, where a histogram of all the voltage levels in the waveform is taken from the oscilloscope's waveform data. The histogram is a plot of the voltage levels in the waveform plotted against the number of samples found at each voltage level. Figure 19.5 shows the histogramming technique being applied to the voltage measurements of complex waveforms.

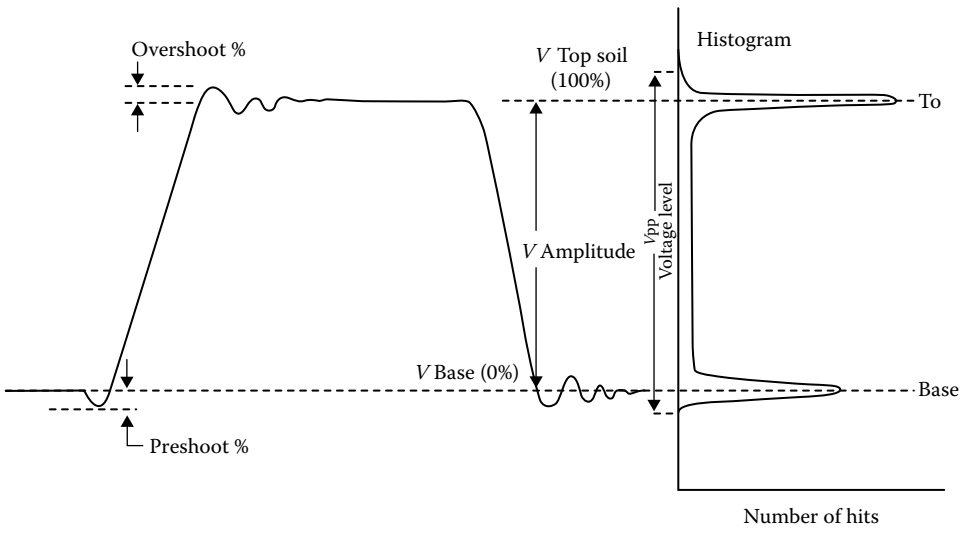

FIGURE 19.5 Voltage histograms as applied by a digital oscilloscope. The complex waveform is measured by the use of the voltage histogram. This histogram is a plot of each voltage level in the display and the number of data points at that level.

19.5 Understanding the Specifications

The oscilloscope's vertical accuracy is one place that a person's mental model of the scope's operation can lead to measurement trouble. For example, the oscilloscope's vertical axis has a frequency response that is not flat across its pass band. However, as noted earlier, the scope has a Gaussian frequency response to produce the most accurate picture of complex signals. This means that the oscilloscope's accuracy specification of ±3% is a dc-only specification. If one were to attempt to measure the amplitude of a signal whose frequency is equal to the bandwidth of the scope, one would have to add another 29.3% to the error term, for a total error of ±32.3%. This is true for both analog and digital oscilloscopes. This limitation can be overcome by carefully measuring the frequency response of the oscilloscope's vertical channels. One will need to repeat this process every time the scope is serviced or calibrated, because the various high-frequency adjustments that may need to be made in the scope's vertical axis will affect the scope's frequency response. One is probably asking, why don't the manufacturers do this for me? The answer is twofold. The first is cost, and the second is that this is not the primary application of an oscilloscope. There are other instruments that are much better suited to the measurement of high-frequency signals. The spectrum analyzer would be this author's first choice.

Additionally, the vertical accuracy is a full-scale specification. This means that at 1 V/div, the full-scale value is typically 8 V. The measurement error for a scope with a ±3% specification under these conditions will be ±0.24 V. If the signal being measured is only 1 V high, the resulting measurement will be ±24% of reading. Check the manual for the scope being used, as some manufacturers will specify full-scale as being 10 or even 10.2 divisions. This will increase the error term because the full-scale term is larger.

In digital oscilloscopes, the vertical accuracy is often expressed as a series of terms. These attempt to describe the analog and digital operations the scope performs on the input signal. Terms might include digitizing resolution, gain, and offset (sometimes called as position). They also might be called out as single- and dual-cursor accuracies. The single-cursor accuracy is a sum of all three terms. In the dual-cursor case, where the voltage measurement is made between two voltage cursors, the offset term will cancel out, leaving only the digitizing resolution and gain errors. For example, the Hewlett-Packard model 54603B has a single-cursor accuracy specification of ±1.2% of full scale, ±0.5% of position value, and a dual-cursor specification of ±0.4% of full scale.

Hint: Always try to make the voltage measurements on the largest possible vertical and widest possible display of the signal.

The horizontal accuracy specifications of analog and digital scopes are very different; however, both are based on a full-scale value. In the analog scope, many manufacturers limit accuracy specifications to only the center eight divisions of their display. This means that a measurement of a signal that starts or ends in either the first or ninth graticule will be even more error prone than stated in the scope's specifications. To the best of this author's knowledge, this limitation does not apply to digital scopes. The horizontal specifications of digital scopes are expressed as a series of terms. These might include the crystal accuracy, horizontal display resolution, and trigger placement resolution. These can be listed as cursor accuracy. For example, the Hewlett-Packard model 54603B has a horizontal cursor accuracy specification of ±0.01% ±0.2% full-scale ±200 ps. In this example, the first term is the crystal accuracy, the second is the display resolution (500 lines), and the final term is twice the trigger placement error. By comparing the analog and digital scopes' horizontal specifications, it can be seen that in either case, the measurement is more accurate if it can be made at full screen. The digital scope is more accurate than its analog counterpart.

Digital scopes also have acquisition system specifications. Here is another place where the operator's mental model of the operation of a digital scope can produce measurement errors. All manufacturers of digital scopes specify the maximum sampling speed of their scope's acquisition system

as well as its memory depth and number of bits. The scope's maximum sampling speed does not apply to all sweep speeds; only memory depth and number of bits applies to all sweep speeds. The scope's maximum sampling speed applies only to its fastest sweep speeds.

The complexity of the digital scope results from the problem of having to sample the input. There is more to be considered than Nyquist's sampling theorem in the operation of a digital scope. For example, how does the scope's maximum sampling rate relate to the smallest time interval that the scope can capture and display? A scope that samples at 100 MSa/s takes a sample every 10 ns; therefore, in principle, it cannot display any event that is less than 10 ns wide because that event will fall between the samples. In practice, however, this limit can—under certain circumstances—be extended. If the scope is operating in an "equivalent time" or "random repetitive" mode and if the signal is repetitive, even if very infrequently, the scope will be able to capture any event that is within its vertical system bandwidth. Figure 19.6 shows an infrequently occurring pulse that is 25 ns wide embedded into a data stream being captured and displayed on an oscilloscope with a maximum sampling speed of 20 MSa/s (sampling interval of 50 ns). Figure 19.6b shows this pulse at a faster sweep speed. An analog scope would produce a similar display of this event, with the infrequent

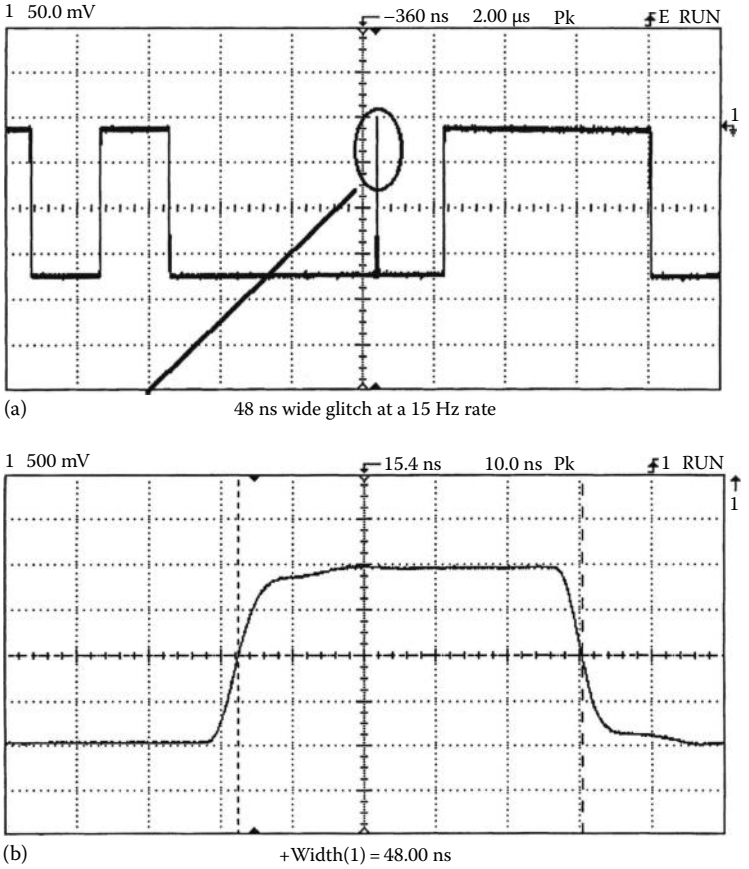

FIGURE 19.6 An infrequently occurring event as displayed on a digital oscilloscope with random repetitive sampling; (a) the event embedded in a pulse train, and (b) shows the same event at a faster sweep speed. The fact that the waveform baseline is unbroken under the narrow pulse indicates that it does not occur in every sweep. The width of this pulse is less than half the scope's sampling period in (b). Both traces are from a Hewlett-Packard model 54603B dual-channel 60 MHz scope.

event being displayed at a lower intensity than the rest of the trace. Notice that the infrequent event does not break the baseline of the trace.

The correct mental model of the digital scope's ability to capture signals needs to be based on the scope's bandwidth, operating modes, and timing resolution. It is the timing resolution that tells the operator how closely spaced the samples can be in the scope's data record.

The most common flaw in many mental models of the operation of a digital scope is related to its maximum sampling speed specification. As noted, the maximum sampling speed specification applies only to the scope's fastest sweep speeds. Some scope manufacturers will use a multiplex A/D system that operates at its maximum sampling speed only in single-channel mode. The scope's memory depth determines its sampling speed at the sweep speed being used for any specific measurement. The scope's memory depth is always equal to the scope's horizontal full-scale setting. For scopes with no offscreen memory, this in 10× the time base setting. If the scope has offscreen memory, this must be taken into account. For example, assume that one has two scopes with a maximum sampling speed of 100 MSa/s. One scope has a memory depth of 5 K points and the other only 1 K. At a sweep speed of 1 μs per division, both scopes will be able to store data into their memory at their full sampling speed, and each will be storing 100 data points per division, for a total of 1000 data points being stored. The scope with the 5 K memory will have a data point in one of every five memory locations, and the scope with the 1 K memory will have a data point in every memory location. If one reduces the sweep speed to 5 μs/div, the deeper memory scope will now fill every one of its memory locations with data points separated by 10 ns. The scope with only 1 K of memory would produce a display only two divisions wide if its sampling speed is not reduced. Scope designers believe that scope users expect to see a full-length sweep at every sweep speed. Therefore, the 1 K scope must reduce its sampling speed to one sample every 50 ns, or 20 MSamples/s, to be able to fill its memory with a full sweep width of data. This 5:1 ratio of sampling speeds between these two scopes will be maintained as their time bases are set to longer and longer sweeps. For example, at 1 s/div, the 5 K scope will be sampling at 500 samples per second, while the 1 K scope will be sampling at only 100 samples/s. One can determine a scope's sampling speed for any specific time base setting from Equation 19.1:

$$S\,(\text{samples/second}) = \frac{\text{Memory depth (samples)}}{\text{Full-scale time base (seconds)}} \tag{19.1}$$

or the scope's maximum sampling speed, whichever is less.

One must look closely at the application to determine if a specific scope is best suited to that application. As a rule, the deeper the memory, the faster the scope will be able to sample the signal at any given time base setting. Memory depth is not free. High-speed memory required to be able to store the data out of the scope's A/D is costly, and deeper memory takes longer to fill, thus reducing the scope's display update rate. Most scopes that provide memory depths of 20 K or more will also give the user a memory depth selection control so that the user can select between fast and deep. (In 1996, Hewlett-Packard Co. introduced two scopes based on an acquisition technology known as MegaZoom (TM) [2] that removes the need for a memory depth control.) A correct mental model for the sampling speed of a digital scope is based on Equation 19.1 and not just on the scope's maximum performance specifications.

Some digital oscilloscopes offer a special sampling mode known as *peak detection*. Peak detection is a special mode that has the effect of extending the scope's sampling speed to longer time records. This special mode can reduce the possibility of an aliased display. The performance of this special mode is specified as the minimum pulse width that the peak detection system can capture. There are several peak detection systems being used by the various manufacturers. Tektronix has an analog-based peak detection system in some of its models, while Hewlett-Packard has a digital system in all of its models. Both systems perform as advertised, and they should be evaluated in the lab to see

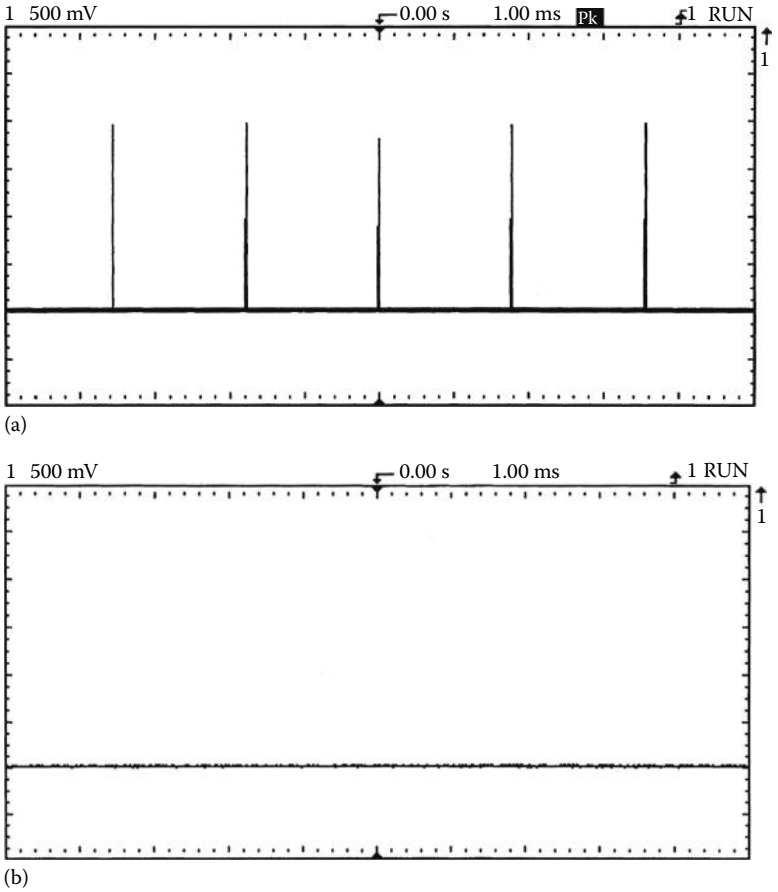

FIGURE 19.7 Peak detection. This special mode has the effect of increasing the scope's sampling speed at time base settings where it would be decimated. In operation, each memory location contains either the maximum or minimum value of the waveform at that location in time. (a) A series of 300 ns wide pulses being captured at a slow sweep speed and (b) the same setup with peak detection disabled. These narrow pulses would appear as intermittent pulses if the scope could be seen in operation with peak detection disabled.

which system best meets one's needs. There is a downside to peak detection systems and that is that they display high-frequency noise that might not be within the bandwidth of the system under test. Figure 19.7 shows a narrow pulse being captured by peak detection and being missed when the peak detection is off.

What effect does display dead time have on the oscilloscope's voltage measurement capabilities? Display dead time applies to both analog and digital oscilloscopes, and it is that time when the oscilloscope is not capturing the input signal. This is also a very important consideration in the operation of a digital scope because it determines the scope's ability to respond to front-panel control commands and to follow changing waveforms. A digital scope that produces an incorrect display of an amplitude-modulated signal is not following this rapidly changing signal because its display update rate is too low. Sampling speed is not related to display update rate or dead time. Display dead time is a function of the scope's ability to process the waveform data from its A/D and plot it on the display. Every major oscilloscope manufacturer has been working on this problem. Tektronix offers a special mode on some of its products known as InstaVu (TM) [3]. This special mode allows these scopes to process up

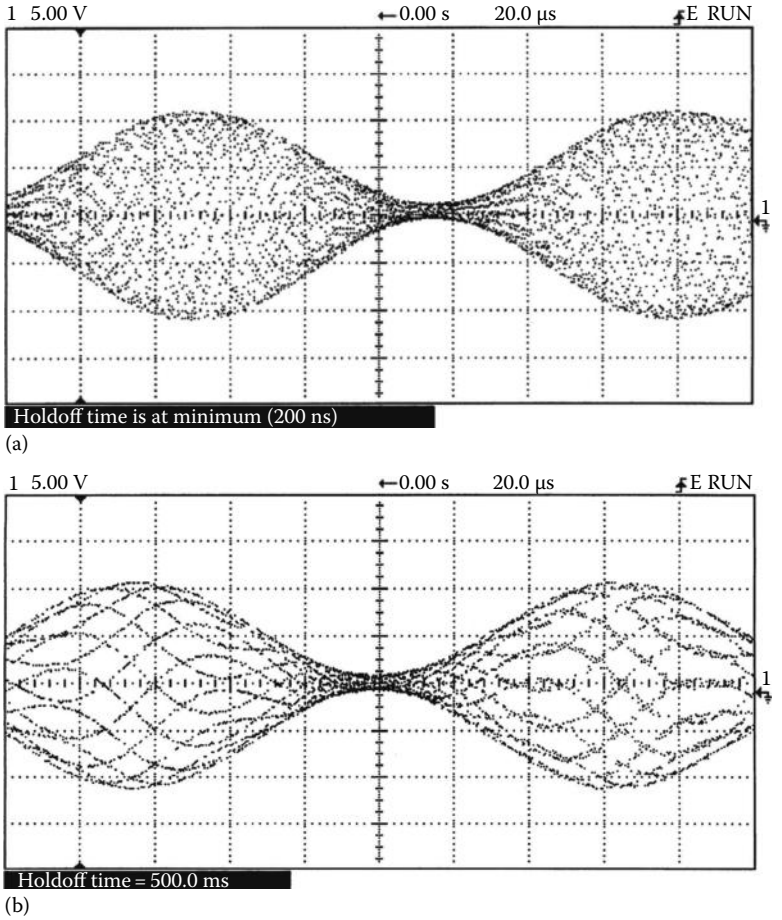

FIGURE 19.8 Display dead time. The time that an oscilloscope is blind to the input signal has an effect on the scope's ability to correctly display rapidly changing signals: (a) an amplitude-modulated signal with a high-speed display and (b) the same signal with the dead time increased by the use of hold-off.

to 400,000 waveforms per second to their display. Hewlett-Packard has developed a multiple parallel processor technology [4] in the HP 54600 series of benchtop scopes that provides a high-speed, low-dead-time display in a low-cost instrument. These instruments can plot 1,500,000 points/s to their display, and they have no dead time at their slower sweep speeds. LeCroy has been applying the PowerPC as an embedded processor for its scopes to increase display throughput. There are other special modes being produced by other vendors, so be sure to understand what these can do before selecting an oscilloscope. Figure 19.8 shows the effect of display update rate on a rapidly changing waveform. An amplitude-modulated signal is displayed with a high-speed display and with the display speed reduced by the use of hold-off.

19.5.1 Triggering

The trigger of the oscilloscope has no direct effect on the scope's ability to measure a voltage except that the trigger does enable the oscilloscope to produce a stable display of the voltage of interest. Reference [5] presents a thorough discussion of this subject.

Conclusion: The mental model that oscilloscope users have created in their minds of the oscilloscope's operation can be helpful in reducing measurement errors. If the operator's mental model is based on the following facts, measurement errors can be minimized:

- Oscilloscopes have a frequency response that affects measurement accuracy.
- Digital scopes are more accurate than analog scopes.
- Analog scopes do not have continuous displays.
- Oscilloscope accuracy specifications always contain a percent of full-scale term.
- Measurements should be made at the largest possible deflection in order to minimize errors.
- Maximum sampling speed is available only at the scope's fastest sweep speeds.
- Deeper memory depth allows faster sampling at more sweep speeds.
- All digital scopes can produce aliases, some more than others.
- Display dead time is an important characteristic of digital scopes that is often not specified.
- Display dead time affects measurement accuracy because it can cause a distorted display.
- The scope with the highest maximum sampling speed specification might not be the most accurate or have the lowest display dead time.
- The operator must have some knowledge of the signals being measured to be able to make the best possible measurements.

The person who has the mental model of the oscilloscope that takes these factors into account will be able to purchase the scope that is best suited to his or her application and not spend too much money on unnecessary additional performance. In addition, that person will be able to make measurements that are up to the full accuracy capabilities of the scope.

19.6 Selecting the Oscilloscope

There are 10 points to consider when selecting an oscilloscope. This author has published a thorough discussion of these points [6], and they are summarized as follows:

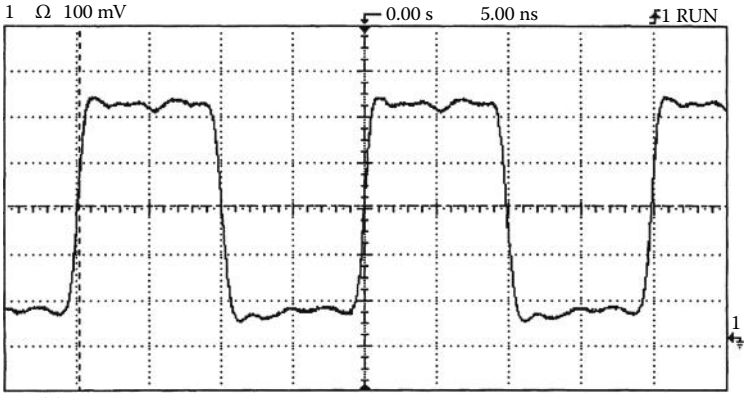
1. *Analog or digital*? There are a few places where the analog scope might be the best choice, and the reader can make an informed selection based on the information presented here.
2. *How much bandwidth*? This is a place where the person selecting an oscilloscope can save money by not purchasing more bandwidth than is needed. When analog oscilloscopes were the only choice, many people were forced to purchase more bandwidth than they needed because they needed to view infrequent or low repetition signals. High-bandwidth analog scopes had brighter CRTs so that they were able to display high-frequency signals at very fast time base settings. At a sweep speed of 5 ns/div, the phosphor is being energized by the electron beam for 50 ns, so the electron beam had to be very high energy to produce a visible trace. This situation does not apply to digital scopes. Now, one needs to be concerned only with the bandwidth required to make the measurement. Figure 19.9 shows the effect of oscilloscope bandwidth on the display of a 50 MHz square wave.

   The oscilloscope's bandwidth should be >2× the fundamental highest frequency signal to be measured.

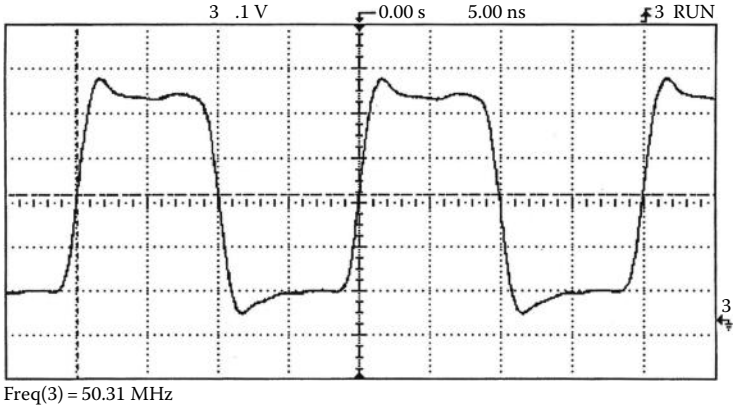
   The bandwidth of the scope's vertical system can affect the scope's ability to correctly display narrow pulses and to make time interval measurements. Because of the scope's Gaussian frequency response, one can determine its ability to correctly display a transient event in terms of rise time with Equation 18.2:

$$t_r = \frac{0.35}{\text{BW}} \tag{19.2}$$

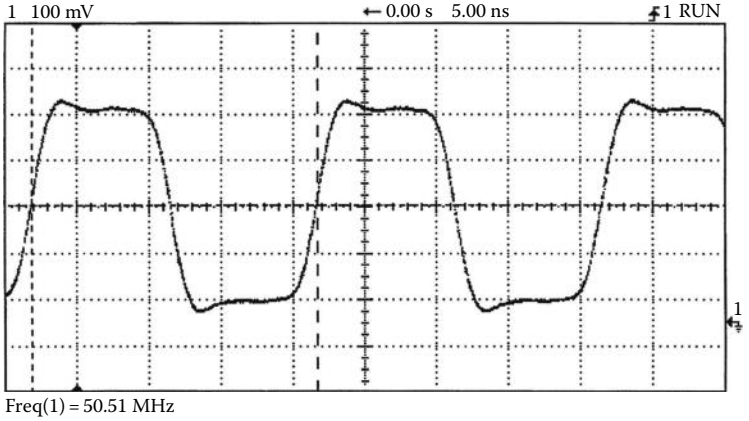
   Therefore, a 100 MHz scope will have a rise time of 3.5 ns. This means that if the scope were to have a signal at its input with zero rise time edges, it would be displayed with 3.5 ns edges. This will affect



Freq(1) = 50.44 MHz
(a) BW = 500 MHz



Freq(3) = 50.31 MHz
(b) BW = 250 MHz



Freq(1) = 50.51 MHz
(c) BW = 100 MHz

FIGURE 19.9 The effect of the scope's bandwidth is shown in this set of waveforms. The same 50 MHz square wave is shown as it was displayed on different bandwidth scopes: (a) 500 MHz bandwidth, (b) 250 MHz bandwidth, (c) 100 MHz bandwidth,

(*continued*)

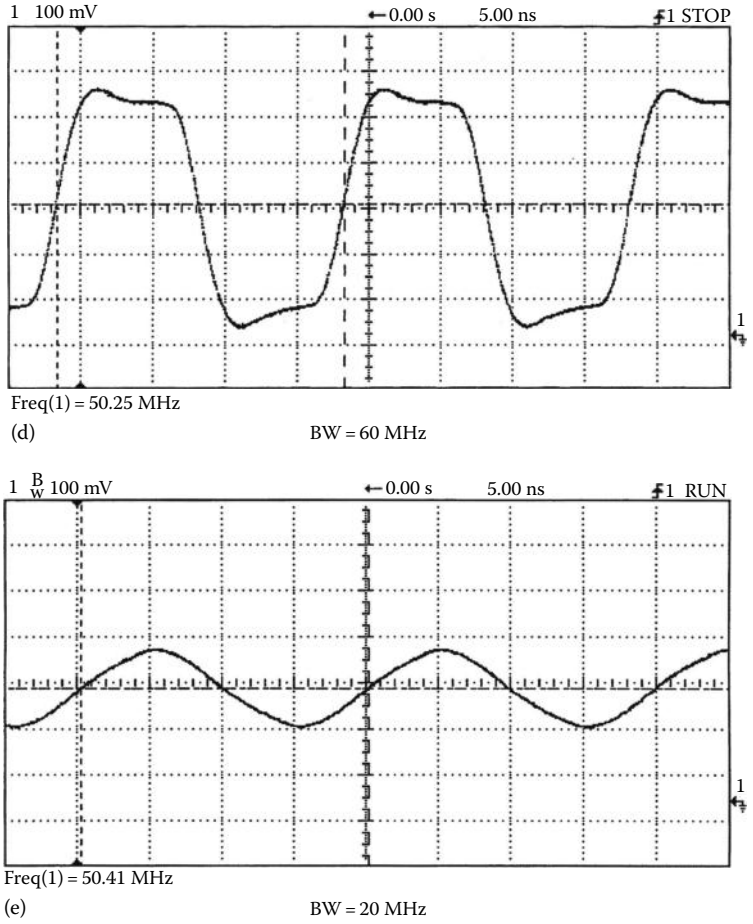


FIGURE 19.9 (continued) The effect of the scope's bandwidth is shown in this set of waveforms. The same 50 MHz square wave is shown as it was displayed on different bandwidth scopes: (d) 60 MHz bandwidth, and (e) 20 MHz bandwidth. Notice that the 100 MHz scope produced a usable display although it was missing the high-frequency details of the 500 MHz display. The reason that the 100 MHz scope looks so good is the fact that its bandwidth is slightly greater than 100 MHz. This performance, which is not specified on any data sheet, is something to look for in any evaluation.

the scope's measurements in two ways. First are narrow pulses. Figure 19.10 shows the same 5 ns wide pulse being displayed on oscilloscopes of 500 and 60 MHz bandwidths, and the effect of the lower bandwidth on this event that is closest to the rise time of the slower scope is apparent.

The second is fast time interval measurements. A measurement of signal rise time is an example. The observed rise time on the scope's display is according to Equation 19.3:

$$t_{\text{observed}} = (t_{\text{signal}}^2 + t_{\text{scope}}^2)^{1/2} \tag{19.3}$$

If a 10 ns rise time were to be measured with a 100 MHz scope, one would obtain a measurement of 10.6 ns based on Equation 19.3. The scope would have made this measurement with a 6% reading error before any other factors, such as time base accuracy, are considered.

The scope's rise time should be at least no more than 1/5 of the shortest time interval to be measured. For time interval measurements, this should be >1/10.

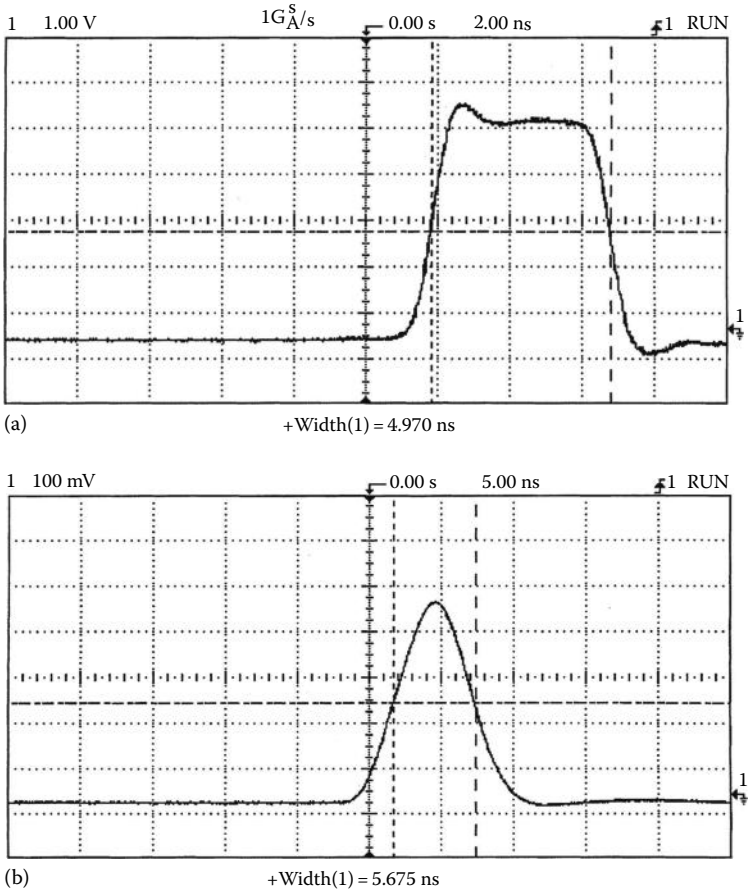

FIGURE 19.10 Bandwidth and narrow events. (a) A 5 ns wide pulse as displayed on a 500 MHz scope and (b) the same pulse displayed on a 60 MHz scope. The 60 MHz scope has a rise time of 5.8 ns, which is longer than the pulse width. This results in the pulse shape being incorrectly displayed and its amplitude being in error.

3. *How many channels*? Most oscilloscopes in use today are dual-channel models. In addition, there are models described as being 2 + 2 and four channels. This is one time where 2 + 2 is not equal to 4. The 2 + 2 models have limited features on two of their channels and cost less than 4-channel models. Most oscilloscope suppliers will hold the 4-channel description only for models with four full-featured channels, but user should be sure to check that the model under consideration so as to be sure if it is a 4- or 2 + 2 model. Either of the four channel classes is useful for applications involving the testing and development of digital-based systems where the relationship of several signals must be observed.

   Hewlett-Packard introduced a new class of oscilloscopes that is tailored for the applications involving both analog and digital technologies and mixed-signal systems. The MSO [3] provides two scope channels and 16 logic channels so that it can display both the analog and digital operations of a mixed-signal system on its display.
4. *What sampling speed*? Do not simply pick the scope with the highest banner specification. One needs to ask, what is the sampling speed at the sweep speeds that my application is most likely to require? As observed in Equation 19.1, the scope's sampling speed is a function of memory depth and full-scale time base setting. If waveforms are mostly repetitive, one can save money by selecting an oscilloscope that provides equivalent time or random repetitive sampling.

5. *How much memory*? As previously discussed, memory depth and sampling speed are related. The memory depth required depends on the time span needed to measure and the time resolution required. The longer the time span to be captured and the finer the resolution required, the more memory one will need. High-speed waveform memory is expensive. It takes time to process a longer memory, so the display will have more dead time in a long memory scope than a shallow memory model. All the suppliers of deep memory scopes provide a memory depth control. They provide this control so that the user can choose between a high-speed display and deep memory for the application at hand. Hewlett-Packard introduced MegaZoom (TM) technology [7] in 1996; it produces a high-speed low-dead-time display with deep memory all the time.
6. *Triggering*? All scope manufacturers are adding new triggering features to their products. These features are important because they allow for triggering on very specific events. This can be a valuable troubleshooting tool because it will let the user prove whether a suspected condition exists or not. Extra triggering features add complexity to the scope's user interface; so be sure to try them out to make sure that they can be applied.
7. *Trustworthy display*? Three factors critically affect a scope's ability to display the unknown and complex signals that are encountered in oscilloscope applications. If the user loses confidence in the scope's ability to correctly display what is going on at its probe tip, productivity will take a real hit. These are display update rate, dead time, and aliasing.

   Because all digital scopes operate on sampled data, they are subject to aliasing. An alias is a false reconstruction of the signal caused by undersampling the original. An alias will always be displayed as a lower frequency than the actual signal. Some vendors employ proprietary techniques to minimize the likelihood of this problem occurring. Be sure to test any scope being considered for purchase on your worse-case signal to see if it produces a correct or aliased display. Do not simply test it with a single-shot signal that will be captured at the scope's fastest sweep speed because this will fail to test the scope's ability to correctly display signals that require slower sweep speeds.
8. *Analysis functions*? Digital oscilloscopes with their embedded microprocessors have the ability to perform mathematical operations that can give additional insight into waveforms. These operations often include addition, subtraction, multiplication, integration, and differentiation. An FFT can be a powerful tool, but do not be misled into thinking that it is a replacement for a spectrum analyzer. Be sure to check the implementation of these features in any scope being considered. For example, does the Fast Fourier Transform (FFT) provide a selection of window functions? Are these analysis functions implemented with a control system that only their designer could apply?
9. *Computer I/O*? Most of the digital scopes on the market today can be interfaced to a PC. Most of the scope manufacturers also provide some software that simplifies the task of making the scope and PC work together. Trace images can be incorporated into documents such as PC Paintbrush (.pcx), tagged image file format (.tiff), Joint Photographic Expert Group (.jpg) files. Waveform data can be transferred to spreadsheet applications for additional analysis. Some scope models are supplied with a disk drive that can store either waveform data or trace images.
10. *Try it out*? Now, one has the information to narrow oscilloscope selection to a few models based on bandwidth, sampling speed, memory depth, and budget requirements. Contact the scope vendors (Table 19.2) and ask for an evaluation unit. While the evaluation unit is in the lab, look for the following characteristics:
    a. *Control panel responsiveness*: Does the scope respond quickly to inputs or does it have to think about it for a while?
    b. *Control panel layout*: Are the various functions clearly labeled? Does the user have to refer to the manual even for simple things?
    c. *Display speed*: Turn on a couple of automatic measurements and check that the display speed remains fast enough to follow changing signals.
    d. *Aliasing*: Does the scope produce an alias when the time base is reduced from fast to slow sweep speeds? How does the display look for the toughest signal?

The oscilloscope is undergoing a period of rapid change. The major manufacturers of oscilloscopes are no longer producing analog models, and the digital models are evolving rapidly. There is confusion in the oscilloscope marketplace because of the rapid pace of this change. Hopefully, this discussion will prove valuable to the user in selecting and applying oscilloscopes in the lab in the years to come.

Inductive and Capacitive Voltage Measurement

Cipriano Bartoletti
Sapienza University of Rome

Luca Podestà
Sapienza University of Rome

Giancarlo Sacerdoti
Sapienza University of Rome

20.1 Introduction

Capacitive and inductive voltage sensors are mainly utilized in low-frequency electric measurements. In this chapter, the capacitive and inductive measurement with large voltage ranges, from 10^{-10} to 10^{7} V, has been discussed. The associated voltage waveforms can be periodic or impulsive. In periodic waveforms, it is often important to measure the spectrum and the subharmonic components, which can vary depending on the position of the measuring devices within the same network. In impulsive measurements, obtaining the maximum voltage values, the pulse lengths, etc., is preferred.

20.2 Capacitive Sensors

The voltage to be measured can be reduced by means of capacitive dividers (Figure 20.1). Capacitive dividers are affected by temperature and frequency and therefore are not important, at least in Europe. Capacitive sensors detect voltage by different methods:

1. Electrostatic force (or torque)
2. Kerr or Pockels effect
3. Josephson effect
4. Transparency through a liquid-crystal device
5. Change in refractive index of the optic fiber or in light pipe

1. The relations that rule the listed capacitive voltage sensors are reported in the succeeding text. The force between two electrodes is (Figure 20.2)

$$F = \varepsilon_0 \frac{S}{d}(V_1 - V_2)^2 \tag{20.1}$$

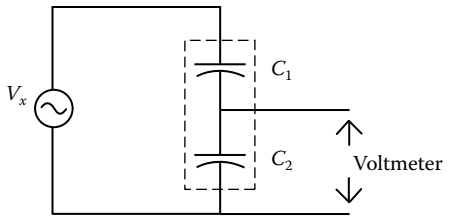

FIGURE 20.1 Schematic arrangement of a capacitive divider.

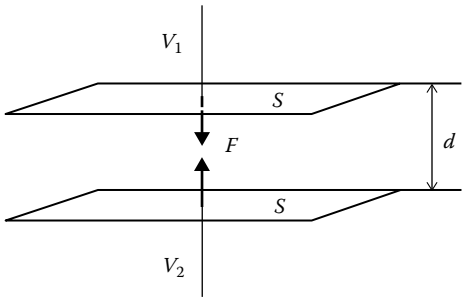

FIGURE 20.2 Force between two electrodes with an applied voltage.

where
ε_0 is the dielectric constant
S is the area of the electrode
d is the distance
V_1, V_2 are the potentials of the electrodes

The *torque* between electrostatic voltmeter quadrants (Figure 20.3) is given by

$$T = \frac{1}{2}\frac{\partial C}{\partial \theta}(V_1 - V_2)^2 \tag{20.2}$$

where
C is the capacitance
θ is the angle between electrodes

To get the torque from the rate of change (derivative) of electrostatic energy versus the angle is easy. Obtaining the torque by mapping the electric field is difficult and requires long and complex field computing.

2. The rotation of the polarization plane of a light beam passing through a KDP crystal under the influence of an electric field (*Pockels effect*) is expressed by (Figure 20.4)

$$\theta = k_p l(V_1 - V_2) \tag{20.3}$$

where
k_p is the electro-optic constant
l is the length of crystal

One obtains a rotation of $\pi/2$ by applying a voltage of the order of 1 kV to a KDP crystal of a few centimeters in length.

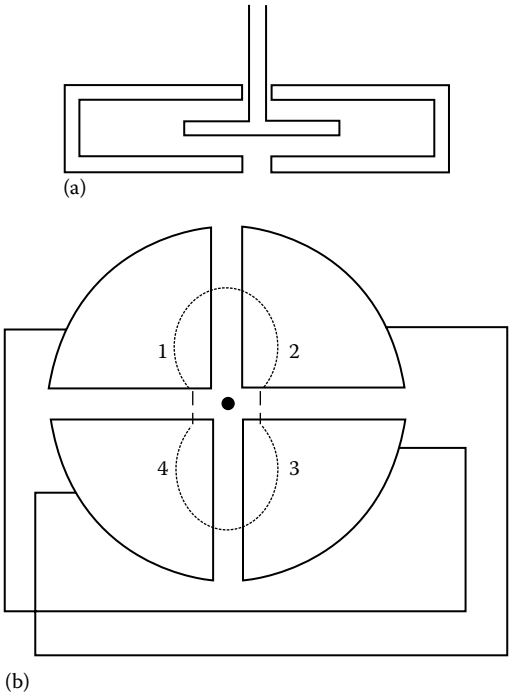

FIGURE 20.3 Scheme of an electrostatic voltmeter. (a) Lateral view and (b) top view: (1), (2), (3), and (4) are the static electrodes; the moving vane is shown in transparency.

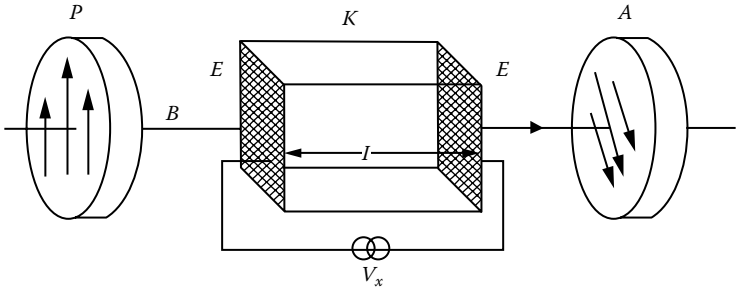

FIGURE 20.4 Scheme of an electro-optic KDP device. *B*, a light beam; *P*, a polarizer; *A*, an analyzer; *K*, a KDP crystal, with the voltage to be measured V_x applied to its transparent electrodes; *E*, transparent electrodes.

If a light beam passes through a light pipe that performs the *Kerr effect*, one observes a quadratic dependence of the rotation versus *V*:

$$\theta \equiv kE^2 \equiv k'V^2 \tag{20.4}$$

3. The *Josephson effect* consists of translation of a voltage into a periodical signal of a certain frequency, carried out by a special capacitive sensor. There is an array of *N* layers of Josephson superconducting junctions; the frequency of emitted signal, when a voltage *V* is applied, is given by

$$\nu = \frac{2eV}{Nh} \tag{20.5}$$

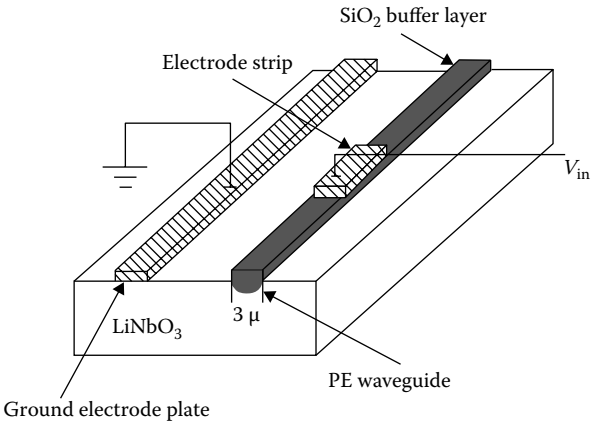

FIGURE 20.5 Li-Nb optical wave guide device.

4. The *transparency* of a liquid-crystal device depends on the difference of potential applied. There are liquid-crystal devices working in transmission or in reflection. A change in transparency is obtained when a difference of potential of a few volts is applied.
5. The *change in refractive index* due to the presence of an electric field can be detected by
   a. Interferometric methods (where the velocity of light is equal to c/n)
   b. Change in light intensity in a beam passing through an optical wave guide device like Li-Nb (Figure 20.5)

By means of method 1, many kinds of instruments (voltmeters) can be realized. Methods 2 through 5 are used in research laboratories but are not yet used in industrial measurements.

20.3 Inductive Sensors

20.3.1 Voltage Transformers

Voltage transformers (VTs) have two different tasks:

- Reduction in voltage values for meeting the range of normal measuring instruments or protection relays
- Insulation of the measuring circuit from power circuits (necessary when voltage values are over 600 V)

VTs are composed of two windings—one primary and one secondary winding. The primary winding must be connected to power circuits; the secondary to measuring or protection circuits. Electrically, these two windings are insulated but are connected magnetically by the core.

One can define the following

$$\text{Nominal ratio} = K_n = \frac{V_{1n}}{V_{2n}} \tag{20.6}$$

as the ratio between the magnitude of primary and secondary rated voltages.

$$\text{Actual ratio} = K = \frac{V_1}{V_2} \tag{20.7}$$

as the ratio between the magnitudes of primary and secondary actual voltages.

Burden is the value of the apparent power (normally at cos $\varphi = 0.8$) that can be provided on the secondary circuit (instruments plus connecting cables).

Burden limits the maximum value of secondary current and then the minimum value of impedance of the secondary circuit is

$$Z_{\min} = \frac{V_{2n}^2}{A_n} \tag{20.8}$$

where A_n is the VT burden.

For example, if $A_n = 25$ VA and $V_{2n} = 100$ V, one obtains

$$Z_{\min} = \frac{100}{0.25} = 400 \text{ W} \tag{20.9}$$

There are two kinds of errors:

1. Ratio error $= h_{\%} = \dfrac{K_n - K}{K}$ (20.10)
2. Angle error = the phase displacement between the primary voltage and the secondary voltage (positive if the primary voltage lags the secondary one).

VTs are subdivided into accuracy classes related to the limits in ratio and angle error (according to CEI and IEC normative classes 0.1, 0.2, 0.5, 1, 3; see Table 20.1). To choose the VT needed, the following technical data must be followed:

- Primary and secondary voltage (rated transformation ratio). Normally, the secondary value is 100 V.
- Accuracy class and rated burden in VA: for example, cl. 0.5 and $A_n = 10$ VA.
- Rated working voltage and frequency.
- Insulation voltage.
- Voltage factor: the ratio between maximum operating voltage permitted and the rated voltage. The standard voltage factor is 1.2 V_n (i.e., the actual primary voltage) for an unlimited period of time (with VT connected with phases) and is 1.9 V_n for a period of 8 h for VT connected between phase and neutral.
- Thermal power is the maximum burden withstood by VT (errors excluded).

TABLE 20.1 Angle and Ratio Error Limit Table Accepted by CEI and IEC Standards

Class	Percentage Voltage (Ratio) Error (±)	Phase Displacement Minutes (±)	Centiradians (±)
0.1	0.1	5	0.15
0.2	0.2	10	0.3
0.5	0.5	20	0.6
1	1	40	1.2
3	3	—	—
3P	3	120	3.5
6P	6	240	7

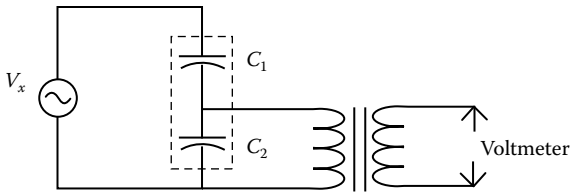

FIGURE 20.6 Capacitive divider and VT device for extremely high voltage.

For extremely high voltage values, both capacitive dividers and VTs are normally used, as shown in Figure 20.6. The capacitive impedance must compensate for the effect of the transformer's internal inductive impedance at the working frequency.

20.3.2 Other Methods

The ac voltage inductive sensors act by interaction between a magnetic field (by an electromagnet excited by voltage to be measured) and the eddy current induced in an electroconductive disk, producing a force or a torque. This can be achieved by the scheme shown in Figure 20.7. The weight of many parts of the indicator can be some tens of grams. The power absorbed is on the order of a few watts. The precision is not high, but it is possible to get these sensors or instruments as they are similar to the widely produced induction energy meters. They are quite robust and are priced between \$50 and \$100, but they are not widely used. The relation between torque and voltage is quadratic:

$$T = k_i V^2 \tag{20.11}$$

The proportionality factor k_i depends on magnet characteristics and disk geometry.

GEC, Landis & Gyr, ABB, Schlumberger, etc., are the major companies that furnish components and instruments measuring voltage by inductive and capacitive sensors.

Current Measurement

Douglas P. McNutt
The MacNauchtan Laboratory

Current-measuring devices are selected for the following:

- Precision
- Stability
- Frequency response, including direct current (dc)
- Galvanic isolation
- Presentation of the data
- Effect on measured circuit

In this chapter, the most common current sensors will be introduced in detail. Some less common sensors will follow after definitions and a bit of magnetic theory, which can be skipped. Any magnetic field sensor can be used as a current sensor, and there are some exotic examples such as quantum effects in low-temperature superconductors used to measure currents in neurons within the brain. This discussion will be limited to measurement of currents in wires with commercially practical devices.

An isolated current sensor is free of any metallic connection to the circuit being measured. It is also essentially free of capacitive coupling so that it is safe to use with grounded amplifiers and other equipment. The quality of the isolation is measured in volts and is usually the breakdown potential of an insulator. 5 kV is typical for personal safety around light industrial power.

By far, the simplest current-to-voltage converter is the resistor. In current-measuring service, it is called a shunt even though it is typically placed in series with the load. That is because shunts are sometimes used to increase the range of another current-measuring device using a connection that bypasses part of the current around a meter. Frequency response of a shunt is good and includes dc. Shunts produce a voltage output that can be presented by a variety of secondary meters including analog meters, digital meters, oscilloscopes, and 4–20 mA converters. Shunts provide no isolation and have a potentially unacceptable effect on the circuit being measured. Shunts used for dc are as accurate as the resistance and the associated voltmeter.

The common moving-coil meter, the D'Arsonval movement [1,2], probably with an internal shunt and/or rectifier, is an easily used device, which is still available. Its isolation is by means of the human eye since that is the only way to read out the result. It is useful for power panels where an operator needs quick data. Accuracy is no better than 2%.

For power frequency, 25–400 Hz service, the current transformer, called a "donut" transformer or CT in the trade, is commonly employed. The current-carrying conductor is passed through the hole in a toroid of magnetic material. A shorted secondary winding of n turns carries current that is $1/n$ times the measured current and is typically passed to another ammeter or used as the current input to a power-measuring device. Isolation is as good as the insulation on the primary conductor, frequency response is fair but does not include dc, there is a minimal effect on the measured circuit, and cost is low. Operational safety is an issue; see the note in the succeeding text.

A variety of noncontact sensors are available for dc sensing. Most depend on the Hall effect, and all require a source of operating power. Frequency response from dc to 200 kHz is advertised. Because operating power is available, output to later processing can be voltage, current, or digital. Accuracy is whatever you want to pay for. Long-term stability depends on dc-coupled operational amplifiers and may exhibit zero drift. Externally, these look much like CTs.

CTs, Hall devices, and other similar noncontact schemes are available in wraparound form so they can be installed without disconnecting power. The wrapping process always involves breaking a magnetic path, and consistency of reassembly becomes a limit on precision. Everything from current sensing probes for oscilloscopes to CTs for 10,000 A circuits can be found as wraparounds.

21.1 Definition of the Ampere

There is a perpetual argument about the number of "fundamental" quantities required to describe our environment. Is there a fundamental unit of electricity or are the electric units derived from more basic things such as mass, length, and time? The U.S. National Institute of Standards and Technology (NIST) currently defines the ampere as "that constant current which, if maintained in two straight parallel conductors of infinite length, of negligible circular cross section, and placed 1 m apart in vacuum, would produce between these conductors a force equal to 2×10^{-7} Newton per meter of length" [3]. Work in progress [4] aims to change that definition to "that current corresponding to the flow of $6.241509468 \times 10^{18}$ elementary charges per second." The change is in line with a recent redefinition of the meter in terms of the velocity of light with the idea of eliminating physical standards, like the standard kilogram used in the current definition of the ampere.

Changes like that are always given long, but exact, scale values so that engineering practices are not affected. For the rest of this discussion, I shall make the assumption that instrumentation is "traceable to the NIST," meaning that one way or another, an electric unit as measured is compared to a standard ampere maintained by NIST. Absolute calibrations using the quantum properties of the Hall effect and the Josephson junction are not practical in the field.

For practical reasons, it is often easier to distribute a voltage standard than a current standard. Chemical cells and, more recently, semiconductor voltage references are quite stable and do not depend on the length of the wires used to connect them together during calibration and use. As a result, current measuring is usually a matter of conversion of current to an equivalent voltage.

An exception is current measurement by comparison to magnetic forces provided by a permanent magnet, and that may be why the older unrationalized centimeter–gram–second, the cgs units with no separate electric unit, are still found in specifications of magnetic quantities. The gauss and the oersted are particular examples of these now deprecated units, but they are still found in the datasheets for magnetic parts. It is this confusion of units that deters many who would measure current away from even attempting calculations involving magnetic devices.

21.2 Magnetics

Magnetic current sensors have advantages over shunts. To understand them, we need to delve into the interaction between currents and magnetic fields. Following Maxwell by way of Sommerfeld [5], it is convenient to describe magnetic effects in terms of two vector fields, **B** and **H**. **H** is the field that is created by an electric current, and **B** is the field that acts on a moving charge or a current-carrying wire. **B** and **H** are related by characteristics of the material in which they coexist. Strictly speaking, **B** is the flux density and **H** is the field, but they are both called the field in less than precise usage.

The SI units of **B** and **H** are the tesla (T) and the ampere per meter (A m^{-1}). They are called rationalized because a ubiquitous 4π has been suppressed in the underlying equations.

For practical engineering, it is still necessary to understand the unrationalized equivalents, the gauss and the oersted, because they are still used in specifications for magnetic materials. To convert from gauss to tesla, divide by 10^4. To convert from oersted to amperes per meter, multiply by $1000/(4\pi)$, a number that is commonly approximated as simply 80, but strictly speaking, the units of **H** in the two systems are dimensionally different and cannot be converted.

The relationship between **B** and **H** is most generally a tensor that reflects spatial anisotropy in the material, but for common magnetic materials used in current sensing, a scalar value μ applies. In SI units, **B** and **H** have different physical dimensions and are not equal in vacuum. The "permeability of free space" μ_0 is defined so that the μ for a material is a dimensionless constant. We say

$$\mathbf{B} = \mu\mu_0\mathbf{H} \tag{21.1}$$

where μ_0 is exactly $4\pi \times 10^{-7}$ H m^{-1}. (H here is the Henry, the SI unit of inductance, base units m^2 kg s^{-2} A^{-2}). For many problems, μ will be a constant of the magnetic material, but when magnetic saturation needs to be considered, it will be a variable. For engineering calculations, μ is often treated as though it depends on frequency. Values of μ range from less than 100 for a high-frequency ferrite to 5000 for transformer iron and to 10^5 for carefully annealed magnetic alloys:

$$\mathbf{H} = \mathbf{I}/(2\pi r) \tag{21.2}$$

The field due to a long straight wire is shown in Figure 21.1 and Equation 21.2. The **H** vector obeys the right-hand rule and is everywhere perpendicular to the wire. The amplitude of **H** is proportional to the current and falls off linearly with the radial distance from the wire. This is the field that makes noncontact sensing of current possible.

The field at the center of a circular loop of wire is shown in Figure 21.2 and Equation 21.3. It obeys the right-hand rule, is proportional to the current, and is inversely proportional to the radius of the loop:

$$\mathbf{H} = \mathbf{I}/r \tag{21.3}$$

A magnetic field can often be calculated by direct application of Maxwell's relations in integral form [6]. The line integral over any closed path of $\mathbf{H} \cdot d\mathbf{l}$ is equal to the current passing through a surface delimited by the closed path.

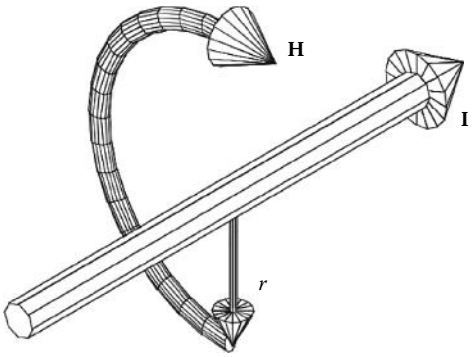

FIGURE 21.1 The magnetic field associated with a long wire carrying current **I**. It is this field that makes contactless sensing of current possible.

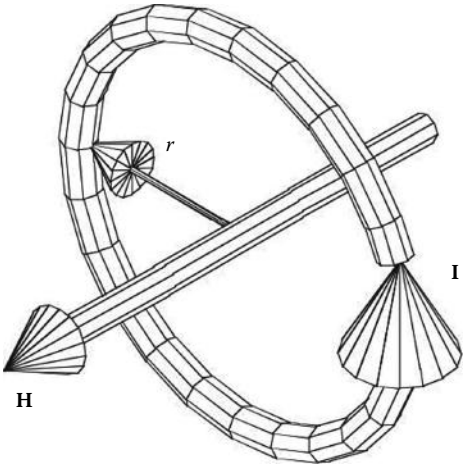

FIGURE 21.2 The magnetic field at the center of a loop of wire carrying current **I**. This is the starting point for many calculations involving inductors and transformers.

Magnetic flux passing through a surface, usually denoted by Φ, is the integral of $\mathbf{B} \cdot \mathbf{n}\, dA$ over the surface with normal vector **n**. The SI unit of Φ is the weber. The unrationalized unit, the line of force, is best relegated to history except that the lines, which form continuous loops, dramatize the fact that it doesn't matter how a surface is drawn to close a bounding line. The flux is the same. It is convenient to think of magnetic lines, forming closed loops, which can be bent but not interrupted or removed.

A carrier of charge, an electron in a wire, a particle in vacuum, or a hole in a semiconductor, moving in a magnetic field, is acted on by a force that is perpendicular to the field and the velocity. For positive charge, the force obeys the right-hand rule. The magnitude of the force is proportional to the charge q, the magnitude of **B**, the velocity **v**, and the sine of the angle between them. It is a vector cross product:

$$\mathbf{F} = q\mathbf{v} \times \mathbf{B} \tag{21.4}$$

A carrier, moving or not, is affected in a similar way by a changing magnetic field. The result is an electromotive force (EMF) in a loop of wire through which a changing magnetic flux passes. The EMF is equal to the rate of change of the flux enclosed by the loop with a change of sign. That is Faraday's law of induction:

$$\text{EMF} = -d\Phi / dt \tag{21.5}$$

Most magnetic materials exhibit hysteresis. That is, the relationship between **B** and **H** depends on the history of the applied **H**. A plot of **B** versus **H** is called a hysteresis loop, and a sample is shown as Figure 21.3.

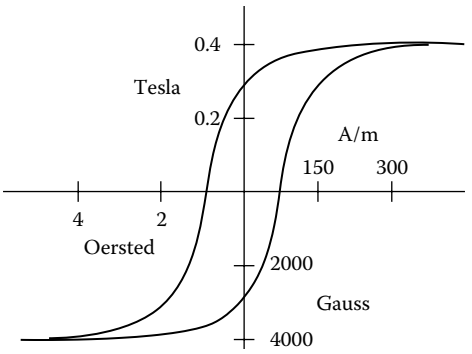

FIGURE 21.3 A hysteresis curve for some rather poor transformer iron. Unrationalized units are shown below and left of the origin because that remains standard practice in the industry.

The area of the loop represents energy. If a magnetic core is repeatedly driven around its hysteresis loop, there is a power loss that is proportional to the area of the loop and the frequency. A material with very large hysteresis is a permanent magnet.

Magnetic materials that are also electric conductors have free carriers, which are affected by alternating magnetic fields. As they move back and forth, they encounter electric resistance and dissipate energy in the form of heat. These eddy currents can be minimized by the use of high-resistance ferrites and powdered iron, by laminating cores, or by keeping the flux small.

21.3 Shunts

Shunts were introduced earlier. They dissipate power as heat, and the resistance changes in response to the rising temperature. The dissipation is proportional to the voltage across the shunt, and a design compromise must be made because low voltage implies less accuracy in the voltmeter. A standard of 50 mV has evolved. Shunts do not provide galvanic isolation between the measured circuit and the measurement device.

Measurement of alternating current (ac) using shunts is also affected by skin effect and the inductance of the shunt. Skin effect can be minimized in the design of the shunt by the use of several parallel sheets of thin metal (Figure 21.4), a feature that also improves heat dissipation. There isn't much to be done about inductance except to minimize size.

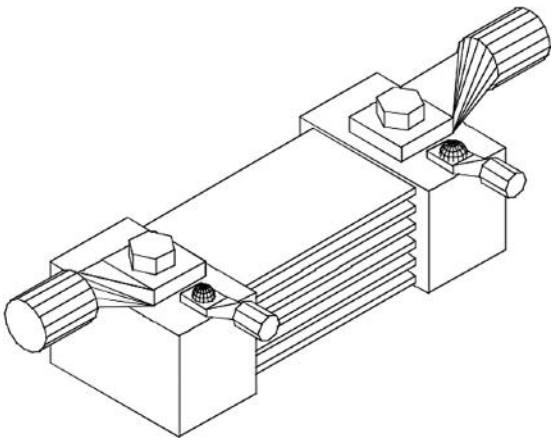

FIGURE 21.4 Multiple sheets of conductor are provided in this shunt to reduce skin effect and allow air cooling. Kelvin connections are provided for the voltmeter so that voltage drops in the high-current connectors are not inadvertently included in the measurement.

Safety is enhanced if shunts are placed in the ground leg of a circuit for that way the output leads, usually only at 50 mV, are near ground. But that introduces a resistance in the ground path and can interfere with common mode requirements of interdevice signal connections. If the shunt is placed in the high side, care must be taken to protect the wiring and the meter to which it is attached from accidental grounds.

Sometimes sufficient accuracy can be obtained by measuring the voltage drop along a length of conductor, which is otherwise required in the installation. In a vehicular service, it is common to sense the voltage drop in a battery cable using a millivoltmeter. Such installations are always high side and should be protected with fuses or other current limiting devices installed near the points of measurement. It is also wise to provide a connection means that is independent of contact resistance where the current-carrying conductor is installed—a Kelvin connection. Including one lead of an in-line fuse holder in the terminals before they are crimped is one such technique.

21.4 Moving Magnet Meter

The simplest current indicator balances the force on a permanent magnet created by current in a wire against a spring. A magnetic material is usually placed around the conductor to concentrate the field and reduce the effect of the magnetic field of the earth. The use is limited to low-precision indicators such as a battery charging meter for a vehicle. It is a dc device.

21.5 D'Arsonval Meter

This indicator balances the force on a current-carrying wire due to a permanent magnet against a spring. The measured current flows in a coil of wire supported in bearings. It is described in elementary texts [1,2], and I will not use space on its details. It is generally a dc instrument, but chart recorders have been built with frequency response in the kHz range using mirrors on the moving coil. They are then called galvanometers. For ac service, these meters are often equipped with internal copper oxide rectifiers and a nonlinear scale to correct for the diode drop. For current ranges above a few mA, they will have an internal shunt.

The moving magnet meter and the D'Arsonval movement are the only current sensors that do not convert current to voltage and then depend on other devices to read out the voltage.

21.6 Electrodynamometer

A variation of the D'Arsonval meter for ac service can be built by replacing the permanent magnet with an electromagnet. The force on the moving coil becomes proportional to both the current being measured and the voltage applied to the coil of the electromagnet. It is sensitive to the relative phase of the voltage and current in just the right way to be useful for measurement of power in a circuit with correction for power factor. An electrodynamometer in a power panel is often the load for a CT.

21.7 RF Ammeter and True rms

Current to a radio transmitting antenna is commonly passed through a small resistor, a shunt, which is thermally connected to a thermocouple or other thermometers and mounted in a thermally insulating blanket. The rise in temperature is a measure of the current and is often sensed with a thermocouple.

This is an example of true root-mean-square (rms) indication. The rms current is the square root of the integral of the square of the instantaneous current over an unspecified time divided by that time. It is intended to represent a stationary ac waveform by a single value, which is equal to the dc, which would dissipate the same power in a resistive load. The radio frequency (RF) ammeter does that precisely. The indication is not particularly linear, but it can easily be calibrated by applying dc to the input.

Other schemes for measuring rms current depend on analog multipliers and subsequent integration. They are limited by crest factor, the ratio of highest instantaneous peak to the rms over a measuring period. Inexpensive meters simply measure the peak, assume a sinusoidal waveform, and scale to rms.

21.8 Current Transformer

Galvanic isolation of current-measuring schemes becomes more and more important when there is no human observer looking at a meter that might be running at a high voltage. The CT remains a popular way to accomplish isolation for ac systems. Other techniques to follow are chosen mostly for their ability to provide isolation.

Consider the magnetics of a toroidal core of high-μ material through which a current-carrying conductor passes. Include a secondary winding of n turns as shown in Figure 21.5. The secondary is connected to a low-resistance load.

In this current transformer, universally referred to as a CT, ac in the single-turn primary attempts to magnetize the core but in so doing creates an EMF and current in the secondary, which tends to cancel the field. If the secondary truly has zero resistance, the current in it exactly cancels the field due to the primary. The result is a secondary current equal to the primary current divided by the number of secondary turns. The secondary current is in phase with the primary current. Because of the tightly closed magnetic loop, there is little effect from nearby conductors or position of the primary wire in the hole.

The secondary circuit can now be connected to a low-resistance current or power sensing device with assurance of calibration. But the secondary resistance is never really zero, and the magnetic coupling is never perfect so there are other considerations.

First, the concept of secondary burden is introduced. It is called that to avoid calling it a "load" because it behaves differently; the best burden is a short circuit. Burden is sometimes expressed as a secondary resistance in ohms but more often as an equivalent power in kVA for a defined current without consideration of phase. When the burden is not a perfect short circuit, energy is dissipated and the magnetic field present in the core is no longer zero. The secondary current leads the primary current with a phase, which depends on frequency.

Manufacturers of CTs have techniques to optimize accuracy of the CT when specified for a particular burden. The finished units may not have the number of secondary turns you would expect but will nonetheless provide results accurate to a percent or so. They have laminations selected to minimize heating of

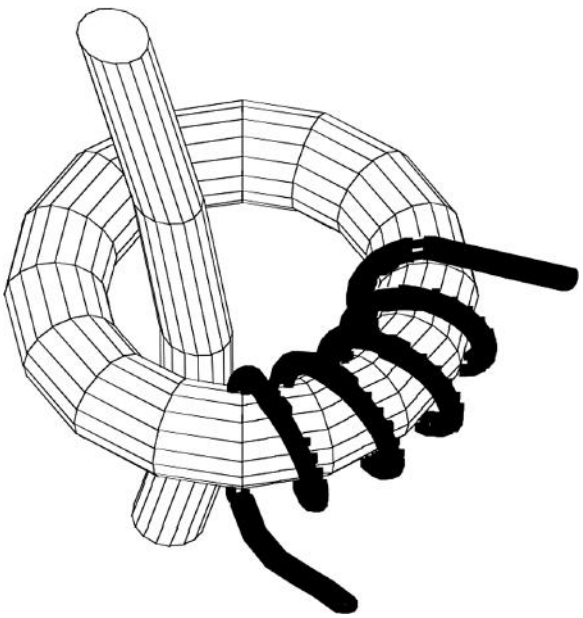

FIGURE 21.5 The ideal CT is tightly coupled with no magnetic gap. Current in the secondary exactly balances current in the single-turn primary so that the magnetic flux in the core is zero.

the core. You will see ratings like 100:5, meaning 100 A in the primary will produce 5 A in the secondary rather than "20 turns." They should be installed in a circuit that provides the burden for which they were calibrated. The voltage across a burden resistor is commonly amplified and passed to a data collection device. CTs for large currents need to be large to avoid magnetic saturation when burdened. Cores are prepared with laminates of silicon iron in the form of disks, concentric rings, or tape, which is wound on a bobbin. Even with the best of materials, eddy current and hysteresis loss are present. When power dissipation is unacceptable, another choice of sensor may be preferable.

Most CTs are used for measurement of low-frequency power and energy. They are found at the front end of kilowatt hour meters used by power providers. RF current in transmitting antennas can be measured with suitable core material. Ferrite cores with appropriate compensation are used for sensing pulse-width-modulated current in switching power supplies. Very large cores are used to sense pulsing beams of high-energy particles. Some oscilloscope probes are highly compensated CTs with a core that can be opened to allow a current-carrying wire to be introduced. With modern winding equipment for toroids, it is possible to put 2000 or more turns on a secondary.* The CT then begins to look more like a current-to-voltage converter in its own right without the need for very small values of the burden resistor and subsequent voltage amplification.

Safety Note: The secondary of a CT should always remain shorted, while there is any possibility of current flow in the primary. With an open secondary, the core can be driven back and forth between saturation in opposite directions resulting in high-speed changes in the internal **B** field. The result is very high, dangerous to life, voltages on the open secondary. Insulation in the secondary circuit can be damaged by arcing. Many CTs are made with a provision for shorting the secondary if the circuit must be opened. Use it.

21.9 Gapped Inductive Sensors

It is common practice in the design of transformers to introduce a small gap in the magnetic path. For even very small gaps, the magnetic properties of the magnetic loop become almost completely determined by the length of the gap, the rest of the material serving only to contain the lines of flux. The analysis of such a device begins with the understanding that the **B** field is continuous in the core and through the gap. The **H** field is not, but it still satisfies the relation that the line integral of $\mathbf{H} \cdot d\mathbf{l}$ around the core is equal to the linked current. For a magnetic path of length s in material of permeability μ with a gap g, the ratio **B**/**H**, the effective permeability, is given by

$$\mu_{\text{eff}} = s/(g + s/\mu) \tag{21.6}$$

that applies for g much smaller than s. Note that when μ is sufficiently large, the effective permeability becomes independent of μ.

Introducing a gap into what would otherwise be a CT and drastically increasing the secondary turns count to 10,000 or more results in a current sensor, which is intrinsically safe because the core cannot saturate (Figure 21.6).† Because the **B** field is always small, the heating effect of eddy currents is less important than in the CT. When loaded with an appropriate resistor, the high inductance of the secondary causes the sensor to act like a current source, which generates a voltage across the load proportional to the primary current with better than 1% linearity. Useful bandwidth of a sensor can be over three decades. The output impedance is high and requires the use of electronic voltmeters. Power dissipation is low even for very high-current models. Output voltage is high enough that simple diode rectifiers can be used to provide for dc output to further processing. In many cases, such a sensor can be used without any special electronics other than a voltmeter.

* C.R. Magnetics is one source of high turns current transformers. Smith Research & Technology, SRT is no longer in active production.

† Smith Research and Technology. Inc., SRT of Colorado Springs once sold sensors like this. They are not currently available.

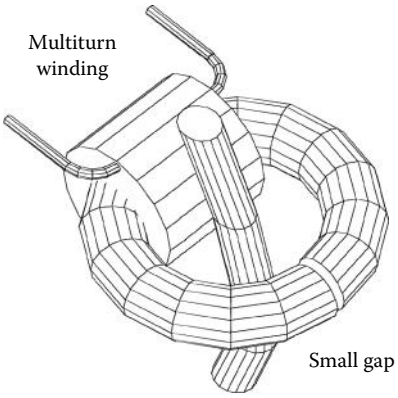

FIGURE 21.6 Placing a gap in the core and dramatically increasing the secondary turn count result in a current-to-voltage converter with high output voltage. The gap can be distributed using a powdered-iron core.

21.10 Hall Effect Sensor

The Hall effect as a sensor for magnetic fields is described in another chapter of this volume and in [7]. It depends on a semiconductor crystal selected for its high carrier mobility and placed in a magnetic field. A current is passed through the crystal along an axis perpendicular to the field. The carriers assume a mean velocity, which causes them to be acted upon by the field, and they move toward the other axis perpendicular to the field. The result is an EMF at the faces of the crystal that can be measured. The EMF is proportional to the field, the bias current, and the mobility.

In principle, such a field sensor could be placed near a current-carrying wire and oriented to sense the field created by the current (Figure 21.1), but the sensitivity is insufficient, and there would always be interfering fields from currents in other nearby wires. A flux concentrator that looks like a CT with a large gap is always used (see Figure 21.7).

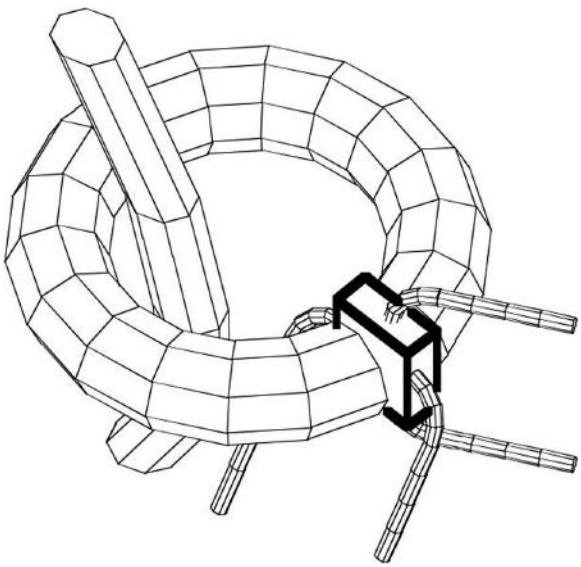

FIGURE 21.7 A semiconducting crystal is placed in the gap of a flux concentrating magnetic core. Bias current on one axis of the crystal produces a Hall voltage on the other.

The device is sensitive to dc and the polarity is preserved. The Hall voltage is a few millivolts, and amplification is always required. Zero drift in the amplifiers must be properly compensated though this is not so important for ac service. The bias current must be carefully controlled, and it can be used to provide intrinsic analog multiplication and metering of power if it is made proportional to the circuit voltage.

Sensitivity is best with the smallest gap, but there must be room for the crystal so gaps are larger than in the gapped inductive sensors. Fringing of the field in the larger gap reduces the natural shielding of the toroid from unwanted magnetic fields.

The accuracy and linearity of the Hall effect sensor can be improved in closed-loop mode. A feedback winding is added to the core and driven by a servo amplifier. The EMF from the Hall device is used to drive the servo amplifier until the field is zero. The output is then the feedback current, which is less than the sensed current by the number of turns in the feedback winding. The frequency response of the closed-loop system is surprisingly good, hundreds of kHz.*

21.11 Clamp-On Sensors

It is often desirable to measure current in an existing system without removing power in order to install a device so most of the magnetic devices are available in a clamp-on configuration. The variety ranges from tiny oscilloscope probes to clamps for 3000 A power buses.

Accuracy is always reduced in a clamp-on mode because the clamp itself constitutes a gap that is uncontrollable and subject to wear. Some manufacturers provide highly polished surfaces that slide together. Others have iron fingers that interlace as the clamp is closed. Still, others don't worry about it because the instrument is intended for field use where accuracy is not so critical.

Some units have handles for one-hand operation while others require a wrench or other tools. An interesting variation is the flexible core by Flexcorp.† Installation is by bending the core and allowing it to spring back to shape.

21.12 Magnetoresistive Sensors

Most of the features of a Hall effect sensor are available if the Hall crystal is replaced by a device whose resistance changes with magnetic field. The discovery of giant magnetoresistive devices has recently made this idea attractive.‡

Such devices still exhibit rather small resistance change and are sensitive to other effects such as temperature so it is imperative that they be used in self-compensating bridge circuits in the manner of a strain gauge. They are also insensitive to polarity of the field.

Zetex has delivered magnetoresistive current sensors using thin-film permalloy in a variety of printed circuit packages. They are constructed in the form of a bridge and require bias and a differential amplifier. Measured current up to 20 A passes through the chip via its solder pins.

21.13 High-Side Sensing

In fairly low-voltage, especially battery-powered, equipment, it has become necessary to monitor and control current used by various parts of an electronic device in the interest of extending battery life and presenting "fuel gauge" information on the state of charge to a user. The systems typically require a reliable common ground that would be unavailable if shunt resistors were to be installed on various parts for monitoring of current on the ground side. A simplified circuit that has been around for a while

* F. W. Bell offers considerable knowledge on its website. There is also a Wikipedia entry at Hall sensor which offers other references.

† Flex-Core offers Split-Core current transformers that can be wrapped around a large conductor.

‡ NVE corporation provides a discussion of the giant magnetoresistive effect at GMR.

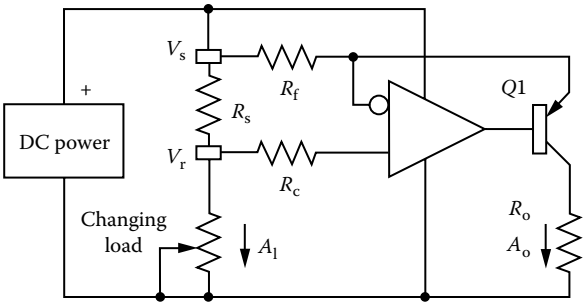

FIGURE 21.8 Schematic for an operational amplifier that converts the voltage across a high-side shunt into a ground-referenced current.

has found a new life in the form of dedicated integrated circuit chips that produce a ground-referenced measure of the voltage across a shunt in the positive power rail.

Referring to Figure 21.8, the current from a power source drives a changing load via a shunt resistor R_s, which is chosen to drop 10–100 mV or so at the maximum current to be measured. The load current creates voltages V_r and V_s with the difference between them equal to the load current A_l times the resistance R_s. The operational amplifier requires that the voltage at its inverting input match the reference voltage V_r, which it accomplishes by turning on PNP transistor $Q1$ just enough that the current in R_f produces the same drop as that across the shunt. The current, A_o, in output resistor R_o, providing that the current gain of $Q1$ is high, is the same as the current in R_f. The overall result is that $R_fA_o = R_sA_l$, and A_o is the same as the load current scaled by R_s/R_f. The current A_o can be used directly as the input of a current switching analog-to-digital converter, or it can be converted to a voltage with resistor R_o or with two op-amps wired as an inverting current-to-voltage converter followed by an inverter.

There are some serious considerations. The op-amp must operate from the possibly high power voltage. Resistor R_c is not critical but is often set to equal R_f to compensate for the less than infinite input resistance of the op-amp. The circuit as shown monitors the current in the load while ignoring the current used by the op-amp and the output. The details of the op-amp, including internal biasing that allows for common mode input at the supply voltage, are nontrivial, but they have been approached by designers of integrated circuits made for the purpose. Those chips may also include R_f, R_c, $Q1$, and an output amplifier leaving only the shunt to be selected. National Semiconductor and Zetex (see the table of suppliers) among others have offerings.

21.14 Fluxgates

In its simplest form, a fluxgate magnetometer uses a driving coil to drive a high-permeability rod into saturation first in one direction and then in the other. A second winding observes the rate of change of the **B** field inductively. In the absence of an external magnetic field, the observed signal is symmetric, but when an external field shifts, the hysteresis loop to the right or left the symmetry is lost. An amplifier tuned and phase locked to the second harmonic of the driving frequency can be used to determine the amplitude of the external field.

In principle, such a fluxgate could be used to sense the field in the gap of a flux concentrator as with the Hall sensor, but it's too big and the linearity would be unacceptable. It's better to think of a way to drive the whole flux concentrator with a pumping frequency similar to that used in a magnetic amplifier.

Driving a toroid this way has the undesirable effect of coupling the pump energy into the circuit being measured, but one can pump two toroids in opposite directions. Now, a current to be sensed passes through both cores and biases one in one direction and one in the other relative to the pump. A pickup winding senses second harmonic, which is demodulated with a phase-locked sensor to preserve the direction of the sensed current.

Linearity is improved by adding one more winding through both toroids, which is driven by a servo amplifier that is satisfied only when the amplitude of the second harmonic is zero; the flux at the measured frequency is zero. This is now the ideal CT. At the frequency of the sensed current, which might be dc, there is zero average flux in the toroids, and the output of the servo amplifier is a true representation of the current being measured reduced by the turn count of the servo winding.

Unfortunately, complicated electronics and considerable power are required to accomplish all of this, but the resulting accuracy is significantly better than anything other than precision shunts. Suppliers* provide equipment, which uses these principles. Many of the details are either patented or proprietary.

21.15 Optical Sensors

The Faraday effect is a rotation of the plane of polarization of light as it passes in a transparent medium parallel to a magnetic field. Optical fibers that do not randomize polarization are available with a small Faraday coefficient. Winding such a fiber on a form to be installed around a wire so that the light propagates parallel to the field produced by current in the wire (Figure 21.1) results in a sensor. A measurable rotation proportional to the current comes about because of the long optical path. When the myriad problems of preparation are solved, the result is a sensor that looks externally like a CT but has no wires. Using a reflecting ring made of yttrium–iron–garnet with a large Faraday coefficient, NIST reports sensitivity of 220 nA. Matsushita Electric Industrial Company makes sensors using thin garnet films. More information can be found in Refs. [8–11].

The analysis of the polarization requires a polarized light source and a polarization analyzer at the receiving end. An advantage of such a sensor is that the fiber leads to and from can be long enough to provide isolation for very high voltages.

Winding and annealing of fiber sensors without destroying the polarization-preserving properties of the fiber and temperature sensitivity of the Faraday coefficient must be addressed. Further information on these sensors can be found in [6].† ABB, Sweden, reports a maximum detectable current of >23 kA, a sensitivity of about 2 A, and a relative error of ±0.15% [6].

21.16 Fault Indicators

Latching indicators that save an indication of high pulse current, which was present sometime in the past, are needed for power distribution systems subject to lightning strikes. Such indicators are often a bar magnet hanging on a transmission wire, which moves into a latched position when a current pulse occurs. Readout is visual and they can be reset and installed on live wires using high-voltage tools.

21.17 Other Schemes

The double balanced mixer, familiar to RF engineers, is also a sensor for low-frequency current. The IF port is usually dc coupled through diodes in a ring configuration. The dc applied there will modulate an RF pump applied to one of the RF ports and recovered on the other. There are no known products that use this principle.

Magnetic amplifiers take advantage of nonlinearity of the **B**–**H** curve in a transformer core. The efficiency of a transformer is adjusted by a dc or low-frequency current, which moves the operating point on the hysteresis curve. Excitation, a pump, is required at a higher frequency, which is passed through the transformer and then synchronously rectified and filtered into a higher-power representation of the

* Fluxgates GMW, Holec, Others Wiki is a start. A Google search for "+Fluxgate +magnetometer +'current sensor' -eddy -patent" generates 310 good places to look for more.

† C.R. Magnetics is one source of high turns current transformers. Smith Research & Technology, SRT is no longer in active production; Smith Research and Technology. Inc., SRT of Colorado Springs once sold sensors like this. They are not currently available.

low-frequency signal. The magnetic windings are designed so that the pump power cancels in the signal circuit. As a current-measuring device, the magnetic amplifier leaves much to be desired in linearity and frequency response, but it does provide isolation and is limited in sensitivity only by the number of turns placed in the sensed winding. The 20 mA dc off-hook current in a telephone is one such application that is probably not used at all anymore.

21.18 Some Generalities and Warnings

Except for very simple loads, the waveform of the current drawn by a load does not resemble the voltage waveform. Besides the well-known phase shift and power factor, current flows in harmonics and subharmonics of the power frequency. Bridge rectifiers with capacitor input filters draw pulses of current near the peaks of the voltage waveform. Triacs cause a phase shift of the fundamental and introduce odd harmonics. Triacs in a full-cycle mode with zero current switching may draw full current for a few cycles followed by zero current for a few more introducing frequency components below the power frequency. Frequency changers are likely to draw current in pulse-width-modulated bursts.

A classic error is to measure true rms voltage and true rms current and multiply the two to get power. Even after having corrected for the phases, this can still be wrong. In short, accurate measurement demands some knowledge of the characteristics of the load. Beware of sensors labeled "true rms" for they may be anything but.

21.19 Current Actuated Switches and Indicators

Another form taken by current sensors is the current actuated switch. There was a time when contacts were placed on the pointer of a D'Arsonval movement to establish upper and lower limits for a process variable. The modern way is to configure a sensor so that it operates a solid-state switch.

When operating power is available, any of the current sensors can be configured as a switch, but when the switch must be controlled solely by the power that can be extracted from the current being measured, the gapped toroid is superior. The high-voltage available can be rectified to control MOSFETs or the base of an open collector Darlington transistor.*

One company [CR Magnetics] markets a light-emitting diode (LED), indicator that shows the presence of ac without any connection or external source of power.

Circuit breakers can be implemented with a magnetic coil or with a bimetallic thermal element. For completeness, there is also the fuse.

Ground fault breakers use a toroidal CT through which the line current is passed twice, once on the way to the load and again on the way back to the neutral wire in such a way as to cancel. Any fault current to ground associated with the load causes the return current to be less than the source and induces voltage on the secondary of the toroid. This is amplified and used to trip a switch. This application demands absolute insensitivity to the position of a current-carrying wire in the hole of the toroid. Gapped sensors typically are not suitable because of magnetic leakage.

21.20 Where to Get Current Sensors

CTs, shunts, and some other sensors are commodity items available from a variety of manufacturers and distributors. Well-known manufacturers of switchgear, General Electric and Westinghouse, have their own CTs for use with their power meters. Test equipment manufacturers, Simpson, Tektronix, Fluke, Extech, and the like, offer handheld current meters. Table 21.1 shows distributors and manufacturers of current sensing equipment. There is no way that a list such as this can be complete. It has selected itself from those companies willing to contribute to the author's library.

* Unpowered current actuated switches are possible using high turn count gapped CTs and power MOSFETs. They are no longer available from SRT.

TABLE 21.1 Selected Manufacturers and Distributors of Current Sensors

ABB, Inc.

Home: http://www.abb.com/

A big company that offers a family of high-accuracy fiber-optic current sensors.

AEMC through Optimum Energy Products Ltd.

#333, 11979 40 St SE, Calgary, AB, Canada T2Z 4M3

e-mail: info@optimumenergy.com

Home: http://www.myaemcstore.com/

AEMC Instruments is a manufacturer of meters, testers, and analyzers, such as current probes and dataloggers.

AEMC clamp-on CTs and other sensors

http://www.myaemcstore.com/c1084/clamp_on_meters.php

http://www.myaemcstore.com/c1104/flexible_current_probes.php

AEMC manufactures clamp-on current transformers and other sensors.

AEMC Instruments

200 Foxborough Blvd., Foxborough, MA 02035

Home: http://www.aemc.com/

Makes CT-based current sensors.

American Aerospace Controls

570 Smith St., Farmingdale, NY 11735

Home: http://www.a-a-c.com/

Has a line of ac and dc current sensors for mounting in remote locations with wiring to collect data.

Amprobe

e-mail: info@amprobe.com

Home: http://amprobe.com

Offers handheld, mostly clamp-on, meters for a wide range of ac currents.

Coilcraft

1102 Silver Lake Road, Cary, IL 60013

e-mail: cust_service@coilcraft.com

Home: http://www.Coilcraft.com

Manufactures smaller CTs mostly for mounting on printed circuit boards.

CR Magnetics, Inc.

3500 Scarlet Oak Blvd., St. Louis, MO 63122

Home: http://www.crmagnetics.com

Provides a full line of CTs and current actuated switches. Their technical references are worth a look.

Dranetz Technologies, Inc.

1000 New Durham Rd., Edison, NJ 08818 4019

Home: http://www.dranetz-bmi.com

Offers a line of equipment for analysis of ac power and is included here although it does not sell instruments dedicated only to current sensing.

Extech Instruments Corporation

285 Bear Hill Road, Waltham, MA 02451 1064

Home: http://www.extech.com/instruments/

Sells a line of handheld meters suitable for current measurement to 2000 A.

TABLE 21.1 (continued) Selected Manufacturers and Distributors of Current Sensors

F. W. Bell

6120 Hanging Moss Rd., Orlando, FL 32807

Home: http://www.fwbell.com

http://www.oeco.com/HallEffectSensors.html

http://www.oeco.com/Current_Sensors.html

F. W. Bell is now part of Pacific Scientific and Danaher. Information on Hall effect and magnetoresistive current sensors can be found on the Internet.

Flex-Core division of Morlan and Associates

Office: 6625 McVey Blvd., Columbus, OH 43235

Factory: 4970 Scioto-Darby Rd., Hilliard, OH 43026

e-mail: flexcore@msn.com

Home: http://www.flex-core.com/

Makes a line of sensors that cover the range of CTs. Of particular interest is their flexible iron core, which can be installed over an existing conductor by bending it.

Fluke

Home: http://www.fluke.com/

http://www.fluke.com/Fluke/usen/products/Clamp-Meters.htm

Fluke, with numerous sales offices and distributors, has a line of sensors for use with their handheld instruments.

GMW Danfysik

955 Industrial Road, San Carlos, CA 94070

Home: http://www.gmw.com/index.html

Deals in laboratory grade equipment for precision noncontact measurement. Precision in the ppm range and prices to match. Up to 10000 ADC and more than 200 kHz.

Holec division of Eaton Electric B.V.

Based in the Netherlands

e-mail: hppbv@pi.net

Home: http://www.eaton.com/EatonCom/ProductsServices/Holec/

Offers zero-flux CTs using servo amplifiers to drive the secondary actively. Their document 5.20.2 helps to understand the principles involved that operate from dc to 500 kHz.

LEM U.S.

Home: http://www.lem.com/

http://www.lem.com/hq/en/content/view/161/153/Open loop

http://www.lem.com/hq/en/content/view/168/155/Closed loop

Offers Hall effect sensors in both open- and closed-loop form for ac and dc currents.

MICRO SWITCH division of Honeywell, Inc.

Power Measurement

Pasquale Arpaia
Università del Sannio

Francesco Avallone
Università di Napoli Federico II

Aldo Baccigalupi
Università di Napoli Federico II

Carmine Landi
Università de L'Aquila

In this chapter, the concept of electric power is first introduced, and then the most popular power measurement methods and instruments in *dc*, *ac*, and *pulse* waveform circuits are illustrated.

Power is defined as the *work performed per unit time*. So, dimensionally, it is expressed as joules per second, J s^{-1}. According to this general definition, electric power is the electric work or energy dissipated per unit time, and dimensionally, it yields

$$\mathrm{J\,s^{-1}} = \mathrm{J\,C^{-1}} \times \mathrm{C\,s^{-1}} = \mathrm{V} \times \mathrm{A} \tag{22.1}$$

where
J = Joules
s = seconds
C = Coulombs
V = volts
A = amperes

The product *voltage times current* gives an electric quantity equivalent to *power*.

22.1 Power Measurements in DC Circuits

Electric power (P) dissipated by a load (L) fed by a dc power supply (E) is the product of the voltage across the load (V_L) and the current flowing in it (I_L):

$$P = V_L \times I_L \tag{22.2}$$

Therefore, a power measurement in a dc circuit can be generally carried out using a voltmeter (V) and an ammeter (A) according to one of the arrangements shown in Figure 22.1. In the arrangement

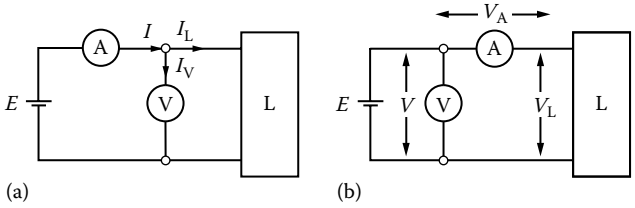

FIGURE 22.1 Two arrangements (a and b) for dc power measurement circuits.

of Figure 22.1a, the ammeter measures the current flowing into the voltmeter, as well as that into the load, whereas in the arrangement of Figure 22.1b, this error is avoided, but the voltmeter measures the voltage drop across the ammeter in addition to that dropping across the load. Thus, both arrangements give a surplus of power measurement absorbed by the instruments. The corresponding measurement errors are generally referred to as insertion errors.
According to the notation,

- I, current measured by the ammeter (Figure 22.1a)
- V, voltage measured by the voltmeter (Figure 22.1b)
- R_V, R_A, internal resistance of the voltmeter and the ammeter, respectively
- R_L, load resistance
- I_V, current flowing into the voltmeter (Figure 22.1a)
- V_A, voltage drop across the ammeter (Figure 22.1b)

The following expressions between the measurand electric power P and the measured power $V \times I$ are derived by analyzing the circuits of Figure 22.1a and b, respectively:

$$P = V_L \times I_L = V \times I \times \left(\frac{R_V - R_L}{R_V} \right) \tag{22.3}$$

$$P = V_L \times I_L = V \times I \times \left(\frac{R_L - R_A}{R_L} \right) \tag{22.4}$$

If

- I_V, compared with I
- V_A, compared with V

are neglected for the arrangements of Figure 22.1a and b, respectively, it approximately yields

$$\frac{I_V}{I} = \frac{R_L}{R_V + R_L} \cong \frac{R_L}{R_V} \cong 0; \quad \frac{V_A}{V} \cong \frac{R_A}{R_A + R_L} \cong \frac{R_A}{R_L} \cong 0 \tag{22.5}$$

consequently, measured and measurand power will be coincident.

On this basis, from Equations 22.3 through 22.5, analytical corrections of the insertion errors can be easily derived for the arrangement of Figure 22.1a and b, respectively.

The instrument most commonly used for power measurement is the *dynamometer*. It is built by (1) two fixed coils, connected in series and positioned coaxially with space between them, and (2) a moving coil, placed between the fixed coils and equipped with a pointer (Figure 22.2a).

The torque produced in the dynamometer is proportional to the product of the current flowing into the fixed coils times that in the moving coil. The fixed coils, generally referred to as *current coils*,

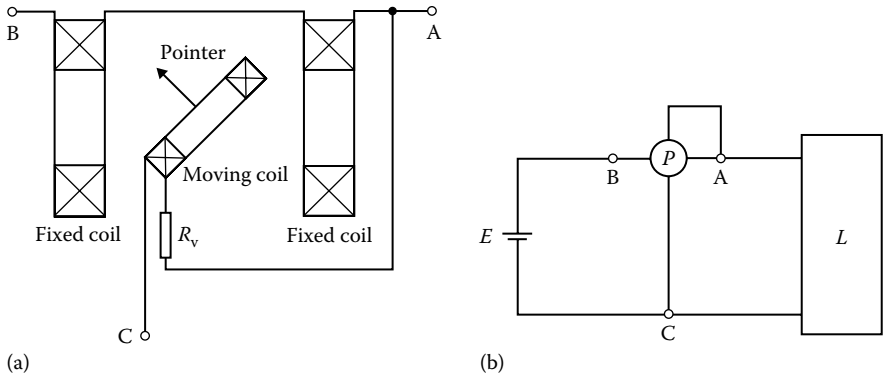

FIGURE 22.2 Power measurement with a dynamometer: (a) working principle and (b) measurement circuit.

carry the load current, while the moving coil, generally referred to as *voltage coil*, carries a current that is proportional, via the multiplier resistor R_V, to the voltage across the load resistor R_L. As a consequence, the deflection of the moving coil is proportional to the power dissipated into the load.

As for the case of Figure 22.1, insertion errors are also present in the dynamometer power measurement. In particular, by connecting the voltage coil between A and C (Figure 22.2b), the current coils carry the surplus current flowing into the voltage coil. Consequently, the power P_L dissipated in the load can be obtained by the dynamometer reading P as

$$P_L = P - \frac{V^2}{R'_v} \tag{22.6}$$

where R'_v is the resistance of the voltage circuit ($R'_v = R_v + R_{vc}$, where R_{vc} is the resistance of the voltage coil). By connecting the moving coil between B and C, this current error can be avoided, but now the voltage coil measures the surplus voltage drop across the current coils. In this case, the corrected value is

$$P_L = P - I^2 R_C \tag{22.7}$$

where R_C is the resistance of the current coil.

22.2 Power Measurements in AC Circuits

22.2.1 Definitions

All the earlier considerations relate to *dc* power supplies. Now look at power dissipation in *ac*-fed circuits. In this case, electric power, defined as voltage drop across the load times the current flowing through it, is the function

$$p(t) = v(t) \times i(t) \tag{22.8}$$

referred to as the *instantaneous power*. In ac, one is mainly interested in the mean value of instantaneous power for a defined time interval. In circuits fed by periodic ac voltages, it is relevant to define the mean power dissipated in one period T (*active power P*):

$$p = \frac{1}{T}\int_0^T p(t)dt \tag{22.9}$$

The simplest case is a sinusoidal power supply feeding a purely resistive load. In this case, $v(t)$ and $i(t)$ are in phase and $p(t)$ is given by

$$p(t) = VI[1 - \cos(2\omega t)] \tag{22.10}$$

where

V and I are the rms values of $v(t)$ and $i(t)$, respectively
ω is the power supply angular frequency

Therefore, the instantaneous power is given by a constant value VI plus the *ac* quantity oscillating with twice the angular frequency of the power supply; thus, the active power is simply the product VI. In this case, all the earlier considerations referring to active power for *dc* circuits are still correct, but voltages and currents must be replaced by the corresponding rms values.

The case of purely reactive loads is the opposite; the voltage drop across the load and current flowing through it are out of phase by 90°. Instantaneous power $p(t)$ is given by

$$p(t) = VI\cos(2\omega t) \tag{22.11}$$

Thus, the active power dissipated by a reactive load is zero, owing to the phase introduced by the load itself between voltage and current.

The simplest cases of sinusoidal power sources supplying purely resistive and purely reactive loads have been discussed. In these cases, the load is expressed by a real or a pure imaginary number. In general, the load is represented by a complex quantity (the impedance value). In this case, load impedance can be represented by its equivalent circuit (e.g., a pure resistance and a pure reactance in series). With this representation in mind, the electric power dissipated in the load Z_L (Figure 22.3) can be expressed by the sum of power components separately dissipated by resistance R_{EQ} and reactance X_{EQ} of the equivalent circuit Z_L.

Considering that no active power is dissipated in the reactance X_{EQ}, it yields

$$P = V_{REQ}I_L = V_L I_L \cos\varphi \tag{22.12}$$

The term $\cos\varphi$ appearing in Equation 22.12 is referred to as the *power factor*. It considers that only a fraction of voltage V_L contributes to the power; in fact, its component V_{XEQ} (the drop across the reactance) does not produce any active power, as it is orthogonal to the current I_L flowing into the load.

Figure 22.4 plots the waveforms of instantaneous power $p(t)$, voltage $v(t)$, and current $i(t)$. The effect of the power factor is demonstrated by a dc component of $p(t)$ that varies from a null value (i.e., $v(t)$ and $i(t)$ displaced by 90°) toward the value VI (i.e., $v(t)$ and $i(t)$ in phase).

The term

$$P_A = V_L I_L \tag{22.13}$$

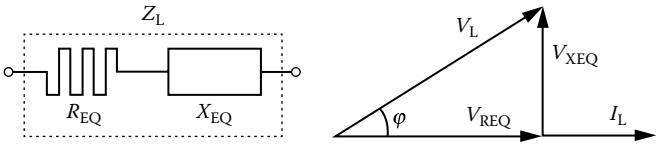

FIGURE 22.3 Voltage drop on the load and on its equivalent components.

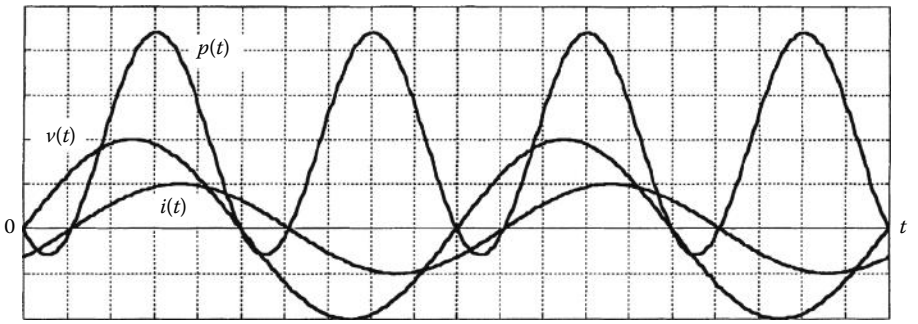

FIGURE 22.4 Waveforms of instantaneous power (p), voltage (v), and current (i).

is called the *apparent power*, while the term

$$Q = V_{XEQ} I_L = V_L I_L \sin\varphi \tag{22.14}$$

is called the *reactive power* because it represents a quantity that is dimensionally equivalent to power. This is introduced as a consequence of the voltage drop across a pure reactance and, therefore, does not give any contribution to the active power. From Figure 22.3, the relationship existing between *apparent power*, *active power*, and *reactive power* is given by

$$P_A = \sqrt{P^2 + Q^2} \tag{22.15}$$

Dynamometers working in ac are designed to integrate instantaneous power according to Equation 22.9. Insertion errors can be derived by simple considerations analogous to the dc case. However, in ac, a phase uncertainty due to the not purely resistive characteristic of voltage circuit arises. In sinusoidal conditions, if ε_w (in radians) is the phase of the real coil impedance and $\cos\varphi$ is the load power factor, the relative uncertainty in active power measurements can be shown to be equal to $-\varepsilon_w T_g \varphi$ where T_g is period. The phase uncertainty depends on the frequency. By using more complex circuits, the frequency range of the dynamometer can be extended to a few tens of kilohertz.

The aforementioned has presented the power definitions applied to *ac* with the restrictions of sinusoidal quantities. In the most general case of distorted quantities, obviously symbolic representation can no longer be applied. In any case, active power is always defined as the mean power dissipated in one period.

As far as methods and instruments for *ac* power measurements are concerned, some circuit classification is required. In fact, the problems are different, arising in circuits as the frequency of power supply increases. Therefore, in the following, *ac* will be classified into (1) line-frequency circuits, (2) low- and medium-frequency circuits (up to a few megahertz), and (3) high-frequency circuits (up to a few gigahertz). Line-frequency circuits will be discussed separately from low-frequency circuits, principally because of the existence of problems related specifically to the three-phase power supply of the main.

22.2.2 Low- and Medium-Frequency Power Measurements

In the following, the main methods and instruments for power measurements at low and medium frequencies are considered.

22.2.2.1 Three-Voltmeter Method

The power dissipation in the load L can be measured using a noninductive resistor R and measuring the three voltages shown in Figure 22.5 [1]. Although one of the voltages might appear redundant on a first analysis of the circuit, in actual fact, three independent data are needed in order to derive power from

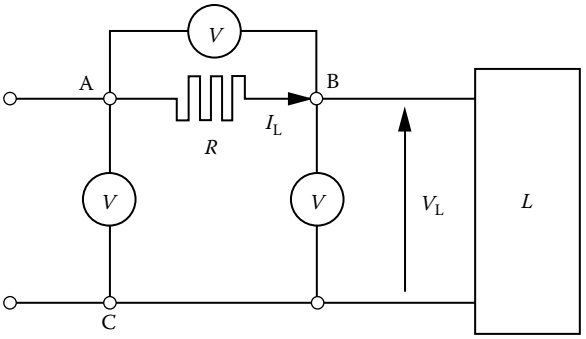

FIGURE 22.5 Three-voltmeter method.

Equation 22.12. In particular, from voltage drops v_{AB} and v_{BC}, the load current and load voltage can be directly derived; instead, v_{AC} is used to retrieve information about their relative phase.

If currents derived by voltmeters are neglected and the current i_L flowing into the load L is assumed to be equal to that flowing into the resistor R, the statement can be demonstrated as follows:

$$\begin{aligned} v_{AC} &= v_L + Ri_L \\ v_{AC}^2 &= R^2 i_L^2 + v_L^2 + 2Rv_L i_L \end{aligned} \tag{22.16}$$

where the small characters indicate instantaneous values. By computing rms values (indicated as capital characters), one obtains the power P_L:

$$\begin{aligned} &\frac{1}{T}\int_0^T v_{AC}^2 dt = \frac{1}{T}\int_0^T R^2 i_L^2 dt = \frac{1}{T}\int_0^T v_L^2 dt + \frac{1}{T}\int_0^T 2Rv_L i_L dt \\ &V_{AC}^2 = RI_L^2 + V_L^2 + 2RP_L \\ &P_L = \frac{V_{AC}^2 - R^2 I_L^2 - V_L^2}{2R} = \frac{V_{AC}^2 - V_{AB}^2 - V_{BC}^2}{2R} \end{aligned} \tag{22.17}$$

Equation 22.17 is also the same in dc by replacing rms values with dc values. Since the result is obtained as a difference, problems arise from the relative uncertainty when the three terms have a sum near zero.

Such a method is still used for high-accuracy applications.

22.2.2.2 Thermal Wattmeters

The working principle of thermal wattmeters is based on a couple of twin thermocouples whose output voltage is proportional to the square of the rms value of the currents flowing into the thermocouple heaters [2].

The principal circuit of a thermal wattmeter is shown in Figure 22.6a. Without the load, with the hypothesis $S \ll r_1$ and $S \ll r_2$, the two heaters are connected in parallel, and, if they have equal resistance r ($r_1 = r_2 = r$), they are polarized by the same current i_p:

$$i_1 = i_2 = \frac{i_p}{2} = \frac{v}{2R + r} \tag{22.18}$$

In this case, the output voltages of the two thermocouples turn out to be equal ($e_1 = e_2$); thus, the voltage Δe measured by the voltmeter is null. In Figure 22.6b, this situation is highlighted by the working point T equal for both thermocouples. By applying a load L with a corresponding current i_L, a voltage

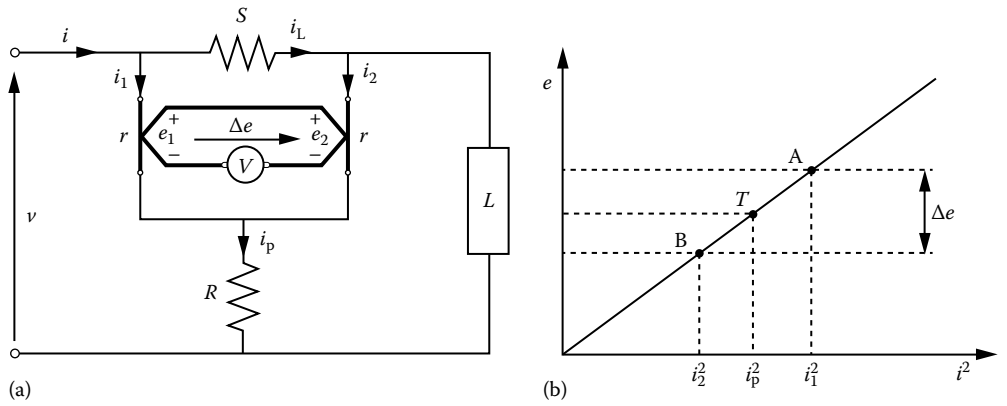

FIGURE 22.6 Thermal wattmeter based on twin thermocouples (a) and working characteristic in ideal conditions (b).

drop across S arises, causing an imbalance between currents i_1 and i_2. With the hypothesis that $r \ll R$, the two heaters are in series; thus, the current imbalance through them is

$$i_1 - i_2 = \frac{Si_L}{2R} \tag{22.19}$$

This imbalance increases the current i_1 and decreases i_2. Therefore, the working points of the two thermocouples change: the thermocouple polarized by the current i_1 operates at A, and the other thermocouple operates at B (Figure 22.6b). In this situation, with the earlier hypotheses, the voltmeter measures the voltage imbalance Δe proportional to the active power absorbed by the load (except for the surplus given by the powers dissipated in R, S, r_1, and r_2):

$$\begin{aligned}\Delta e &= k\left(\left\langle i_1^2\right\rangle - \left\langle i_2^2\right\rangle\right) = k\left(\left\langle (i_p + i_L)^2\right\rangle - \left\langle (i_P - i_L)^2\right\rangle\right) \\ &= k\left\langle 4i_p i_L\right\rangle = k_1\left\langle v(t)i(t)\right\rangle = k_1 P\end{aligned} \tag{22.20}$$

where the notation $\langle i \rangle$ indicates the time average of the quantity i.

If the two thermocouples cannot be considered as twins and linear, the power measurement accuracy will be obviously compromised. This situation is shown in Figure 22.7 where the two

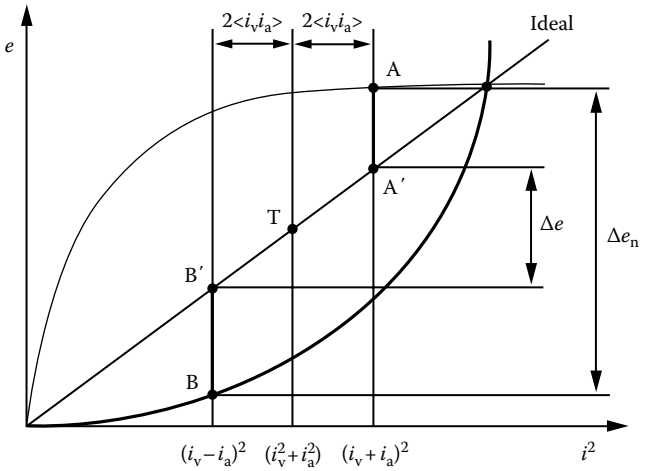

FIGURE 22.7 Ideal and actual characteristics of thermal wattmeter thermocouples.

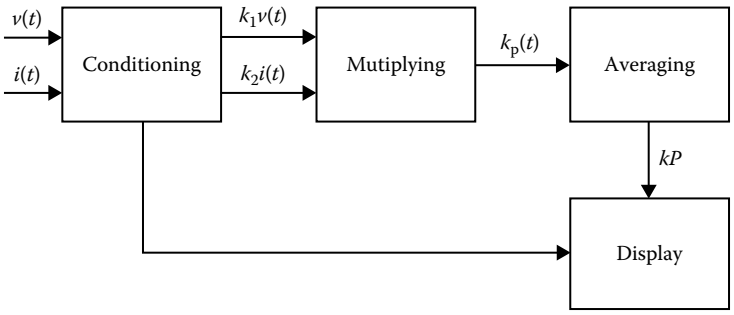

FIGURE 22.8 Block diagram of a multiplier-based wattmeter.

thermocouples are supposed to have two quite different nonlinear characteristics. In this case, the voltage measured by voltmeter will be Δe_n instead of Δe.

Wattmeters based on thermal principle allow high accuracy to be achieved in critical cases of highly distorted wide-band spectrum signals.

22.2.2.3 Wattmeters Based on Multipliers

The multiplication and averaging processes (Figure 22.8) involved in power measurements can be undertaken by electronic means.

Electronic wattmeters fall into two categories, depending on whether multiplication and averaging operations are performed in a continuous or discrete way. In continuous methods, multiplications are mainly carried out by means of analog electronic multipliers. In discrete methods, sampling wattmeters take simultaneous samples of voltage and current waveforms, digitize these values, and provide multiplication and averaging using digital techniques.

Analogous to the case of dynamometers, the resistances of the voltage and current circuits have to be taken into account (see Equations 22.6 and 22.7). Also, phase errors of both current ε_{wc} and voltage ε_{wv} circuits increase the relative uncertainty of power measurement, for example, in case of sinusoidal conditions increased at $(\varepsilon_{wc} - \varepsilon_{wv})T_g\varphi$.

22.2.2.4 Wattmeters Based on Analog Multipliers

The main analog multipliers are based on a transistor-based popular circuit such as a four-quadrant multiplier [3], which processes voltage and current to give the instantaneous power and an integrator to provide the mean power (Figure 22.9). More effective solutions are based on (1) time division multipliers (TDMs) and (2) Hall effect-based multipliers.

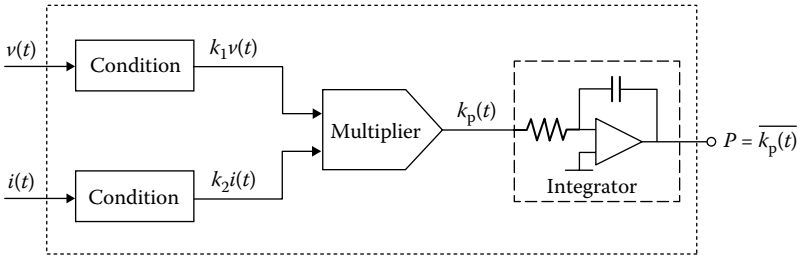

FIGURE 22.9 Block diagram of a four-quadrant, multiplier-based wattmeter.

22.2.2.4.1 TDM-Based Wattmeters

The block diagram of a wattmeter based on a TDM is shown in Figure 22.10 [4]. A square wave v_m (Figure 22.11a) with constant period T_g, and duty cycle and amplitude determined by $i(t)$ and $v(t)$, respectively, is generated. If T_g is much smaller than the period of measurands $v_x(t)$ and $v_\gamma(t)$, these voltages can be considered as constant during this time interval.

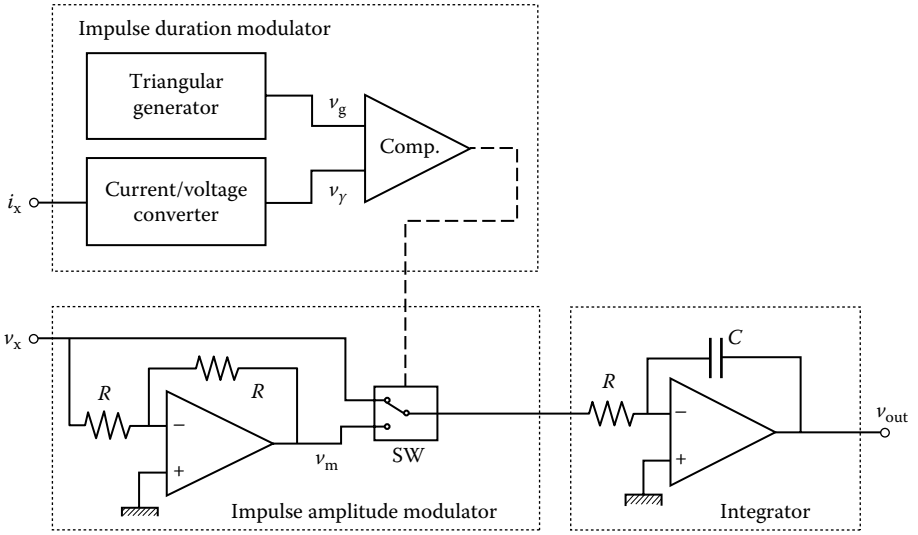

FIGURE 22.10 Block diagram of a TDM-based wattmeter.

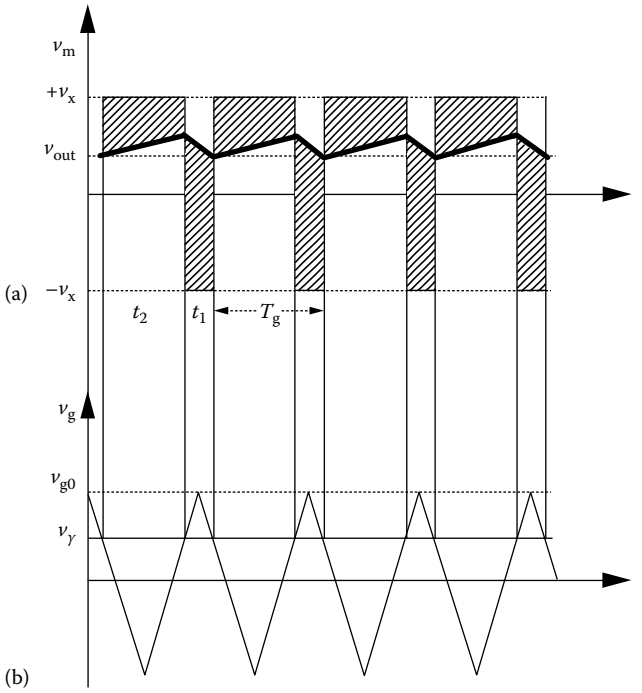

FIGURE 22.11 Waveform of the TDM-based power measurement: (a) impulse amplitude modulator output and (b) ramp generator output.

The duty cycle of v_m is set by an impulse duration modulator circuit (Figure 22.10). The ramp voltage $v_g(t)$ (Figure 22.11b) is compared to the voltage $v_\gamma(t)$ proportional to $i(t)$, and a time interval t_2, whose duration is proportional to $v_\gamma(t)$, is determined. If

$$v_g(t) = \frac{4V_{g0}}{T_g}t \quad \text{when } 0 \le t \le \frac{T_g}{4} \tag{22.21}$$

then from simple geometrical considerations, one obtains

$$t_2 = 2\left(\frac{T_g}{4} - \frac{v_y T_g}{4V_{g0}}\right) \tag{22.22}$$

and

$$t_1 - t_2 = \frac{T_g}{V_{g0}}v_y \tag{22.23}$$

The amplitude of $v_m(t)$ is set by an impulse amplitude modulator circuit. The output square wave of the impulse duration modulator drives the output $v_m(t)$ of the switch SW to be equal to $+v_x$ during the time interval t_1 and to $-v_x$ during the time interval t_2 (Figure 22.11a).

Then, after an initial transient, the output voltage $v_{out}(t)$ of the low-pass filter (integrator) is the mean value of $v_m(t)$:

$$v_{out} = \frac{1}{RC}\int_0^t v_m(t)dt = K'\left(\int_0^{t_1} v_x(t)dt - \int_{t1}^{t_1+t_2} v_x(t)dt\right) = K'v_x(t_1 - t_2) = Kv_x v_y \tag{22.24}$$

The high-frequency limit of this wattmeter is determined by the low-pass filter, and it must be smaller than half of the frequency of the signal $v_g(t)$. The frequency limit is generally between 200 Hz and 20 kHz and can reach 100 kHz. Uncertainties are typically 0.01%–0.02% [5].

22.2.2.4.2 Hall Effect-Based Wattmeters

As is well known, in a Hall effect transducer, the voltage $v_H(t)$ is proportional to the product of two time-dependent quantities [6]:

$$v_H(t) = R_H i(t)B(t) \tag{22.25}$$

where

R_H is the hall constant
$i(t)$ is the current through the transducer
$B(t)$ is the magnetic induction

In the circuit of Figure 22.12a, the power P is determined by measuring $v_H(t)$ through a high-input impedance averaging voltmeter and by considering that $v_x(t) = ai(t)$ and $i_x(t) = bB(t)$, where a and b are proportionality factors:

$$P = \frac{1}{T}\int_0^T v_x(t)\cdot i_x(t)dt = ab\frac{1}{T}\int_0^T i(t)\cdot B(t)dt = abR_H V_H \tag{22.26}$$

where

T is the measurand period
V_H is the mean value of $v_H(t)$

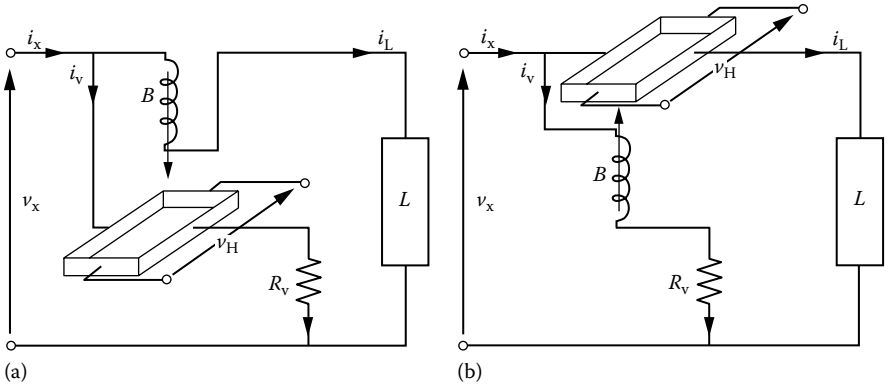

FIGURE 22.12 Configurations of the Hall effect-based wattmeter: (a) polarizing current set by resistor and (b) polarizing current set by load.

In the usual realization of the Hall multiplier (0.1% up to a few megahertz), shown in Figure 22.12a, the magnetic induction is proportional to the load current, and the optimal polarizing current i_v is set by the resistor R_v.

For the frequency range up to megahertz, an alternative arrangement is shown in Figure 22.12b, in which the load current I_L flows directly into the Hall device, acting as a polarizing current, and the magnetic field is generated by the voltage v. In this same way, the temperature influence is reduced for line-frequency applications with constant-amplitude voltages and variable load currents.

In the megahertz to gigahertz range, standard wattmeters use probes in waveguides with rectifiers.

22.2.2.5 Wattmeters Based on Digital Multipliers

22.2.2.5.1 Sampling Wattmeters

The most important wattmeter operating on discrete samples is the sampling wattmeter (Figure 22.13). It is essentially composed of two analog-to-digital input channels, each constituted by (1) a conditioner (C), (2) a sample/hold (S/H), (3) an analog-to-digital converter (ADC), (4) a digital multiplier (MUL), and (5) summing (SUM), dividing (DIV), and displaying units (DISP). The architecture is handled by a processing unit not shown in Figure 22.13.

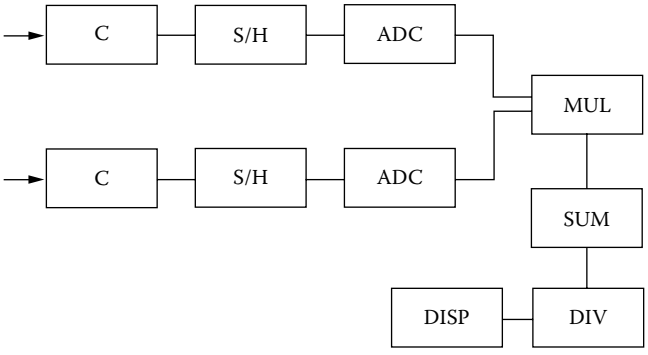

FIGURE 22.13 Block diagram of the sampling wattmeter.

If samples are equally spaced, the active power is evaluated as the mean of the sequence of instantaneous power samples $p(k)$:

$$\overline{P} = \frac{1}{N}\sum_{k=0}^{N-1} p(k) = \frac{1}{N}\sum_{k=0}^{N-1} v(k)i(k) \tag{22.27}$$

where

N represents the number of samples in one period of the input signal
$v(k)$ and $i(k)$ are the kth samples of voltage and current, respectively

A previous estimation of the measurand fundamental period is made to adjust the summation interval of Equation 22.27 and/or the sampling period in order to carry out a synchronous sampling [7]. The sampling period can be adjusted by using a frequency multiplier with phase-locked loop (PLL) circuit driven by the input signal [8]. Alternatively, the contribution of the sampling error is reduced by carrying out the mean on a high number of periods of the input signal.

In the time domain, the period estimation of highly distorted signals, such as pulse-width modulation (PWM), is made difficult by the numerous zero crossings present in the waveform. Some types of digital filters can be used for this purpose. An efficient digital way to estimate the period is the discrete integration of the PWM signal. In this way, the period of the fundamental harmonic is estimated by detecting the sign changes of the cumulative sum function [9]:

$$S(k) = \sum_{i=1}^{k} p_i \quad k = 1,2,\ldots,N \tag{22.28}$$

If the summation interval is extended to an integer number of periods of the $S(k)$ function, a "quasi-synchronous" sampling [10] is achieved through a few simple operations (cumulative summation and sign detection), and the maximum synchronization error is limited to a sampling period. Through relatively small increases in computational complexity and memory size, the residual error can be further reduced through a suitable data processing algorithm, that is, the multiple convolution in the time domain of triangular windows [9]. Hence, the power measurement can be obtained as

$$P_{(B)} = \frac{1}{\sum_{k=0}^{2B(N^{\star}-1)} w(k)} \sum_{k=0}^{2B(N^{\star}-1)} w(k)p(k) \tag{22.29}$$

where

$p(k)$ is the kth sample of the instantaneous power
$w(k)$ is the kth weight corresponding to the window obtained as the convolution of B triangular windows [10]

Another way to obtain the mean power is through the consideration of the harmonic components of voltages and currents in the frequency domain using the discrete Fourier transform [11]. In particular, a fast Fourier transform algorithm is used in order to improve efficiency. Successively, a two-step research of the harmonic peaks is carried out: (1) the indexes of the frequency samples corresponding to the greatest spectral peaks provide a rough estimate of the unknown frequencies when the wide-band noise superimposed onto the signal is below threshold; (2) a more accurate estimate of harmonic frequencies is carried out to determine the fractional bin frequency (i.e., the harmonic determination under the frequency resolution); to this aim, several approaches such as zero padding, interpolation techniques, and flattop window-based technique can be applied [12].

22.2.3 Line-Frequency Power Measurements

For line applications where the power is directly derived by the source network, the assumption of infinite power source can be reliably made, and at least one of the two quantities voltage or current can be considered as sinusoidal. In this case, the definition of the power as the product of voltage and current means that only the power at the fundamental frequency can be examined [13].

22.2.3.1 Single-Phase Measurements

Single-phase power measurements at line frequency are carried out by following the criteria previously mentioned. In practical applications, the case of a voltage greater than 1000 V is relevant; measurements must be carried out using voltage and current transformers inserted as in the example of Figure 22.14. The relative uncertainty is equal to

$$\frac{\Delta P}{P} = \left(\eta_w + \eta_a + \eta_v\right) + \left(\varepsilon_w + \varepsilon_a + \varepsilon_v\right) tg\varphi_c \tag{22.30}$$

where

η_w and ε_w are the instrumental and phase uncertainty of the wattmeter
η_a and η_v are the ratio uncertainties of current (CT) and voltage (VT) transformers
ε_a and ε_v are their phase uncertainties, respectively

If the load current exceeds the current range of the wattmeter, a current transformer must be used, even in the case of low voltages.

22.2.3.2 Polyphase Power Measurements

Three-phase systems are the polyphase systems most commonly used in practical industrial applications. In the following, power measurements on three-phase systems will be derived as a particular case of polyphase systems (systems with several wires) and analyzed for increasing costs: (1) balanced and symmetrical systems, (2) three-wire systems, (3) two-wattmeter-based measurements, (4) unbalanced systems, (5) three-wattmeter-based measurements, and (6) medium-voltage systems.

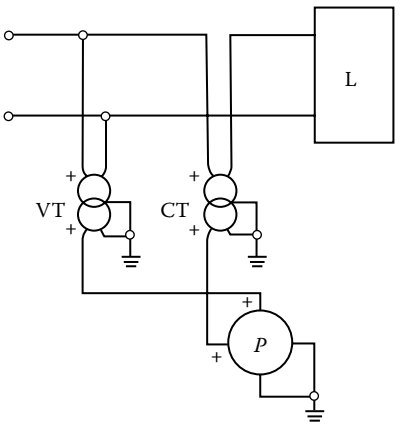

FIGURE 22.14 Single-phase power measurement with voltage (VT) and current (CT) transformers.

22.2.3.3 Measurements on Systems with Several Wires

Consider a network with sinusoidal voltages and currents composed by n wires. For the currents flowing in such wires, the following relation is established:

$$\sum_{1}^{n} \dot{I}_{\mathrm{i}} = 0 \tag{22.31}$$

The network can be thought as composed of $n - 1$ single-phase independent systems, with the common return on any one of the wires (e.g., the sth wire). Then, the absorbed power can be measured as the sum of the readings of $n - 1$ wattmeters, each one inserted with the current circuit on a different wire and the voltmeter circuit between such a wire and the sth one (Figure 22.15):

$$P = \sum_{1}^{n-1} \left(\dot{V}_{\mathrm{is}} \times \dot{I}_{\mathrm{i}} \right) \tag{22.32}$$

The absorbed power can be also measured by referring to a generic point O external to the network. In this case, the absorbed power will be the sum of the readings of n wattmeters, each inserted with the ammeter circuit on a different wire and the voltmeter circuit connected between such a wire and the point O:

$$P = \sum_{1}^{n} \left(\dot{V}_{\mathrm{io}} \times \dot{I}_{\mathrm{i}} \right) \tag{22.33}$$

22.2.3.4 Power Measurements on Three-Wire Systems

Active power in a three-phase power system can generally be evaluated by three wattmeters connected as shown in Figure 22.16.

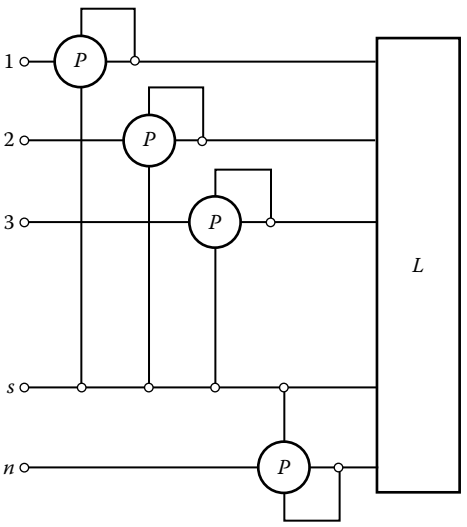

FIGURE 22.15 Power measurement on systems with several wires.

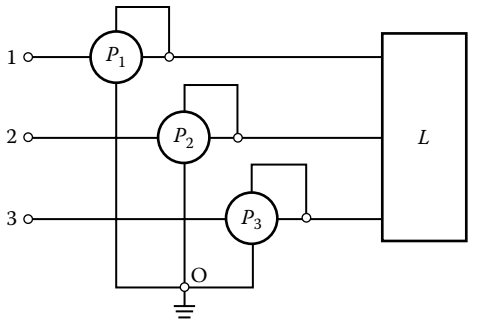

FIGURE 22.16 Power measurement on three-wire systems.

For each power meter, the current lead is connected on a phase wire, and the voltmeter lead is connected between the same wire and an artificial neutral point O, whose position is fixed by the voltmeter impedance of power meters or by suitable external impedances.

Under these conditions, absorbed power will be the sum of the three-wattmeter indications:

$$P = \sum_{1}^{3} \left(\dot{V}_{io} \times \dot{I}_i \right) \tag{22.34}$$

If the three-phase system is provided by four wires (three phases with a neutral wire), the neutral wire is utilized as a common wire.

22.2.3.5 Symmetrical and Balanced Systems

The supply system is symmetrical, and the three-phase load is balanced; that is,

$$\begin{cases} V_1 = V_2 = V_3 \\ I_1 = I_2 = I_3 \end{cases} \tag{22.35}$$

In Figure 22.17, the three possible kinds of insertion of an instrument S (an active power or a reactive power meter) are illustrated. The first (Figure 22.17) was described in the last section; if S is a wattmeter, the overall active power is given by three times its indication and similarly for the reactive power if S is a reactive power meter. Notice that a couple of twin resistors with the same resistance *R* of the voltage circuit of S are placed on the other phases to balance the load.

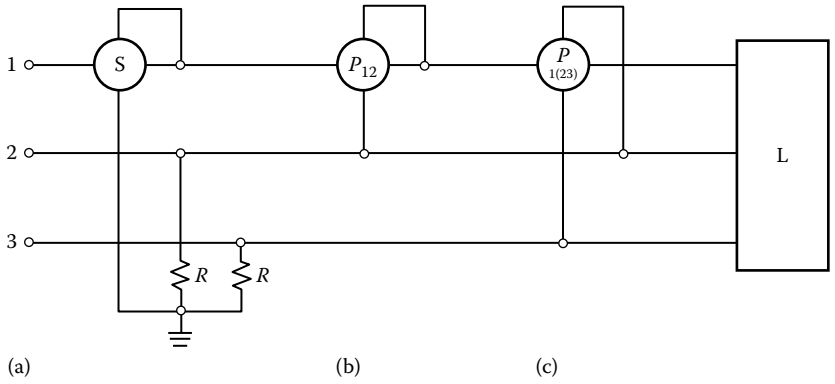

FIGURE 22.17 The three kinds of insertion of a power meter.

The other two insertions are indicated by the following convention: S_{ijk} indicates a reading performed with the current leads connected to the line "i" and the voltmeter leads connected between the phases "j" and "k." If "i" is equal to "j," one is omitted (e.g., the notation P_{12} (Figure 22.17b). The active power absorbed by a single phase is usually referred to as P_1.

The wattmeter reading corresponding to the (c) case in Figure 22.17 is equal to the reactive power Q_1 involved in phase 1, save for the factor $\sqrt{3}$. Hence, in the case of symmetrical and balanced systems, the overall reactive power is given by

$$Q = 3Q_1 = \frac{3P_{1(23)}}{\sqrt{3}} = \sqrt{3}P_{1(23)} \tag{22.36}$$

In fact, one has

$$P_{1(23)} = \dot{I}_1 \times \dot{V}_{23} \tag{22.37}$$

but

$$\begin{aligned} \dot{V}_{12} + \dot{V}_{23} + \dot{V}_{31} = 0 \quad &\Rightarrow \quad P_{1(23)} = \dot{I}_1 \times (-\dot{V}_{12} - \dot{V}_{31}) \\ \dot{V}_{13} = -\dot{V}_{31} \quad &\Rightarrow \quad P_{1(23)} = -\dot{I}_1 \times \dot{V}_{12} + \dot{I}_1 \times \dot{V}_{13} \\ \begin{cases} \dot{I}_1 \times \dot{V}_{12} = P_{12} \\ \dot{I}_1 \times \dot{V}_{13} = P_{13} \end{cases} \quad &\Rightarrow \quad P_{1(23)} = P_{13} - P_{12} \end{aligned}$$

In the same manner, the following relationships, which are valid for any kind of supply and load, can be all proved:

$$\begin{aligned} P_{1(23)} &= P_{13} - P_{12} \\ P_{2(31)} &= P_{21} - P_{23} \\ P_{3(12)} &= P_{32} - P_{31} \end{aligned} \tag{22.38}$$

If the supply system is symmetrical, $P_{1(23)} = \sqrt{3}Q_1$.

In fact, moving from the relationship (Figure 22.18),

$$P_{1(23)} = \dot{I}_1 \times \dot{V}_{23} = I_1 V_{23} \cos\beta \tag{22.39}$$

where $\beta = 90° - \varphi_1$, one obtains $P_{1(23)} = \sqrt{3}E_1 I_1 \sin\varphi_1 = \sqrt{3}Q_1$.

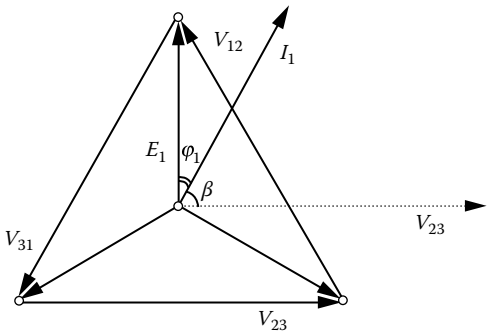

FIGURE 22.18 Phasor diagram for a three-phase symmetrical and balanced system.

In the same manner, the other two corresponding relationships for $P_{2(31)}$ and $P_{3(12)}$ are derived. Hence,

$$\begin{aligned} P_{1(23)} &= \sqrt{3}Q_1 = P_{13} - P_{12} \\ P_{2(31)} &= \sqrt{3}Q_2 = P_{21} - P_{23} \\ P_{3(12)} &= \sqrt{3}Q_3 = P_{32} - P_{31} \end{aligned} \tag{22.40}$$

22.2.3.6 Power Measurements Using Two Wattmeters

The overall active power absorbed by a three-wire system can be measured using only two wattmeters. In fact, Aron's theorem states the following relationships:

$$\begin{aligned} P &= P_{12} + P_{32} \\ P &= P_{23} + P_{13} \\ P &= P_{31} + P_{21} \end{aligned} \tag{22.41}$$

Analogously, the overall reactive power can be measured by using only two reactive power meters:

$$\begin{aligned} Q &= Q_{12} + Q_{32} \\ Q &= Q_{23} + Q_{13} \\ Q &= Q_{31} + Q_{21} \end{aligned} \tag{22.42}$$

Here, one of the previous statements, that is,

$$P = P_{12} + P_{32}$$

is proved. The two wattmeters connected as shown in Figure 22.19 furnish P_{12} and P_{32}.

Hence, the sum of the two readings gives

$$\begin{aligned} P_{12} + P_{32} &= \dot{I}_1 \times \dot{V}_{12} + \dot{I}_3 \times \dot{V}_{32} = \dot{I}_1 \times \left(\dot{E}_1 - \dot{E}_2\right) + \dot{I}_3 \times \left(\dot{E}_3 - \dot{E}_2\right) \\ &= \dot{I}_1 \times \dot{E}_1 - \dot{I}_1 \times \dot{E}_2 + \dot{I}_3 \times \dot{E}_3 - \dot{I}_3 \times \dot{E}_2 = \dot{I}_1 \times \dot{E}_1 + \dot{I}_3 \times \dot{E}_3 - \left(\dot{I}_1 + \dot{I}_3\right) \times \dot{E}_2 \\ &= \dot{I}_1 \times \dot{E}_1 + \dot{I}_3 \times \dot{E}_3 + \dot{I}_2 \times \dot{E}_2 = P_1 + P_2 + P_3 = P \end{aligned} \tag{22.43}$$

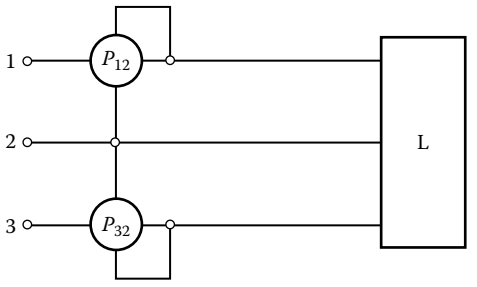

FIGURE 22.19 Power measurements using two wattmeters.

Provided that the system has only three wires, Aron's theorem applies to any kind of supply and load. In the case of symmetrical and balanced systems, it also allows the reactive power to be evaluated:

$$Q = \sqrt{3} \cdot (P_{32} - P_{12}) \tag{22.44}$$

Using Equations 22.41 and 22.44, the power factor is

$$\cos\varphi = \frac{P_{12} + P_{32}}{\sqrt{(P_{12} + P_{32})^2 + 3(P_{32} - P_{12})^2}} = \frac{P_{12} + P_{32}}{\sqrt{4P_{12}^2 + 4P_{32}^2 - 4P_{12}P_{32}}} = \frac{1 + (P_{12}/P_{32})}{2\sqrt{(P_{12}/P_{32})^2 - (P_{12}/P_{32}) + 1}} \tag{22.45}$$

Aron's insertion cannot be utilized when the power factor is low. In fact, if the functions

$$\begin{aligned} \cos(\varphi + 30) &= \frac{P_{12}}{VI} \\ \cos(\varphi - 30) &= \frac{P_{32}}{VI} \end{aligned} \tag{22.46}$$

are considered (Figure 22.20), it can be argued that (1) for $\varphi \leq 60°$, P_{12} and P_{32} are both greater than zero; (2) for $\varphi > 60°$, $\cos(\varphi - 30)$ is still greater than zero; and $\cos(\varphi + 30)$ is lower than zero.

The absolute error in the active power is

$$\Delta P = \frac{\partial\left(P_{12} + P_{32}\right)}{\partial P_{12}}\Delta P_{12} + \frac{\partial\left(P_{12} + P_{32}\right)}{\partial P_{32}}\Delta P_{32} = \Delta P_{12} + \Delta P_{32} \tag{22.47}$$

This corresponding relative error is greater as P_{12} and P_{32} have values closer to each other and are opposite in polarity; in particular, for $\cos\varphi = 0$ ($\varphi = 90°$), the error is infinite.

If η_w and ε_w are the wattmeter amplitude and phase errors, respectively, then the error in the active power is

$$\frac{\Delta P}{P} = \frac{\left(\eta_w + \varepsilon_w tg\varphi_{12}\right)P_{12} + \left(\eta_w + \varepsilon_w tg\varphi_{32}\right)P_{32}}{P_{12} + P_{32}} = \eta_w + \varepsilon_w \frac{Q}{P} \tag{22.48}$$

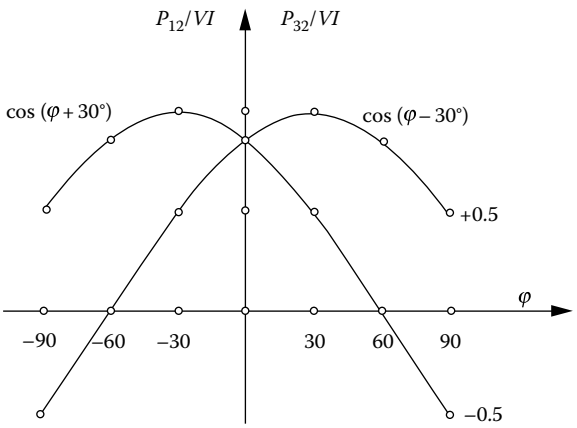

FIGURE 22.20 Sign of powers in Aron's insertion.

Let two wattmeters with nominal values V_0, I_0, $\cos\varphi_0$, and class c be considered; the maximum absolute error in each reading is

$$\Delta P = \frac{cV_0 I_0 \cos\varphi_0}{100} \tag{22.49}$$

Therefore, the percentage error related to the sum of the two indications is

$$\frac{\Delta P}{P} = \frac{cV_0 I_0 \cos\varphi_0}{\sqrt{3}VI\cos\varphi} = 1.11\frac{cV_0 I_0 \cos\varphi_0}{VI\cos\varphi} \tag{22.50}$$

equal to approximately the error of only one wattmeter inserted in a single-phase circuit with the same values of I, V, and $\cos\varphi$. Consequently, under the same conditions, the use of two wattmeters involves a measurement uncertainty much lower than that using three wattmeters.

If Aron's insertion is performed via current and voltage transformers, characterized by ratio errors η_a and η_v and phase errors ε_a and ε_v, respectively, the active power error is

$$\frac{\Delta P}{P} = \frac{(\eta_{TOT} + \varepsilon_{TOT} tg\varphi_{12})P_{12} + (\eta_{TOT} + \varepsilon_{TOT} tg\varphi_{32})P_{32}}{P_{12} + P_{32}} = \eta_{TOT} + \varepsilon_{TOT}\frac{Q}{P} = \eta_{TOT} + \varepsilon_{TOT} tg\Phi_c \tag{22.51}$$

where $\cos\Phi_c$ is the conventional power factor

$$\left.\begin{aligned}\eta_{TOT} &= \eta_w + \eta_a + \eta_v \\ \varepsilon_{TOT} &= \varepsilon_w + \varepsilon_a + \varepsilon_v\end{aligned}\right\}$$ the error sums with η_w and ε_w being the wattmeter errors

22.2.3.7 Symmetrical Power Systems Supplying Unbalanced Loads

If the load is unbalanced, the current amplitudes are different from each other, and their relative phase is not equal to 120°. Two wattmeters and one voltmeter have to be connected as proposed by Barbagelata [13] (Figure 22.21). The first wattmeter can provide P_{12} and P_{13}, and the second one gives P_{31} and P_{32}.

From Aron's theorem, the active power is

$$P = P_{12} + P_{32} \tag{22.52}$$

and then the reactive power Q is

$$Q = Q_1 + Q_2 + Q_3 = \frac{1}{\sqrt{3}}[P_{13} - P_{12} + \underline{P_{21}} - \underline{P_{23}} + P_{32} - P_{31}] \tag{22.53}$$

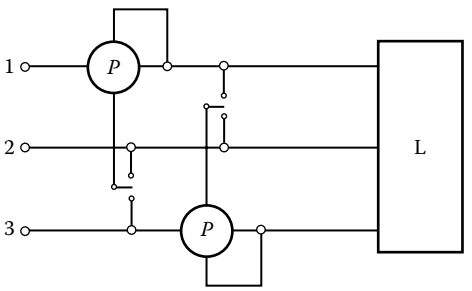

FIGURE 22.21 Barbagelata's insertion for symmetrical and unbalanced systems.

For the underlined terms, from Aron's theorem, it follows that

$$P = P_{13} + P_{23} = P_{12} + P_{32} = P_{21} + P_{31} \tag{22.54}$$

then

$$P_{13} + P_{23} = P_{21} + P_{31} \quad \Rightarrow \quad P_{21} - P_{23} = P_{13} - P_{31}$$

Thus, one obtains

$$Q = \frac{1}{\sqrt{3}}[2(P_{13} - P_{31}) + P_{32} - P_{12}] \tag{22.55}$$

Therefore, using only four power measurements, the overall active and reactive powers can be obtained.

The main disadvantage of this method is that the four measurements are not simultaneous; therefore, any load variations during the measurement would cause a loss in accuracy. In this case, a variation proposed by Righi [13] can be used. In this variation, three wattmeters are connected as shown in Figure 22.22 and give simultaneously P_{12}, P_{32}, and $P_{2(31)}$. Reactive power is

$$Q = \frac{1}{\sqrt{3}}\left[\underline{P_{13}} - P_{12} + P_{21} - P_{23} + P_{32} - \underline{P_{31}}\right] \tag{22.56}$$

Analogously as aforementioned, from Aron's theorem, it follows that

$$P_{21} - P_{23} = P_{13} - P_{31} \quad \Rightarrow \quad P_{2(31)} = P_{21} - P_{23} = P_{13} - P_{31} \tag{22.57}$$

then

$$Q = \frac{1}{\sqrt{3}}[P_{32} - P_{12} + 2P_{2(31)}] \tag{22.58}$$

For symmetrical and unbalanced systems, another two-wattmeter insertion can be carried out (Figure 22.23). The wattmeters give

$$\begin{aligned} P_{1(30)} &= \dot{E}_3 \times \dot{I}_1 = j\frac{\dot{V}_{12}}{\sqrt{3}} \times \dot{I}_1 = -\frac{Q_{12}}{\sqrt{3}} \\ P_{3(10)} &= \dot{E}_1 \times \dot{I}_3 = j\frac{\dot{V}_{23}}{\sqrt{3}} \times \dot{I}_3 = -\frac{Q_{32}}{\sqrt{3}} \end{aligned} \tag{22.59}$$

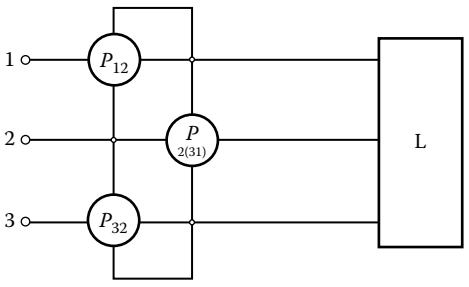

FIGURE 22.22 Righi's insertion for symmetrical and unbalanced systems.

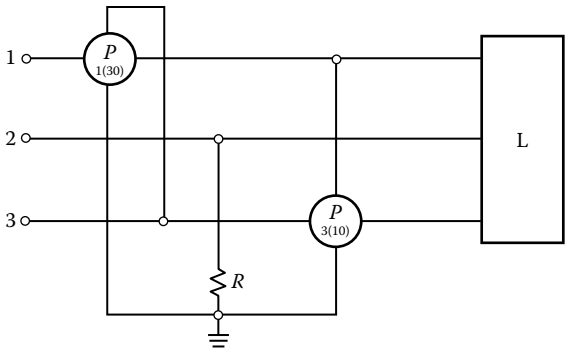

FIGURE 22.23 Two-wattmeter-based insertion for symmetrical and unbalanced systems.

Hence, the overall reactive power is

$$Q = Q_{12} + Q_{32} = \sqrt{3}\left[-P_{1(30)} + P_{3(10)}\right] \tag{22.60}$$

22.2.3.8 Three-Wattmeter Insertion

A three-wire, three-phase system can be measured by three wattmeters connected as in Figure 22.24. The artificial neutral point position does not affect the measurement; it is usually imposed by the impedance of the voltmeter leads of the wattmeters.

22.2.3.9 Medium-Voltage, Three-Wattmeter Insertion

Analogously to the single-phase case, for medium-voltage circuits, the three-wattmeter insertion is modified as in Figure 22.25.

22.2.3.10 Method Selection Guide

For three-wire systems, the flow chart of Figure 22.26 leads to selecting the most suitable method according to system characteristics.

22.2.4 High-Frequency Power Measurements

Meters used for power measurements at radio or microwave frequencies are generally classified as *absorption type* (containing inside their own load, generally 50 Ω. for radio frequency [RF] work) and *transmitted* or *through-line type* (where the load is remote from the meter). Apart from the type, power meters are mainly based on thermistors, thermocouples, diodes, or radiation sensors. Therefore, to work properly,

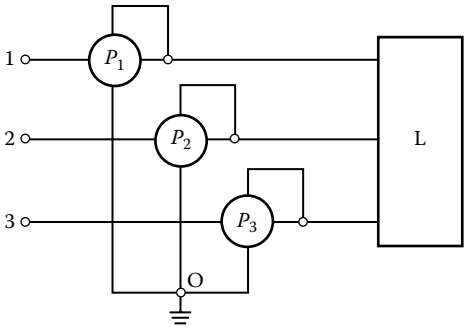

FIGURE 22.24 Three-wattmeter-based insertion for three-wire, three-phase systems.

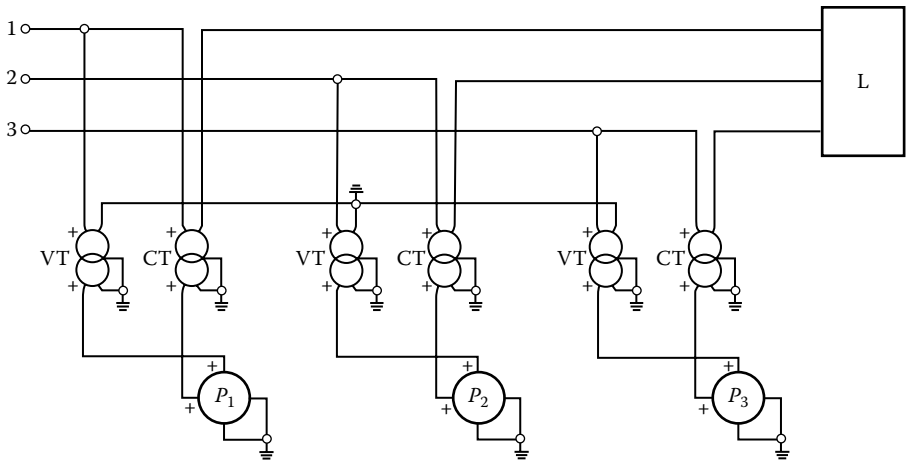

FIGURE 22.25 Medium-voltage, three-wattmeter insertion.

the sensor should sense all the RF power (P_{LOAD}) incoming into the sensor itself. Nevertheless, line-to-sensor impedance mismatches cause partial reflections of the incoming power ($P_{INCIDENT}$) so that a meter connected to a sensor does not account for the total amount of reflected power ($P_{REFLECTED}$). The relationship existing among power dissipated on the load, power incident, and power reflected is obviously

$$P_{LOAD} = P_{INCIDENT} - P_{REFLECTED} \tag{22.61}$$

Directional couplers are instruments generally used for separating incident and reflected signals so that power meters can measure each of them separately. In Figure 22.27, the longitudinal section of a directional coupler for waveguides is sketched. It is made up by two waveguides properly coupled through two holes. The upper guide is the *primary waveguide* and connects the power source and load; the lower guide is the *secondary waveguide* and is connected to the power meter. To explain the workings of directional couplers, incident and reflected waves have been sketched separately in Figure 22.27a and b. In particular, section (a) depicts a directional coupler working as incident wave separator, whereas section (b) shows the separation of the reflected wave. The correct working is based on the assumption that the distance between the holes matches exactly *one quarter of the wave length* (λ). In fact, in the secondary waveguide, each hole will give rise to two waves going in opposite directions (one outside and the other inside the waveguide); consequently, in front of each hole, two waves are summed with their own phases. The assumption made on the distance between the holes guarantees that, in front of one hole, (1) the two waves propagating outside the waveguide will be in phase, causing an enforcing effect in that direction, (2) while, in front of the other hole, the two waves (always propagating outside) will be in opposition, causing a canceling effect in that direction. The enforcing and canceling effects for incident and reflected waves are opposite. In particular, according to the directions chosen in Figure 22.27, incident power propagates on the right side and is canceled on the left side (Figure 22.27a), while reflected power propagates on the left side and is canceled on the right side (Figure 22.27b). Therefore, directional couplers allow separate measurement of incident and reflected power by means of power meters applied, respectively, on the right and on the left sides of the secondary waveguide.

In any case, the secondary waveguide must be correctly matched from the impedance point of view at both sides (by adaptive loads and/or a proper choice of the power meter internal resistance) in order to avoid unwanted reflections inside the secondary waveguide.

Directional couplers are also used to determine the *reflection coefficient* ρ of the sensor, which takes into account mismatch losses and is defined as

$$P_{REFLECTED} = \rho^2 \times P_{INCIDENT} \tag{22.62}$$

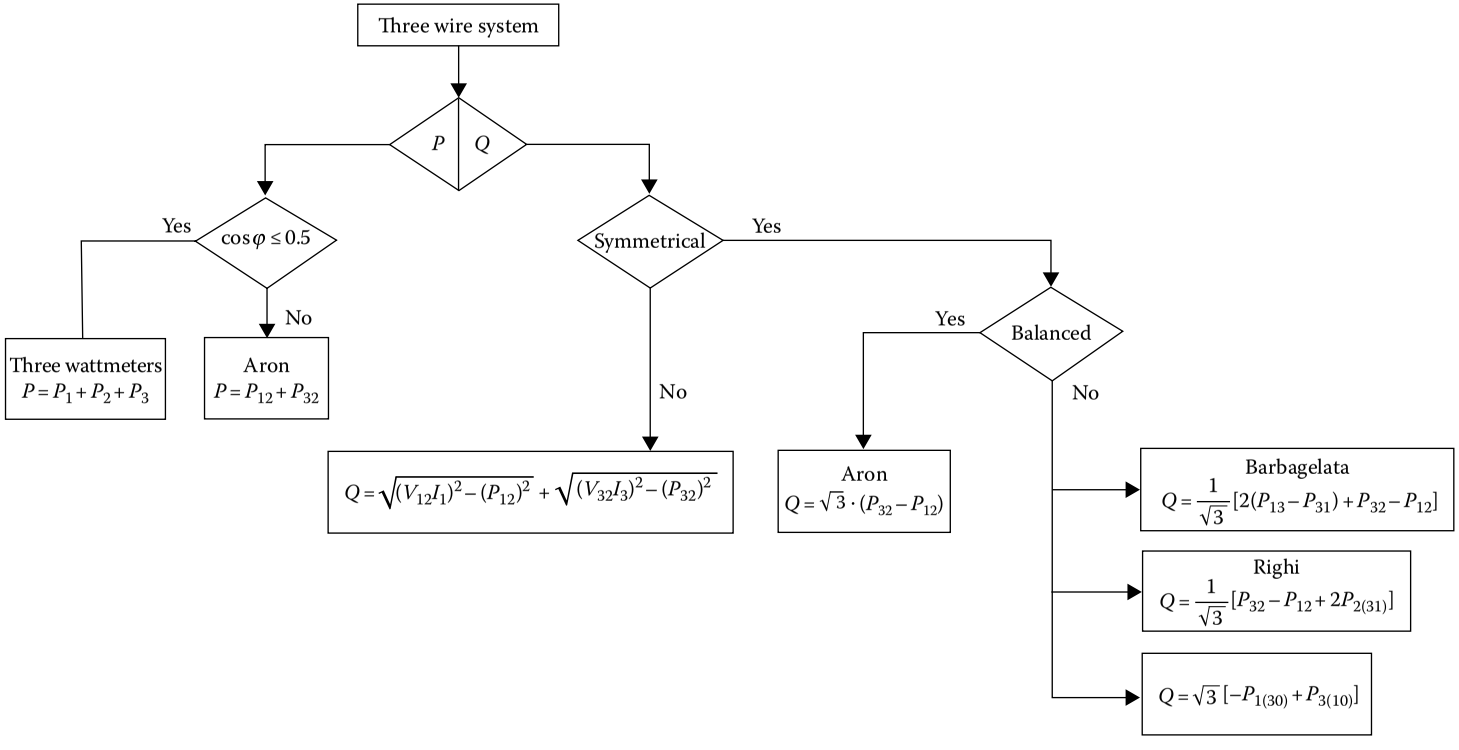

FIGURE 22.26 Method selection guide for power measurements on three-wire systems.

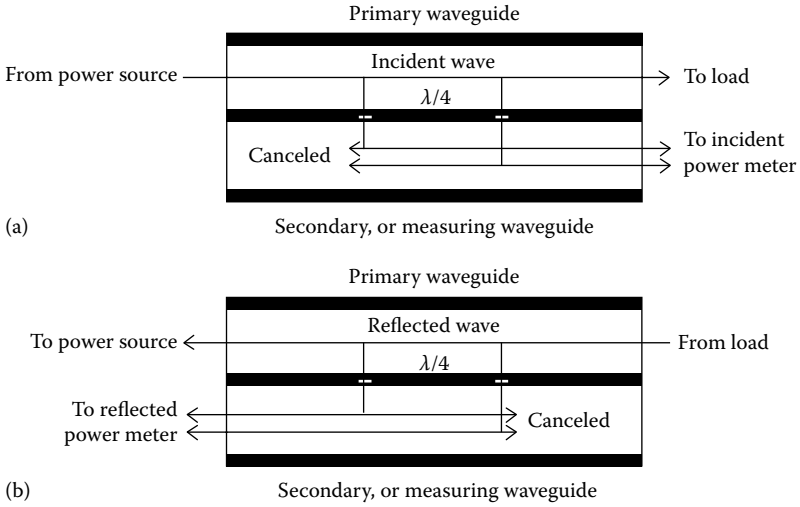

FIGURE 22.27 Directional couplers for separating incident (a) from reflected (b) power.

In order to take into account also the absorptive losses due to dissipation in the conducting walls of the sensor, leakage into instrumentation, power radiated into space, etc., besides the reflection coefficient, the *effective efficiency* η_C of the sensor should also be considered. Generally, the reflection coefficient and effective efficiency are included into the *calibration factor K*, defined as

$$K = \eta_C(1-\rho^2)\times 100 \tag{22.63}$$

For example, a calibration factor of 90% means that the meter will read 10% below the incident power. Generally, calibration factors are specified by sensor manufacturers at different values of frequency.

22.2.4.1 Thermal Methods

In this section, the main methods based on power dissipation will be examined, namely, (1) thermistor based, (2) thermocouple based, and (3) calorimetric.

22.2.4.1.1 Thermistor-Based Power Meters

A thermistor is a resistor made up of a compound of highly temperature-sensitive metallic oxides [14]. If it is used as a sensor in a power meter, its resistance becomes a function of the temperature rise produced by the applied power. In Figure 22.28, typical power-resistance characteristics are reported for several values of the operating temperature.

The working principle of the thermistor power meter is illustrated in Figure 22.29 [15]: two thermistors (R_{T1} and R_{T2}) are connected (1) in parallel, for measurand signals appearing at the RF input (P_{RF}), and (2) in series, for the following measuring circuit (e.g., a bridge). The capacitance C_1 prevents the power dc component from flowing to the thermistors; the C_2 stops the RF power toward the bridge.

A bridge with a thermistor or a barretter in one arm is called a *bolometer*. Bolometer-based measurements can be performed with (1) a manual bolometer with variation of the bias current, (2) a manual bolometer with substitution method, or (3) a self-balancing bolometer.

The *manual bolometer with a variation of the bias current* is illustrated in Figure 22.30. Its working principle consists of two steps. In the first, no RF power is applied to the sensor; the equilibrium is obtained by varying the dc power supply E until the sensor resistance R_B, related to the dc power flowing in it, is equal to R. In this condition, let the current I flowing into the sensor be equal to I_1.

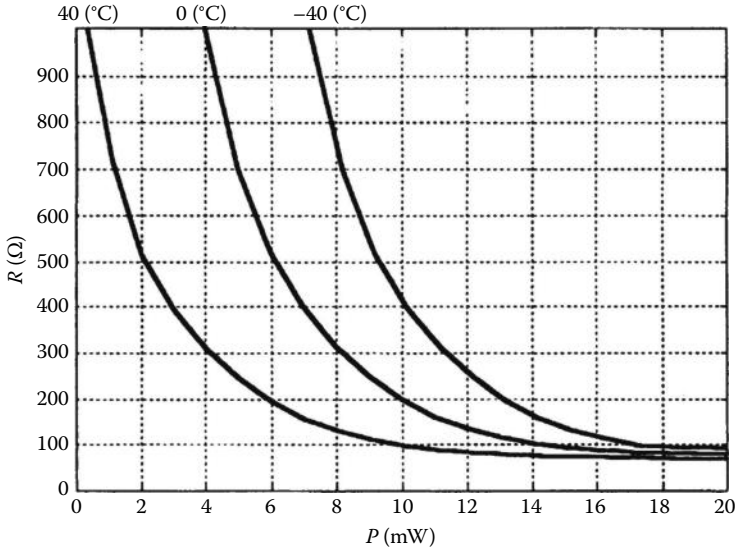

FIGURE 22.28 Typical power-resistance characteristics of commercial thermistors.

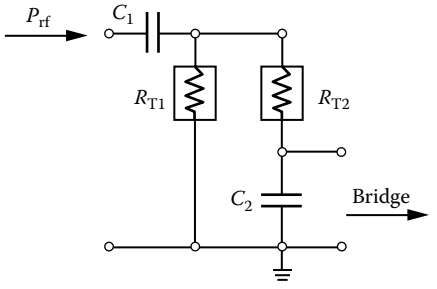

FIGURE 22.29 Working principle of the thermistor-based power meter.

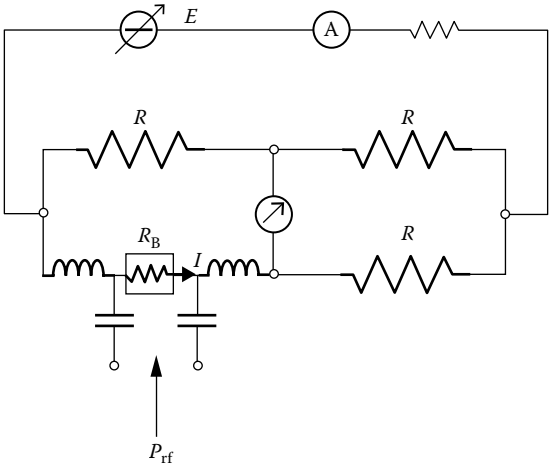

FIGURE 22.30 The manual bolometer.

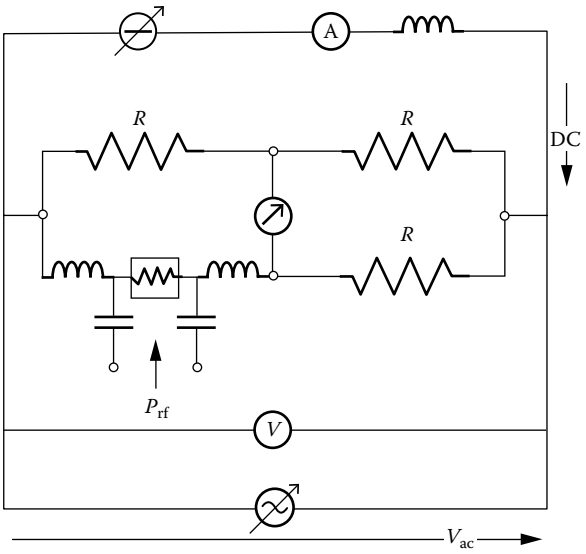

FIGURE 22.31 Manual bolometer with substitution method.

In the second step, an RF power P_{RF} is fed to the sensor; the power increase must be compensated by a dc power decrease, which is performed by lowering the bridge dc supply voltage E; in this case, let I be equal to I_2.

Since the power dissipated in the sensor has been maintained constant in both steps, the power P_{RF} can be evaluated as

$$P_{RF} = \frac{R}{4}\left(I_1^2 - I_2^2\right) \tag{22.64}$$

The *manual bolometer with substitution method* (Figure 22.31) consists of two sequential steps; in the first, both RF power (P_{RF}) and dc power (P_{dc}) are present, and the power (P_d) necessary to lead the bridge to the equilibrium is

$$P_d = P_{dc} + P_{RF} \tag{22.65}$$

During the second step, P_{RF} is set to zero, and an alternative voltage V_{ac} is introduced in parallel to the dc power supply. In this case, the power P_d necessary to balance the bridge

$$P_d = P_{dc} + P_{ac} \tag{22.66}$$

is obtained by varying v_{ac}.

Since P_d is the same in both cases, the power supplied by the alternative generator is equal to P_{RF}:

$$P_{RF} = P_{ac} = \frac{V_{ac}^2}{4R} \tag{22.67}$$

Equation 22.66 implies that the RF power can be obtained by a voltage measurement. The *self-balancing bolometer* (Figure 22.32) automatically supplies a dc voltage V to balance the voltage variations due to

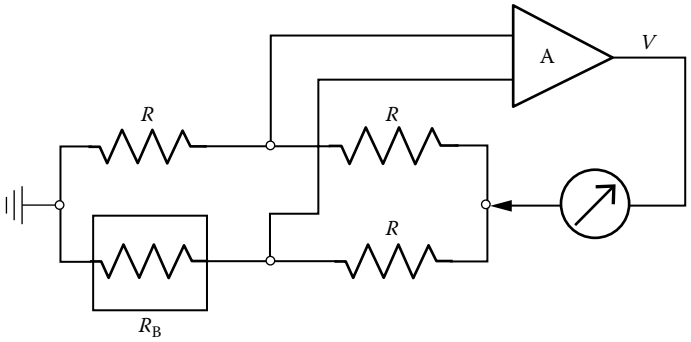

FIGURE 22.32 Self-balancing bolometer.

sensor resistance R_B changes for an incident power P_{RF}. At equilibrium, R_B is equal to R, and the RF power will then be

$$P_{RF} = \frac{V^2}{4R} \tag{22.68}$$

As mentioned earlier, the thermistor resistance depends on the surrounding temperature. This effect is compensated in an instrument based on two self-balancing bridges [15]. The RF power is input only to one of these, as shown in Figure 22.33.

The equilibrium voltages V_c and V_{RF} feed a chopping and summing circuit, whose output $V_c + V_{RF}$ goes to a voltage-to-time converter. This produces a pulse train V_1, whose width is proportional to $V_c + V_{RF}$. The chopping section also generates a signal with amplitude proportional to $V_c - V_{RF}$ and a frequency of a few kilohertz, which is further amplified. The signals V_1, and V_2 enter an electronic switch whose output is measured by a medium value meter M. This measure is proportional to the RF power because

$$P_{RF} = \frac{(V_c + V_{RF})(V_c - V_{RF})}{4R} \quad \Rightarrow \quad P_{RF} = \frac{V_c^2 - V_{RF}^2}{4R} \tag{22.69}$$

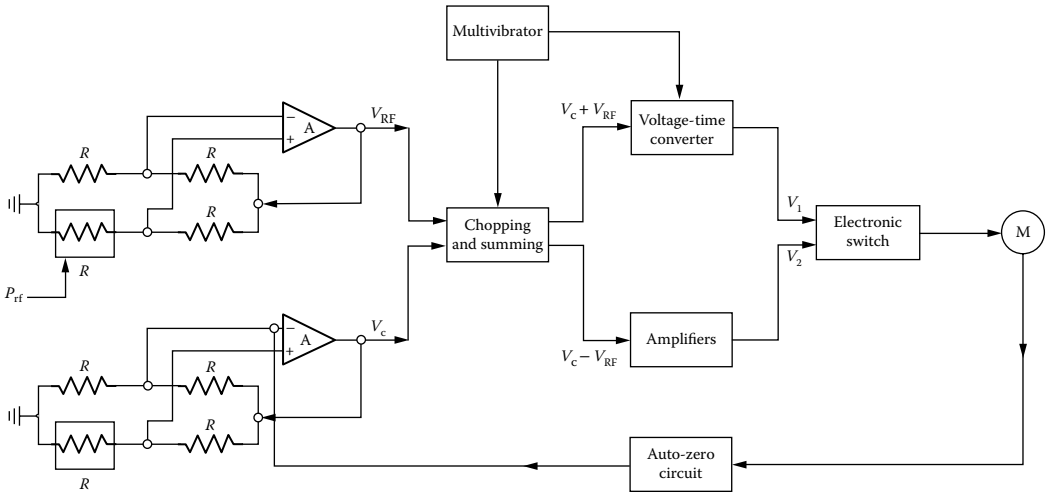

FIGURE 22.33 Power meter based on two self-balancing bridges.

Owing to the differential structure of the two bolometers, this device is capable of performing RF power measurements independent of the surrounding temperature. In addition, an offset calibration can be carried out when P_{RF} is null and V_c is equal to V_{RF}.

These instruments can range from 10 mW to 1 μW and utilize sensors with frequency bandwidths ranging from 10 kHz to 100 GHz.

22.2.4.1.2 Thermocouple-Based Power Meters

Thermocouples [14] can be also used as RF power meters up to frequencies greater than 40 GHz. In this case, the resistor is generally a thin-film type. The sensitivity of a thermocouple can be expressed as the ratio between the dc output amplitude and the input RF power. Typical values are 160 μV mW^{-1} for minimum power of about 1 μW.

The measure of voltages of about some tens of millivolts requires strong amplification, in that the amplifier does not have to introduce any offset. With this aim, a chopper microvoltmeter is utilized [16], as shown in Figure 22.34.

The thermocouple output voltage V_{dc} is chopped at a frequency of about 100 Hz; the resulting square wave is filtered of its mean value by the capacitor C and then input to an ac amplifier to further reduce offset problems. A detector, synchronized to the chopper, and a low-pass filter transform the amplified square voltage in a dc voltage finally measured by a voltmeter.

22.2.4.1.3 Calorimetric Method

For high frequencies, a substitution technique based on a calorimetric method is utilized (Figure 22.35) [17]. First, the unknown RF power P_{RF} is sent to the measuring device t, which measures the equilibrium temperature. Then, once the calorimetric fluid has been cooled to its initial temperature, a dc power P_{dc} is applied to the device and regulated until the same temperature increase occurs in the same time interval. In this way, thermal energy equivalence is established between the known P_{dc} and the measur- and P_{RF}.

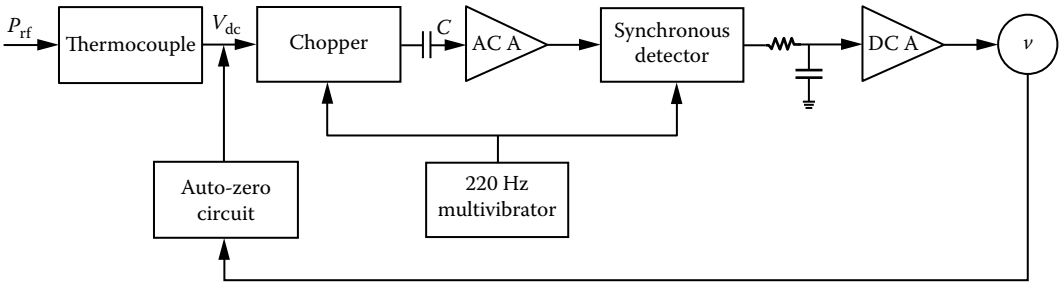

FIGURE 22.34 Power meter with thermocouple-based sensor.

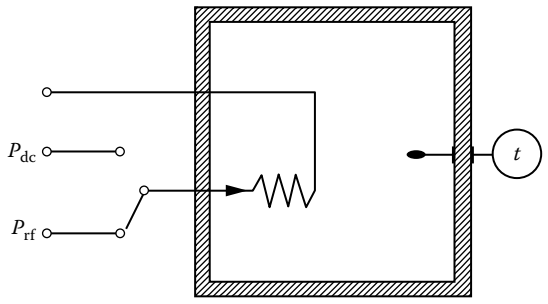

FIGURE 22.35 Calorimetric method based on a substitution technique.

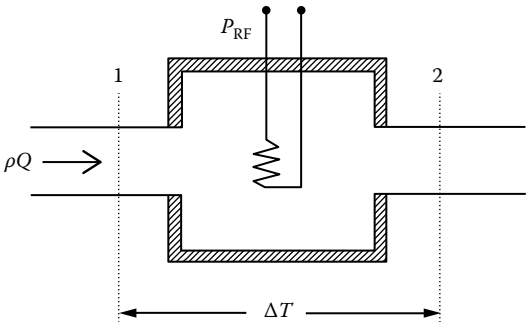

FIGURE 22.36 Calorimetric method based on a comparison technique.

A comparison version of the calorimetric method is also used for lower-frequency power measurements (Figure 22.36). The temperature difference ΔT of a cooling fluid is determined between the input (1) and the output (2) sections of a cooling element where the dissipated power P is measured. In this case, the power loss will correspond to P:

$$P = C_p \rho Q \Delta T \tag{22.70}$$

where

C_p is the specific heat
ρ is the density
Q is the volume flow, respectively, of the refreshing fluid

22.2.5 Diode Sensor-Based Power Measurements

Very sensitive (up to 0.10 nW, –70 dB m), high-frequency (10 MHz–20 GHz) power measurements are carried out through a diode sensor by means of the circuit in Figure 22.37 [18]. In particular, according to a suitable selection of the components in this circuit, (1) true-average power measurements or (2) peak power measurements can be performed.

The basic concept underlying *true-average power measurements* exploits the nonlinear squared region of the characteristic of a low-barrier Schottky diode (nondashed area in Figure 22.38). In this region, the current flowing through the diode is proportional to the square of the applied voltage; thus, the diode acts as a squared-characteristic sensor.

In the circuit of diode sensor-based wattmeters shown in Figure 22.37, the measurand v_x, terminated on the matching resistor R_m, is applied to the diode sensor D_s working in its squared region in order to produce a corresponding output current i_c in the bypass capacitor C_b. If C_b, has been suitably selected, the voltage V_c between its terminals, measured by the voltmeter amplifier V_a, is proportional to the average of i_c, that is, to the average of the squares of instantaneous values of the input signal v_x and, hence, to the true-average power.

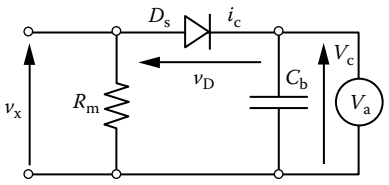

FIGURE 22.37 Circuit of the diode sensor-based power measurement.

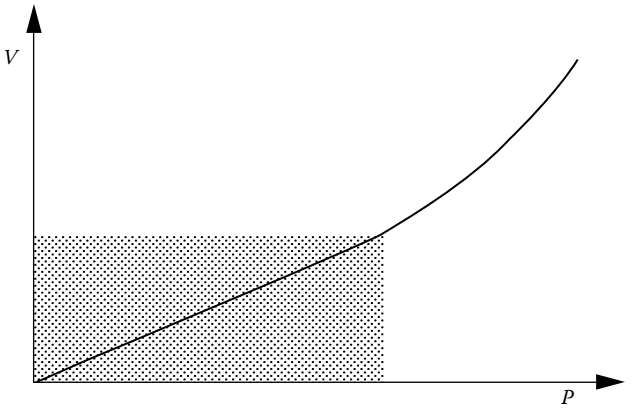

FIGURE 22.38 Characteristic of a low-barrier Schottky diode.

In the true-average power measurement of nonsinusoidal waveforms having the biggest components at low frequency, such as RF amplitude modulated (AM), the value of C_b, must also satisfy another condition. The voltage v_d on the diode must be capable of holding the diode switched on into conduction even for the smallest values of the signal. Otherwise, in the valleys of the modulation cycle, the high-frequency modulating source is disconnected by the back-biased diode, and the measurement is therefore misleading.

On the other hand, for the same signal but for a different selection of the C_b value, the circuit can act as a peak detector for *peak power measurements*. As a matter of fact, the voltage v_c on the bypass capacitor C_b during the peak of the modulation cycle is so large that in the valleys, the high-frequency peaks are not capable of switching on the diode into conduction; thus, these peaks do not contribute to the measured power level.

If higher power levels have to be measured (10–100 mW), the sensing diode is led to work out of the squared region into its linear region (dashed area in Figure 22.38). In this case, the advantage of true-average power measurements for distorted waveforms is lost, and for peak power measurements, since the diode input–output characteristic is nonlinear and the output is squared, spectral components different from the fundamental introduce significant measuring errors.

22.2.6 Radiation Sensor-Based Power Measurements

Very high-frequency power measurements are usually carried out by measuring a radiant flux of an electromagnetic radiation through a suitable sensor. In particular, semiconductor-based radiation microsensors have gained wider and wider diffusion [19], in that size reduction involves several well-known advantages such as greater portability, fewer materials, and a wider range of applications. One of the most familiar applications of radiation sensor-based power measurements is the detection of object displacement. Furthermore, they are also commonly used for low-frequency power noninvasive measurements.

Radiation sensors can be classified according to the measurand class to which they are sensitive: nuclear particles or electromagnetic radiations. In any case, particular sensors capable of detecting both nuclear particles and electromagnetic radiations, such as gamma and X-rays, exist and are referred to as nucleonic detectors.

In Table 22.1, the different types of radiation sensors utilized according to the decrease of the measurand wavelength from microwaves up to nuclear (X, gamma, and cosmic) rays are indicated.

In particular, *microwave* power radiation sensors are mainly used as noncontacting detectors relying on ranging techniques using microwaves [20]. Shorter and longer (radar) wavelength microwave devices are employed to detect metric and over-kilometer displacements, respectively.

Beyond applications analogous to microwave, power radiation *infrared* sensors also find use as contact detectors. In particular, there are two types of infrared detectors: thermal and quantum. The thermal type includes contacting temperature sensors such as thermocouples and thermopiles, as well as noncontacting pyroelectric detectors. On the other hand, the quantum type,

TABLE 22.1 Operating Field of Main Radiation Power Sensors

Operating Field (Wavelength)	Microwave (1, 10^{-3} m)	Infrared (10^{-3}, 10^{-6} m)	Visible and Ultraviolet (10^{-6}, 10^{-9} m)	Nuclear Rays (10^{-8}, 10^{-15} m)
Sensors	Noncontacting displacement sensors	Pyroelectric, photoconductive, photovoltaic	Photoconductive, photovoltaic	Scintillation counters, plastic films, solid-state, thermolum

although characterized by a strong wavelength dependence, has a faster response and includes photoconductive (spectral range: 1–12 μm) and photovoltaic (0.5–5.5 μm) devices.

The main power radiation *visible and ultraviolet* sensors are photoconductive cells, photodiodes, and phototransistors. Photodiodes are widely used to detect the presence, the intensity, and the wavelength of light or ultraviolet radiations. Compared to photoconductive cells, they are more sensitive, smaller, more stable, and linear and have lower response times. On the other hand, phototransistors are more sensitive to light.

At very low light levels, rather than silicon-based microsensors, *nuclear radiation* power microsensors are needed. In this case, the most widespread devices are scintillation counters, solid-state detectors, plastic films, and thermoluminescent devices. The scintillation counter consists of an active material that converts the incident radiation to pulses of light and a light–electric pulse converter. The active material can be a crystal, plastic fluorine, or a liquid. The scintillator size varies greatly according to the radiation energy, from thin solid films to large tanks of liquid to detect cosmic rays. A thin (5 μm) plastic polycarbonate film or a thermoluminescent material (e.g., LiF) can measure the radiation power falling on a surface. The film is mechanically damaged by the propagation of highly α-ionizing particles. Consequent etching of the film reveals tracks that can be observed and counted.

22.3 Pulse Power Measurements

Pulse waveforms are becoming more and more diffused in several fields such as telecommunications and power source applications. The *pulse power* P_p is defined as the average power P_m in the pulse width:

$$P_p = \frac{P_m}{\tau_d} \tag{22.71}$$

where τ_d is the duty cycle of the pulse waveform (i.e., the pulse width divided by the waveform period). If the pulse width cannot be accurately defined (e.g., nonrectangular pulses in the presence of noise), the pulse power P_p becomes unmeaningful. In this case, the *peak envelope power* is introduced as the maximum of the instantaneous power detected on a time interval, including several periods of the pulse waveform (but negligible with respect to the modulation period, in the case of PWM waveforms).

Several techniques are used to measure pulse power [21]. In particular, they can be classified according to the *pulse frequency* and the necessity for *constraining real-time applications* (i.e., measuring times, including a few of the modulation periods). For real-time, low-frequency applications (up to 100 kHz), the algorithms mentioned in the earlier sections on wattmeters based on digital multipliers can be applied [9].

If constraining limits of real-time do not have to be satisfied, either digital or analog techniques can be utilized. As far as the digital techniques are concerned, for high-frequency applications, if the measurand pulse waveform is stationary over several modulation periods, digital wattmeters based on equivalent sampling can be applied, with accuracies increasing according to measuring times. As far as the analog techniques are concerned, three traditional methods are still valid: (1) average power per duty cycle, (2) integration–differentiation, and (3) dc/pulse power comparison.

A block diagram of an instrument measuring *average power per duty cycle* is illustrated in Figure 22.39. At first, the mean power of the measurand pulse signal, terminated on a suitable load, is measured by

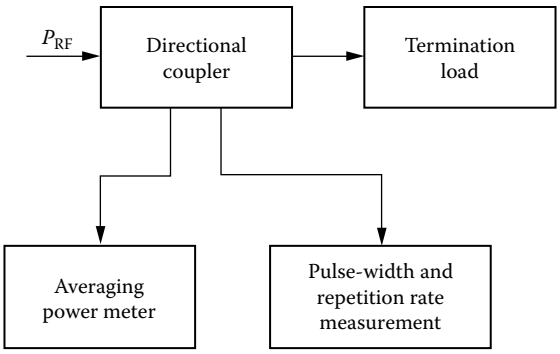

FIGURE 22.39 Block diagram of an instrument measuring average power per duty cycle.

means of an average power meter; then, the pulse width and the pulse waveform period are measured by a digital counter. Finally, the power is obtained by means of Equation 22.71.

The *integration–differentiation* technique is based on a barretter sensor capable of integrating the measurand and on a conditioning and differentiating circuit to obtain a voltage signal proportional to the measurand power. The signal is input to the barretter sensor, having a thermal constant such that the barretter resistance will correspond to the integral of the input. The barretter is mounted as an arm of a conditioning Wheatstone bridge; in this way, the barretter resistance variations are transformed into voltage variations, and an integrated voltage signal is obtained as an output of the bridge detecting arm. This signal, suitably integrated to reach a voltage signal proportional to the output, is detected by a peak voltmeter calibrated in power. Analogously to the selection of the time constant of an *RC* integrating circuit, attention must be paid to the thermal constant selection of the barretter in order to attain the desired accuracy in the integration. With respect to the measurand pulse period, a very long thermal constant will give rise to insufficient sensitivity. On the other hand, a very short constant approaching the pulse duration will give rise to insufficient accuracy.

The *dc/pulse power comparison* technique is based on the concept of first revealing the peak envelope power through a diode sensor and then comparing the peak to a known dc source with a dual-trace scope. A block diagram of an instrument based on this concept is illustrated in Figure 22.40. The peak

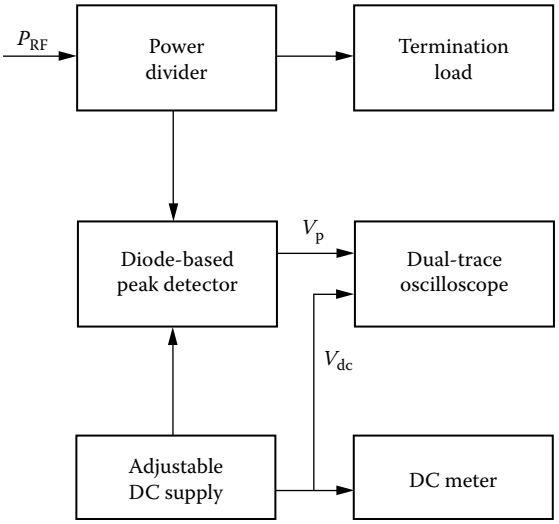

FIGURE 22.40 Block diagram of an instrument based on dc/pulse power comparison technique.

of the measurand pulse signal terminated on a suitable load is sensed by a peak detector by obtaining a proportional signal V_p. This signal is input to a channel of a dual-trace oscilloscope, and the envelope peak is displayed. An adjustable dc source is input to the other channel of the scope to obtain a signal V_{dc} to be compared to the envelope peak signal. When the two signals are made equal, a dc voltage meter directly calibrated in peak power measures the output power.

Power Factor Measurement

Michael Z. Lowenstein
Harmonics Limited

Electricity can be thought of as a means of delivering power from one place to another to do work. The laws and relationships for delivering power were originally developed for direct current (dc). Power delivered, expressed in *watts*, was calculated by multiplying the voltage and current as shown in Equation 23.1:

$$P_{dc} = EI \tag{23.1}$$

The situation becomes more complex when alternating current (ac) is used to deliver power. Figure 23.1 shows a sine wave representing either ac or voltage. Since the instantaneous value of the wave is continually changing, a numerical quantity is defined to represent an average property of this wave. This quantity, the root-mean-square, or *rms* value, calculated by squaring the instantaneous value, integrating it during one cycle, dividing by the period, and taking the square root of the result, is equal to the peak value of the ac wave divided by the square root of 2, or, for ac current, $I_{rms} = i_{peak}/\sqrt{2}$. In the physical world, a sine wave ac having an rms value of 1 A (A = ampere), passed through a resistive load, produces the same heating effect as 1 A of dc. Thus, one might expect delivered ac power to be easily calculated in watts using Equation 23.1 and inserting rms values for current and voltage. While this simple relationship holds true for the instantaneous voltage and current values as shown in Equation 23.1a in general,

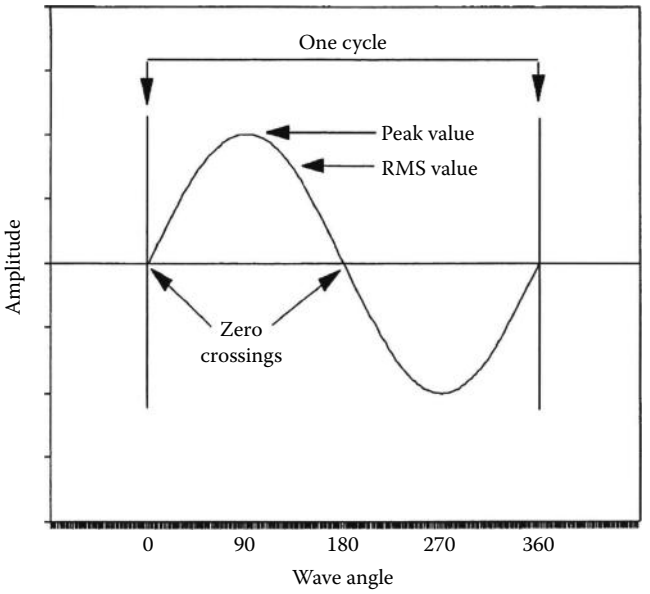

FIGURE 23.1 Sine wave characteristics. One cycle of a continuous wave is shown. The wave begins at a zero-crossing, reaches a positive peak, and continues through zero to a negative peak and back to zero. The wave repeats every 360°. The wave angle can also be expressed as a function of frequency f and time t. For a given frequency, the wave angle is related to the expression, $2\pi ft$.

it is not true for the rms quantities except for the special case when the ac current and voltage are restricted to perfect sine waves *and* the load is a pure resistance:

$$p_{\text{inst}} = ei \tag{23.1a}$$

In real-world situations where current and/or voltage waveforms are not perfectly sinusoidal and/or the loads are other than resistive, the relationships are no longer simple, and the power delivered, or *active power*, is usually less than the product of rms voltage and current, as shown in Equation 23.2:

$$p_{\text{ac}} \leq E_{\text{rms}} I_{\text{rms}} \tag{23.2}$$

The product of rms voltage and rms current does, however, define a quantity termed *apparent power*, U, as shown in Equation 23.3:

$$U = E_{\text{rms}} I_{\text{rms}} \tag{23.3}$$

A derived term, the *power factor*, F_{p}, used to express the relationship between delivered or active power, P, and apparent power, U, is defined by Equation 23.4:

$$F_{\text{p}} = \frac{P}{U} \tag{23.4}$$

From Equations 23.2 through 23.4, it is clear that the value of F_{p} must lie in a range between zero and one. This chapter focuses on (1) ac power relationships and the calculation of power factor, (2) the physical meaning of these relationships, and (3) measurement techniques and instrumentation for determining these relationships and calculating power factor.

23.1 Reasons for Interest in Power Factor

Power factor is a single number that relates the active power, *P*, to the apparent power, *U*. Electric components of a utility distribution system are designed on a kVA basis; that is, they are designed to operate at a given voltage and carry a rated current without undue temperature rise. Transformer and conductor sizes are chosen on this basis. While active power does useful work, reactive and harmonic powers do no useful work, absorb system capacity, and increase system losses, but reactive and harmonic powers are needed to provide magnetic fields or nonlinear currents. *The capacity of electric systems is limited by apparent power, not active power. Power factor expresses, with a single value, the extent to which an electric distribution system is efficiently and effectively utilized.* A low value for the power factor means that much of the system capacity is not available for useful work. From a utility viewpoint, this means reduced ability to deliver revenue-producing active power; from a user viewpoint, a low-power factor reduces the available active power or requires increased system size to deliver needed power.

23.2 AC Electric Loads

23.2.1 Linear Loads

Electric loads in ac power systems with sinusoidal voltages are categorized by the way they draw current from the system. Loads that draw sinusoidal currents, that is, the current waveshape is the same as the voltage waveshapes, are defined as *linear loads*. Historically, a high percentage of electric loads have been linear. Linear loads include (1) induction motors, (2) incandescent lighting, and (3) heaters and heating elements. Linear loads use ac electric power directly to accomplish their functions.

23.2.2 Nonlinear Loads

Electric loads that draw nonsinusoidal currents, that is, the current waveshape differs from the voltage waveshape, are defined as *nonlinear loads*. As energy savings and efficient use of electricity are emphasized, an increased percentage of nonlinear electric devices, both new and replacement, are being installed. Nonlinear loads include (1) adjustable-speed motor drives, (2) fluorescent and arc-discharge lighting, (3) computers and computerized controls, and (4) temperature-controlled furnaces and heating elements. Nonlinear loads, rather than using ac electric power directly, often convert ac power into dc before it is used to accomplish their functions. A common element in nonlinear loads is some kind of rectifier to accomplish this ac to dc conversion. Rectifiers do not draw sinusoidal currents.

23.3 AC Power Relationships

23.3.1 Sinusoidal Voltage and Current

Power calculations for sinusoidal ac electric systems require knowledge of the rms voltage, the rms current, and the phase relationships between the two. Figure 23.2 illustrates possible phase relationships between voltage and current. If the positive-going zero-crossing of the voltage is considered the reference point, then the nearest positive-going zero-crossing of the current can occur at a wave angle either less than or greater than this reference. If the current zero-crossing occurs before the reference, the current is said to *lead the* voltage. If the current zero-crossing occurs after the reference, the current is *lagging*. If the zero-crossing for the current coincides with the reference, the two waves are said to be *in phase*. The wave angle, θ, by which the current leads or lags the voltage is called the *phase angle*, in this case, 30°.

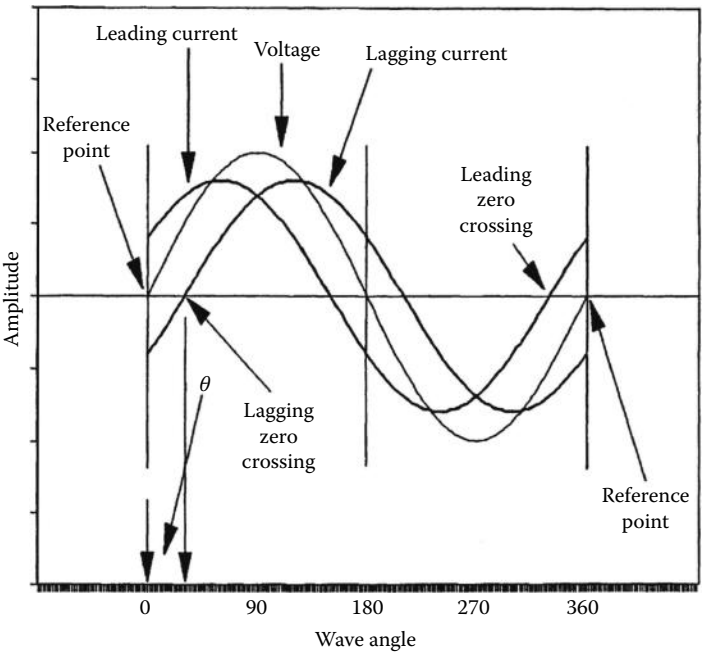

FIGURE 23.2 Sine wave phase angle. Two waves with the same zero-crossing are *in phase*. A sine wave that crosses zero before the reference wave is *leading*, and one that crosses zero after the reference wave is *lagging*. The *phase angle* θ illustrated is 30° lagging.

23.3.2 Single-Phase Circuits

23.3.2.1 Power Calculations

The power delivered to do work is easily calculated [1]. Given a sinusoidal voltage of rms magnitude E and sinusoidal current of rms magnitude I, displaced by angle θ, at time t,

$$\text{Instantaneous voltage} = e\sqrt{2}E\sin(2\pi ft)$$
$$\text{Instantaneous current} = i = \sqrt{2}I\sin(2\pi ft - \theta)(\text{note that } \theta \text{ can have a positive or negative value}) \tag{23.5a}$$

$$\text{Instantaneous power } = p = ei$$
$$p = 2E\sin(2\pi ft)\sin(2\pi ft - \theta)$$
$$p = EI\cos(\theta) - EI\cos(4\pi ft - \theta) \tag{23.5b}$$
$$\text{Average power over an integral number of cycles } p = EI\cos(\theta)$$

$$\text{Power factor } F_p = \frac{P}{U} = \frac{EI\cos(\theta)}{EI} = \cos(\theta) \tag{23.5c}$$

Equation 23.5 is the fundamental equation that defines power for systems in which the current and voltage are sinusoidal. The application of this equation is illustrated for three cases: (1) the current and voltage are in phase, (2) the current and voltage are out of phase by an angle less than 90°, and (3) the current and voltage are out of phase by exactly 90°.

23.3.2.2 AC Power Examples

Figure 23.3 shows voltage current and power when the voltage and current are in phase and the current displacement angle is zero (0). (An example would be a resistance space heater.) The power curve is obtained by multiplying together the instantaneous values of voltage and current as the wave angle is varied from 0° to 360°. Instantaneous power, the product of two sine waves, is also a sine wave. There are two zero-crossings per cycle, dividing the cycle into two regions. In region (1), both the voltage and current are positive, and the resultant product, the power, is positive. In region (2), both the voltage and current are negative, and the power is again positive. The average power in watts, given by Equation 23.5, $EI\cos(0°) = EI$, is the maximum power that can be delivered to do work. *When sinusoidal voltage and current are in phase, the delivered power in watts is the same as for dc and is the maximum that can be delivered*. The power factor $F_p = \cos(0°) = 1$ or *unity*.

Figure 23.4 shows voltage, current, and power when the current lags the voltage by 60°. (An example might be a lightly loaded induction motor.) The power sine wave again is obtained by multiplying together the instantaneous values of voltage and current. There are now four zero-crossings per cycle, dividing the cycle into four regions. In regions (2) and (4), voltage and current have the same sign, and the power is positive. In regions (1) and (3), voltage and current have opposite signs, resulting in a negative value for the power. The average power in watts, given by Equation 23.5, $EI\cos(60°) = EI(0.5)$, is less than the maximum that could be delivered for the particular values of voltage and current. *When voltage and current are out of phase, the delivered power in watts is always less than the maximum*. In this example, $F_p = \cos(60°) = 0.5$.

Figure 23.5 shows voltage, current, and power when the current lags the voltage by 90°. (This situation is not attainable in the real world.) The power sine wave again is obtained by multiplying together the instantaneous values of voltage and current. Again, four zero-crossings divide the cycle into four regions. In regions (2) and (4), the power is positive, while in regions (1) and (3), the power is negative.

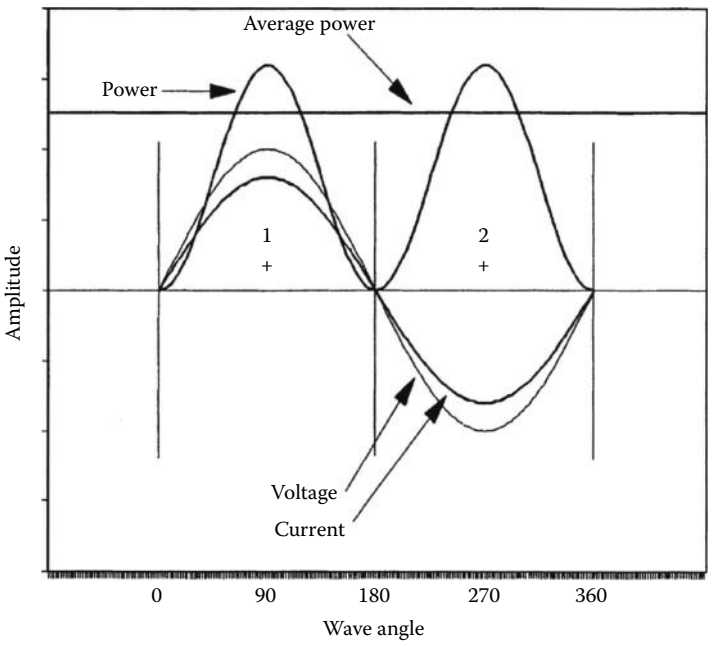

FIGURE 23.3 Voltage, current, and power for sine waves in phase. The vertical scales for voltage and current are equal. The scale for power is relative and is selected to permit the display of all three waves on a single graph. The voltage and current are in phase and both are sinusoidal. The power is positive everywhere, and average power delivered to do work is the maximum power.

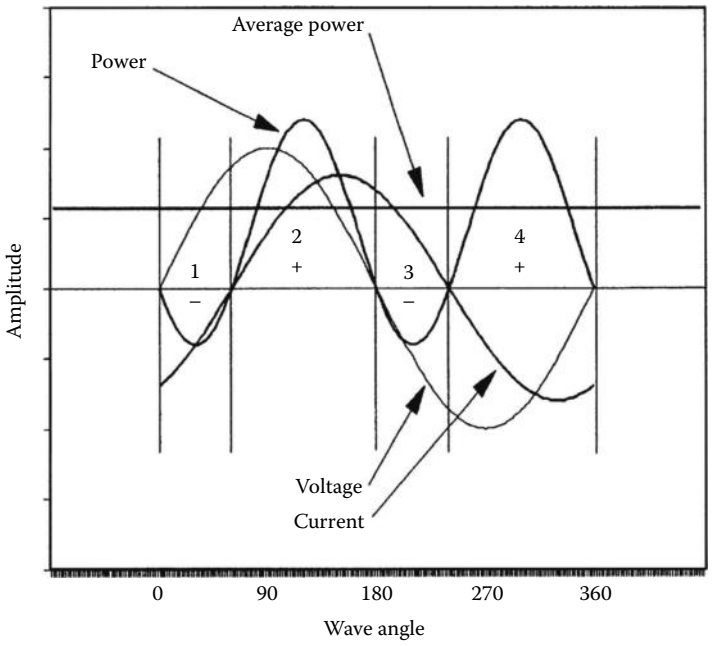

FIGURE 23.4 Voltage, current, and power for sine waves 60° out of phase. The vertical scales for voltage and current amplitudes are the same as those for Figure 23.3. Current lags voltage by 60° and both are sinusoidal. The power is positive in regions (2) and (4) and negative in regions (1) and (3). Average power delivered to do work is less than the maximum power.

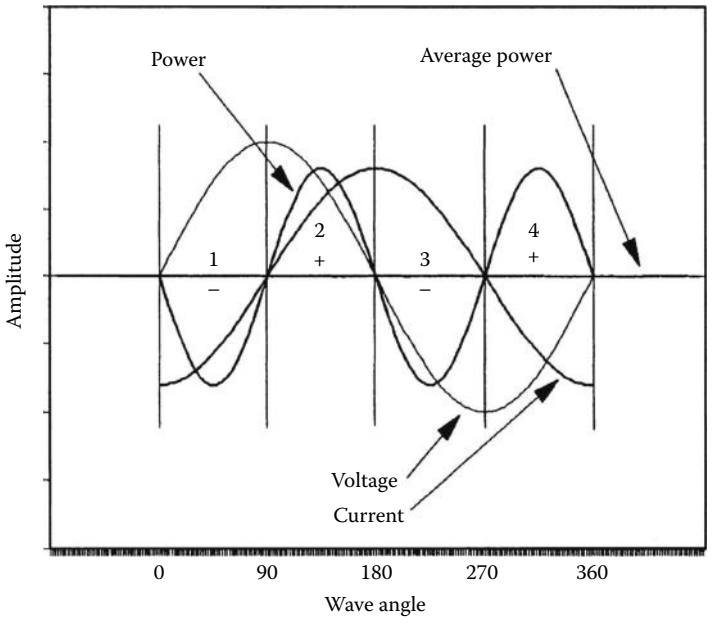

FIGURE 23.5 Voltage, current, and power for sine waves 90° out of phase. The vertical scales for voltage and current amplitudes are the same as those for Figure 23.3. Current lags voltage by 90° and both are sinusoidal. The power is positive in regions (2) and (4) and negative in regions (1) and (3) and is of equal absolute magnitude in all four regions. Average power delivered to do work is zero.

The average power in watts is given by Equation 23.5, $EI\cos(90°) = 0$. No matter what the values of voltage and current, *when voltage and current are exactly 90° out of phase, the delivered power in watts is always zero*. The power factor $F_p = \cos(90°) = 0$.

23.3.2.3 Power Factor

Resolving the current into orthogonal components on a phasor diagram illustrates how delivered power can vary from a maximum to zero, depending on the phase angle between the voltage and the current sine waves. Figure 23.6 shows the voltage vector along with the current resolved into orthogonal components [1]. The current I at an angle θ relative to the voltage can be resolved into two vectors: $I\cos(\theta)$ and $I\sin(\theta)$. The in-phase component $I\cos(\theta)$ multiplied by the voltage gives average power in watts. The current component that is 90° out of phase with the voltage, $I\sin(\theta)$, is not associated with delivered power and does not contribute to work. For want of a better name, this was often termed the *wattless component* of the current. Since this wattless current could be associated with magnetic fields, it was sometimes termed *magnetizing current* because, while doing no work, this current interacts through the inductive reactance of an ac motor winding to provide the magnetic field required for such a motor to operate.

Three types of power have been defined for systems in which both the voltage and current are sinusoidal. Throughout the years, a number of different names have been given to the three power types. The names in present usage will be emphasized.

Active power is given the symbol P and is defined by Equation 23.5:

$$P = EI\cos(\theta) \tag{23.5d}$$

Other names for active power include (1) real power and (2) delivered power. Active power is the power that does the work. Note that while all power quantities are volt–ampere products, only *active power is expressed in watts*.

Reactive power is given the symbol Q and is defined by the equation:

$$Q = EI\sin(\theta) \tag{23.6}$$

Other names for reactive power include (1) imaginary power, (2) wattless power, and (3) magnetizing power. Reactive power is expressed in $voltamperes_{reactive}$ or *vars*. If the load is predominantly inductive, current lags the voltage, and the reactive power is given a positive sign. If the load is predominantly capacitive, current leads the voltage, and the reactive power is given a negative sign.

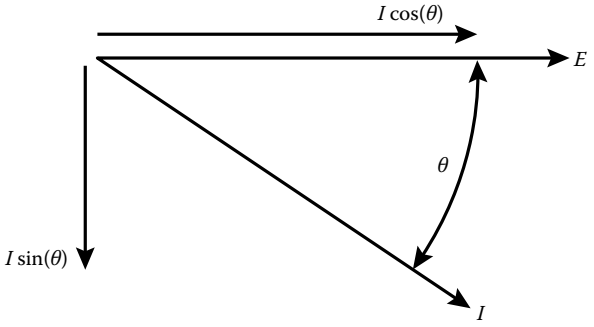

FIGURE 23.6 Phasor diagram for current and voltage. Voltage is the reference phasor. The current I has been resolved into orthogonal components $I\cos(\theta)$ and $I\sin(\theta)$. (From Bullock, D.F., Methods of measuring apparent power, GE Meter, *Missouri Valley Electrical Association Annual Engineering Conference*, Kansas City, MO, 1996.)

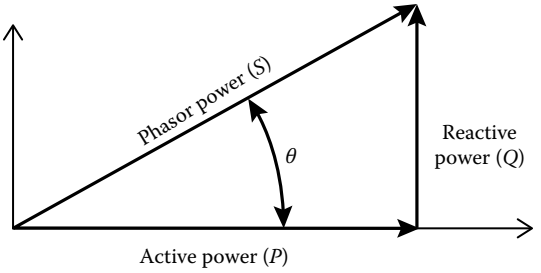

FIGURE 23.7 Power triangle showing the geometric relationships between active, reactive, and phasor power. Power factor is defined geometrically as cos θ.

Phasor power is given the symbol *S* and is defined by the equation:

$$S = \sqrt{p^2 + Q^2} \tag{23.7}$$

Phasor power was called apparent power for many years, and it will be seen in a later section that phasor power *S, for sinusoidal voltages and currents*, is identical to what is now called apparent power *U*. Phasor power is expressed in *voltamperes* or *VA*.

Figure 23.7 is a phasor diagram, often called a *power triangle*, which illustrates the relationships among the three types of power defined earlier. Reactive power is orthogonal to active power and is shown as positive for lagging current. It is clear that the definition of phasor power, Equation 23.7, is geometrically derived from active and reactive power.

Power factor is given the symbol F_p and *for sinusoidal quantities* is defined by the equation:

$$F_p = \frac{\text{Active power}}{\text{Phasor power}} = \frac{P}{S} = \frac{\text{Watts}}{\text{Voltamps}} = \cos\theta \tag{23.8}$$

Since the power factor can be expressed in reference to the displacement angle between voltage and current, power factor so defined should be termed *displacement power factor*, and the symbol is often written as $F_{p\ \text{displacement}}$. Values for displacement power factor range from one (unity) to zero as the current displacement angle varies from 0° (current and voltage in phase) to 90°. Since the cosine function is positive in both the first and fourth quadrants, the power factor is positive for both leading and lagging currents. To completely specify the voltage–current phase relationship, the words *leading* or *lagging* must be used in conjunction with power factor. Power factor can be expressed as a decimal fraction or as percent. For example, the power factor of the case shown in Figure 23.4 is expressed as either 0.5% lagging or 50% lagging.

23.3.3 Polyphase Circuits

23.3.3.1 Power Calculations

The power concepts developed for single-phase circuits with sinusoidal voltages and currents can be extended to polyphase circuits. Such circuits can be considered to be divided into a group of two-wire sets, with the neutral conductor (or a resistively derived neutral for the case of a delta-connected, three-wire circuit) paired with each other conductor. Equations 23.3 and 23.5 can be rewritten to define power terms equivalent to the single-phase terms. In these equations,

k represents a phase number, m is the total number of phases, and α and β are, respectively, the voltage and current phase angles with respect to a common reference frame:

$$p = \sum_{k=1}^{m} E_k I_k \cos(\alpha - \beta) \tag{23.9}$$

$$Q = \sum_{k=1}^{m} E_k I_k \sin(\alpha - \beta) \tag{23.10}$$

and, restating Equation 23.7,

$$S = \sqrt{P^2 + Q^2}$$

For example, a three-phase sinusoidal power distribution service, with phases a, b, and c

$$p = E_a I_a \cos(\alpha_a - \beta_a) + E_b I_b \cos(\alpha_b - \beta_b) + E_c I_c \cos(\alpha_c - \beta_c)$$

$$Q = E_a I_a \sin(\alpha_a - \beta_a) + E_b I_b \sin(\alpha_b - \beta_b) + E_c I_c \sin(\alpha_c - \beta_c)$$

$$S = \sqrt{P^2 + Q^2}$$

23.3.3.2 Power Factor

Power factor is defined by Equation 23.11. Note that it is no longer always true to say that power factor is equal to the cosine of the phase angle. In many three-phase balanced systems, the phase angles of all three phases are equal and the cosine relationship holds. In unbalanced systems, such as that represented by the phasor diagram Figure 23.8, each phase has a different phase angle, the phase voltages and currents are not equal, and the cosine relationship fails [3]:

$$F_p = \frac{\text{Total active power}}{\text{Phasor power}} = \frac{P_{\text{Equation 23.9}}}{S} = \frac{\text{Watts}}{\text{Voltamps}} \textit{often} \neq \cos\theta \tag{23.11}$$

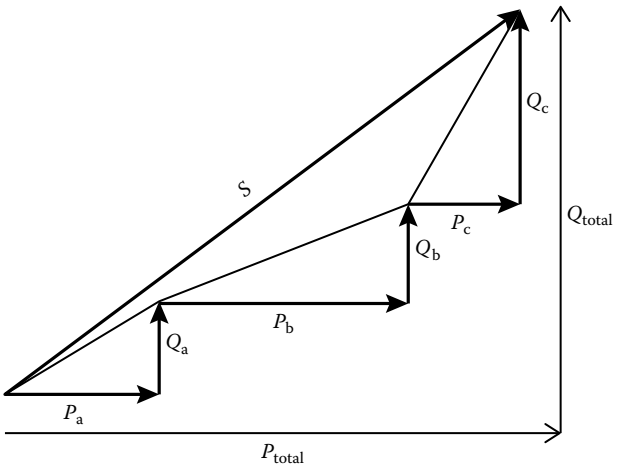

FIGURE 23.8 Phasor diagram for a sample polyphase sinusoidal service in which each phase has a different phase angle. Power factor cannot be defined as the cosine of the phase angle in this case. (From Bullock, D.F., *Phase Angle Relationships, Part 1: Theory*, GE Meter, Arkansas Electric Meter School, Fayetteville, AR, 1995.)

23.3.4 Nonsinusoidal Voltage and Current

23.3.4.1 Fourier Analysis

Figure 23.9 shows voltage, current, and power for a typical single-phase nonlinear load, a computer switch-mode power supply. Due to the nature of the bridge rectifier circuit in this power supply, current is drawn from the line in sharp spikes. The current peak is only slightly displaced from the voltage peak, and the power is everywhere positive. However, power is delivered to the load during only part of the cycle, and the average power is much lower than if the current had been sinusoidal. The current waveshape required by the load presents a problem to the ac power system, which is designed to deliver only sine wave current. The solution to this problem is based on mathematical concepts developed in 1807 for describing heat flow by Jean Baptiste Joseph Fourier, a French mathematician [4]. Fourier's theorem states that any periodic function, however complex, can be broken up into a series of simple sinusoids, the sum of which will be the original complex periodic variation. Applied to the present electric problem, Fourier's theorem can be stated: *any periodic nonsinusoidal electric waveform can be broken up into a series of sinusoidal waveforms, each a harmonic of the fundamental, the sum of which will be the original nonsinusoidal waveform*.

23.3.4.2 Harmonics

Harmonics are defined as continuous integral multiples of the fundamental waveform. Figure 23.10 shows a fundamental sine wave and two harmonic waves—the third and fifth harmonics. The harmonic numbers 3 and 5 express the number of complete cycles for each harmonic wave per cycle of the fundamental (or first harmonic). Each harmonic wave is defined by its harmonic number, its amplitude, and its phase relationship to the fundamental. Note that the fundamental frequency can have any value without changing the harmonic relationships, as shown in Table 23.1.

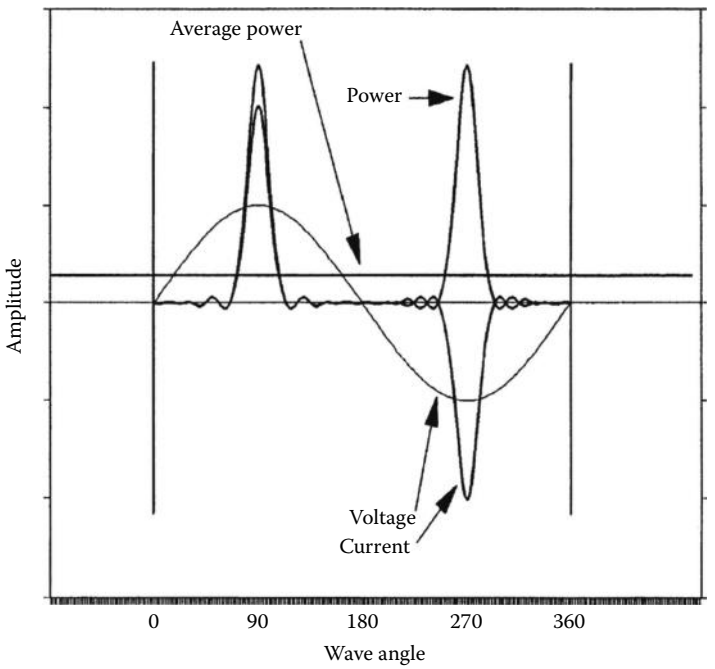

FIGURE 23.9 Voltage, current, and power for a single-phase, switch-mode computer power supply, a typical nonlinear load. The current is no longer sinusoidal.

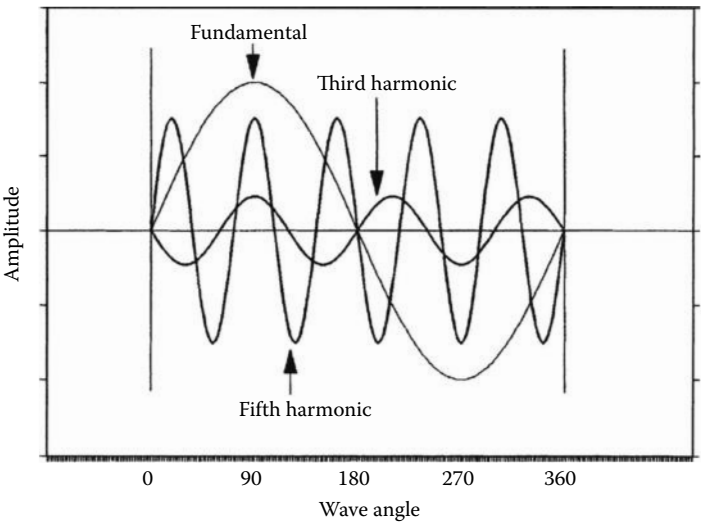

FIGURE 23.10 Harmonics are continuous integral multiples of the fundamental frequency. The fifth harmonic is shown, in phase with the fundamental, while the third harmonic is 180° out of phase.

TABLE 23.1 Harmonics and Their Relationship to the Fundamental Frequency

Harmonic Number	Frequency (Hz)	Frequency (Hz)	Frequency (Hz)
1	60	50	400
2	120	100	800
3	180	150	1200
4	240	200	1600
5	300	250	2000

23.3.4.3 Power Calculations

Calculating power delivered to do work for a nonlinear load is somewhat more complicated than if the current were sinusoidal. If the fundamental component of the voltage at frequency f is taken as a reference (the a-phase fundamental for a polyphase system), the subscript "1" means the fundamental, and E denotes the peak value of the voltage; then, the voltage can be expressed as

$$\varepsilon_{a1(t)} = E_{a1} \sin(2\pi ft + 0°)$$

The voltage fundamental will then have an amplitude E_{a1} and pass through zero in the positive-going direction at time $t = 0$. If h = harmonic number, and E_h and I_h are peak amplitudes of the harmonic voltage and current, respectively, then general expressions for any harmonic will be

$$e_{h(t)} = E_h \sin\left(2\pi fht + \alpha_h^\circ\right)$$

$$i_{h(t)} = I_h \sin\left(2\pi fht + \beta_h^\circ\right)$$

To compute the power associated with a voltage and current waveform, take advantage of the fact that products of harmonic voltages and currents of different frequency have a time average of zero.

Only products of voltages and currents of the same frequency are of interest, giving a general expression for harmonic power as

$$p_{h(t)} = E_h I_h \sin\left(2\pi fht + \alpha_h^\circ\right)\sin\left(2\pi fht + \beta_h^\circ\right)$$

Simplifying with trigonometric identities, evaluating over an integral number of cycles, and replacing peak voltage and current with rms values, the average power becomes

$$p_{h(t)} = E_h I_h \cos\left(\alpha_h^\circ - \beta_h^\circ\right)$$

For a *single-phase system* where h is the harmonic number and H is the highest harmonic, the total average power or active power is given by

$$p = \sum_{h=1}^{H} E_h I_h \cos\left(\alpha_h - \beta_h\right) \tag{23.12}$$

Total average reactive power is given by

$$Q = \sum_{h=1}^{H} E_h I_h \sin\left(\alpha_h - \beta_h\right) \tag{23.13}$$

It should be noted that in the real world, the actual contribution of harmonic frequencies to active and reactive power is small (usually less than 3% of the total active or reactive power). The major contribution of harmonic frequencies to the power mix comes as distortion power, which will be defined later.

For a *polyphase system* wherein r is the phase identification and N is the number of conductors in the system, including the neutral conductor, total average power for a polyphase system is given by

$$p = \sum_{r=1}^{N-1}\sum_{h=1}^{H} E_{rh} I_{rh} \cos(\alpha_{rh} - \beta_{rh}) \tag{23.14}$$

Total average reactive power is given by

$$Q = \sum_{r=1}^{N=1}\sum_{h=1}^{H} E_{rh} I_{rh} \sin(\alpha_{rh} - \beta_{rh}) \tag{23.15}$$

23.3.5 Power Factor

23.3.5.1 Single-Phase Systems

For a single-phase system, phasor power is again given by Equation 23.7 and illustrated by Figure 23.7, where P is the algebraic sum of the active powers for the fundamental and all the harmonics (Equation 23.12) and Q is the algebraic sum of the reactive powers for the fundamental and all the harmonics (Equation 23.13). Therefore, phasor power is based on the fundamental and harmonic active and reactive powers. It is found, however, that phasor power S is no longer equal to apparent power U and a new power phasor must be defined to recognize the effects of waveform distortion. A phasor representing the distortion, termed *distortion power* and given the symbol D, is defined by

$$D = \pm\sqrt{U^2 - S^2} \tag{23.16}$$

Without further definite information as to the sign of distortion power, its sign is selected the same as the sign of the total active power. The relationships among the various power terms are displayed in Figure 23.11, a 3D phasor diagram. Power factor, in direct parallel with sinusoidal waveforms, is defined by the equation

$$F_p = \frac{\text{Total active power}}{\text{Apparent power}} = \frac{P}{U} = \frac{\text{Watts}}{\text{Voltamps}} \tag{23.17}$$

From Equations 23.7 and 23.16, we obtain

$$S = \sqrt{p^2 + Q^2} \tag{23.7}$$

$$U = \sqrt{S^2 + D^2} = \sqrt{P^2 + Q^2 + D^2} \tag{23.18}$$

It is clear that when waveforms are sinusoidal, that is, linear loads are drawing current, there is no distortion power and Equation 23.18 reduces to Equation 23.7. Likewise as shown in Figure 23.13, as the distortion power vector goes to zero, the figure becomes 2D and reduces to Figure 23.7, and U becomes equal to 5. When, however, nonlinear loads are drawing harmonic currents from the system, U will be greater than S. As already noted, the contribution of the harmonics to the total power quantities is small, and one is frequently interested mainly in the fundamental quantities.

The power factor associated only with the fundamental voltage and current components was termed the displacement power factor $F_{\text{p displacement}}$ where Equations 23.7 and 23.8 are written as [5]

$$S_{60} = \sqrt{P_{60}^2 + Q_{60}^2}$$

and

$$F_{\text{p displacement}} = \frac{P_{60}}{S_{60}}$$

When harmonics are present, F_p is always smaller than $F_{\text{p displacement}}$.

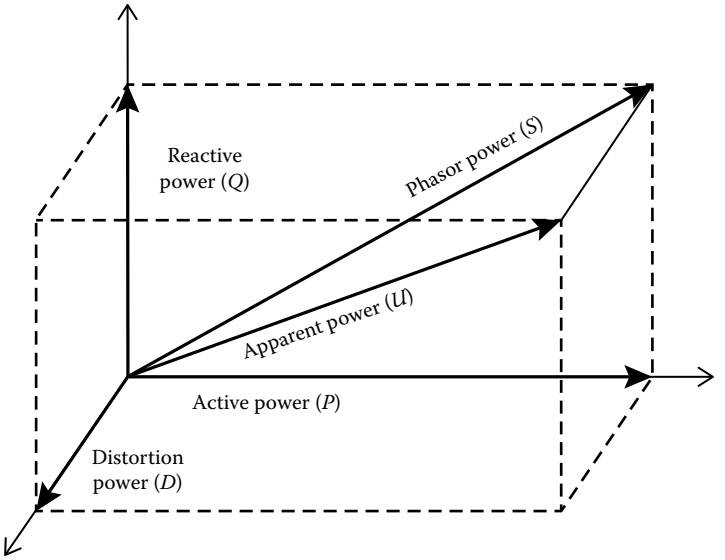

FIGURE 23.11 Phasor diagram for a single-phase, nonsinusoidal service in which the voltage and current contain harmonics. Geometric relationships are shown between active, reactive, phasor, distortion, and apparent powers.

23.3.5.2 Polyphase Systems

For a polyphase system, phasor power, *S*, is again given by Equation 23.7, but one must now use the total values for *P* and *Q* calculated using Equations 23.14 and 23.15. One can then define the apparent power *U* in one of two ways:

- *Arithmetic apparent power.* The *arithmetic apparent power* is given the symbol U_a and is defined by Equation 23.19, where E_r and I_r are the rms values for the respective phases and *M* equals the number of phases. U_a is a scalar quantity:

$$U_a = \sum_{r=1}^{M-1} E_r I_r \tag{23.19}$$

- *Apparent power. Apparent power is* given the symbol *U* and is defined by Equation 23.18 using total values for *P* and *Q* as defined by Equations 23.14 and 23.15 and a total value for *D* determined using Equation 23.16 for each phase. Figure 23.12 illustrates the two alternative concepts for polyphase apparent power [6]. Note that U_a uses arithmetic addition of vector magnitudes and is equal to apparent power *U* only if the polyphase voltages and currents have equal magnitudes and equal angular spacings, a situation that often exists in balanced three-phase systems. The two alternative definitions of apparent power, *U* and U_a, give rise to two possible values for power factor: (1) $F_p = P/U$, and (2) $F_{pa} = P/U_a$. Apparent power *U* and power factor F_p are the preferred definitions since using U_a can give unexpected results with some nonsymmetric service arrangements such as four-wire delta, and, with extremely unbalanced resistive loads, F_{pa} can exceed 1.0. Despite these shortcomings, arithmetic apparent power has become quite widely used due to the comparative simplicity of its measurement and calculation. With the advent of sophisticated digital meters, there is no longer any advantage to using arithmetic apparent power, and its use will surely decrease.

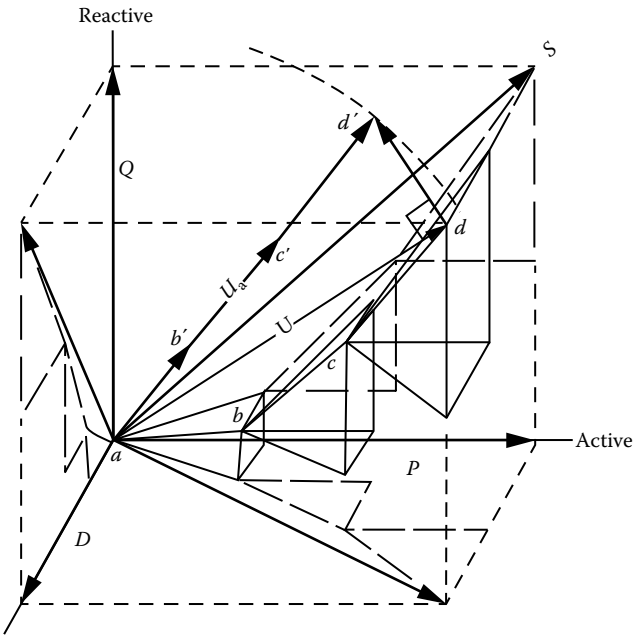

FIGURE 23.12 Phasor diagram for a three-phase, nonsinusoidal service in which the voltage and current contain harmonics. Arithmetic apparent power U_a is the length of the segmented line abed and is a scaler quantity U_a that can be represented by the line ab′c′d′. The diagonal ad, a vector quantity, is the apparent power *U*. (From Bullock, D.F. and Elmore, D.D., *MIND UR PS & QS, GE Meter EEI-AEIC Meter and Service Committee Meeting*, Dallas, TX, 1994.)

23.4 Power Factor "Measurement"

There are no instruments that measure power factor directly. (Power stations and large substations often use phase angle meters with a power factor scale representing $\cos(\theta)$ to display power factor. Such meters are accurate only for sinusoidal balanced polyphase systems.) One must remember that, of all the ac power quantities discussed, the only ones that can be directly measured are voltages, currents, and their time relationships (phase angles). All other ac power quantities are derived mathematically from these measured quantities. The only one of these derived values that has physical reality is the active power P (the quantity that does work); the others are mathematical constructs. Therefore, correct determination of power factor requires accurate measurement of voltage and current and proficient mathematics.

23.4.1 Metering for Linear Loads

By the early 1920s, the concepts of active, reactive, and apparent (since renamed phasor) power and power factor were known, and metering capabilities had been developed to enable their determination. Energy meters utilizing voltage and current coils driving an induction disk inherently measured active power P ($EI\cos\theta$), which was displayed on a mechanical register. Using the trigonometric identity $EI\sin\theta = EI\cos(90° + \theta)$, with voltage delayed 90°, a similar energy meter displayed reactive power Q, and, with these two values, displacement power factor was calculated. Voltage delay (phase shifting) was accomplished using specially wound transformers.

Through the years, the method of obtaining the 90° phase shift has been updated. Analog electronic meters are available that provide the 90° phase shift electronically within the meter. More recently, digital meters have been developed that sample voltages and currents at regular intervals and digitize the results. Voltages and currents are multiplied as they are captured to compute active power. Past voltage samples delayed by a time equal to a quarter cycle (90°) are multiplied by present current values to obtain reactive power. Active–reactive metering of this type is a widely utilized method for determining displacement power factor for utility billing. These meters do not accurately measure the effect of harmonic currents because the delay of the voltage samples is based on the fundamental frequency and is incorrect for the harmonics. (The important fifth harmonic, which is frequently the predominant harmonic component, is accurately measured because it is delayed 450° (5 × 90°), which is equivalent to the correct 90° delay).

23.4.2 Metering for Nonlinear Loads

With the application of high-speed digital computing techniques to measurement of ac currents and voltages, together with digital filtering, the quantities necessary for accurate and correct calculation of power factor are susceptible to direct computation. In practice, the ac waveforms are sampled at a frequency greater than twice the highest frequency to be measured, in compliance with well-known sampling theories. Data obtained can be treated using Fourier's equations to calculate rms values for voltage, current, and phase angle for the fundamental and each harmonic frequency. Power quantities can be obtained with digital filtering in strict accordance with their *ANSI/IEEE STD* 100 definitions. Power quantities can be displayed for the fundamental only (displacement power factor) or for fundamental plus all harmonics (power factor for nonsinusoidal waveforms).

23.4.3 Metering Applications

Instruments with the capabilities described earlier are often called *harmonic analyzers* and are available in both single-phase and polyphase versions. They can be portable, in which case they are often used for power surveys or panel mounted for utility and industrial revenue metering. Polyphase analyzers can be connected as shown in Figures 23.13 and 23.14. Care must be taken to connect the instrument properly.

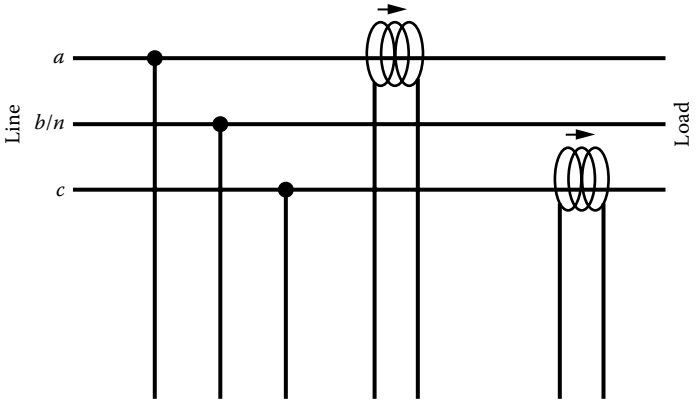

FIGURE 23.13 Meter connections for a one-, two-, or three-phase, three-wire service. Voltage leads are connected to phases *a*, *b*, and *c or* to a, c, and neutral as the system dictates. Care must be taken to connect the voltage lead for each phase to the input corresponding to the input for the current transformer reading that phase, and directional characteristics of the transformers must be observed. Only two current connections are required.

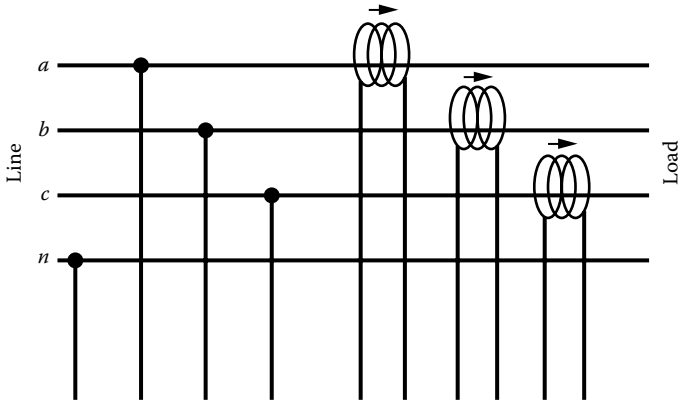

FIGURE 23.14 Meter connections for a three-phase, four-wire wye- or delta-connected service. Voltage leads are connected to phases *a*, *b*, and *c* and to the neutral. Care must be taken to connect the voltage lead for each phase to the input corresponding to the input for the current transformer reading that phase, and directional characteristics of the transformers must be observed. In situations where measurement of neutral currents is desired, a fourth current transformer can be used to read the neutral. A fourth voltage connection might be used to read neutral-ground voltages.

Both voltage leads and current transformers must be connected to the proper phases, and the current transformers must also be placed with the correct polarity. Most instruments use color-coded voltage connectors. Correct polarity is indicated on the current transformers by arrows or symbols, and complete hookup and operating instructions are included. When single-phase instruments are used, the same precautions must be followed for making connections.

23.5 Instrumentation

Table 23.2 lists a sampling of harmonic and power factor measuring instruments available from major manufacturers. All instruments listed use some type of Fourier calculations and/or digital filtering to determine power values in accordance with accepted definitions. Many can be configured to measure nonharmonic-related power quality concerns. Unless otherwise noted, all instruments require the

purchase of one current probe per input. Probes are available for measuring currents from 5 A to several thousand amperes. For comparison purposes, priced probes will be those with a 600 A range. Voltage leads are usually supplied as standard equipment. Table 23.3 contains addresses of these manufacturers.

Defining Terms

Active power: A term used to express the real power delivered to do work in an ac distribution system.
Apparent power: A term used to express the product of volts and amperes in an ac distribution system in which voltage and/or current is nonsinusoidal.
Harmonic power: A term used to express the power due to harmonic frequencies in an ac distribution system in which voltage and/or current is nonsinusoidal.
Phasor power: A term used to express the product of volts and amperes in an ac distribution system in which voltage and current are sinusoidal.
Power factor: A single number, calculated by dividing active power by either the phasor power or the apparent power, which describes the effective utilization of ac distribution system capacity.
Reactive power: A term used to express the imaginary power that does no work but provides magnetization to enable work in an ac distribution system.

Phase Measurement

Peter O'Shea
Royal Melbourne Institute of Technology

The notion of "phase" is usually associated with *periodic* or repeating signals. With these signals, the waveshape perfectly repeats itself every time the *period* of repetition elapses. For periodic signals one can think of the phase at a given time as the fractional portion of the period that has been completed. This is commonly expressed in degrees or radians, with full cycle completion corresponding to 360° or 2π radians. Thus, when the cycle is just beginning, the phase is zero. When the cycle is half completed, the phase is half of 360°, or 180° (see Figure 24.1). It is important to note that if phase is defined as the portion of a cycle that is completed, the phase depends on where the beginning of the cycle is taken to be. There is no universal agreement on how to specify this beginning. For a sinusoidal signal, probably the two most common assumptions are that the start of the cycle is (1) the point at which the maximum value is achieved and (2) the point at which the negative to positive zero-crossing occurs. Assumption (1) is common in many theoretical treatments of phase and for that reason is adopted in this chapter. It should be noted, however, that assumption (2) has some benefits from a measurement perspective, because the zero-crossing position is easier to measure than the maximum.

The measurement of phase is important in almost all applications where sinusoids proliferate. Many means have therefore been devised for this measurement. One of the most obvious measurement techniques is to directly measure the fractional part of the period that has been completed on a cathode-ray oscilloscope (CRO). Another approach, which is particularly useful when a significant amount of noise is present, is to take the Fourier transform of the signal. According to the Fourier theory, for a sinusoidal signal, the energy in the Fourier transform is concentrated at the frequency of the signal; the initial phase of the signal (i.e., the phase at time, $t = 0$) is the phase of the Fourier transform at the point of this energy concentration. The measurements of initial phase and frequency obtained from the Fourier transform can then be used to deduce the phase of the signal for any value of time.

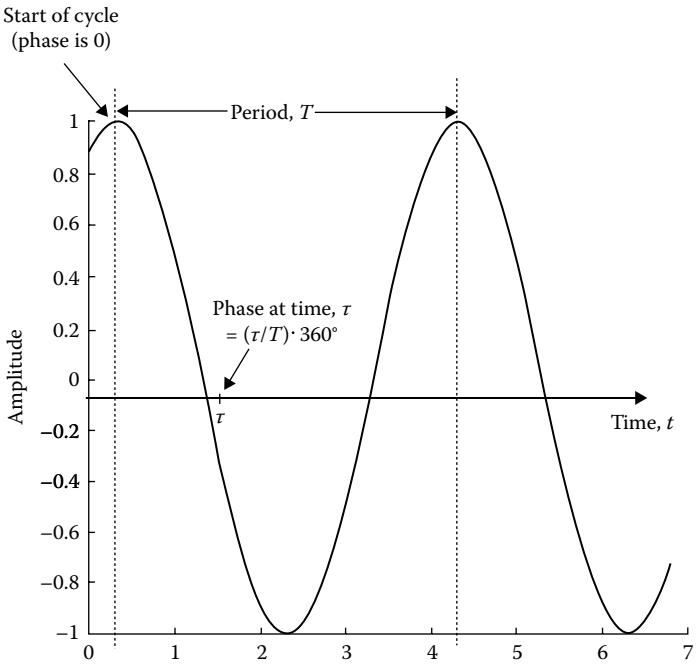

FIGURE 24.1 The phase of a periodic sinusoidal signal. The time scale is arbitrary.

Frequently what is needed in practice is a measurement of the *phase difference* between two signals of the same frequency; that is, it is necessary to measure the *relative phase* between two signals rather than the *absolute phase* of either one (see Figure 24.2). Often, in the measurement of the relative phase between two signals, both signals are derived from the same source. These signals might, for example, be the current and voltage of a power system; the relative phase, ϕ, between the current and voltage would then be useful for monitoring power usage, since the latter is proportional to the cosine of ϕ.

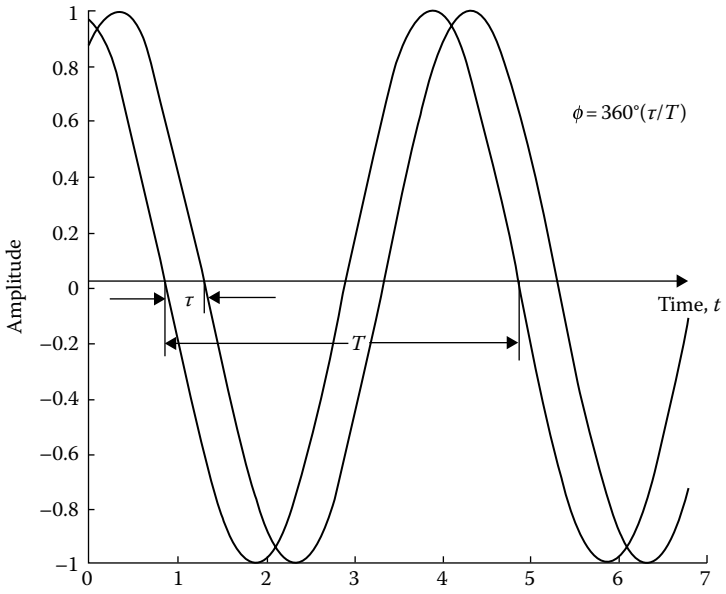

FIGURE 24.2 Two signals with a relative phase difference of ϕ between them. The time scale is arbitrary.

Several techniques are available for the measurement of "relative phase." One crude method involves forming "Lissajous figures" on an oscilloscope. In this method, the first of the two signals of interest is fed into the vertical input of a CRO, and the other is fed into the horizontal input. The result on the oscilloscope screen is an ellipse, the intercept and maximum height of which can be used to determine the relative phase. Other methods for determining relative phase include the crossed-coil meter (based on electromagnetic induction principles), the zero-crossing phase meter (based on switching circuitry for determining the fractional portion of the period completed), the three-voltmeter method (based on the use of three signals and trigonometric relationships), and digital methods (based on analog-to-digital [A/D] conversion and digital processing).

24.1 Amplitude, Frequency, and Phase of a Sinusoidal Signal

An arbitrary sinusoidal signal can be written in the following form:

$$s(t) = A\cos(2\pi ft + \phi_0) = A\cos(\omega t + \phi_0) \tag{24.1}$$

where

A is the peak amplitude
f is the frequency
ω is the angular frequency
ϕ_0 is the phase at time $t = 0$

This signal can be thought of as being the real part of a complex phasor that has amplitude, A, and which rotates at a constant angular velocity $\omega = 2\pi f$ the complex plane (see Figure 24.3).

Mathematically, then, $s(t)$ can be written as follows:

$$s(t) = \Re\mathrm{e}\left\{Ae^{j2\pi ft+\phi_0}\right\} = \Re\mathrm{e}\{z(t)\} \tag{24.2}$$

where

$z(t)$ is the complex phasor associated with $s(t)$
$\Re\mathrm{e}\{.\}$ denotes the real part

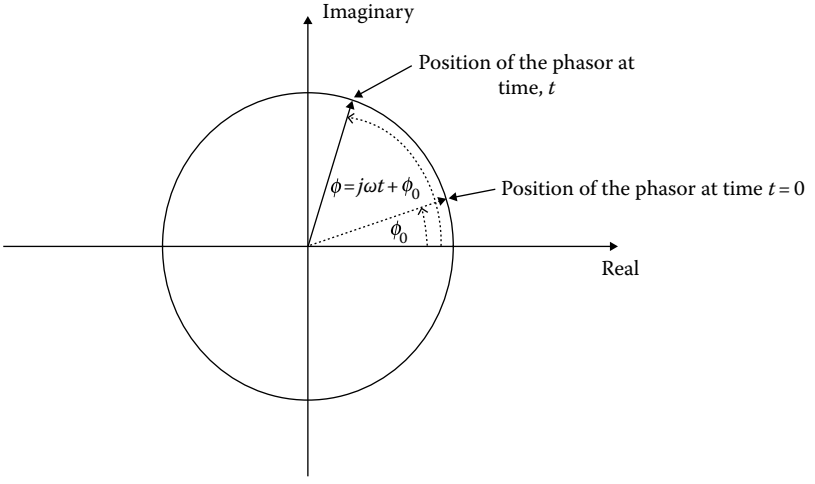

FIGURE 24.3 A complex rotating phasor, $A\exp(j\omega t + \phi_0)$. The length of the phasor is A and its angular velocity is ω. The real part of the phasor is $A\cos(\omega t + \phi_0)$.

The "phase" of a signal at any point in time corresponds to the angle that the rotating phasor makes with the real axis. The initial phase (i.e., the phase at time $t = 0$) is ϕ_0. The "frequency" f of the signal is $1/2\pi$ times the phasor's angular velocity.

There are a number of ways to define the phase of a real sinusoid with unknown amplitude, frequency, and initial phase. One way, as already discussed, is to define it as the fractional part of the period that has been completed. This is a valid and intuitively pleasing definition and one that can be readily generalized to periodic signals that contain not only a sinusoid but also a number of harmonics. It cannot, however, be elegantly generalized to allow for slow variations in the frequency of the signal, a scenario that occurs in communications with phase and frequency modulation. Gabor put forward a definition in 1946 that can be used for signals with slowly varying frequency. He proposed a mathematical definition for generating the complex phasor, $z(t)$, associated with the real signal, $s(t)$. The so-called *analytic signal* $z(t)$ is defined according to the following definition [1]:

$$z(t) = s(t) + jH\{s(t)\} \tag{24.3}$$

where $H\{\ \}$ denotes the *Hilbert transform* and is given by

$$H\{s(t)\} = p.v.\left[\int_{-\infty}^{+\infty} \frac{s(t-\tau)}{\pi\tau} d\tau\right] \tag{24.4}$$

with *p.v.* signifying the Cauchy principal value of the integral [2].

The imaginary part of the analytic signal can be generated practically by passing the original signal through a "Hilbert transform" filter. From Equations 24.3 and 24.4, it follows that this filter has impulse response given by $1/\pi t$. The filter can be implemented, for example, with one of the HSP43xxx series of integrated circuits (ICs) from Harris Semiconductor. Details of how to determine the filter coefficients can be found in [2].

Having formally defined the analytic signal, it is possible to provide definitions for phase, frequency, and amplitude as functions of time. They are given as follows:

$$\text{Phase: } \phi(t) = \arg\{z(t)\} \tag{24.5}$$

$$\text{Frequency: } f(t) = \frac{1}{2\pi}\frac{d[\arg\{z(t)\}]}{dt} \tag{24.6}$$

$$\text{Amplitude: } A(t) = \text{abs}[z(t)] \tag{24.7}$$

The definitions for phase, frequency, and amplitude can be used for signals whose frequency and/or amplitude varies slowly with time. If the frequency and amplitude do vary with time, it is common to talk about the "instantaneous frequency" or "instantaneous amplitude" rather than simply the frequency or amplitude.

Note that in the analytic signal, the imaginary part lags the real part by 90°. This property actually holds not only for sinusoids but for the real and imaginary parts of all frequency components in "multicomponent" analytic signals as well. The real and imaginary parts of the analytic signal then correspond to the "inphase (I)" and "quadrature (Q)" components used in communications systems.

In a balanced three-phase electric power distribution system, the analytic signal can be generated by appropriately combining the different outputs of the electric power signal; that is, it can be formed according to

$$z(t) = v_a(t) + \frac{j}{\sqrt{3}}[v_c(t) - v_b(t)] \tag{24.8}$$

where

$v_a(t)$ is the reference phase
$v_b(t)$ is the phase that leads the reference by 120°
$v_c(t)$ is the phase that lags the reference by 120°

24.2 Phase of a Periodic Nonsinusoidal Signal

It is possible to define "phase" for signals other than sinusoidal signals. If the signal has harmonic distortion components present in addition to the fundamental, the signal will still be periodic, but it will no longer be sinusoidal. The phase can still be considered to be the fraction of the period completed. The "start" of the period is commonly taken to be the point at which the initial phase of the fundamental component is 0, or at a zero-crossing. This approach is equivalent to just considering the phase of the fundamental and ignoring the other components. The Fourier method provides a very convenient method for determining this phase—the energy of the harmonics in the Fourier transform can be ignored.

24.3 Phase Measurement Techniques

24.3.1 Direct Oscilloscope Methods

CROs provide a simple means for measuring the phase difference between two sinusoidal signals. The most straightforward approach to use is direct measurement; that is, the signal of interest is applied to the vertical input of the CRO, and an automatic time sweep is applied to the horizontal trace. The phase difference is the time delay between the two waveforms measured as a fraction of the period. The result is expressed as a fraction of 360° or of 2π rad; that is, if the time delay is 1/4 of the period, then the phase difference is 1/4 of 360° = 90° (see Figure 24.2). If the waveforms are not sinusoidal but are periodic, the same procedure can still be applied. The phase difference is just expressed as a fraction of the period or as a fractional part of 360°.

Care must be taken with direct oscilloscope methods if noise is present. In particular, the noise can cause triggering difficulties that would make it difficult to accurately determine the period and/or the time delay between two different waveforms. The "HF reject" option, if available, will alleviate the triggering problems.

24.3.2 Lissajous Figures

Lissajous figures are sometimes used for the measurement of phase. They are produced in an oscilloscope by connecting one signal to the vertical trace and the other to the horizontal trace. If the ratio of the first frequency to the second is a rational number (i.e., it is equal to one small integer divided by another), then a closed curve will be observed on the CRO (see Figures 24.4 and 24.5). If the two frequencies are unrelated, then there will be only a patch of light observed because of the persistence of the oscilloscope screen.

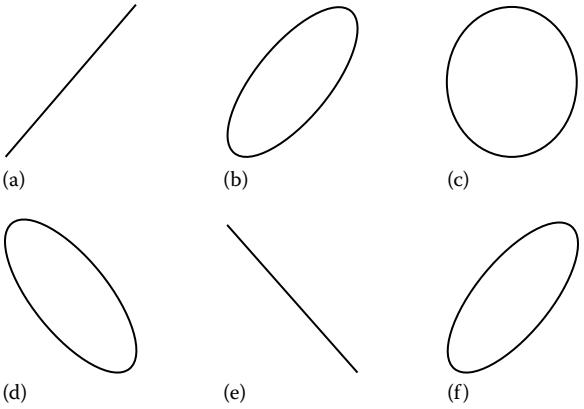

FIGURE 24.4 Lissajous figures for two equal-amplitude, frequency-synchronized signals with a relative phase difference of (a) 0, (b) $\pi/4$, (c) $\pi/2$, (d) $3\pi/4$, (e) π, and (f) $-\pi/4$.

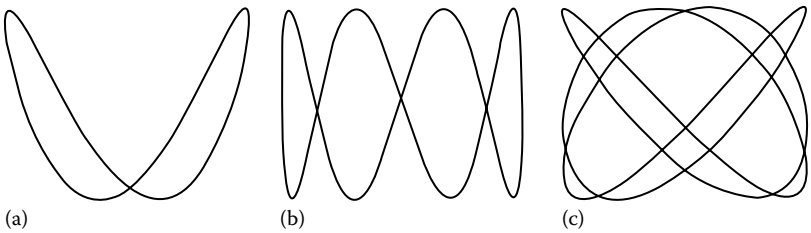

FIGURE 24.5 Lissajous figures for two signals with vertical frequency: horizontal frequency ratios of (a) 2:1, (b) 4:1, and (c) 4:3.

If the two signals have the same frequency, then the Lissajous figure will assume the shape of an ellipse. The ellipse's shape will vary according to the phase difference between the two signals and according to the ratio of the amplitudes of the two signals. Figure 24.6 shows some figures for two signals with synchronized frequency and equal amplitudes, but different phase relationships. The formula used for determining the phase is

$$\sin(\phi) = \pm\frac{Y}{H} \tag{24.9}$$

where

H is half the maximum vertical height of the ellipse
Y is the intercept on the *y-axis*

Figure 24.7 shows some figures for two signals that are identical in frequency and have a phase difference of 45°, but with different amplitude ratios. Note that it is necessary to know the direction that the Lissajous trace is moving in order to determine the sign of the phase difference. In practice, if this is not known a priori, then it can be determined by testing with a variable frequency signal generator. In this case, one of the signals under consideration is replaced with the variable frequency signal. The signal generator is adjusted until its frequency and phase equal that of the other signal input to the CRO. When this happens, a straight line will exist. The signal generator frequency is then increased a little, with the relative phase thus being effectively changed in a known direction. This can be used to determine the correct sign in Equation 24.9.

Lissajous figure methods are a little more robust to noise than direct oscilloscope methods. This is because there are no triggering problems due to random noise fluctuations. Direct methods are,

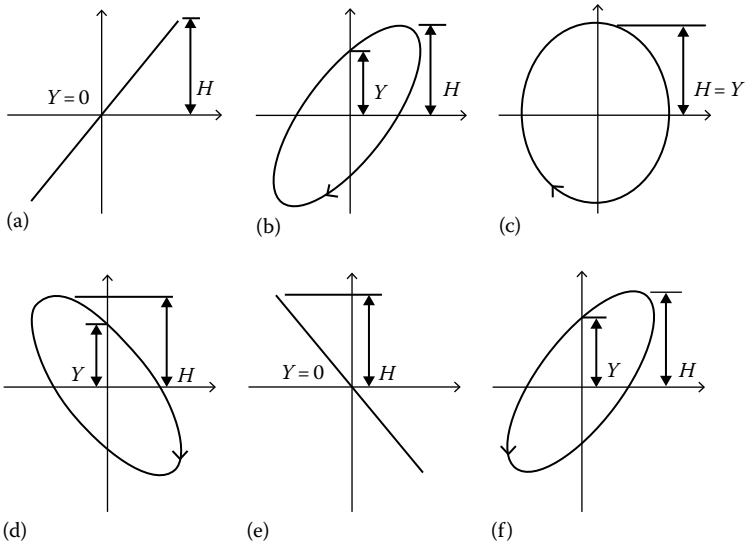

FIGURE 24.6 Lissajous figures for two signals with synchronized frequency and various phase differences: (a) phase difference = 0°, (b) phase difference = 45°, (c) phase difference = 90°, (d) phase difference = 135°, (e) phase difference = 180°, and (f) phase difference = 315°.

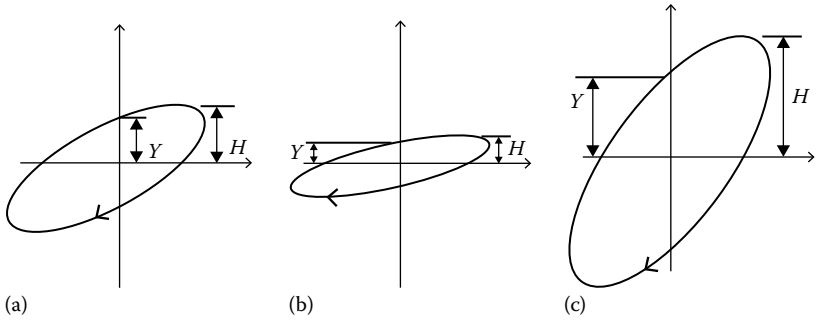

FIGURE 24.7 Lissajous figures for two signals with synchronized frequency, a phase difference of 45°, and various amplitude ratios: (a) amplitude ratio of 1, (b) amplitude ratio of 0.5, and (c) amplitude ratio of 2.

however, much easier to interpret when harmonics are present. The accuracy of oscilloscope methods is comparatively poor. The uncertainty of the measurement is typically in excess of 1°.

24.3.3 Zero-Crossing Methods

This method is currently one of the most popular methods for determining phase difference, largely because of the high accuracy achievable (typically 0.02°). The process is illustrated in Figure 24.8 for two signals, denoted *A* and *B*, that have the same frequency but different amplitudes. Each negative to positive zero-crossing of signal *A* triggers the start of a rectangular pulse, while each negative to positive zero-crossing of signal *B* triggers the end of the rectangular pulse. The result is a pulse train with a pulse width proportional to the phase angle between the two signals. The pulse train is passed through an averaging filter to yield a measure of the phase difference. It is also worth noting that if the positive to negative zero-crossings are also used in the same fashion and the two results are averaged, the effects of dc and harmonics can be significantly reduced.

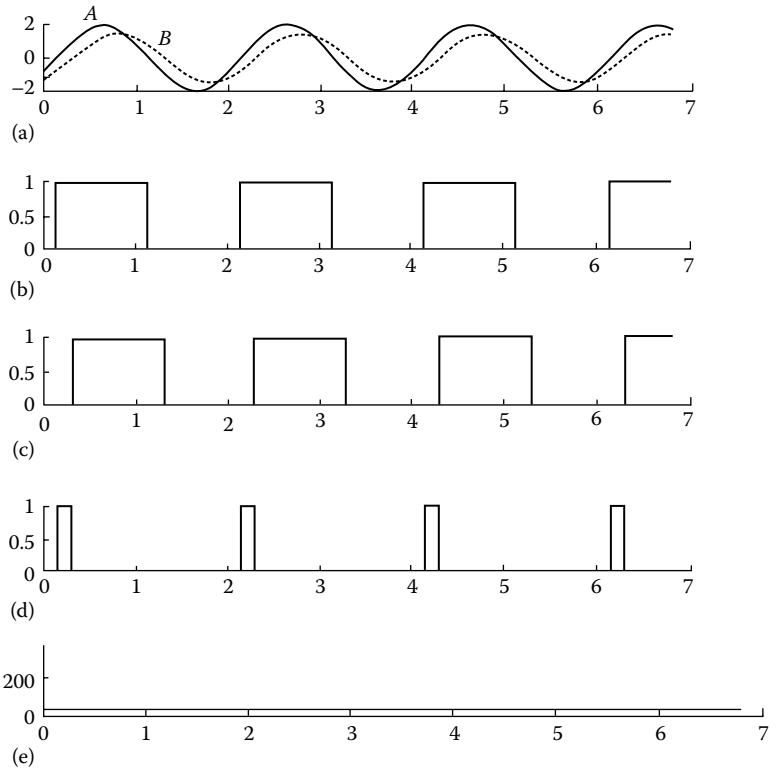

FIGURE 24.8 Input, output, and intermediate signals obtained with the zero-crossing method for phase measurement. Note that the technique is not sensitive to signal amplitude: (a) The two input signals, *A* and *B*; (b) zero-crossing detector output for *A*; (c) zero-crossing detector output for *B*; (d) bistable flip-flop output (the input signals are shown in (b) and (c)); (e) phase difference (degrees) obtained by averaging bistable output.

To implement the method practically, the analog input signals must first be converted to digital signals that are "high" if the analog signal is positive and "low" if the analog signal is negative. This can be done, for example, with a Schmitt trigger, along with an resistive-capacitive (*RC*) stabilizing network at the output. In practice, high-accuracy phase estimates necessitate that the switching of the output between high and low be very sharp. One way to obtain these sharp transitions is to have several stages of "amplify and clip" preceding the Schmitt trigger.

The digital portion of the zero-crossing device can be implemented with an edge-triggered RS flip-flop and some ancillary circuitry, while the low-pass filter on the output stage can be implemented with an RC network.

A simpler method for measuring phase based on zero-crossings involves the use of an exclusive or (XOR) gate. Again, the analog input signals must first be converted to digital pulse trains. The two inputs are then fed into an XOR gate and finally into a low-pass averaging filter. A disadvantage with this method is that it is only effective if the duty cycle is 50% and if the phase shifts between the two signals are between 0 and π rad. It is therefore not widely used.

24.3.4 Three-Voltmeter Method

The measurement of a phase difference between two voltage signals, v_{ac} and v_{bc}, can be expedited if there is a common voltage point, c. The voltage between points b and a (v_{ba}), the voltage between points b and c (v_{bc}), and the voltage between points c and a (v_{ca}) are measured with three different voltmeters. A vector diagram is constructed with the three measured voltages as shown in Figure 24.9. The phase difference

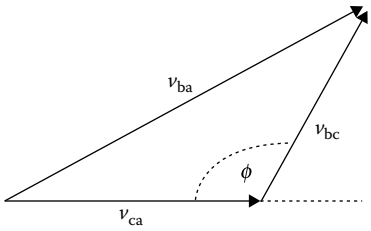

FIGURE 24.9 A vector diagram for determining the phase angle, ϕ, between two ac voltages, v_{ac} and v_{bc}, with the three-voltmeter method.

between the two vectors, v_{ac} and v_{bc}, is determined using a vector diagram (Figure 24.9) and the cos rule. The formula for the phase difference, ϕ, in radians is given by

$$\pi - \phi = \cos^{-1}\left(\frac{v_{ca}^2 + v_{bc}^2 - v_{ba}^2}{2v_{ca}v_{bc}}\right) \tag{24.10}$$

24.3.5 Crossed-Coil Method

The crossed-coil phase meter is at the heart of many analog power factor meters. It has two crossed coils, denoted A and B, positioned on a common shaft but aligned at different angles (see Figure 24.10). The two coils move as one, and the angle between them, β, never changes. There is another independent nonrotating coil, C, consisting of two separate parts, "enclosing" the rotating part (see Figure 24.10). The separation of coil C into two separate parts (forming a Helmholtz pair) allows the magnetic field of coil C to be almost constant in the region where the rotating A and B coils are positioned.

Typically the system current, I, is fed into coil C, while the system voltage, V, is applied to coil A via a resistive circuit. The current in coil A is therefore in phase with the system voltage, while the current in coil C is in phase with the system current. Coil B is driven by V via an inductive circuit, giving rise to a current that lags V (and therefore the current in coil A) by 90°. In practice, the angle between the currents in coils A and B is not quite 90° because of the problems associated with achieving purely resistive and purely inductive circuits. Assume, then, that this angle is β. If the angle between the currents in coil B and in coil C is ϕ, then the angle between the currents in coils A and C is $\beta + \phi$. The average torque induced in coil A is proportional to the product of the average currents in coils A and C and to

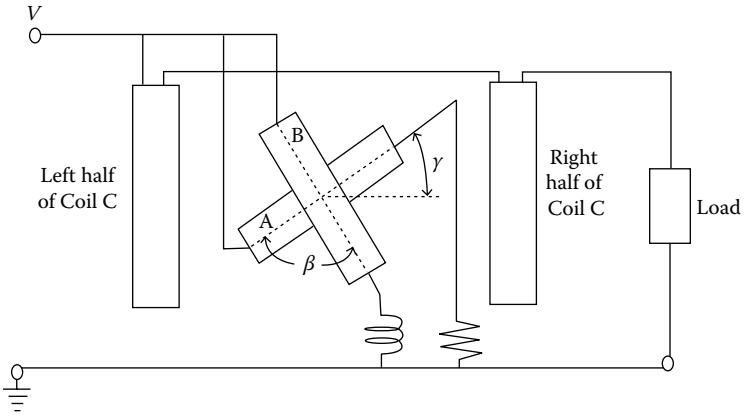

FIGURE 24.10 Diagram of a crossed-coil device for measuring phase. Coils A and B are the rotating coils. Coil C (left and right parts) is the stationary coil.

the cosine of the angle between coil A and the perpendicular to coil C. The average torque induced in coil A is therefore governed by the following equation:

$$\overline{T}_A \propto I_A I_C \cos(\phi + \beta)\cos(\gamma) = k_A \cos(\phi + \beta)\cos(\gamma) \tag{24.11}$$

where

I_A and I_C are constants
$\phi + \beta$ is the relative phase between the currents in coils A and C
γ is the angle between coil A and the perpendicular to coil C
$\propto$ signifies "is proportional to"

Assuming that the current in coil B lags the current in coil A by β, then the average torque in coil B will be described by

$$\overline{T}_B \propto I_B I_C \cos(\phi)\cos(\gamma + \beta) = k_B \cos(\phi)\cos(\gamma + \beta) \tag{24.12}$$

where

I_B is a constant
ϕ is the relative phase between the currents in coils B and C
the other quantities are as in Equation 24.11

Now, the torques due to the currents in coils A and B are designed to be in opposite directions. The shaft will therefore rotate until two torques are equal; that is, until

$$k_A \cos(\phi + \beta)\cos(\gamma) = k_B \cos(\phi)\cos(\gamma + \beta) \tag{24.13}$$

If $k_A = k_B$, then Equation 24.13 will be satisfied when $\phi = \gamma$. Thus, the A coil will be aligned in the direction of the phase shift between the load current and load voltage (apart from errors due to the circuits of the crossed coils not being perfectly resistive/inductive). Thus, a meter pointer attached to the A plane will indicate the angle between load current and voltage. In practice, the meter is usually calibrated to read the cosine of the phase angle rather than the phase angle and also to allow for the errors that arise from circuit component imperfections.

The accuracy of this method is limited, due to the heavy use of moving parts and analog circuits. Typically, the measurement can only be made accurate to within about 1° angle.

24.3.6 Synchroscopes and Phasing Lamps

The crossed-coil meter previously described is used as the basis for *synchroscopes*. These devices are often used in power generation systems to determine whether two generators are phase and frequency synchronized before connecting them together. In synchroscopes, the current from one generator is fed into the fixed coil and the current from the other generator is fed into the movable crossed coils. If the two generators are synchronized in frequency, then the meter needle will move to the position corresponding to the phase angle between the two generators. If the generators are not frequency synchronized, the meter needle will rotate at a rate equal to the difference between the two generator frequencies. The direction of rotation will indicate which generator is rotating faster.

When frequency synchronization occurs (i.e., the meter needle rotation ceases) and the phase difference is zero, the generators can be connected together. Often in practice, the generators are connected before synchronization occurs; the generator coming online is deliberately made a little higher in frequency so that it can provide extra power rather than be an extra drain on the system. The connection is still made, however, when the instantaneous phase difference is zero.

Phasing lamps are sometimes used as a simpler alternative to synchroscopes. A lamp is connected between the two generators, and any lack of frequency synchronization manifests as a flickering of the lamp. A zero-phase difference between the two generators corresponds to maximum brightness in the lamp.

24.3.7 Vector Voltmeters and Vector Impedance Methods

Alternating voltages (and currents) are often characterized as vectors consisting of a magnitude and a phase, with the phase being measured relative to some desired reference. Many instruments exist that can display the voltage amplitude and phase of a signal across a wide range of frequencies. These instruments are known as *vector voltmeters* or *network analyzers*. The phase and amplitude as a function of frequency can be obtained very simply in principle by taking the Fourier transform of the signal and simply reading the amplitude and phase across the continuum of frequencies. To achieve good accuracy, this is typically done with down-conversion and digital processing in the baseband region. The down-conversion can be analog, or it can be digital. The procedure is described more fully in the succeeding paragraphs.

To determine the real part of the voltage vector at a given frequency f, the signal is first down-converted by mixing with a local oscillator signal, $\cos(2\pi ft)$. This mixing of the signal recenters the frequency component of interest at 0 Hz. The resultant signal is low-pass filtered, digitally sampled (if not in the digital domain already), and averaged. The digital sampling and averaging enables the amplitude of the newly formed 0 Hz component to be evaluated. The imaginary part is obtained in similar fashion by mixing the signal with $\sin(2\pi ft)$, low-pass filtering, digitally sampling, and again averaging the samples. The amplitude and phase of the voltage vector, V, are obtained from the real and imaginary parts using the standard trigonometric relationships:

$$\text{Magnitude} = \text{Abs}(V) = \sqrt{[\Re\text{e}\{V\}]^2 + [\text{Im}\{V\}]^2} \tag{24.14}$$

$$\text{Phase} = \arg(V) = \arctan\left(\frac{\text{Im}\{V\}}{\Re\text{e}\{V\}}\right) \tag{24.15}$$

where $\Re\text{e}\{.\}$ and $\text{Im}\{.\}$ denote the real and imaginary parts, respectively.

The procedure for forming the vector voltage is summarized in the block diagram in Figure 24.11. In practice, the down-conversion can be carried out in more than one step. For high-frequency signals, for example, the first stage might shift a large band of frequencies to the audio region, where further down-conversion is carried out. Alternatively, the first stage might shift a band of frequencies to the intermediate frequency (IF) band and the second stage to the audio band.

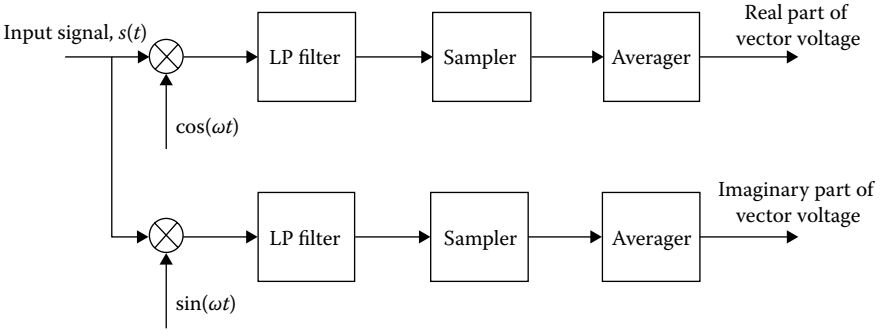

FIGURE 24.11 Vector voltmeter block diagram. The vector voltmeter determines the voltage (amplitude and phase or real and imaginary parts) of the component of the input signal at frequency f.

Just as it is possible to analyze a voltage signal and produce a magnitude and phase across any given frequency band, so it is possible to obtain a frequency profile of the magnitude and phase of a *current* signal. If current vectors and voltage vectors can be obtained for given impedance, then it is possible to obtain "vector impedance." This impedance is defined simply as the result of the complex division of voltage by current:

$$Z = \frac{V}{I} \tag{24.16}$$

The calculations of vector impedances are useful for such applications as impedance matching, power factor correction, and equalization.

Typically, much of the current processing for vector voltmeters and vector impedance meters is done digitally. One of the great advantages of this type of processing is the high accuracy achievable. Accuracies of 0.02° are common, but this figure is improving with developing technology. The high sampling rates that can be employed (typically beyond 1 GHz) cause the errors in the A/D conversion to be spread out over very large bandwidths. Since the ultimate measurement of a vector voltage or impedance is usually made over a very narrow bandwidth, the errors are substantially eliminated. The developments in technologies that enable greater accuracy are (1) sampling rate increases, (2) word-length increases, and (3) increased A/D converter fidelity.

24.3.8 Phase Standard Instruments

For high-precision phase measurements and calibration, "phase standard" instruments can be used. These instruments provide two sinusoidal signal outputs, whose phase difference can be controlled with great accuracy. They typically use crystal-controlled timing to digitally synthesize two independent sinusoids with a variable user-defined phase difference. The Clarke-Hess 5500 Digital Phase Standard is one such instrument. For this standard, the sinusoids can have frequencies ranging from 1 Hz to 100 kHz, while amplitudes can vary between 50 mV and 120 V rms. The phase can be set with a resolution of 0.001°, with a typical accuracy of about 0.003°.

24.3.9 Fast Fourier Transform Method

This method is one in which virtually all the processing is done in the digital domain. It operates on the pulse code modulated (PCM) digital samples of a signal. This and other similar methods are very promising means for measuring phase. This is because of the digital revolution that has resulted in cheap, fast, accurate, and highly versatile digital signal processors (DSPs). The latter are small computer chips capable of performing fast additions and multiplications that can be programmed to emulate conventional electronic functions such as filtering, coding, and modulation. They can also be programmed to perform a wide variety of functions not possible with analog circuitry. Up until the end of the 1980s, digital measurement was limited by the relatively inaccurate A/D conversion process required before digital processing could be performed. Developments in the early 1990s, however, saw the introduction of oversampling analog-to-digital converters (ADCs), which can achieve accuracies of about 1 part in 100,000 [3], ADC speeds as well as DSP chips are now running reliably at very high speeds.

In the fast Fourier transform (FFT) method, the digital signal samples are Fourier transformed with an FFT [2]. If the signal is sinusoidal, the initial phase is estimated as that value of the phase where the Fourier transform is maximized [4]. The frequency of the signal is estimated as that value of frequency where the Fourier transform is maximized. Once measurements of the frequency f and initial phase ϕ_0 have been obtained, the phase at any point in time can be calculated according to

$$\phi = 2\pi ft + \phi_0 \tag{24.17}$$

One important practical issue in the measurement of the frequency and initial phase with an FFT arises because the FFT yields only *samples* of the Fourier transform; that is, it does not yield a continuous Fourier transform. It is quite possible that the true maximum of the Fourier transform will fall *between* samples of the FFT. For accurate measurement of frequency and initial phase, then, it is necessary to *interpolate* between the FFT samples. An efficient algorithm to do this is described in [5].

The FFT method is particularly appealing where there is significant noise present, as it is effective down to quite low signal-to-noise ratios (SNRs). It provides an optimal estimate of the frequency and initial phase, provided that the background noise is white and Gaussian and that no harmonic components are present [4]. If harmonics are present, the estimate of the phase is commonly taken as the phase at the FFT peak corresponding to the fundamental; this is not an optimal estimate, but serves well in many applications. An optimal estimate in the case when harmonics are present can be obtained, if necessary, with the algorithms in [6–8]. DSP chips such as the Texas Instruments TMS320C3x family, the Analog Devices ADSP21020 chip, or the Motorola MC5630x series can be used to implement the real-time FFTs.

If long word-lengths are used (say 32 bit) to perform the arithmetic for the FFTs, then determination of the phase from the samples of the FFT is virtually error-free. The only significant inaccuracy incurred in determining the phase is due to the ADC errors. Moreover, the error due to the digitization will typically be spread out over a large bandwidth, only a small amount of which will be "seen" in the phase measurement. With a high-quality ADC, accuracies of less than 0.001° are possible.

24.3.10 Phase-Locked Loops

If the frequency of a signal changes significantly over the period of the measurement, the FFT method previously described will provide inaccurate results. If the signal's frequency does change substantially during measurement, one means to estimate the phase of the signal is to use a phase-locked loop (PLL). In this case, the signal, $s(t) = A\sin(\omega t + \phi(t))$, can be thought of as a constant frequency component, $A\sin(\omega t)$, which is phase modulated by a time-varying phase component, $\phi(t)$. The problem then reduces largely to one of demodulating a phase-modulated (PM) signal. A PLL can be used to form an estimate of the "phase-modulating" component, $\phi(t)$, and the overall phase of the signal, ϕ_{oa}, can be estimated according to

$$\phi_{oa}(t) = \omega t + \hat{\phi}(t) \tag{24.18}$$

Either analog or digital PLLs (DPLLs) can be used, although higher accuracy is attainable with DPLLs. Analog PLLs for demodulating a frequency-modulated (FM) signal are discussed in Chapter 84 and in [12]. The DPLL was developed as an extension of the conventional analog PLL and is therefore similar in structure to its analog counterpart. The DPLL is discussed in [9,10]. The equation to demodulate the digital modulated signal with a first-order DPLL is a simple recursive equation [9].

A block diagram of the DPLL for demodulating a PM signal is shown in Figure 24.12. In this diagram, n represents the discrete-time equivalent of continuous time t. It can be seen that there are

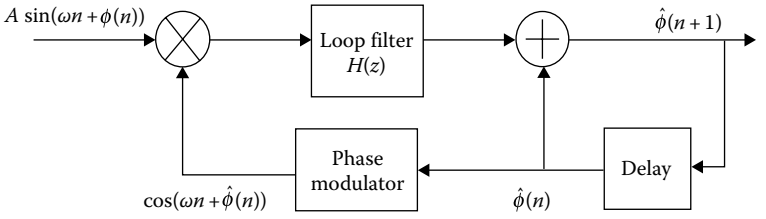

FIGURE 24.12 Block diagram of a DPLL to implement phase demodulation.

strong similarities between Figure 24.12 and the analog PLL-based FM demodulator in Chapter 81. Both have phase comparators (implemented by the multiplier in Figure 24.12), both have loop filters, and both have modulators (either PM or FM) in the feedback loop.

The DPLL can easily be extended to measure the phase of a signal consisting not just of a fundamental component but also of harmonically related components. Details are provided in [11]. The DPLL is near optimal for phase estimation in white Gaussian background noise down to a signal power-to-noise power ratio of about 8 dB [10].

The DPLL will function effectively whether the phase is constant or time varying. Unlike the FFT, the DPLL is a recursive algorithm, with the feedback involved in the recursion creating a vulnerability to quantization errors. However, with proper precautions and long word-lengths, the DPLL will introduce minimal processing error. The main error would then arise from the inaccuracy of the ADC. With appropriate conditioning, one could expect the DPLL to provide accuracies approaching 0.001°.

24.4 Phase-Sensitive Demodulation

It is frequently necessary to track the phase of a carrier that "jitters" in some uncertain manner. This tracking of the carrier phase is necessary for synchronous demodulation schemes, where the phase of the demodulating signal must be made equal to the phase of the carrier. This is briefly re-explained here. Consider, for example, double-sideband (DSB) amplitude modulation. In DSB, the modulated signal is given by $f_s(t) = A[k+\mu m(t)]\cos(\omega_c t)$, where $m(t)$ is the message signal, A is the amplitude of the unmodulated carrier, μ is the modulation index, k is the proportion of modulating signal present in the modulated signal, and $\cos(\omega_c t)$ is the carrier. Demodulation is typically carried out by multiplying $f_s(t)$ by the carrier and then low-pass filtering so that the demodulated signal is given by

$$f_d(t) = \frac{A_c[k + \mu m(t)]}{2} \tag{24.19}$$

However, if because of carrier uncertainty, one multiplies the modulated signal by $\cos(\omega_c t + \phi)$, then the demodulated signal is given by

$$f_d(t) = \frac{A_c[k + \mu m(t)]\cos(\phi)}{2} \tag{24.20}$$

It can be seen from Equation 24.20 that the error in the carrier phase can affect both the amplitude and the sign of the demodulated signal. The phase errors can thus yield substantial errors in system output. The following sections outline important techniques used for tracking the phase of carriers and thus reducing phase errors.

24.4.1 Phase-Locked Loop for Carrier Phase Tracking

The PLL is well known as a means for demodulating FM signals. It is also frequently used for tracking the phase of a carrier in noise, so that a copy of the carrier with correct phase is available for demodulation. This tracking is simple enough if a (noisy) copy of the carrier is directly available; either a digital or analog PLL can be used. In either case, the input can be assumed to have the form $A\sin(\omega t + \phi(t))$, where $\phi(t)$ is the carrier phase. The PLL consists of a multiplier (effectively a phase comparator), a phase modulator, and a loop filter. The design of the loop filter is critical if noise is to be optimally removed. In proper operation, the PLL output will track the phase of the incoming signal (i.e., of the carrier). If a copy of the carrier is not available but needs to be inferred from the modulated signal, the demodulation task is more difficult. DPLLs using a DSP chip can be particularly helpful in this case; the carrier

can be adaptively estimated using intelligent algorithms, with convergence to the "correct" signal being registered when certain desired features of the demodulated signal are observed.

The PLL is quite versatile. It can function in relatively low-noise environments (typically down to about 8 dB SNR). It can be implemented digitally. It can also cope with substantial carrier frequency variations by increasing the order of the loop filter [12] (this is often necessary, for example, in satellite communications because of the Doppler effect). At very low SNR, however, the PLL fails badly. Recent developments in digital signal processing have seen the development of an alternative based on hidden Markov models (HMMs), which will function down to about −5 dB SNR [13]. The HMM method is discussed in the next section.

24.4.2 Hidden Markov Model-Based Carrier Phase Tracker

In the HMM method, the problem of estimating the phase and frequency of a noisy waveform is couched as a "state estimation" problem. The phase of the signal at any point in time can go from 0 to 360°. The 0 to 360° value range is divided into a finite number of intervals or "states," so that the phase at any time occupies a particular (though unknown) state. Similarly, the angular frequency normalized by the sampling frequency at any time in a digital system must be between $-\pi$ and $+\pi$. This value range is also divided into a number of states, so that the frequency at any time has a (hidden or unknown) state associated with it. The frequency is assumed to be a first-order Markov process, and probabilities are assigned to the possibility of the frequency changing from one state to another for successive values of time, that is, frequency transition probabilities are assigned. Large frequency changes are assigned low probabilities, while small changes are assigned high probabilities. The problem of estimating the true phase and frequency states underlying the noisy signal then reduces to one of estimating which states the phase and frequency occupy as time evolves, given the observed noisy signal and the transition probabilities. Computationally efficient optimal algorithms have been developed to estimate these "optimal state sequences" for both the phase and frequency. Details are provided in [13].

24.5 Power Factor

Of particular interest in many applications is the phase angle between the current and voltage of a system. This angle is important because it is a measure of the power that is dissipated in the system. The following paragraphs discuss this angle, its cosine (the system power factor), and its measurement.

In a linear electric circuit that is fed by a current of peak amplitude, I_M, with an angular frequency of ω, the current will have the form, $I_M \cos(\omega t)$. The system voltage will be given by $V_M \cos(\omega t + \phi)$, where V_M is the peak voltage and ϕ is the phase difference between the current and voltage. Then the average power dissipated in the circuit will be given by

$$P_{av} = \frac{1}{2} V_M I_M \cos(\phi) = V_{rms} I_{rms} \cos(\phi) \tag{24.21}$$

where V_{rms} and I_{rms} are the root-mean-square (rms) values of the voltage and current, respectively. The term $\cos(\phi)$ is known as the *power factor*. It may alternatively be expressed as the ratio of real average power to the product of the rms values of voltage and current, respectively:

$$PF = \frac{P_{av}}{V_{rms} I_{rms}} \tag{24.22}$$

The previous expression is, in fact, a general definition of power factor for any current and voltage waveforms. For the special case of sinusoidal voltage and currents, *PF* reduces to $\cos(\phi)$.

There are a number of ways to measure the power factor. One way is to use a wattmeter to measure the real average power and a voltmeter and an ammeter to measure the rms voltage and current, respectively. The power factor is then determined according to Equation 24.22. This is probably the most effective way when the currents and/or voltages are nonsinusoidal. This procedure can easily be implemented with "digital power meters." The power is measured by time-averaging the product of the instantaneous voltage and current, while the rms values are calculated by taking the square root of the time-averaged value of the square of the parameter of interest—current or voltage. Some digital power meters also provide an analysis of the individual harmonics via FFT processing. These meters are accurate and versatile and consequently very popular.

A more direct method is based on the crossed-coil meter, the operation of which was described earlier in this chapter. Note that this meter is a "single-phase meter," which is accurately designed for one frequency only. Errors will occur at other frequencies because of the dependence of the crossed-coil meter method on a constant and known phase angle between the currents in the crossed coils.

With balanced polyphase circuits, it is possible to use a single-phase meter applied to one of the phases. Alternatively, one can use specially designed polyphase meters. In a three-phase meter, for example, one phase is connected to the fixed coil, while the other two phases are connected to the crossed coils on the rotating shaft. The crossed coils are constructed with a 60° angle between them. With four-phase systems, consecutive lines are 90° out of phase. Two of these consecutive lines are connected to the two crossed coils, and the angle between the coils is made equal to 90°.

With unbalanced polyphase circuits amid the presence of harmonics, each of the harmonic components has its own power factor, and so it is likely to be misleading to use a meter that measures a single angle. These methods based on the crossed-coil meter are thus much more limited than their digital counterparts.

24.6 Instrumentation and Components

Table 24.1 lists some ICs and DSP chips that can be used in the various techniques for measuring phase. The list is really only illustrative of what is available. Table 24.2 lists some companies that manufacture these products. An extensive (and indeed rapidly increasing) product range for DSP chip-based products, with details being available from the companies listed in Table 24.2. Table 24.3 lists instruments used for phase measurement. These instruments include CROs, vector voltage meters, vector impedance meters, crossed-coil meters and digital power meters, zero-crossing meters, and phase standards. Again, the table is only representative, as the full range of available instruments is enormous. Addresses of some of the relevant companies are provided in Table 24.4.

Energy Measurement

Arnaldo Brandolini
Politecnico di Milano

Alessandro Gandelli
Politecnico di Milano

Energy is one of the most important physical quantities in any branch of science and engineering and especially in electrical engineering. Energy exchange processes lead to the study of electric networks from the physical point of view and allow an in-depth knowledge of power transfer within the electrical world and between electric and other forms of energy.

The definitions of energy and power represent the starting point for any successive study:

1. Energy is the amount of work that the system is capable of doing.
2. Power is the time rate of doing work.

Energy can be mathematically defined as the definite integral of the power over a given time interval Δt.

The power p available in a two-terminal section of an electric circuit is given by the product of the voltage v across the terminals and the current i flowing through the section itself ($p = vi$). The electric energy (E) flowing through the same section is defined by the integral of the power over the observation interval:

$$E(\Delta t) = \int_{t_0}^{\Delta t + t_0} p\,dt \tag{25.1}$$

For this reason, energy measurement is a dynamic measurement, which means it varies with time. The energy measurement unit is the joule (J), but for the electric energy, the watt-hour (W-h) is most common.

The electrostatic energy is defined as the product of the electric charge and the difference of electric potential.

Electricity is generated from different forms of energy (thermal, hydraulic, nuclear, chemical, etc.); after electric transfer and distribution processes, it is converted to other forms of energy. The main feature of electric energy is the simplicity by which one can transfer it over long distances, control the distribution, and measure energy consumption.

25.1 DC Energy Measurements

The simplest way to perform this measurement is to measure voltage and current and then compute the product:

$$E = VI\Delta t \tag{25.2}$$

where Δt is the observation interval measured by means of a chronometer or a time counter.

Note that direct current (dc) systems are limited to a restricted number of applications in power systems, for example, electric traction, electric drives, electrochemical power plants, and HVDC transmission system in limited operating conditions. All these cases, nevertheless, allow energy measurement on either the dc or alternating current (ac) side of the network.

The dc energy measurement has been performed in the past by means of different methodologies and instruments such as electrodynamic measurement devices (Electrodynamics dc Energy Meter) operating as an integrating wattmeter (Figure 25.1). This measuring instrument is built using a small dc motor without iron, whose magnetic field is generated by the line current flowing through a coil arranged as the fixed part of the system. The rotor is connected in series with an additional resistor and is powered by the line voltage (V). Because of the lack of the iron in the magnetic circuit, the rotor magnetic flux ϕ is strictly proportional to the current I.

The rotor current (derived from the line voltage) is

$$I_V = \frac{(V - E)}{R} \tag{25.3}$$

where

$E = k_1 \Gamma \phi$ is the emf induced by the angular speed Γ

R is the total resistance of the voltage circuit

It is possible to make the emf E negligible because of low angular speed Γ, limited amplitude of the flux ϕ, and a significant resistance R. In this way, Equation 25.3 becomes

$$I_V \approx \frac{V}{R} \tag{25.4}$$

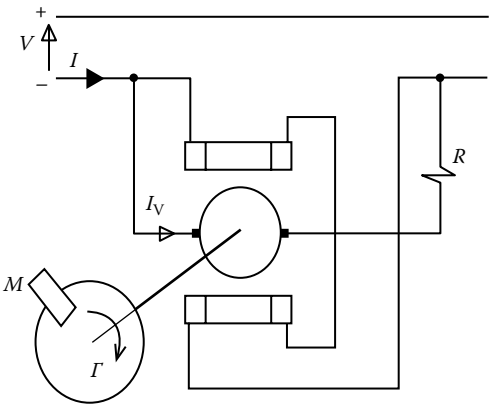

FIGURE 25.1 The electrodynamic dc energy meter. *M*, permanent magnet.

The torque C_m provided by the motor can be written as

$$C_m = k_2 \phi I_v \approx k_3 I \frac{V}{R} = k_4 P \tag{25.5}$$

C_m is therefore approximately proportional to the power P flowing through the line. It is necessary, however, to remember that this torque could create a high angular speed to the rotor, because of constantly incrementing speed. In order to maintain dynamic equilibrium, a simple aluminum disk mounted on the rotor axis and placed in a constant magnetic field provided by a permanent magnet M is added to the dc motor system. In this way, the induced currents in the disk introduce a damped torque proportional to the angular speed Γ, so, at equilibrium, there is a linear dependence of Γ on the power P. Thus,

$$E = \int_{\Delta t} P dt = k_5 \int_{\Delta t} \Gamma dt \tag{25.6}$$

A mechanical counter transfers the rotating motion into a digital representation of the total energy consumed during a specific time interval Δt in the power system.

25.2 AC Induction Energy Meters

The most traditional and widely used ac energy meter is the *induction meter*. This device is built by means of three electric circuits, magnetically coupled, two of them fixed and one rotating around the mechanical axis of the system. Figure 25.2 shows the two fixed circuits, (1) and (2), which are the voltage and the current coils. The third circuit is the rotating disk (3), generally made of aluminum, mounted on a rigid axis (4) transmitting the disk rotation to a mechanical counter (6), which provides the energy display.

The fixed circuits (1) and (2) provide magnetic fluxes interacting with the rotating disk. Fixed circuits (1) and (2) form a C shape and the disk is placed in their iron gaps. Another similar structure, arranged using a permanent magnet (5), is placed over the disk as well. The magnetic fluxes generated by the voltage and current circuits are at the same frequency and are sinusoidal. They induce currents in the

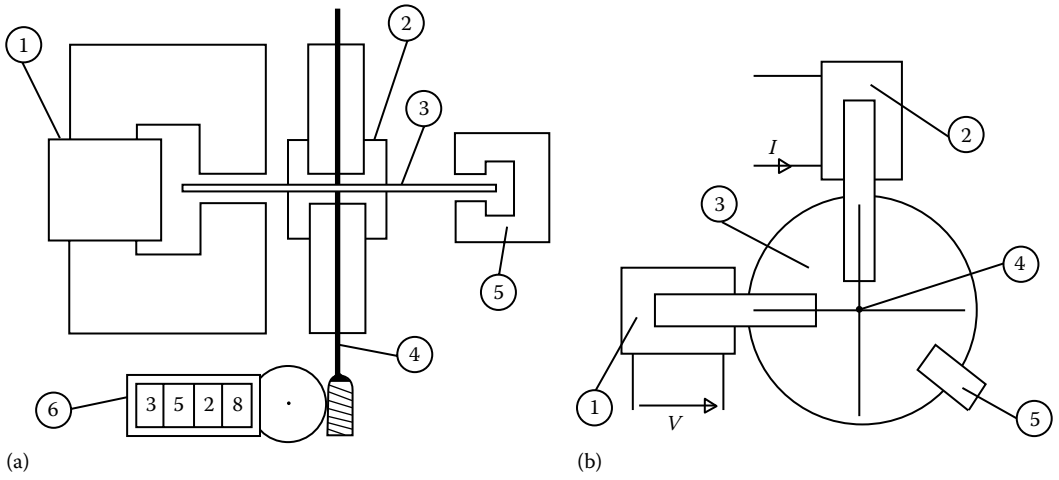

FIGURE 25.2 (a) Side view of an ac induction energy meter: (1) voltage coil and magnetic circuit; (2) current coil and magnetic circuit; (3) aluminum rotating disk; (4) disk axis; (5) permanent magnet; (6) mechanical display. (b) Top view of an ac induction energy meter; (1) voltage coil and magnetic circuit; (2) current coil and magnetic circuit; (3) aluminum rotating disk; (4) disk axis; (5) permanent magnet.

rotating disk that, by means of a cross-interaction with the two generating fluxes, provide mechanical torque acting on the disk. The torque is given by

$$C_m = KVI\sin(\alpha) \tag{25.7}$$

where

C_m is the mechanical torque
K is the system constant
V is the rms of the value of the applied voltage
I is the rms of the value of the applied current
α is the phase angle between the fluxes generated by V and I

The acting torque causes the disk to rotate around its axis. This rotation reaches a dynamic equilibrium by balancing the torque C_m of the voltage and current coils and the reacting torque generated by permanent magnet. The resulting angular speed, Γ, is therefore proportional to the flowing power if

- The angular speed Γ of the disk is much smaller than the voltage and current frequency ω.
- The phase difference between the voltage and current fluxes is equal to $\alpha = \pi - \varphi$, where φ is the phase difference between the voltage and current signals.

The angular speed of the rotating disk can be written as

$$\Gamma = \frac{1}{k}\omega\frac{R_3}{Z_3^2}(M_1 I)\left(\frac{M_2 V}{Z_2}\right)\cos(\phi) = KP \tag{25.8}$$

where

Γ is the angular speed of the rotating circuit (conductor disk), in rad s^{-1}
K is the instrument constant, in rad s^{-1} W^{-1}
P is the mean power in the circuit, in W
$1/k$ is the constant, in Ω V^{-2} s^{-2}
ω is the voltage and current frequency, in rad s^{-1}
R_3 is the equivalent resistance of the rotating disk, relative to the induced current fields, in Ω
Z_3 is the equivalent impedance of the rotating disk, relative to the induced current fields, in Ω
(M_2V/Z_2) is the rms value of the common flux related to the circuits *n*. 1 and 3, in Wb
(M_1I) is the rms value of the common flux related to the circuits *n*. 2 and 3, in Wb
Z_2 is the impedance of the voltage circuit (*n*. 1), in Ω
V is the rms value of the applied voltage, in V
I is the rms value of the applied current, in A
ϕ is the phase difference between current and voltage signals

The integral of Γ over a defined period Δt is proportional (with enough accuracy) to the energy flowing in the power circuit. Thus, it is true that the instrument constant K is strictly related (but not proportional) to the signal frequency ω.

25.3 Static Energy Meters

The development of electronic multipliers led to their use in energy meters that directly multiply voltage by current. In their first version, electronic multipliers used analog components (operational amplifiers, resistors, capacitors, etc.), while recent devices use digital components and programmable logic systems. Voltage and current signals are processed to obtain a signal proportional to the real power flowing into the line. The result is integrated over the observation time in order to calculate the *measured* energy. The devices based on these components are completely static (i.e., they do not have any moving parts).

Moreover, because these electronic components have a frequency range from dc to high frequencies, instruments based on them can be applied to dc, ac, or distorted power systems (some care must be taken in order to provide a correct sampling of signals in all-digital systems).

There are many different prototypes in this class of energy meters. The first realizations were based on analog multipliers and, even if they were not able to replace the traditional induction energy meters, they represented a good solution for all those applications where an increased accuracy was required (up to 0.2%). Now, more sophisticated digital instruments are under design and development, based on dedicated structures mainly implementing digital signal processors (DSPs) as powerful tools for numerical computation and sigma-delta analog-to-digital converters (ADCs) in order to optimize the conversion process.

Many of these instruments can be analyzed by means of the following functional descriptions.

25.3.1 Electronic Energy Meter

Figure 25.3 shows the block diagram of an electronic energy meter. The main feature of this type of instrument is the presence of voltage inputs on both voltage and current channels, because the electronic circuitry accepts only voltage signals. It has negligible current consumption from the system under measurement, due to high input impedance. Moreover, the maximum amplitude level of the input signal must be limited to around 5–15 V. For this reason, the conditioning apparatus must guarantee the correct current-to-voltage transformation and the proper voltage reduction. This type of instrument can work at dc (which omits voltage and current transformers) or ac power systems and can also measure energy from distorted signals.

25.3.2 Conditioning System for DC Electronic Energy Meters

The basic blocks of the conditioning system for a dc energy meter are formed from a voltage divider for the voltage input and a shunt for the current input. After these passive components, two preamplifiers are usually introduced before the processing system. The current preamplifier is very important because

1. The voltage output level of the current shunt is very low, even at full scale ($\leq$1 V).
2. Many times, the current input has to support overloaded signals; the presence of a variable gain amplifier allows acceptable working conditions for the system.
3. It can be used to implement an active filter before signal processing.

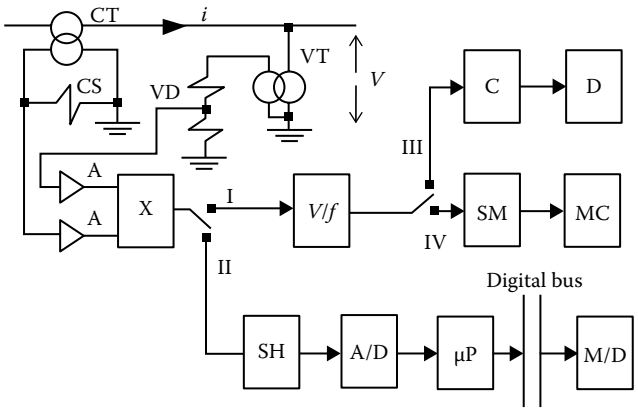

FIGURE 25.3 Electronic energy meter. Mechanical display option (I–IV). Electronic display option (I–III). Electronic display option and digital processing of the power signal (II). 25.3.3 Voltage and Current Adapters for AC Electronic Energy Meters

The most common devices to process ac signals for static energy meters are the traditional voltage and current transformers. They must be made with proper components to achieve the right amplitude of the voltage inputs (by nonreactive shunts for the current transformers and nonreactive voltage dividers for the voltage transformers). After the transformers, and related devices, a second block, based on electronic amplifiers, provides the final analog processing of the input signals, as for the dc conditioning systems. It is useful to introduce this second processing element because analog filters are generally required when the input signals need to be digitally processed.

25.3.4 Electronic-Analog Energy Meters with Digital Output

These instruments provide the product of the two input signals (both voltages) through an analog multiplier that evaluates a voltage output proportional to the power of the input signals. This output can be followed by a filtering block.

The output signal is proportional to the instantaneous electric power flowing through the line. To calculate the energy, it is now necessary to complete the process by integrating over the observation time. This last procedure can be performed in two different ways.

23.3.4.1 First Procedure

The power signal at the output of the analog multiplier is applied to the input of a voltage frequency converter. Thus, the power information is converted from a voltage level to the frequency pulse sequence, for which the counting process performs the integration of the power in the observation interval, that is, the measurement of energy.

The final measurement can be performed by means of an electronic counter with digital display or using a dc step motor incrementing the rotor angular position every pulse by a fixed angular increment. The rotor position is shown by a mechanical counter (similar to the system mounted on the induction energy meters) indicating the total number of complete rotations performed by the system, proportional to the energy of the system under measurement. This second arrangement is normally adopted because it allows a permanent record of the energy information, which is not subject to possible lack of electric energy as in the first case.

25.3.4.2 Second Procedure

This arrangement is based on an ADC connected to the output of the analog multiplier. The sampling process is driven by an internal clock. Thus, the ADC provides uniform sampling over the signal period and, under the condition imposed by the sampling theorem, the sum of the samples is proportional to the integral of the power signal, that is, to the energy during the observation interval.

The calculation is performed by means of a dedicated CPU and then the results are sent to the digital memory to be stored and displayed. They can also be used to manage any other automatic processes based on the energy measurement. For this purpose, data are available on a data bus (serial or parallel) connecting the measuring system with other devices.

The sampling process is performed by a sample and hold circuit.

25.3.5 All-Digital Energy Meters

The most advanced solution for energy measurement can be found in all-digital meters (Figure 25.4), where both the voltage and current signals are sampled before any other processing. Thus, the data bus presents the sampled waveforms in digital form, giving the opportunity to perform a wide choice of digital signal processing on the power and energy information. Both sampling devices are driven by a CPU, providing synchronized sampling signals.

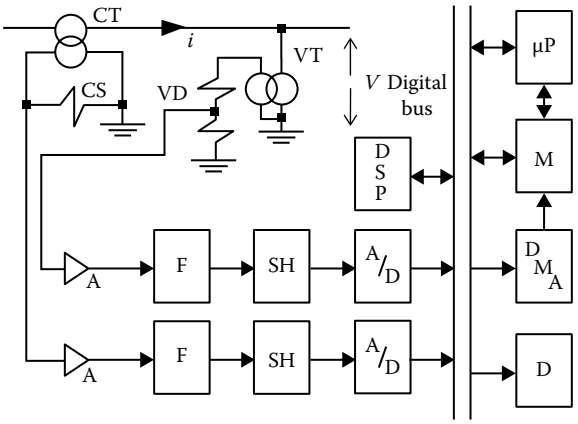

FIGURE 25.4 All-digital energy meter. CT, current transformer; VT, voltage transformer; CS, current shunt; VD, voltage divider; A, analog signal processing block; F, analog electronic filter; SH, sample and hold; A/D, analog-to-digital converter; μP, microprocessor (CPU); M, memory; DSP, digital signal processor; DMA, direct memory access circuit; D, display.

Sometimes, the system is equipped with a DSP capable of providing hardware resources to implement real-time evaluation of complex parameters (i.e., signal transforms) of the signal and energy measurement. Dedicated hardware and software performing instrument testing are also integrated into the meter to complete the device with the most advanced features.

Filters able to meet the sampling theorem requirements, programmable gain amplifiers, and sample and hold circuits generally precede the ADCs.

Data management is arranged in two possible ways: sending the sampled data directly to the processing system for calculations or accessing the memory using DMA procedures, so the data string for a specific time period is first stored and then used for computation of energy and related parameter values. Final results of this computation are then available on the system bus to be sent to the other system resources or to be displayed.

25.4 Accuracy of Energy Meters

Accuracy of energy meters is defined by means of relative parameters (in percent) obtained from a testing process by powering the instrument with a constant (nominal) voltage signal and a variable current signal (5%, 10%, 20%, 50%, 100%, and 120% of the nominal value). The testing procedures are performed by comparing the meter under test with a standard meter (Figure 25.5) or using equivalent methods.

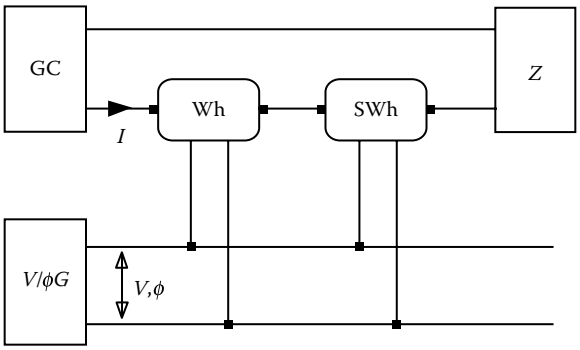

FIGURE 25.5 Testing circuit arrangement to compare an industrial meter (W-h) with a standard energy meter (SW-h). CG, variable-amplitude current generator; $V/\phi G$, variable-amplitude and phase voltage generator; Z, load impedance.

The accuracy of commercial electromechanical (induction) energy meters is generally around 2%. Energy meters with accuracies of 1% have also been built. Electronic energy meters have a better accuracy, generally between 0.5% and 0.2%.

Electrical Conductivity and Resistivity

Michael B. Heaney
Huladyne Research and Consulting

Electrical resistivity is a key physical property of all materials. It is often necessary to accurately measure the resistivity of a given material. The electrical resistivity of different materials at room temperature can vary by over 20 orders of magnitude. No single technique or instrument can measure resistivities over this wide range. This chapter describes a number of different experimental techniques and instruments for measuring resistivities. The emphasis is on explaining how to make practical measurements and avoid common experimental errors. More theoretical and detailed discussions can be found in the sources listed at the end of this chapter.

26.1 Basic Concepts

The electrical resistivity of a material is a number describing how much that material resists the flow of electricity. Resistivity is measured in units of ohmmeters (Ω m). If electricity can flow easily through a material, that material has low resistivity. If electricity has great difficulty flowing through a material, that material has high resistivity. The electrical wires in overhead power lines and buildings are made of copper or aluminum. This is because copper and aluminum are materials with very low resistivities (about 20 nΩ m), allowing electrical power to flow very easily. If these wires were made of high-resistivity material like some types of plastic (which can have resistivities about 1 EΩ m [1×10^{18} Ω m]), very little electrical power would flow.

Electrical resistivity is represented by the Greek letter ρ. Electrical conductivity is represented by the Greek letter σ and is defined as the inverse of the resistivity. This means a high resistivity is the same as a low conductivity and a low resistivity is the same as a high conductivity:

$$\sigma \equiv \frac{1}{\rho} \tag{26.1}$$

This chapter will discuss everything in terms of resistivity, with the understanding that conductivity can be obtained by taking the inverse of resistivity. The electrical resistivity of a material is an intrinsic physical property, independent of the particular size or shape of the sample. This means a thin copper wire in a computer has the same resistivity as the Statue of Liberty, which is also made of copper.

26.2 Simple Model and Theory

Figure 26.1 shows a simple microscopic model of electricity flowing through a material [1]. While this model is oversimplified and incorrect in several ways, it is still a very useful conceptual model for understanding resistivity and making rough estimates of some physical properties. A more correct understanding of the electrical resistivity of materials requires a thorough understanding of quantum mechanics [2].

On a microscopic level, electricity is simply the movement of electrons through a material. The smaller white circle in Figure 26.1 represents one electron flowing through the material. For ease of explanation, only one electron is shown. There are usually many electrons flowing through the material simultaneously. The electron tends to move from the left side of the material to the right side because an external force (represented by the large minus and plus signs) acts on it. This external force could be due to the voltage produced by an electrical power plant or a battery connected to the material. As the electron moves through the material, it collides with the "stationary" atoms of the material, represented by the larger black circles. These collisions tend to slow down the electron. This is analogous to a pinball machine. The electron is like the metal ball rolling from the top to the bottom of a pinball machine, pulled by the force of gravity. The metal ball occasionally hits the pins and slows down. Just like in different pinball machines, the number of collisions the electron has can be very different in different materials. A material that produces many collisions is a high-resistivity material. A material that produces few collisions is a low-resistivity material.

The resistivity of a material can vary greatly at different temperatures. The resistivity of metals usually increases as temperature increases, while the resistivity of semiconductors usually decreases as temperature increases. The resistivity of a material can also depend on the applied magnetic field.

The discussion thus far has assumed that the material being measured is homogeneous and isotropic. Homogeneous means the material properties are the same everywhere in the sample. Isotropic means

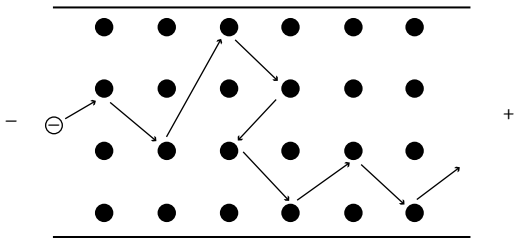

FIGURE 26.1 Simple model of electricity flowing through a material under an applied voltage. The white circle is an electron moving from left to right through the material. The black circles represent the stationary atoms of the material. Collisions between the electron and the atoms slow down the electron, causing electrical resistivity.

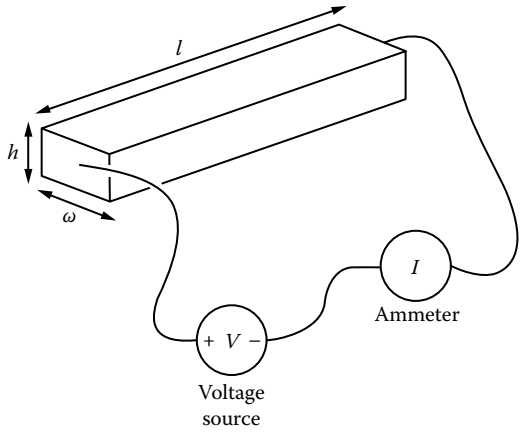

FIGURE 26.2 A two-point technique for measuring the resistivity of a bar of material. The voltage source applies a voltage across the bar, and the ammeter measures the current flowing through the bar.

the material properties are the same in all directions. This is not always a valid assumption. A more exact definition of resistivity is the proportionality coefficient ρ relating a local applied electric field to the resultant current density:

$$E \equiv \rho J \tag{26.2}$$

where

E is the electric field (V m^{-1})
J is the current density (A m^{-2})
ρ is a proportionality coefficient (Ω m)

Equation 26.2 is one form of Ohm's law. Note that E and J are vectors and ρ is, in general, a tensor. This implies that the current does not necessarily flow in the direction of the applied electric field. In this chapter, isotropic and homogeneous materials are assumed, so ρ is a scalar (a single number).

Now consider the bar-shaped sample shown in Figure 26.2. The electric field E is given by the voltage V divided by the distance l over which the voltage is applied:

$$E \equiv \frac{V}{l} \tag{26.3}$$

The current density J is given by the current I, divided by the cross-sectional area A through which the current flows:

$$J \equiv \frac{I}{A} \tag{26.4}$$

where the area A in Figure 26.2 is equal to the width w times the height h. Combining Equations 26.2 through 26.4 and rearranging gives

$$V = \frac{I\rho l}{A} \tag{26.5}$$

Now define a new quantity called "resistance" R with the definition:

$$R \equiv \frac{\rho l}{A} \tag{26.6}$$

Combining Equations 26.5 and 26.6 then gives

$$I = \frac{V}{R} \tag{26.7}$$

where

I is the current in amps (A) flowing through the sample
V is the voltage in volts (V) applied across the sample
R is the resistance in ohms (Ω) of the sample

Equation 26.7 is another form of Ohm's law.

Note that the resistance R can depend on the size and shape of the sample, while ρ is independent of the size or shape of the sample. For example, if the length l of the sample bar is doubled, the resistance will double but the resistivity will remain constant.

The quantitative relationship between the resistivity ρ and the simple microscopic model shown in Figure 26.1 is given by

$$\rho = \frac{m}{ne^2\tau} \tag{26.8a}$$

where

m is the mass of an electron
n is the number of electrons per unit volume carrying current in the material
e is the electric charge on an electron
τ is the average time between collisions of an electron with the stationary atoms of the material

If there were more electrons per unit volume, they could carry more current through the material. This would lower the resistivity. If the electric charge on the electrons were greater, then the applied voltage would pull harder on the electrons, speeding them up. This would lower the resistivity. If the average time between collisions with the stationary atoms were longer, then the electrons could get through the material quicker. This would lower the resistivity. If electrons could be made more massive, they would move slower and take longer to get through the material. This would increase the resistivity.

26.3 Experimental Techniques for Measuring Resistivity

26.3.1 Two-Point Technique

The resistivity of a material can be obtained by measuring the resistance and physical dimensions of a bar of material, as shown in Figure 26.2. In this case, the material is cut into the shape of a rectangular bar of length l, height h, and width w. Copper wires are attached to both ends of the bar. This is called the two-point technique, since wires are attached to the material at two points. A voltage

source applies a voltage V across the bar, causing a current I to flow through the bar. (Alternatively, a current source could force current through the sample bar, while a voltmeter in parallel with the current source measures the voltage induced across the sample bar.) The amount of current I that flows through the bar is measured by the ammeter, which is connected in series with the bar and voltage source. The voltage drop across the ammeter should be negligible. The resistance R of the bar is given by Equation 26.8b:

$$R = \frac{V}{I} \tag{26.8b}$$

where
R is the resistance in Ω
V is the voltage in V
I is the current in A

The physical dimensions can be measured with a ruler, a micrometer, or other appropriate instrument. The two-point resistivity of the material is then

$$\rho \equiv \frac{Rwh}{l} \tag{26.9}$$

where
ρ is the resistivity in Ω m
R is the measured resistance in Ω
w, h, and l are the measured physical dimensions of the sample bar in meters

In practice, measuring resistivity with a two-point technique is often not reliable. There is usually some resistance between the contact wires and the material or in the measuring equipment itself. These additional resistances make the resistivity of the material measure higher than it really is. A second potential problem is modulation of the sample resistivity due to the applied current. This is often a possibility for semiconducting materials. A third problem is that contacts between metal electrodes and a semiconducting sample tend to have other electrical properties that give wrong estimates for the actual sample resistivity. The four-point measurement technique overcomes many of these problems.

26.3.2 Four-Point Technique

Figure 26.3 shows the four-point measurement technique on a bar of material. Four wires are attached to the sample bar as shown. A current source forces a constant current through the ends of the sample bar. A separate ammeter measures the amount of current I passing through the bar. A voltmeter simultaneously measures the voltage V produced across the inner part of the bar. (Alternatively, a voltage source could apply a voltage across the outer contacts, while an ammeter in series with this voltmeter measures the current flowing through the sample bar.)

The four-point resistivity of the material is then

$$\rho = \frac{Vwh}{Il'} \tag{26.10}$$

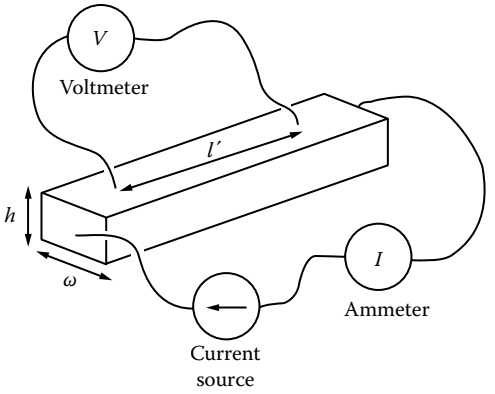

FIGURE 26.3 A four-point technique for measuring the resistivity of a bar of material. The current source forces a current through the bar, which is measured by a separate ammeter. The voltmeter measures the voltage across the middle of the bar.

where

ρ is the resistivity in Ω m
V is the voltage measured by the voltmeter in V
w is the width of the sample bar measured in m
h is the height of the sample bar measured in m
I is the current the ammeter measures flowing through the sample in A
l' is the distance between the two points where the voltmeter wires make contact to the bar, measured in m

Note that the total length l of the bar is not used to calculate the four-point resistivity: the length l' between the two inner contacts is used.

26.3.3 Common Experimental Errors

There are many experimental pitfalls to avoid when making resistivity measurements. The most common sources of error arise from doing a two-point measurement on a material that has any of the contact problems discussed earlier. For this reason, it is advisable to do four-point measurements whenever possible. This section describes experimental techniques to avoid errors in measuring resistivity:

1. The most difficult part of making resistivity measurements is often making good electric contacts to the sample. The general technique for making good electric contacts is to clean the areas of the sample where contacts are to be made with alcohol or an appropriate solvent and then apply the contacts. If this does not work, try scraping the surface with a razor blade where contact is to be made or cutting the sample to expose a fresh surface. Contacts can be made in many ways, such as using alligator clips and silver paint, squeezing a wire against the material, soldering wires to the material, and pressing small pieces of indium or a similar soft metal onto the contact areas. Contacts can age: a good contact can become a bad contact over time. It might be necessary to make fresh contacts to a sample that has aged. There are many complications involved in the electrical properties of contacts. Refer to the sources listed at the end of this chapter for more extensive discussions.
2. The measurement system should be calibrated before measuring any material samples. Calibration procedures are usually described in the equipment manuals.
3. The input resistance (or "impedance") of the voltmeter should be at least 10^5 higher than the resistance of the sample bar. The input impedance is usually listed in the equipment specifications.

Note that some voltmeters and electrometers have sufficiently high impedance between either of the inputs and ground, but not between the two inputs. In this case, it is necessary to use two voltmeters/electrometers (each with one input connected to the ground and the other input connected to the sample bar). Measure the difference between them to obtain the voltage across the sample.

4. The measurement system should be tested before measuring any material samples. First, test "short" with a thick copper wire or sheet in place of the sample. Then, test "open" with nothing in place of the sample. Finally, test with a known, calibrated resistor whose resistance is within an order of magnitude of the sample resistance.
5. The geometry of the sample and electric contacts can be important. Contacts are often made by painting silver paint or applying metal electrodes to the sample. If these contact areas are large or close to each other, this could reduce the accuracy of the resistivity measurement. It is best to make the two voltage contacts in a four-point measurement as small or thin as possible and make the distance between inner electrodes much larger than the sample thickness. This also allows a more accurate estimate of the effective volume of the sample being probed.
6. It is critical that the four contacts to the sample bar in a four-point measurement are completely independent; there should be nothing other than the material of the bar connecting each of the four wires at the bar. For example, when pieces of indium are used to attach wires to a small sample, it is easy to smudge two adjacent indium pieces into one another. Those two contacts are no longer independent and could easily cause errors. Visually inspect the contacts for this condition. If visual inspection is impractical, measure the resistance between the wires going to adjacent contacts. An unusually low resistance might indicate that two contacts are touching each other.
7. The applied voltage or current can cause heating of the material, which can change its resistivity. To avoid this problem, start with very small voltages or currents, and increase until the measured voltages and currents are at least 10 times larger than the random fluctuations of the meters. Then make sure the measured resistance is constant with time: the average resistance should not drift more than 10% in a few minutes.
8. Even if heating of the sample is not a problem, Ohm's law is not always obeyed. Many materials have a resistance that varies as the applied voltage varies, especially at higher voltages. Test for a linear relationship between current and voltage by measuring the resistance at several voltages on both sides of the measurement voltage. Whenever possible, make measurements in the linear (ohmic) region, where resistance is constant as voltage changes.
9. If one or both of the contacts to the voltmeter are bad, the voltmeter may effectively be disconnected from the material. In this situation, the voltmeter might display some random voltage unrelated to the voltage in the material. It might not be obvious that something is wrong, since this random voltage could accidentally appear to be a reasonable value. Check for this by setting the current source to zero amps and seeing if the voltmeter reading drops to zero volts. If it does not, try remaking the two inner contacts.
10. A critical check of a four-point measurement is to reverse the leads and remeasure the resistance. First, turn the current source to zero amps. Without disturbing any of the four contacts at the sample, swap the two sets of wires going to the voltmeter and the current source/ammeter. The two wires that originally plugged into the voltmeter should now plug into one terminal of the current source and one terminal of the ammeter. The two wires that originally plugged into the current source and ammeter should now plug into the voltmeter. Turn the current source on and remeasure the resistance. Note that current is now being forced to flow between the two inner contact points on the sample, while the voltage is being measured between the two outer contacts on the sample. The two measured resistances should be within 10% of each other.
11. The resistivity of some materials can depend on how much light is hitting the material. This is especially a problem with semiconductors. If this is a possibility, try blocking all light from the sample during measurement.

26.3.4 Sheet Resistance Measurements

It is often necessary to measure the resistivities of thin films or sheets of various materials. If the material can be made into the form of a rectangle, then the resistivity can be measured just like the bar samples in Figure 26.2:

$$\rho \equiv \frac{Vwh}{Il} \tag{26.11}$$

where

ρ is the sample resistivity in Ω m
V is the voltage measured by the voltmeter in V
w is the width of the sample measured in m
h is the thickness of the sample measured in m
I is the current the ammeter measures flowing through the sample in A
l is the length of the film measured in m

For the special case of a square film, the width w is equal to the length l and Equation 26.11 becomes

$$\rho \text{ (of square film)} \equiv \frac{Vh}{I} \tag{26.12}$$

The resistivity of a square film of material is called the "sheet resistivity" of the material and is usually represented by the symbol ρ_s. The "sheet resistance" R_s is defined by

$$R_s \equiv R \text{ (of square film)} = \frac{V}{I} \tag{26.13}$$

where

V is the voltage measured by the voltmeter in V
I is the current the ammeter measures flowing through the sample in A

The units for sheet resistance are Ω, but people commonly use the units "Ω per square." The sheet resistance is numerically equal to the measured resistance of a square piece of the material. Note that sheet resistance is independent of the size of the square measured, and it is not necessary to know the film thickness to measure sheet resistance. This makes sheet resistance a useful quantity for comparing different thin films of materials.

It is usually more convenient to measure thin-film samples of arbitrary shape and size. This is usually done by pressing four collinear, equally spaced contacts into a film whose length and width are both much greater than the spacing between contacts. In this situation, the sheet resistance is [3]

$$R_s = 4.532\frac{V}{I} \tag{26.14}$$

where

V is the voltage measured across the two inner contacts
I is the current applied through the two outer contacts

In many practical cases, the size of the thin-film sample will not be much greater than the spacing between the four-point contacts. In other cases, it might be necessary to measure a thin film near a corner or edge. In this situation, use geometric correction factors to accurately estimate the sheet resistance. These correction factors are available for the most commonly encountered sample geometries [3].

26.3.5 Instrumentation for Four-Point Resistivity Measurements

The resistivities of thin films of materials are often measured using commercial four-point probes. These probes generally have four equally spaced, collinear metal points that are pressed against the surface of the film. A current is applied between the outer two points, while the voltage is measured across the inner two points. These probes can also be used to measure the resistivity of bulk samples. Some companies that make probes and systems specifically for four-point resistivity measurements are listed in Table 26.1.

26.3.6 Instrumentation for High-Resistivity Measurements

Many materials such as rocks, plastics, and paper have very high resistivities, up to 1 EΩ m. The techniques described earlier for measuring resistivity are usually not reliable for these materials. In particular, it is often not possible to make a four-point measurement. One problem is that high voltages are needed to get any measurable current flowing through these materials. A second problem is that very long time constants prevent making steady-state measurements. A third problem is that the surfaces of these materials can often have significantly lower resistivity than the bulk, due to defects or other contamination. Measurements using the techniques described earlier then give falsely low values for the bulk resistivity. The best way to measure the resistivity of these materials is to use a specialized commercial instrument. These are designed to separate out the bulk resistivity from the surface resistivity and to minimize the many other problems encountered when measuring very high resistivities. Table 26.2 lists some companies that make high-resistivity measurement systems.

26.3.7 van der Pauw Technique

The four-point measurement technique described earlier has assumed the material sample has the shape of a rectangular thin film or a bar. There is a more general four-point resistivity measurement technique that allows measurements on samples of arbitrary shape, with no need to measure all the physical dimensions of the sample. This is the van der Pauw technique [4]. There are four conditions that must be satisfied to use this technique:

1. The sample must have a flat shape of uniform thickness.
2. The sample must not have any isolated holes.
3. The sample must be homogeneous and isotropic.
4. All four contacts must be located at the edges of the sample.

In addition to these four conditions, the area of contact of any individual contact should be at least an order of magnitude smaller than the area of the entire sample. For small samples, this might not be possible or practical. If sufficiently small contacts are not achievable, it is still possible to do accurate van der Pauw resistivity measurements, using geometric correction factors to account for the finite size of the contacts. See Ref. [5] for further details.

The inset illustration of Figure 26.4 illustrates one possible sample measurement geometry. A more common geometry is to attach four contacts to the four corners of a square-shaped sheet of the material.

The procedure for doing a van der Pauw measurement is as follows:

1. Define a resistance $R_{ij,kl} \equiv V_{kl}/I_{ij,}$, where $V_{kl} \equiv V_k - V_l$ is the voltage between points k and l and I_{ij} is the current flowing from contact i to contact j.
2. Measure the resistances $R_{21,34}$ and $R_{32,41}$. Define $R_>$ as the greater of these two resistances and $R_<$ as the lesser of these two resistances.
3. Calculate the ratio $R_>/R_<$ as the corresponding value of the function $f(R_>/R_<)$ from Figure 26.4. Be careful to use the appropriate horizontal scale!

TABLE 26.1 (continued) Companies That Make Four-Point Resistivity Measurement Probes and Systems

Company and Comments
QuadTech, Inc. 100 Nickerson Rd., Suite 3 Marlborough, MA 01752-9605 Tel: (800) 253-1230 Fax: (508) 485-0295 http://www.quadtechinc.com QuadTech makes a four-point ohmmeter capable of measuring resistances from 1 μΩ to 2 MΩ
Quantum Design 11578 Sorrento Valley Rd. San Diego, CA 92121-1311 Tel: (800) 289-6996 Fax: (619) 481-7410 http://www.quandsn.com Quantum Design makes an automated system for measuring four-point resistivity, Hall mobility, and other properties over the temperature range 2–400 K in magnetic fields up to 14 T

4. Calculate the resistivity ρ_a using

$$\rho_a = \frac{\pi d(R_> + R_<) f(R_>/R_<)}{\ln 4} \tag{26.15}$$

where
ρ_a is the resistivity in Ω m
d is the thickness of the sample in m
resistances $R_>$ and $R_<$ are measured in Ω
ln 4 is approximately 1.3863

It is not necessary to measure the width or length of the sample.

5. Switch the leads to measure $R_{43,12}$ and $R_{14,23}$. Repeat steps 3 and 4 to calculate ρ_b using these new values for $R_>$ and $R_<$. If the two resistivities ρ_a and ρ_b are not within 10% of each other, either the contacts are bad or the sample is too nonuniform to measure reliably. Try making new contacts. If the two resistivities ρ_a and ρ_b are within 10% of each other, the best estimate of the material resistivity ρ is the average:

$$\rho = \frac{(\rho_a + \rho_b)}{2} \tag{26.16}$$

Note: The function $f(R_>/R_<)$ plotted in Figure 26.4 is defined by the transcendental equation:

$$f\left(\frac{R_>}{R_<}\right) \equiv \frac{-\ln 4(R_>/R_<)}{[1 + (R_>/R_<)\ln\{1 - 4^{-[(1+R_>/R_<)f]^{-1}}\}]} \tag{26.17}$$

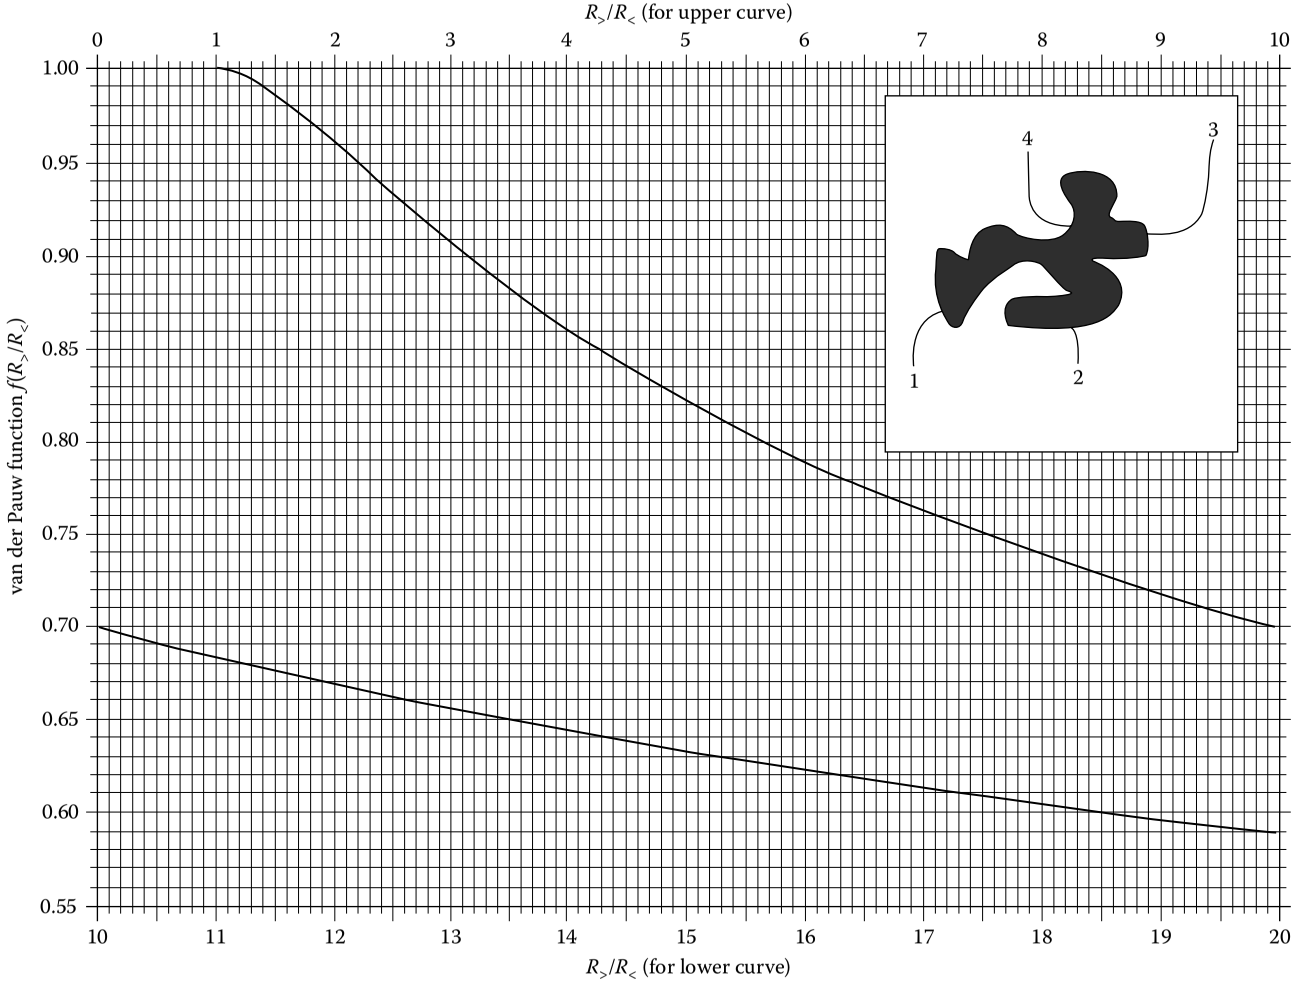

FIGURE 26.4 The van der Pauw technique. The inset shows one of the possible measurement geometries. The graph shows the function $f(R_>/R_<)$ needed to find the resistivity in Equation 26.15.

Defining Terms

Conductance: The inverse of resistance.

Conductivity: The inverse of resistivity.

Contact resistance: The resistance between the surface of a material and the electric contact made to the surface.

Four-point technique: A method for measuring the resistivity of a material, using four electric contacts to the material, which avoids many contact resistance problems.

Resistance: The physical property of a particular piece of a material, quantifying the ease with which electricity can flow through it. Resistance will depend on the size and shape of the piece of material.

Resistivity: The intrinsic physical property of a material quantifying the ease with which electricity can flow through it. Resistivity will not depend on the size and shape of the piece of material. Higher resistivity means the flow of electricity is more difficult.

Sheet resistance: The resistance of a square thin film or sheet of material.

Two-point technique: A method for measuring the resistivity of a material, using two electric contacts to the material.

van der Pauw technique: A method of measuring the four-point resistivity of an arbitrarily shaped material sample.

Charge Measurement

Saps Buchman
Stanford University

John T. Mester
Stanford University

T.J. Sumner
Imperial College

Electric charge, a basic property of elementary particles, is defined by convention as negative for the electron and positive for the proton. In 1910, Robert Andrews Millikan (1868–1953) demonstrated the quantization and determined the value of the elementary charge by measuring the motion of small charged droplets in an adjustable electric field. The SI unit of charge, the *coulomb* (C), is defined in terms of base SI units as

$$1 \text{ coulomb} = 1 \text{ ampere} \times 1 \text{ second} \tag{27.1a}$$

In terms of fundamental physical constants, the coulomb is measured in units of the elementary charge e:

$$1\text{C} = 1.60217733 \times 10^{19} e \tag{27.1b}$$

where the relative uncertainty in the value of the elementary charge is 0.30 ppm [1].

Charge measurement is widely used in electronics, physics, radiology, and light and particle detection, as well as in technologies involving charged particles or droplets (e.g., toners used in copiers). Measuring charge is also the method of choice for determining the average value for small and/or noisy electric currents by utilizing time integration. The two standard classes of charge-measurement devices are the electrostatic voltmeters and the charge amplifiers.

Electrostatic instruments function by measuring the mechanical displacement caused by the deflecting torques produced by electric fields on charged conductors [2,3]. Electrostatic voltmeters also serve as charge-measurement devices, using the fact that charge is a function of voltage and instrument capacitance. This class of instruments can be optimized for a very wide range of measurements, from about 100 V to 100 kV full scale, with custom devices capable of measuring voltages in excess of 200 kV. The accuracy of electrostatic voltmeters is about 1% of full scale, with typical time constants of about 3 s. Their insulation resistance is between 10^{10} and 10^{15} Ω, with instrument capacitances in the range of 1–500 pF. Figure 27.1 gives a schematic representation of several types of electrostatic voltmeters.

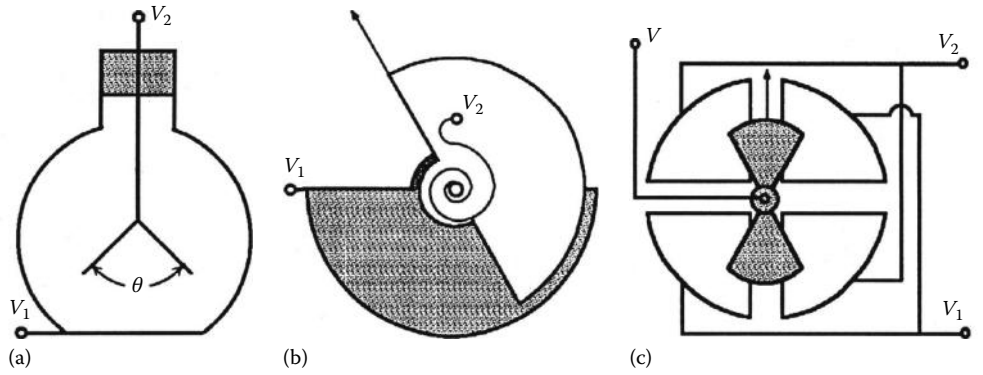

FIGURE 27.1 Examples of the repulsion, attraction, and symmetrical mechanical configurations of electrostatic voltmeters: (a) gold-leaf electroscope, (b) schematic representation of an attraction electrostatic voltmeter, and (c) a symmetrical quadrant electrostatic voltmeter. (From Harris, F., *Electrical Measurements*, John Wiley & Sons, New York, 1952.)

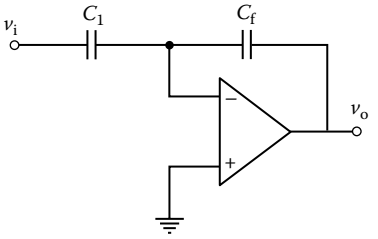

FIGURE 27.2 Basic concept of the charge amplifier. The output voltage is $v_o = C_1/C_f \times v_i$.

Modern electronic instruments have replaced in great measure the *electrostatic voltmeters* as devices of choice for the measurement of charge. The charge amplifier is used for the measurement of charge or charge variation [4]. Figure 27.2 shows the basic configuration of the charge amplifier. The equality of charges on C_1 and C_f results in

$$v_0 = \frac{C_1}{C_f} v_i \quad \text{or} \quad \Delta v_0 = \frac{C_1}{C_f} \Delta v_i \tag{27.2}$$

This same measurement principle is realized in the *electrometer*. The charge, Q, to be measured is transferred to the capacitor, C, and the value, V, of the voltage across the capacitor is measured: $Q = CV$. Figure 27.3 shows the block diagram for the typical digital electrometer [5]. Charge is measured in the coulomb mode, in which a capacitor C_f is connected across the operational amplifier, resulting in the input capacitance AC_f. Typical gain A for these amplifiers is in the range 10^4–10^6, making AC_f very large and thus eliminating the problem of complete charge transfer to the input capacitor of the coulombmeter. Electrometers have input resistances in the range 10^{14}–10^{16} Ω, resulting in very long time constants and thus minimizing the discharging of the capacitor. Typical leakage currents are from 5×10^{-14} to 5×10^{-16}A, again minimizing the variation in the charge. In the coulombmeter mode, electrometers can measure charges as low as 10^{-15} C and currents as low as 10^{-17} A.

Errors in charge-measurement instruments are caused by extraneous currents [5]. These currents are generated as thermal noise in the shunt resistance, by resistive leakage and by triboelectric, piezoelectric, pyroelectric, electrochemical, and dielectric absorption effects. The coulombmeter

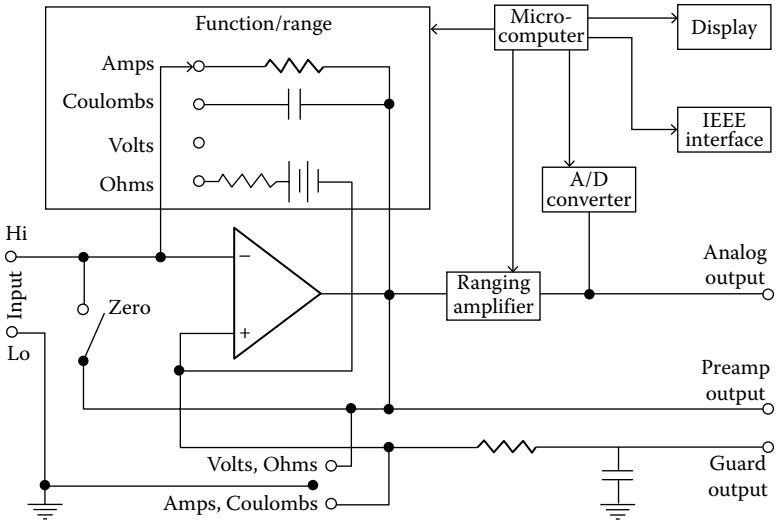

FIGURE 27.3 Conceptual block diagram of the digital electrometer. In the coulomb function, the charge to be determined is transferred to the corresponding capacitor, and the voltage across this capacitor is measured.

function of the electrometers does not use internal resistors, thus eliminating this thermal noise source. Triboelectric charges due to friction between conductors and insulators can be minimized by using low-noise triaxial cables and by reducing mechanical vibrations in the instrument. Under mechanical stress, certain insulators will generate electric charge due to piezoelectric effects. Judicious choices of materials and reduction of stress and mechanical motion can significantly reduce this effect.

Trace chemicals in the circuitry can give rise to electrochemical currents. It is therefore important to thoroughly clean and dry chemicals of all sensitive circuitry. Variations in voltages applied across insulators cause the separation and recombination of charges and thus give rise to dielectric absorption parasitic currents. The solution is to limit the voltages applied to insulators used for high-sensitivity charge measurements to less than about 5 V.

Dielectric materials used in sensitive charge-measurement experiments should be selected for their high resistivity (low-resistive leakage), low water absorptivity, and minimal piezoelectric, pyroelectric, triboelectric, and dielectric absorption effects. Sapphire and polyethylene are two examples of suitable materials. *Guarding* is used to minimize both shunt currents and errors associated with the capacitance of cables and connectors. The block diagram in Figure 27.3 shows typical guarding arrangements for modern electrometers.

27.1 Electrostatic Voltmeters

Electrostatic voltmeters and the more sensitive mechanical electrometers use an indicator to read out the position of a variable capacitor. Depending on their mechanical configuration, the electrostatic voltmeters can be categorized into three types: repulsion, attraction, and symmetrical [2,3]. The moving system in the high-sensitivity instruments is suspended from a torsion filament or pivoted in precision bearings to increase ruggedness. A wide variety of arrangements are used for the capacitive elements, including parallel plates, concentric cylinders, and hinged plates. Motion damping of the moving parts is provided by air or liquid damping vanes or by eddy current damping.

One of the oldest devices used to measure charge is the *gold-leaf electroscope*, shown in Figure 27.1a. Thin leaves of gold are suspended from a conductive contact that leads out of a protective case through an insulator. As charge applied to the contact is transferred to the leaves, the leaves separate by a certain angle,

the mutual repulsion being balanced by gravity. In principle, this device can also be used to measure the voltage difference between the contact electrode and the outer case, assuming the capacitance as a function of leaf separation angle is known. The electroscope is an example of a repulsion-type device, as is the Braun voltmeter in which the electroscope leaves are replaced by a balanced needle [2]. The delicate nature and low accuracy of this class of instruments limit their use in precise quantitative measurement applications.

An example of an attraction electrostatic voltmeter used for portable applications is shown in Figure 27.1b. While the fixed sector disk is held at V_1, the signal V_2 is applied to the movable sector disk through a coil spring that supplies the balancing torque. Opposite charges on the capacitor cause the movable plate to rotate until the electric attraction torque is balanced by the spring. If a voltage $V = V_1 - V_2$ is applied, the electric torque is given by [3]

$$\tau = \frac{dU}{d\theta} = \frac{d(1/2(CV)^2)}{d\theta} = \frac{1}{2}V^2\frac{dC}{d\theta} \tag{27.3}$$

The balancing spring torque is proportional to angular displacement, so the angle at equilibrium is given by

$$\frac{1}{2}V^2\frac{dC}{d\theta} = K\theta \tag{27.4}$$

Since the rotation is proportional to V^2, such an instrument can be used to measure ac voltages as well.

Symmetrical instruments are used for high-sensitivity, low-voltage measurements. The voltage is applied to a mobile element positioned between a symmetrical arrangement of positive and negative electrodes. Common mode displacement errors are thus reduced, and the measurement accuracy increased. One of the first devices sensitive enough to be called an "electrometer" was the quadrant electrometer shown schematically in Figure 27.1c. As a voltage difference, $V_1 - V_2$, is applied across the quadrant pairs, the indicator is attracted toward one pair and repelled by the other. The indicator is suspended by a wire allowing the stiffness of the suspension to be controlled by the potential V, so that the displacement is given by [2]

$$\theta = K\left[(V_1 - V_2)\left(V - \frac{1}{2}(V_1 - V_2)\right)\right] \tag{27.5}$$

where K is the unloaded spring constant of the suspension.

The advantage of electrostatic instruments is that the only currents they draw at dc are the leakage current and the current needed to charge up the capacitive elements. High-performance symmetrical electrostatic instruments have leakage resistances in excess of 10^{16} Ω, sensitivities of better than 10 μV, and capacitances of 10–100 pF. They are capable of measuring charges as small as 10^{-16} C and are sensitive to charge variations of 10^{-19} C.

Historically, as stated earlier, the symmetrical electrostatic voltmeters have been called "electrometers." Note that this can give rise to some confusion, as the term *electrometer* is presently also used for the electronic electrometer. This is a high-performance dc multimeter with special input characteristics and high sensitivity, capable of measuring voltage, current, resistance, and charge.

Modern noncontacting electrostatic voltmeters have been designed for voltage measurements up to the 100 kV range. An advantage of these instruments is that no physical or electric contact is required between the instrument and test surface, ensuring that no charge transfer takes place. Kawamura et al. [6] report the design of an attraction-type device that uses a strain gage to determine the displacement of a movable plate electrode. Hsu and Muller [7] have constructed a micromechanical shutter to modulate the capacitance between the detector electrode and the potential surface to be measured. Trek Inc. [8] electrostatic voltmeters achieve a modulated capacitance to the test surface by electromechanically vibrating the detector electrode. Horenstein [9], Gunther [10], and MacDonald and Fallone [11] have employed noncontacting electrostatic voltmeters to determine the charge distributions on semiconductor and insulator surfaces. Tables 27.1 and 27.2 contain a selection of available commercial devices and manufacturers.

TABLE 27.1 Instruments Used in Charge Measurement Applications

Instrument Manufacturer	Model #	Description

27.2 Charge Amplifiers

The conversion of a charge, Q, into a measurement voltage involves at some stage the transfer of that charge onto a reference capacitor, C_r. The voltage, V_r, developed across the capacitor gives a measure of the charge as $Q = V_r/C_r$. There are two basic amplifier configurations for carrying out such measurements using the reference capacitor in either a *shunt* or *feedback* arrangement.

27.2.1 Shunt Amplifiers

Figure 27.4 shows a typical circuit in which the reference capacitor is used in a shunt mode. In this example, it is assumed that the charge that is to be measured is the result of the integrated current delivered by a time-dependent current source, $i(t)$. With the measurement circuit disconnected (switch in position s2), the charge on the source capacitor, C_s, at time τ will be $Q = \int_0^C i(t)dt$ (assuming Q starts from zero at $t = 0$), and the output voltage, V_o will be zero, as the input voltage to the (ideal) operational amplifier is zero. On closing the switch in position s1, the charge on C_s will then be shared between it and C_r and

$$V_o = \left(\frac{R_1 + R_2}{R_2}\right)\frac{Q}{C_s + C_r} \tag{27.6}$$

In order to accurately relate the output voltage to the charge Q, not only does the gain of the noninverting amplifier and the reference capacitance need to be known, which is relatively straightforward, but it is also necessary to know the source capacitance. This is not always easy to determine. The effect of any uncertainty in the value of C_s can be reduced by increasing the value of the reference capacitor to the point where it dominates the total capacitance. However, in so doing, the output voltage is also reduced and the measurement becomes more difficult. The dependence of the measurement on C_s is one of the main limitations to this simple method of charge measurement. In addition, any leakage currents into the input of the operational amplifier, through the capacitors, or back into the source circuitry during the measurement period will affect the result. For the most accurate measurements of low charge levels, *feedback amplifiers* are more commonly used.

27.2.2 Feedback Amplifiers

Figure 27.5 shows a circuit where the reference capacitor now provides the feedback path around the operational amplifier. The output voltage from this configuration for a given charge Q transfers from the source is then

$$V_o = \frac{AQ}{C_s + AC_r} \tag{27.7}$$

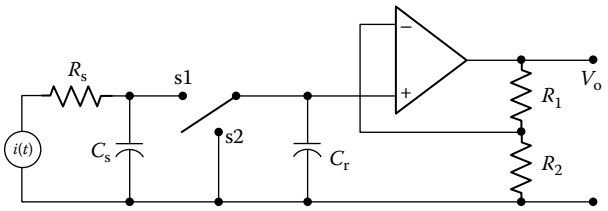

FIGURE 27.4 Schematic representation of a charge amplifier using a shunt reference capacitor. With the switch in position sl, the measurement circuit is connected and the charge is proportional to the output voltage and to the sum $C_s + C_r$. Note the significant sensitivity to C_s.

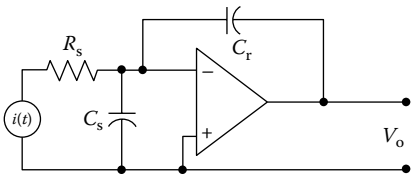

FIGURE 27.5 Schematic representation of a charge amplifier with reference feedback capacitor. The charge is proportional to the output voltage and to the sum $C_s + AC_r$, where A is the amplifier gain. Note the reduced sensitivity to C_s.

where A is the open-loop gain of the operational amplifier. For most situations, $AC_r > C_s$ and the charge measurement becomes independent of the source capacitance. In addition, the inverting input to the operational amplifier is kept close to ground potential, reducing the magnitude of leakage currents in that part of the circuit. However, in contrast to these two benefits is the new problem that the input bias current for the operational amplifier is integrated by the feedback capacitor, producing a continual drift in the output voltage. Several solutions have been used to overcome this problem, including the use of a parallel feedback resistor, R_f, which suppresses the integrating behavior at low frequencies (periods longer than R_fC_r), balancing the bias current with another externally provided current and incorporating a reset switch that discharges the circuit each time the output voltage ramps beyond a set trigger level.

The sensitivity of feedback amplifiers depends on the noise sources operating within any specific application. The most impressive performance is obtained by amplifiers integrated into charge-coupled device (CCD) chips that can, under the right operational conditions, provide sensitivities measured in terms of a few electron charges. To illustrate the important parameters involved in the design of ultralow-noise charge preamplifiers for CCD-type applications, consider the circuit shown in Figure 27.6. The source (detector) is now shown as a biased photodiode, which is assumed to be producing individual bursts of charge each time a photon (e.g., an x-ray) interacts in it. In this example, the photodiode is coupled to the amplifier using a large value capacitor, C_c. This blocks the direct current path from the diode bias supply, V_b, but provides a low-impedance path for the short-duration charge deposits. The preamplifier is a variant on that shown in Figure 27.5, in which there is now a parallel feedback resistor to provide baseline restoration on long time scales and an field effect transistor (FET) transistor to reduce the effect of the operational amplifier input bias current by virtue of its high current gain factor, β.

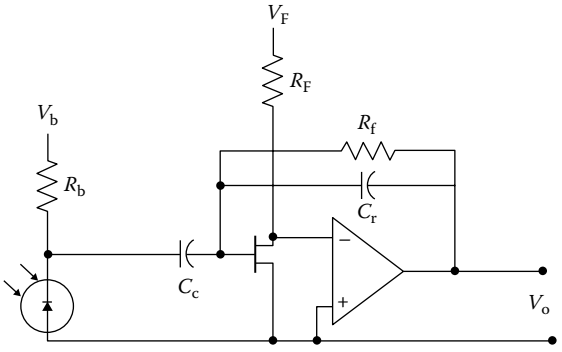

FIGURE 27.6 Typical ultralow-noise charge preamplifier configuration for charge pulse readout from ionization-type radiation detectors (e.g., x-ray detection using photodiodes or CCDs). The large capacitor C_c provides a low-impedance path for the short charge deposit pulses, while the parallel feedback resistor provides baseline restoration on long time scales. An FET transistor reduces the effect of the operational amplifier input bias current.

In practice, the dominant noise contributions in most applications of this type come from Johnson (current) noise in the bias and feedback resistors, shot noise on the photodiode bias current, voltage noise across the FET, and finally the inevitable 1/*f* component. The two resistors effectively feed thermal current noise into the input of the integrator. Similarly, the shot noise associated with the photodiode bias current feeds into the input. Together, these components are known as *parallel* noise and the total parallel noise charge, q_p, is given by

$$q_p = \sqrt{\left(\frac{4kT}{R_f + R_b} + 2eI_b(T)\right)\frac{1}{\Delta B}} \tag{27.8}$$

where

k is the Boltzmann's constant
e is the charge on the electron
T is the absolute temperature
ΔB is the bandwidth associated with the measurement that will depend on the details of subsequent shaping amplifier stages [12]

Voltage noise across the FET (and hence operational amplifier inputs) will arise from junction noise in the FET itself and from Johnson noise in its bias resistor, R_F. In practice, the FET junction noise usually dominates, in which case this *series* noise, q_s, contribution is given by

$$q_s = \sqrt{\varepsilon_n^2 C_{in}^2 \Delta B} \tag{27.9}$$

where

ε_n is the junction voltage noise for the FET in $V\sqrt{Hz^{-1}}$
C_{in} is the total capacitance seen at the gate of the FET

This will include both the source capacitance and the gate capacitance of the FET and any stray capacitance. The total noise is then the quadrature sum of Equations 27.8 and 27.9. The different dependencies on the bandwidth for Equations 27.8 and 27.9 imply there will be some optimum bandwidth for the measurement and this will depend on the relative contributions from each. 1/*f* noise manifests itself as a bandwidth-independent term that again must be added in quadrature. The Johnson noise associated with the resistors and FET junction will show a temperature dependence decreasing with $\sqrt{T}$. For the FET, this reduction does not continue indefinitely and there is usually an optimum temperature for the FET around 100 K. Photodiode bias currents also fall with decreasing temperature, and, for silicon devices, this is about a factor of 2 for every 10 K drop in temperature. Most ultralow-noise applications thus operate at reduced temperature, at least for the sensitive components. Bias resistors and feedback resistors are kept as high as possible (typically >100 MΩ), and FETs are specially selected for low junction voltage noise (typically 1 $nV\sqrt{Hz^{-1}}$). Ideally, photodiode capacitances should be kept as low as possible, and there is also interplay between the FET junction noise, ε_n, and the FET gate capacitance that is affected by altering the FET bias current, which can be used to fine-tune the series noise component.

Finally, there is another noise component that can often be critical and difficult to deal with. This is from microphonics. There are two effects. First, the feedback reference capacitor is typically made as small as possible (<1 pF) to reduce the effect of noise in the following shaping amplifier stages. This makes it sensitive to any stray capacitances and if there are vibrations in the system that alter the local geometry, then this can change the feedback capacitance that changes the "gain" of the preamplifier. Second, the photodiode will be operating with some applied bias voltage (often several tens of volts), and any change in its apparent capacitance through mechanical movement of components will result in

charge being moved around. These charge movements will be sensed by the charge amplifier. Ultralow-noise applications that ignore mechanical stability in their design phase are in peril. Tables 27.1 and 27.2 contain a selection of available commercial devices and manufacturers.

27.3 Applications

The Millikan technique of measuring charges on particles suspended in electric fields continues to be developed for various applications. Kutsuwada et al. [13] use a modified Millikan experiment to measure the charge distribution on electrophotographic toner particles of various sizes. They show a comparison of the results obtained using an ordinary Millikan apparatus and a modified system in which an additional ac electrode has been inserted in the hyperbolic quadrupole electrode assembly. The two methods agree to within a small multiplicative calibration factor. A different method of measuring the charge of toner particles uses the q/d meter [14] in which q and d refer, respectively, to the charge and the diameters of the particles. In the q/d meter, the charged particles are transported horizontally in a steady laminar air flow and move vertically in an electric field until deposited on a registration electrode. The position at which the particle is deposited on the registration electrode defines the charge-to-diameter ratio. The size of the deposited particle is then measured, thus completing the determination of the charge distribution for various particle sizes.

The experiments searching for fractional charges [15] make use of superconducting niobium spheres 0.25 mm in diameter, suspended in vacuum at 4.2 K in a magnetic field. The vertical position of the spheres is modulated by an alternating electric field and measured with an ultrasensitive magnetometer. Positrons and electrons generated by radioactive sources are used to cancel all integer charges on the spheres. Fractional charges are detected and measured as that residual charging of the niobium spheres that cannot be neutralized by the integral charges from the radioactive sources. Although this experiment is sensitive to about 0.01 electron charges (10^{-21} C), it has produced no conclusive evidence of fractional charges.

A similar approach, using force modulation, is used for the noncontact measurement of charge on gyroscopes [16]. Out-of-phase equal forces are applied to an electrostatically suspended gyroscope at a frequency well within the suspension control bandwidth. The charge of the gyroscope is then proportional to modulation frequency component of the suspension control effort. The sensitivity of this method is about 10^{-12} C gyroscope charge, limited by the allowable modulation force and position sensor noise.

Noncontact measurement of charge on liquid drops in a microgravity environment can be also performed using field mill instruments [17]. A mechanical chopper is used to modulate the electric field induced by the spherical charge on a grounded sensing plate. The resulting alternating current from sensor to ground is a measure of the charge on the drop. In a refinement of this method, the modulation is achieved by varying the distance between charge and sensor. The authors [18] claim that this system provides an increase in sensitivity of two to three orders of magnitude over the original technique.

Optical sensors based on the Pockels effect [19] are used to measure the space-charge field in gaseous dielectrics. The Pockels effect involves the change in the birefringence of certain crystalline materials on the application of an electric field. In the measuring system, a circularly polarized beam is detected after passing through the Pockels sensor and a polarizing plate. The detected intensity varies linearly with the intensity of the electric field applied to the sensor. This system is capable of performing a vector measurement of the electric field produced by the space charge, determining both intensity and direction.

Optical methods of charge measurement are also used for particles whose physical structure depends on their charge. An example is the degree of dissociation of the end groups of polystyrene particles in colloidal solutions [20]. In this application, the intensities of the Raman scattering spectrum lines depend on the degree of dissociation of the polystyrene end groups and thus determine the charge of these particles.

A widely used application of charge measurement is as an integral element of radiation dosimetry. Radiation is passed through ionization chambers, where the generated ions are collected and the charge

measured with electrometers. Ionization chambers used in dosimetry for radiation therapy have typical sensitivities in the range 0.02–0.2 nC R^{-1}. Coulombmeter electrometers with sensitivities of 1–10 pC are therefore required for this application.

Defining Terms

Charge, also **electric charge:** A basic property of elementary particles, defined by convention as negative for the electron and positive for the proton. The SI unit of charge is the coulomb (C), defined as 1 ampere (A) × 1 second (s).

Charge amplifier: Charge-measurement instrument. The charge is transferred to a reference capacitor and the resulting voltage across the capacitor is measured. Shunt and feedback versions of the charge amplifier have the reference capacitor used in shunt and feedback mode, respectively.

Electrometer: *Historic usage,* type of electrostatic voltmeter. *Modern usage*, electronic electrometer, a high-performance dc multimeter with special input characteristics and high sensitivity, capable of measuring voltage, current, resistance, and charge.

Electrostatic instrument: An instrument that functions by measuring the mechanical displacement or strain caused by electric fields.

Electrostatic voltmeter: Electrostatic instrument used to measure charge. The charge is determined as a function of voltage and instrument capacitance.

Capacitance and Capacitance Measurements

Halit Eren
Curtin University

28.1 Theory of Capacitance

A capacitor is a system of two conducting electrodes separated by a dielectric material. The electrodes have equal and opposite charges. The capacitance C of a capacitor is equal to the ratio of the absolute value of the charge Q to the absolute value of the voltage between the electrodes, which can be expressed as

$$C = \frac{Q}{V} \tag{28.1}$$

where
C is the capacitance in farads (F)
Q is the charge in coulomb (C)
V is the voltage (V)

The unit of capacitance, the farad, is a large unit; practical capacitors have capacitances in microfarads (μF or $l0^{-6}$ F), nanofarads (nF or 10^{-9} F), and picofarads (pF or 10^{-12} F). The conversions of these units are shown in Table 28.1.

The capacitance C depends on the size and shape of charged bodies and their relative positions; examples are shown in Table 28.2. Generally, capacitance is inherent wherever an electrostatic field is present. In many electronic systems, it is necessary to deal not only with the capacitances that are designed consciously within the circuits but also with the unwanted interference and the stray capacitances that are introduced externally or internally at various stages of the circuits. For example, some sensors operate

TABLE 28.1 Capacitance Unit Conversions

Microfarads	Nanofarads	Picofarads
l0^{-6} F	10^{-9} F	10^{-12} F
0.000001 μF	0.001 nF	1.0 pF
0.001 μF	1.0 nF	1,000 pF
1.0 μF	1000 nF	1,000,000 pF

on capacitance principles, giving useful signals; in others, capacitance is inherent but undesirable. In many cases, cables and external circuits introduce additional capacitances that need to be accounted for the desirable operation of the system. In these cases, Table 28.2 is useful to identify and analyze possible sources of capacitances where charged bodies are involved.

The capacitance of structure can be determined by solving Laplace's equations $\nabla^2 V(x,y,z) = 0$ with appropriate boundary conditions. The boundary conditions specify the electrode voltages V_1 and V_2 of the plates. Laplace's equation yields to V and the electric field $E(x,y,z) = -\nabla V(x,y,z)$ between the electrodes. The charge of each electrode can also be obtained by integration of the flux density over the surface are of each electrode, as

$$Q = \int \varepsilon(x,y,z)E(x,y,z)dA \tag{28.2}$$

If the capacitor is made from two parallel plates, as shown in Figure 28.1, the capacitance value in terms of dimensions can be expressed by

$$C = \frac{\varepsilon A}{d} = \varepsilon_r \varepsilon_0 \frac{A}{d} \tag{28.3}$$

where

ε is the dielectric constant or permittivity of material
ε_r is the relative dielectric constant (in air, $\varepsilon_r = 1$)
ε_0 is the dielectric constant of vacuum (8.854188×10^{-12} F m^{-1})
d is the distance of the plates in m
A is the effective area of two parallel plates in m^2

In arriving to Equation 28.3, the fringe field is neglected for small distances, d, between the plates.

Capacitances can also be expressed in terms of dielectric properties currents and voltages. Suppose that a uniform dielectric between two parallel plates has a resistance, R, which can be written as

$$R = \frac{d\rho}{A} \tag{28.4}$$

where ρ is the specific resistance of the dielectric in Ω m. Then, using Equation 28.3 and eliminating d and A gives

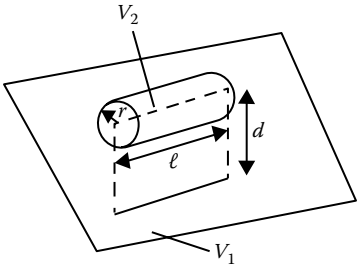
$$C = \frac{\varepsilon\rho}{R} \tag{28.5}$$

TABLE 28.2 Capacitances of Various Electrode Systems

 Parallel plates with a homogeneous dielectric	$C = \dfrac{\varepsilon A}{d}$
 Parallel plates with a two constituent dielectric	$C = \dfrac{(\varepsilon_1 r + \varepsilon_2)A}{(1+r)d}$, where r value is the volumetric ratio
 Parallel plates with two different dielectrics	$C = \dfrac{\varepsilon A}{(d_1/\varepsilon_1) + (d_2/\varepsilon_2)}$
 Coaxial cylinders with single dielectric	$C = \dfrac{4\pi\varepsilon\ell}{\ln(r_2/r_1)}$
 Coaxial cylinders with three dielectrics	$C = \dfrac{2\pi\varepsilon_0\ell}{\ln[(r_2/r_1)^{\varepsilon_0/\varepsilon_1} \times (r_3/r_2)^{\varepsilon_0/\varepsilon_2} \times (r_4/r_3)^{\varepsilon_0/\varepsilon_3}]}$ $= \left(\dfrac{1}{C_1} + \dfrac{1}{C_2} + \dfrac{1}{C_3}\right)^{-1}$

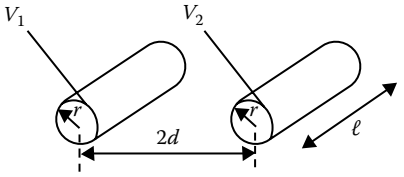
(*continued*)

TABLE 28.2 (continued) Capacitances of Various Electrode Systems



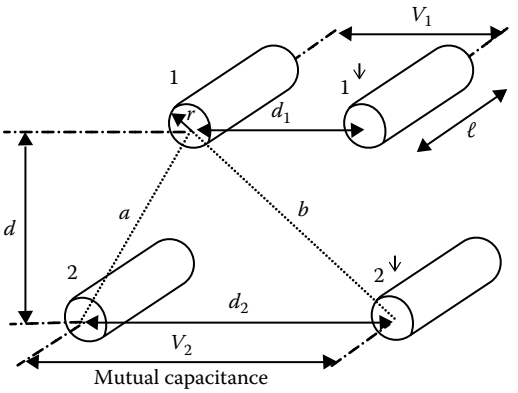
Cylinder parallel with plate

$$C = \frac{\pi\varepsilon\ell}{\ln\left[(d/r)+\sqrt{(d/r)^2-1}\right]} = \frac{2\pi\varepsilon\ell}{\cosh^{-1}(d/r)}$$



Parallel cylinders with equal radius

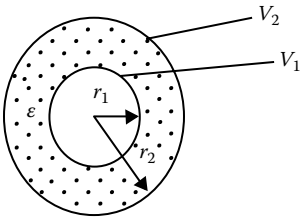
$$C = \frac{\pi\varepsilon\ell}{\ln\left[(d/r)+\sqrt{(d/r)^2-1}\right]} = \frac{\pi\varepsilon\ell}{\cosh^{-1}(d/r)}$$



Mutual capacitance

$$C_{11} = \frac{\pi\varepsilon\ell}{\ln(d_1/r)} + \frac{\pi\varepsilon}{2}\frac{\ln(b/a)}{[\ln(a/r)]\ln(b/r)}$$

$$C_{21} = C_{12} = \frac{\pi\varepsilon\ell}{2}\frac{\ln(b/a)}{[\ln(a/r)]\ln(b/r)}$$



Concentric spheres

$$C = \frac{4\pi\varepsilon r_1 r_2}{r_2 - r_1}$$

A voltage V across the capacitor causes a leakage current $I_l = V/R$ such that

$$C = \frac{\varepsilon\rho I_1}{V} \tag{28.6}$$

This indicates that the leakage current of a capacitor is simply proportional to its capacitance value.

As seen in Equations 28.3 and 28.4, the value of the capacitance is proportional to the permittivity of the dielectric material used. In the construction of capacitors, the permittivity of commonly used materials is given in Table 28.3.

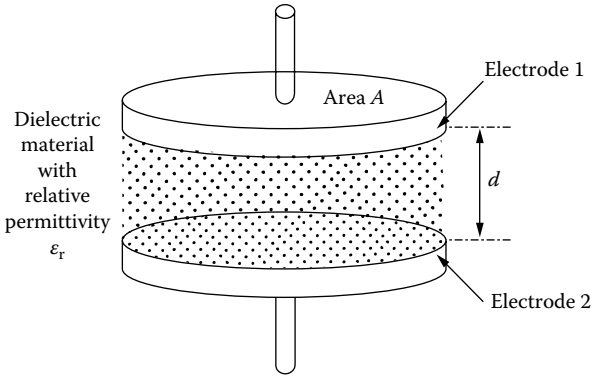


FIGURE 28.1 A basic capacitor made from two parallel plates. The capacitance between two charged bodies depends on the permittivity of the medium in between, the distance between the bodies, and the effective area. Capacitance can also be expressed in terms of the absolute values of the charge and the absolute values of the voltages between the bodies.

TABLE 28.3 Permittivity (Dielectric Constants of Materials Used in Capacitors)

Material	Permittivity
Vacuum	1.0
Air	1.0006
Teflon	2.1
Polyethylene, etc.	2.0–3.0
Impregnated paper	4.0–6.0
Glass and mica	4.0–7.0
Ceramic (low *K*)	≤20.0
Ceramic (medium *K*)	80.0–100.0
Ceramic (high *K*)	≥1000.0

28.2 Construction and Types of Capacitors

Commonly used fixed capacitors are constructed with dielectric materials of air, paper, mica, polymers, and ceramics. A comprehensive list of common capacitors and their characteristics are given in Tables 28.4 and 28.5. Variable capacitors are generally made with air or ceramic-dielectric materials. The capacitors used in electronic circuits can be classified as low-loss, medium-loss, and high-tolerance capacitors.

- *Low-loss capacitors* such as mica, glass, low-loss ceramic, and low-loss plastic film capacitors generally have good capacitance stability. These capacitors are expensive and often selected in precision applications, for example, telecommunication filters.
- *Medium-loss capacitors* have medium stability in a wide range of ac and dc applications. These are paper, plastic film, and medium-loss ceramic capacitors. Their applications include coupling, decoupling, bypass, energy storage, and some power electronic applications (e.g., motor starter, lighting, power line applications, and interference suppressions).
- *High-tolerance capacitors* such as aluminum and tantalum electrolytic capacitors deliver high capacitances. Although these capacitors are relatively larger in dimension, they are reliable and have longer service lives. They are used in polarized voltage applications, radios, televisions, consumer goods, as well as military equipment, and harsh industrial environmental applications.

TABLE 28.4 Characteristics of Common Capacitors

Capacitor Types	Range	Tolerance (%)	Voltage Range (V)	Temperature Range (°C)	Temperature Coefficient (ppm/°C)	Frequency Range	Permittivity ($\varepsilon/\varepsilon_0$ C²/N m²)	Dielectric Strength (C/C_0)	Dissipation Factor (%)	Insulation Resistance (MΩ/μF)	Typical Average Failure Rates (Fail per 10^6 h)

There are also specially designed capacitors (e.g., mica, glass, oil, gas, and vacuum). These capacitors are used particularly in high-voltage (35 kV) and high-current (200 A) applications.

In the majority of cases, the manufacturing process of the capacitors begins by forming one plate using metallization of one side of a flexible dielectric film. A foil such as aluminum is used as the other plate. The film/foil combination is rolled on a suitable core with alternate layers slightly extended and then heat treated. In some cases, two-foil layers are divided by a dielectric film or paper impregnated with oil.

Generally, capacitors are two-terminal devices with one electrode as the ground terminal. However, if both terminals are separated from the common terminal, the additional capacitances between ground and electrodes might have to be taken into account. Usually, capacitance between electrodes and ground are small compared to the dominant capacitance between plates. Three-terminal capacitances exist and are manufactured in many different ways, as illustrated in Table 28.2.

As far as construction materials and construction techniques are concerned, the capacitors can broadly be classified as electrolytic, ceramic, paper, polymer, mica, variable capacitors, or integrated circuit (IC) capacitors.

Paper capacitors: Usually, paper capacitors are made with thin (5–50 μm in thickness) wood pulp. A number of sheets are used together to eliminate possible chemical and fibrous defects that may exist in each sheet. The paper sheets are placed between thin aluminum foils and convolutedly wound, as shown in Figure 28.2. The moisture of the paper is removed at high-temperature vacuum drying method before the capacitor is vacuum impregnated with oil, paraffin, or wax. The losses and self-inductance in these capacitors are sizeable and frequency dependent. The applications are usually restricted to low frequencies and high voltages. When impregnated with silicone oil, they can withstand voltages up to 300 kV.

Electrolytic capacitors: This describes any capacitor in which the dielectric layer is formed by an electrolytic method. The electrolytic capacitors in dry foil form may be similar in construction to the paper film capacitors; that is, two-foil layers separated by an impregnated electrolyte spacer and are rolled together. In this case, one of the plates is formed using metallization of one side of a flexible dielectric film. A foil (e.g., aluminum) is used as the plate. The capacitor is then hermetically sealed in aluminum or plastic can, as shown in Figure 28.3. These capacitors can be divided into two main subgroups.

Tantalum electrolytic: The anode consists of sintered tantalum powder and the dielectric is Ta_2O_5, which has a high value of ε_r. A semiconductor layer MnO_2 surrounds the dielectric. The cathode made from graphite is deposited around MnO_2 before the capacitor is sealed. The form of a tantalum electrolytic capacitor includes a porous anode slug to obtain a large active surface. These capacitors are highly stable and reliable, with good temperature ranges, and are suitable for high-frequency applications.

Aluminum electrolytic capacitors: Aluminum foil is oxidized on one side as $A1_2O_3$. The oxide layer is the dielectric having a thickness of about 0.1 μm and high electric field strength (7×10^5 V mm^{-1}). A second

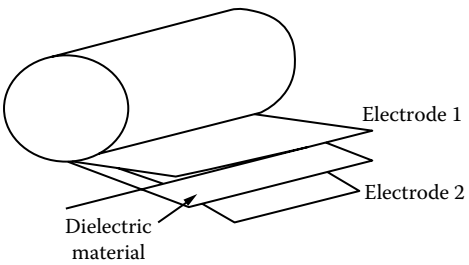

FIGURE 28.2 Construction of a typical capacitor. Dielectric material sheets are placed between electrode foils and convolutedly wound. The moisture of the dielectric material is removed at high temperatures by vacuum drying technique before the capacitor is impregnated with oil, paraffin, or wax.

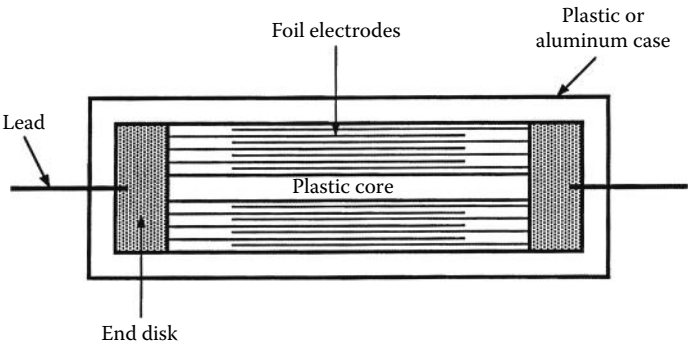

FIGURE 28.3 Construction of an electrolytic capacitor. The two-foil layer electrodes are separated by an impregnated electrolyte paper spacer and rolled together on a plastic core. Usually, a flexible metalized dielectric film is used as one of the plates and a common foil is used for the other. The capacitor is then hermetically sealed in aluminum or plastic can.

layer acting as the cathode, made from etched Al foil, is inserted. The two layers are separated by a spacer when the layers are rolled and mounted.

Electrolytic capacitors must be handled with caution, since in these capacitors, the electrolytic can be easily polarized. That is, the anode should always be positive with respect to the cathode. If not connected correctly, hydrogen gas will form; this damages the dielectric layer, causing a high leakage current or blowup. These capacitors can be manufactured in values up to 1.0 F. They are used in not so critical applications such as coupling, bypass, and filtering. However, they are not useful at frequencies above 1 kHz.

Ceramic and glass capacitors: The dielectric is a ceramic material with deposited metals. They are usually rod or disk shaped. They have good temperature characteristics and are suitable for high-frequency applications. There are many different types, such as the following: (1) *Low K ceramic*: These capacitors are made with materials that contain a large fraction of titanium dioxide (TiO_2). The relative permittivity of these materials varies from 10 to 500, with negative temperature coefficient. The dielectric is TiO_2 + MgO + SiO_2, suitable in high-frequency applications in filters, tuned circuits, coupling and bypass circuits, etc. (2) *High K ceramic*: The dielectric contains a large fraction of barium titanate, $BaTiO_3$, mixed with $PbTiO_3$ or $PbZrO_3$ giving relative permittivity of 250–10,000. They have high losses and also have high-voltage time dependence with poor stability. (3) *Miniature ceramic capacitors*: These are used in critical high-frequency applications. They are made in the ranges of 0.25 pF to 1 nF. (4) *Dielectric ceramic capacitors*: The material is a semiconducting ceramic with deposited metals on both sides. This arrangement results in two depletion layers that make up the very thin dielectric. In this way, high capacitances can be obtained. Due to thin depletion layers, only small dc voltages are allowed. They are used in small and lightweight equipment such as hearing aids.

Glass capacitors are made with glass dielectric materials. The properties of glass dielectrics are similar to ceramics.

Polymer capacitors: Various polymers, such as polycarbonate, polystyrol, polystyrene, polyethylene, and polypropylene, are used as the dielectric material. The construction is similar to that of paper capacitors. Polystyrene capacitors, in particular, are very stable and are virtually frequency independent. They have low voltage ratings and are used in transistorized applications as tuning capacitors and standard capacitors.

Mica capacitors: A thin layer of mica, usually muscovite mica ($\geq$0.003 mm), is stapled with Cu foil or coated with a layer of deposited silver. They are then vacuum impregnated and coated with epoxy. The field strength of these capacitors is very high (10^5 V mm^{-1}) and resistivity $\rho = 10^6$–10^{15} Ω m. These capacitors are available in values from 1.0 pF to several microfarads for high-voltage (from 100 to 2000 V) and high-frequency applications. They have tolerances between ±20% and ±0.5%.

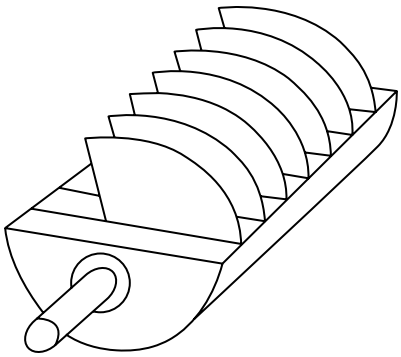

FIGURE 28.4 A variable capacitor consists of two assemblies of spaced plates positioned together by insulation members such that one set of plates can be rotated. The majority of variable capacitors have air as the dielectric. They are commonly used in adjustment of resonant frequencies of tuned circuits in receivers and transmitters. By shaping the plates suitably, they can be made to be linear or logarithmic.

Variable capacitors: These capacitors usually have air as the dielectric and consist of two assemblies of spaced plates positioned together by insulation members such that one set of plates can be rotated. A typical example of variable capacitors is given in Figure 28.4. Their main use is the adjustment of resonant frequency of tuned circuits in receivers and transmitters, filters, etc. By shaping the plates, various types of capacitances can be obtained, such as *linear capacitance*, in which capacitance changes as a linear function of rotation, and *logarithmic capacitance*.

Variable capacitors can be grouped as precision types, general-purpose types, transmitter types, trimmer types, and special types such as the phase shifters.

Precision-type variable capacitors are used in bridges, resonant circuits, and many other instrumentation systems. The capacitance swing can be from 100 to 5000 pF. They have excellent long-term stability with very tight tolerances.

General-purpose type variable capacitors are used as tuning capacitors in radio and other broadcasting devices. They are available in many laws such as straight-line frequency and straight-line wavelength. The normal capacitance swing is from 400 to 500 pF. In some cases, a swing range of 10–600 pF is available.

Transmitter-type variable capacitors are similar to general-purpose variable capacitors, but they are specially designed for high-voltage operations. The vanes are rounded and spaced wider to avoid flashover and excessive current leakages. The swing of these capacitors can go from few picofarads up to 1000 pF. In some cases, oil filling or compressed gases are used to increase operating voltages and capacitances.

Trimmer capacitors are used for coil trimming at intermediate radio frequencies. They can be air-spaced rotary types (2–100 pF), compression types (1.5–2000 pF), ceramic-dielectric rotary types (5–100 pF), and tubular types (up to 3 pF).

Sometimes, special type variable capacitors are produced for particular applications, such as differential and phase shift capacitors in radar systems. They are used for accurate measurement of time intervals, high-speed scanning circuits, transmitters and receivers, etc.

Integrated circuit capacitors: IC capacitors are designed and constructed for use in microelectronic circuits. They include miniature ceramic capacitors, tantalum oxide solid capacitors, and tantalum electrolyte solid capacitors. The ceramic and tantalum oxide IC capacitors are encapsulated and are fitted with endcaps for direct surface mounting onto circuit boards. The beam-leaded tantalum electrolytic IC capacitors are usually attached by pressure bonding. Typical values of these capacitors are 1 pF to 27 nF for temperature compensating ceramic, 100–3000 pF for tantalum oxide, 390 pF to 0.47 μF for general-purpose ceramic, and 0.1–10 μF for tantalum electrolyte. Operating voltages ranges from 25 to 200 V for ceramic, 12–35 V for tantalum electrolyte, and 12–25 V for tantalum oxide.

IC capacitors are made mostly within MOS IC technology since it is easier to deposit tantalum and other materials. The plates of IC capacitors are generally formed by two heavily doped polysilicon layers, formed on a thick layer of oxide. The dielectric is usually made from a thin layer of silicon oxide. These capacitors are temperature stable, with a temperature coefficient of about 20 ppm/°C. In addition, IC capacitive sensors can easily be constructed by incorporating dielectrics sensitive to physical variables. Usually, the metallization layer formed on top of the dielectric forms a shape to provide access to measured physical variable to the dielectric.

Voltage variable capacitors: These capacitors make use of the capacitive effect of the reversed-biased p–n junction diode. By applying different reverse-bias voltages to the diode, the capacitance can be changed. Hence, the name varicap or varactor diodes are given to these devices. Varactors are designed to provide various capacitance ranges from a few picofarads to more than 100 pF. For improved performances, it is also possible to make use of high-speed switching silicon diodes as voltage variable capacitors. However, they are limited by the very low maximum capacitance availability. Typical applications of these varactor diodes are in the tuning circuits in radio frequency receivers. Present-day varactor diodes operate into the microwave part of the spectrum. These devices are quite efficient as frequency multipliers at power levels as large as 25 W. The efficiency of a correctly designed varactor multiplier can exceed 50% in most cases. It is also worth noting that some Zener diodes and selected silicon power-supply rectifier diodes can work effectively as varactors at frequencies as high as 144 MHz. In the case of the Zener diode, it should be operated below its reverse breakdown voltage.

28.3 Characteristics of Capacitors

Capacitors are characterized by dielectric properties, breakdown voltages, temperature coefficients, insulation resistances, frequency and impedances, power dissipation and quality factors, reliability, and aging properties. Typical characteristics of common capacitors are given in Tables 28.4 and 28.5. Some of the important characteristics will be explained next.

Dielectric properties: Dielectrics of capacitors can be made from polar or nonpolar materials. Polar materials have dipolar characteristics; that is, they consist of molecules whose ends are oppositely charged. This polarization causes oscillations of the dipoles at certain frequencies, resulting in high losses.

Capacitor properties are largely determined by the dielectric properties. For example, the losses in the capacitors occur due to the current leakage and the dielectric absorption. These losses are frequency dependent, as typified by Figure 28.5.

The dielectric absorption introduces a time lag during the charging and discharging of the capacitor, thus reducing the capacitance values at high frequencies and causing unwanted time delays in circuits. The leakage current, on the other hand, prevents indefinite storage of energy in the capacitor.

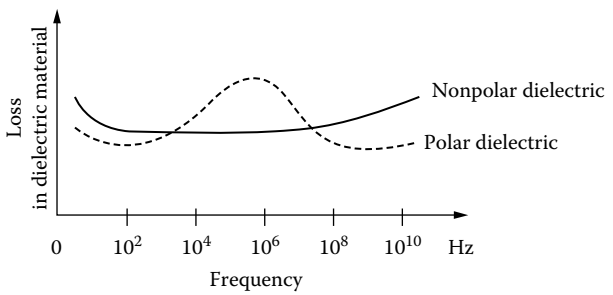

FIGURE 28.5 The frequency dependence of dielectric losses. The dielectric material of capacitors can be polar or nonpolar. In polar materials, polarization causes oscillations at certain frequencies, resulting in high losses at those frequencies. The dielectric losses introduce a time lag during the charging and discharging of the capacitors, thus reducing the capacitance values.

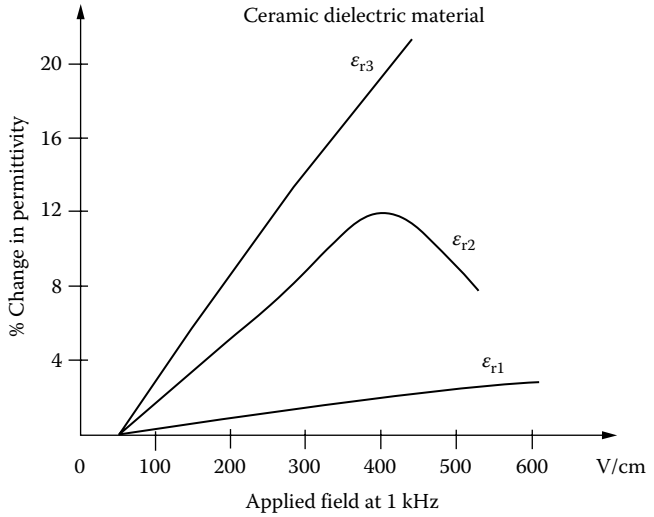

FIGURE 28.6 Changes in relative permittivity versus field strength. The dielectric strength depends on the temperature, frequency, and applied voltage. Increases in the applied voltage cause higher changes in the dielectric strength. If the capacitor is subjected to high operating voltages, the electric field in the dielectric exceeds the breakdown value that can damage the dielectric permanently.

An associated parameter to leakage currents is the leakage resistance, which is measured in megohms, but usually expressed in megohm–microfarads or ohms–farads. The leakage resistance and capacitance introduces time constants that can vary from a few days for polystyrene to several seconds in some electrolytic capacitors. It is important to mention that the leakage current does not only depend on the properties of the dielectric materials but also depends on the construction and structural integrity of capacitors. This is particularly true for capacitors having values less than 0.1 μF, having very thin dielectric materials between the electrodes.

Breakdown voltage: If the capacitor is subjected to high operating voltages, the electric field in the dielectric exceeds the breakdown value, which damages the dielectric permanently. The dielectric strength, which is the ability to withstand high voltages without changing properties, depends on the temperature, frequency, and the applied voltage. An example of this dependence on the applied voltage is given in Figure 28.6. It is commonly known that the use of capacitors below their rated values increases the reliability and the expected lifetime. The standard voltage ratings of most capacitors are quoted by the manufacturers as 50, 100, 200, 400, and 600 V. Tantalum and electrolytic capacitors have ratings of 6, 10, 12, 15, 20, 25, 35, 50, 75, 100 V, and higher.

Usually, values for surge voltages are given to indicate the ability of capacitors to withstand high transients. Typically, the surge voltage for electrolytic capacitors is 10% above the rated voltage, 50% for aluminum capacitors, and about 250% for ceramic and mica capacitors.

The rated reverse voltages of electrolytic capacitors are limited to 1.5 V and, in some cases, to 15% of the rated forward voltages.

Temperature coefficient: The temperature characteristics of capacitors largely depend on the temperature properties of the dielectric materials used, as given in Figure 28.7. The temperature coefficients of glass, Teflon, mica, and polycarbonate are very small, whereas in ceramic capacitors, they can relatively be much higher.

Insulation resistance: The insulation resistance of capacitors is important for effective operations in many circuits since the insulation resistance is very susceptible to temperature and humidity. For example, unsealed capacitors show large and rapid changes against temperature and humidity,

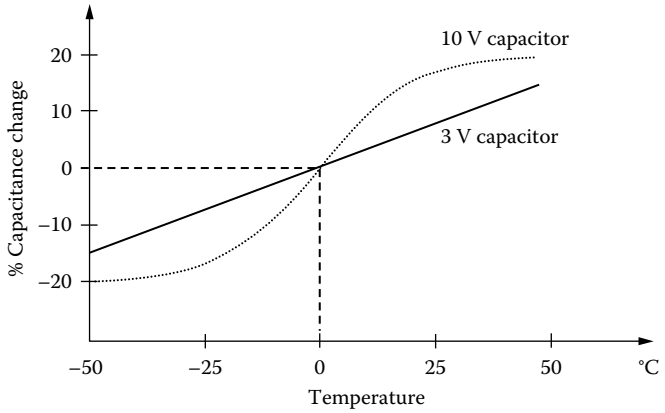

FIGURE 28.7 The temperature dependence of capacitors. The temperature characteristics of capacitors are largely dependent on the temperature properties of the dielectric materials used. The variations in capacitances due to temperature are also dependent on the type of capacitor and the operational voltages. The temperature coefficient of glass, Teflon, mica, and polycarbonate are very small and relatively high in ceramic capacitors.

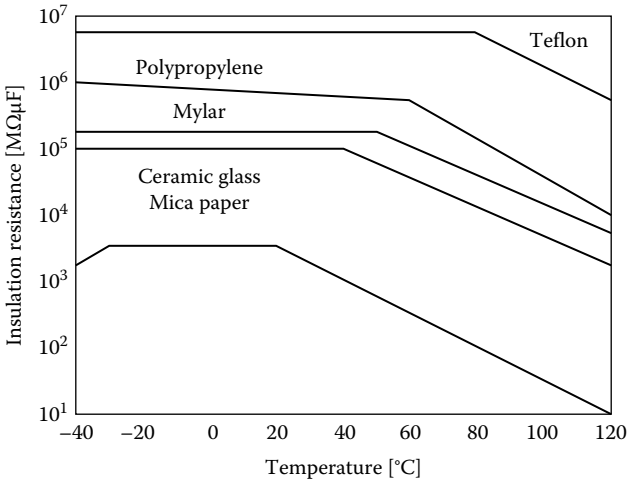

FIGURE 28.8 Temperature dependence of insulation resistance. The insulation resistance of many capacitors is not affected at low temperatures. However, under high-temperature conditions, the change in insulation resistance can be approximated by an exponential relation. The insulation resistance is also susceptible to variations in humidity.

which can make them unsuitable for many circuits. For most capacitors, the change in insulation resistance is an exponential function of temperature ($R_{T1} = R_{T2}e^{K(T1-T2)}$). This can be substantial in high-temperature operations. The temperature dependence of insulation resistance of common capacitors is shown in Figure 28.8.

Frequency and impedance: Practical capacitors have increases in losses at very low and at very high frequencies. At low frequencies, the circuit becomes entirely resistive and the dc leakage current becomes effective. At very high frequencies, the current flowing through the capacitor become important and the dielectric losses increase. Approximate ranges of useable frequencies of capacitors are provided in Tables 28.4 and 28.5.

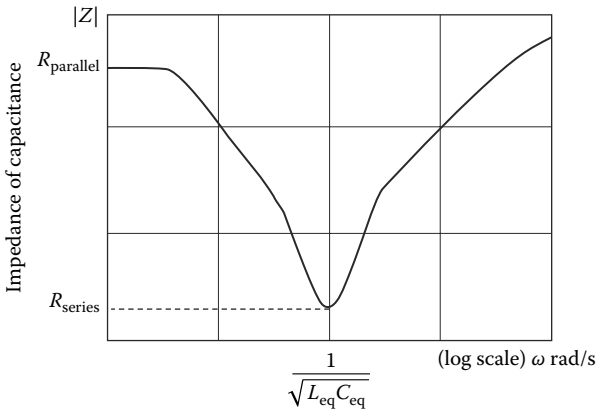

FIGURE 28.9 Frequency and impedance relation of capacitors. The losses and inherent inductance affects the ideal operation of capacitors; hence, the impedance becomes a function of the frequency. Depending on the construction, all capacitors will resonate at some frequency.

An ideal capacitor should have an entirely negative reactance, but losses and inherent inductance prevent ideal operation. Depending on the construction, capacitors will resonate at certain frequencies due to unavoidable construction-based inductances. A typical impedance characteristic of a capacitor is depicted in Figure 28.9.

Power–dissipation and quality factors: Ideally, a capacitor should store energy without dissipating any power. However, due to equivalent resistances, R_{eq}, real power will be dissipated. Therefore, the power factor of a capacitor can be expressed as

$$\text{PF} = \cos\theta = \frac{R_{eq}}{Z_{eq}} \tag{28.7}$$

where
θ is the phase angle
Z_{eq} is the equivalent total impedance

An important characteristic, the *dissipation factor* of capacitors, is expressed as

$$\text{DF} = \tan\delta = \frac{R_{eq}}{X_{eq}} \tag{28.8}$$

where
δ is the angle of loss
X_{eq} is the equivalent reactance

The dissipation factor depends on the frequency. Capacitors are designed such that this dependence is minimal. The measurement of dissipation factor δ is made at 1 kHz and 1.0 Vrms applied to the capacitor. A typical dissipation factor curve is depicted in Figure 28.10.

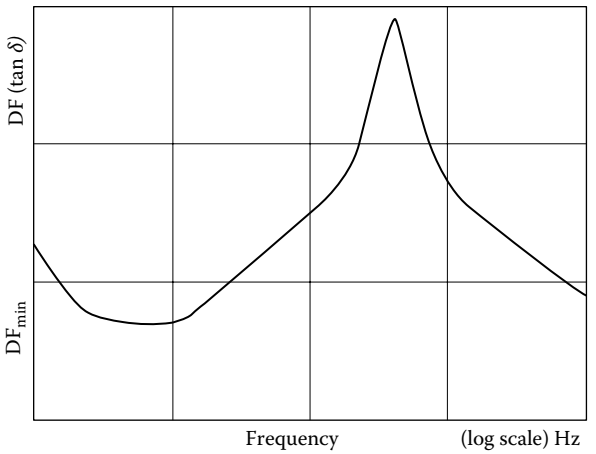

FIGURE 28.10 Power–dissipation factors. In ideal operations, capacitors should store energy without dissipating power. Nevertheless, due to resistances, some power will be dissipated. The dissipation depends on the frequency. The standard measurement of dissipation factor δ is determined by applying a voltage of 1.0 Vrms at 1 kHz.

28.4 Selection, Reliability, and Standards of Capacitors

28.4.1 Capacitor Selection

Experience shows that a substantial part of component failures in electronic equipment is due to capacitors. The major cause of this can be attributed to the improper selection and inappropriate applications of capacitors. The following factors are therefore important criteria in the selection of capacitors in circuit applications: (1) the capacitance *values and tolerances* are determined by operating frequencies and by requirements of timing, energy storage, phase shifting, coupling, or decoupling; (2) the *voltages* are determined by the type and nature of the source, ac, dc, transient, surges, and ripples; (3) the *stability* is determined by operating conditions like temperature, humidity, shock, vibration, and life expectancy; (4) the *electric properties* are determined by life expectancy, leakage current, dissipation factor, impedance, and self-resonant frequency; (5) the mechanical properties are determined by the types and construction, for example, size, configuration, and packaging; and (6) the cost is determined by the types and physical dimensions of capacitors and the required tolerance.

28.4.2 Capacitor Reliability

Some of the common causes of capacitor failure are due to voltage and current overloads, high temperature, humidity, shock, vibration, pressure, frequency effects, and aging. The voltage overload produces an excessive electric field in the dielectric that results in the breakdown or total destruction of the dielectric. The electric current overload caused by rapid voltage variations results in current transients. If these currents are of sufficient amplitude and duration, the dielectric can be deformed and damaged, resulting in drastic changes in capacitance values, and thus leading to malfunctioning of the equipment. The high temperatures are mainly due to voltage and current overloads. Overheating and high temperatures accelerate the dielectric aging. This causes the plastic film to be brittle and also introduces cracks in the hermetic seals. The moisture and humidity due to severe operating environments can cause corrosions, reducing the dielectric strength, and lowering the insulation resistance. The mechanical effects are mainly the pressure, variation, shock, and stress, which can cause mechanical damages of seals that

result in electric failures. Aging deteriorates the insulation resistance and affects the dielectric strength. The aging is usually determined by shelf life; information about aging is supplied by the manufacturers.

28.4.3 Capacitor Standard Values and Tolerances

General-purpose capacitor values tend to be grouped close to each other in a bimodal distribution manner within their tolerance values. Usually, the tolerances of standard capacitors are 5%, 10%, and 20% of their rated values, as shown in Table 28.6. Nevertheless, tolerances of precision capacitors are much tighter—in the range of 0.25%, 0.5%, 0.625%, 1%, 2%, and 3% of the rated values. Undoubtedly, these capacitors are much more expensive than the general-purpose range.

For capacitors in the small pF range, the standard tolerances are ±1.5, ±1, ±0.5, ±0.25, and ±0.1 pF. Usually, low tolerance ranges are achieved by selecting good-quality materials and elaborate manufacturing.

Standard capacitors are constructed from interleaved metal plates using air as the dielectric material. The area of the plates and distance between them are determined and constructed with precision. National Bureau of Standards maintains a bank of primary standard air capacitors that can be used to calibrate the secondary and working standards in laboratory and industrial application. The working standards of small capacitances are obtained by using air capacitors, whereas working standards of larger capacitances are made from solid dielectric materials. Usually, silver-mica capacitors are selected as working standards since they are very stable, exhibit low dissipation factors and small temperature coefficients, and aging effects are excellent. They are available in decade mounted forms with multiplication factors of 10.

28.5 Capacitors in Circuits

The capacitor is used as a two-terminal element in electric circuits with the current–voltage relationship given by

$$i(t) = \frac{C\,dv(t)}{dt} \tag{28.9}$$

where C is the capacitance.

The circuit representation is given in Figure 28.11a.

From the $v(t)$, $i(t)$ relationship, the instantaneous power of this element can then be given by

$$p(t) = v(t)i(t) \tag{28.10}$$

The stored energy in the capacitor at time t s can be calculated as

$$w(t) = \int Cv(t)\left\{\frac{dv(t)}{dt}\right\}dt$$

$$= \frac{[Cv^2(t)]}{2} \tag{28.11}$$

If the voltage across the capacitor is time varying, the energy stored in the capacitor in a time interval $t_1 - t_2$ can be calculated from Equation 28.11 as

$$W = \left(\frac{1}{2}\right)C[v^2(t_2) - v^2(t_1)] \tag{28.12}$$

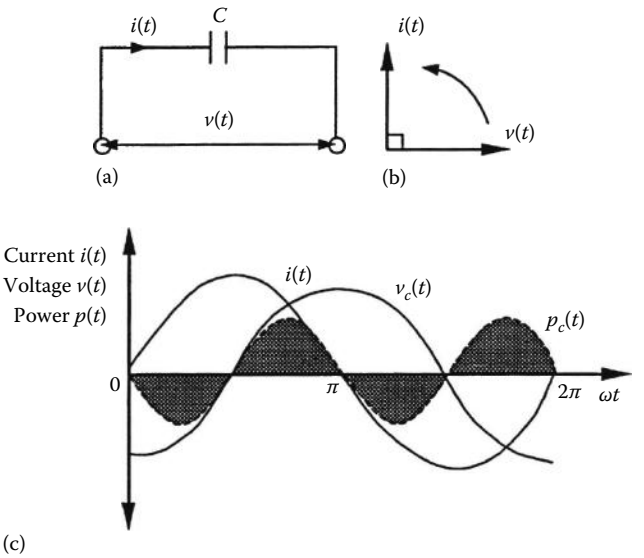

FIGURE 28.11 A capacitor as a two-terminal circuit element: (a) connection of a capacitor in electric circuits, (b) voltage–current relationship under sinusoidal operations, and (c) the power, voltage, and current relationships. The power has positive and negative values with twice the frequency of the applied voltage.

Although the voltage assumes different values in time interval $t_1 - t_2$, if the initial and final voltages are equal (e.g., $v(t_1) = v(t_2)$), then the net energy stored in the capacitor will be equal to zero. This implies that the energy stored in the capacitor is returned to the circuit during that time interval; that is, the capacitor transforms the energy without dissipation. The stored energy in the capacitor is associated with the electrostatic field and, in the absence of the electrostatic field, the energy will be zero.

From the voltage–current relationship in Equation 28.9, it can be seen that a capacitor is a passive element. That is, if the voltage is known, the current can be immediately determined by differentiating the voltage. Conversely, if the current is known, then the voltage can be determined by integration. If the voltage $v(t)$ is considered as an input variable, and the current $i(t)$ as an output variable, then the behavior of the current in a certain time interval is completely determined by the behavior of the voltage in this interval. In this case, the solution of the differential equation has the forced component only. Here, the particular solution of the voltage–current differential equation coincides with a full solution and the Laplace transform gives the relationship

$$I(s) = sCV(s) \tag{28.13}$$

From this, the input–output relationship yields the impedance of the capacitor as

$$Z(s) = \frac{1}{sC}$$

or (28.14)

$$Y(s) = sC$$

Under the stationary conditions, $s \to 0$, $Z \to \infty$, and $Y \to 0$.

In the sinusoidal condition, $s = j\omega = 2\pi f$, where f is the frequency and, hence,

$$Z(j\omega) = \frac{1}{\{j\omega C\}} = \frac{-j}{\{\omega \mathrm{C}\}} \tag{28.15}$$

and

$$Y(j\omega) = j\omega C \tag{28.16}$$

The capacitor can then be characterized under sinusoidal conditions, by a reactance of $X_C = 1/\omega C$, measured in ohms with the current leading the voltage by 90°, as shown in the phasor diagram in Figure 28.11b.

In sinusoidal operations, the instantaneous power $p(t) = v(t)i(t)$ can be calculated as

$$v(t) = V_{\max} \cos \omega t = \sqrt{2} V \cos \omega t \tag{28.17}$$

Using the relationship given by Equation 28.9, the current can be written as

$$i(t) = \frac{C\,dv}{dt} = -\omega C \sqrt{2} V \sin \omega t \tag{28.18}$$

giving

$$p(t) = v(t)i(t) = -2\omega CV^2 \sin\omega t \cos\omega t = \frac{V^2 \sin 2\omega t}{X_C} \tag{28.19}$$

This indicates that the average power is zero because of the $\sin 2\omega t$ term, but there is a periodic storage and return of energy and the amplitude of that power is V^2/X_C. The power, voltage, and current relationships in a capacitor are given in Figure 28.11c.

28.5.1 Series and Parallel Connections

The formulae for series and parallel connection of capacitors can be obtained from the impedances of such connections as shown in Figure 28.12a and b. For the series connection, the impedances are added such that

$$\frac{1}{sC} = \frac{1}{sC_1} + \frac{1}{sC_2} + \cdots + \frac{1}{sC_n} \tag{28.20}$$

where C_1, C_2, …, C_n are the capacitance of the capacitors connected in series.

Thus, the equivalent value of the capacitances in series connection can be expressed by

$$C = \left\{ \frac{1}{C_1} + \frac{1}{C_2} + \cdots + \frac{1}{C_n} \right\}^{-1} \tag{28.21}$$

The final capacitance value will always be smaller than the smallest value.

In a similar way, the equivalent capacitance of parallel connections can be expressed as

$$C = C_1 + C_2 + \cdots + C_n \tag{28.22}$$

and the final value of C is always larger than the largest capacitance in the circuit.

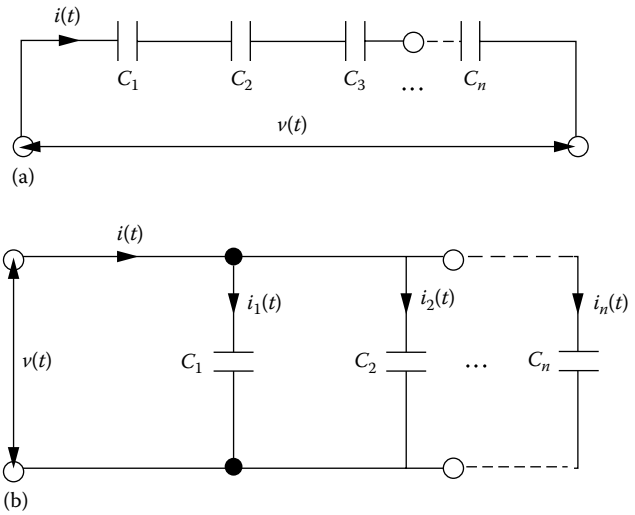

FIGURE 28.12 Series and parallel connection of capacitors: (a) series connection and (b) parallel connection. In the series connection, the final capacitance value will always be smaller than the smallest value of the capacitor in the circuit, whereas in parallel connection, the final value is greater than the largest capacitance.

28.5.2 Distributed Capacitance Circuits

Capacitance is inherent whenever an electric potential exists between two conducting bodies, albeit in electric circuits, communication equipment, electronic circuit boards, computer devices, and so on. For example in electric circuits, its effect will be most noticeable in the coils and in the transmission lines. In the case of coils, there are small capacitances between adjacent turns, between turns that are not adjacent, between terminal leads, between turns and ground, etc. Each of the various capacitances associated with the coil stores a quantity of electrostatic energy that is determined by the capacitance involved and the fraction of the total coil voltage that appears across it. The total effect is that the numerous small coil capacitances can be replaced by a single capacitor of appropriate size shunted across the coil terminals. This equivalent capacitance is called either the *distributed capacitance* or the *self-capacitance* of the coil, and it causes the coil to show parallel resonance effects under some conditions. In the case of a mismatched or unterminated transmission line, the distributed capacitance, together with the inductive effects, will create a phase difference between the voltage and current in the line. This phase difference depends on the type of termination and the electric length of the line and, as a result, the input impedance of the line can effectively be an equivalent capacitor when its electric length is less than a quarter wavelength for an open-circuit termination or between a quarter wavelength and half a wavelength for a short-circuit termination.

28.5.3 Capacitor Equivalent Circuits

The electric equivalent circuit of a capacitor consists of a pure capacitance (C_p), plate inductances (L_1, L_2), plate resistances (R_1, R_2), and a parallel resistance R_p that represents the resistance of the dielectric or leakage resistance, as shown in Figure 28.13. The capacitors that have high leakage currents flowing through the dielectric have relatively low R_p values. Very low leakage currents are represented by extremely large R_p values. Examples of these two extremes are electrolytic capacitors that have high leakage current (low R_p) and plastic film capacitors, which have very low leakage current (high R_p). Typically, an electrolytic capacitor might easily have several microamperes of leakage current ($R_p < 1$ MΩ), while a plastic film capacitor could have a resistance greater than 100,000 MΩ

It is usual to represent a low leakage capacitor (high R_p) by a series resistance–capacitance (*RC*) circuit, while those with high leakage (low R_p) are represented by parallel *RC* circuits. However, when a capacitor is measured in terms of the series *C* and *R* quantities, it is desirable to resolve them into parallel equivalent circuit quantities. This is because the (parallel) leakage resistance best represents the quality of the capacitor dielectric.

28.5.4 Capacitive Bridges and Measurement of Capacitance

Bridges are used to make precise measurements of unknown capacitances and associated losses in terms of known external capacitances and resistances. The most commonly used bridges are series *RC* bridge, parallel *RC* bridge, Wien bridge, and Schering bridge.

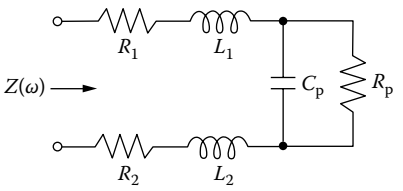

FIGURE 28.13 The capacitor equivalent circuit. A practical capacitor has resistance and inductances. Often, the electric equivalent circuit of a capacitor can be simplified by a pure capacitance C_p and a parallel resistance R_p by neglecting resistances R_1, R_2 and inductances L_1, L_2. In low leakage capacitors where R_p is high, the equivalent circuit can be represented by a series *RC* circuit.

28.5.4.1 Series Resistance–Capacitance Bridge

Figure 28.14 is a series *RC* bridge, which is used for the comparison of a known capacitance with an unknown capacitance. The unknown capacitance is represented by C_x and R_x. A standard adjustable resistance R_1 is connected in series with a standard capacitor C_1. The voltage drop across R_1 balances the resistive voltage drop when the bridge is balanced. The additional resistor in series with C_x increases the total resistive component, so that small values of R_1 will not be required to achieve balance. Generally, the bridge balance is most easily achieved when capacitive branches have substantial resistive components. To obtain balance, R_1 and either R_3 or R_4 are adjusted alternately. This type of bridge is found to be most suitable for capacitors with a high-resistance dielectric and hence very low leakage currents.

At balance,

$$Z_1 Z_3 = Z_2 Z_x \tag{28.23}$$

Substituting impedance values gives

$$\left(R_1 - \frac{j}{\omega C_1}\right) R_3 = \left(R_x - \frac{j}{\omega C_2}\right) R_2 \tag{28.24}$$

Equating the real terms gives

$$R_x = \frac{R_1 R_3}{R_2} \tag{28.25}$$

and equating *imaginary* terms gives

$$C_x = \frac{C_1 R_2}{R_3} \tag{28.26}$$

An improved version of the series *RC* bridge is the *substitution bridge*, which is particularly useful to determine the values of capacitances at radio frequencies. In this case, a series-connected *RC* bridge is balanced by disconnecting the unknown capacitance C_x and resistance R_x and replacing it by an adjustable standard capacitor C_s and adjustable resistor R_s. After having obtained the balance position, the unknown capacitance and resistance C_x an R_x are connected in parallel to the capacitor C_s.

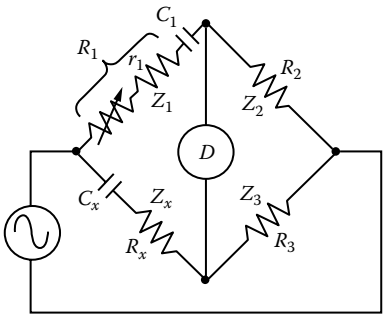

FIGURE 28.14 A series *RC* bridge. In these bridges, the unknown capacitance is compared with a known capacitance. The voltage drop across R_1 balances the resistive voltage drop in branch Z_2 when the bridge is balanced. The bridge balance is most easily achieved when capacitive branches have substantial resistive components. The resistors R_1 and either R_3 or R_4 are adjusted alternately to obtain the balance. This type of bridge is found to be most suitable for capacitors with high-resistance dielectrics; hence, they have very low leakage currents.

The capacitor C_s and resistor R_s are adjusted again for the rebalance of the bridge. The changes in the ΔC_s and ΔR_s lead to unknown values as

$$C_x = \Delta C_s \quad \text{and} \quad R_x = \Delta R_s \left(\frac{C_{s1}}{C_x} \right)^2 \tag{28.27}$$

where C_{s1} is the value of C_s in the initial balance condition.

28.5.4.2 Parallel Resistance–Capacitance Bridge

Figure 28.15 illustrates a parallel *RC* bridge. In this case, the unknown capacitance is represented by its parallel equivalent circuit C_x in parallel with R_x. The Z_2 and Z_3 impedances are pure resistors with either or both being adjustable. The Z_1 is balanced by a standard capacitor C_1 in parallel with an adjustable resistor R_1. The bridge balance is achieved by adjustment of R_1 and either R_2 or R_3. The parallel *RC* bridge is found to be most suitable for capacitors with a low-resistance dielectric, hence relatively high leakage currents. At balance,

$$\frac{1}{((1/R_1) + j\omega C_1)} R_3 = \frac{1}{((1/R_x) + j\omega C_x)} R_2 \tag{28.28}$$

Equating *real* terms gives

$$R_x = \frac{R_3 R_1}{R_2} \tag{28.29}$$

and equating *imaginary* terms gives

$$C_x = \frac{C_1 R_2}{R_3} \tag{28.30}$$

28.5.4.3 Wien Bridge

Figure 28.16 shows a Wien bridge. This is a special resistance-ratio bridge that permits two capacitances to be compared once all the resistances of the bridge are known. At balance, it can be proven that the unknown resistance and the capacitance are

$$R_x = \frac{R_3(1 + \omega^2 R_1^2 C_1^2)}{\omega^2 R_1 R_2 C_1^2} \tag{28.31}$$

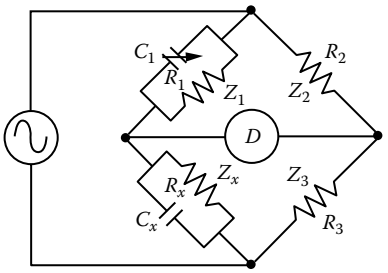

FIGURE 28.15 A parallel *RC* bridge. The unknown capacitance is represented by its parallel equivalent circuit, C_x in parallel with R_x. The bridge balance is achieved by adjustment of R_1 and either R_3 or R_4. The parallel *RC* bridge is found to be most suitable for capacitors with a low-resistance dielectric, hence relatively high leakage currents.

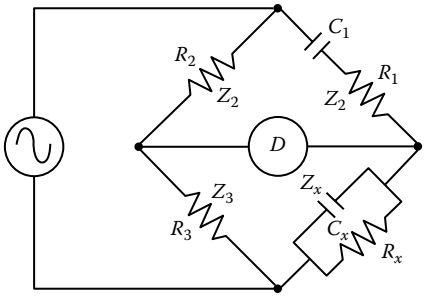

FIGURE 28.16 The Wien Bridge. This bridge is used to compare two capacitors directly. It finds applications particularly in determining the frequency in *RC* oscillators. In some cases, capacitors C_1 and C_x are made equal and ganged together so that the frequency at which the null occurs varies linearly with the capacitance.

and

$$C_x = \frac{C_1 R_2}{[R_3(1+\omega^2 R_1^2 C_1^2)]} \tag{28.32}$$

It can also be shown that

$$\omega^2 = \frac{1}{R_1 C_1 R_x C_x} \tag{28.33}$$

As indicated in Equation 28.33, the Wien Bridge has an important application in determining the frequency in *RC* oscillators. In frequency meters, C_1 and C_x are made equal, and the two capacitors are ganged together so that the frequency at which the null occurs varies linearly with capacitances.

28.5.4.4 Schering Bridge

Figure 28.17 illustrates the configuration of the Schering Bridge. This bridge is used for measuring the capacitance, the dissipation factors, and the loss angles. The unknown capacitance is directly proportional to the known capacitance C_3. That is, the bridge equations are

$$C_x = \frac{C_3 R_2}{R_1} \quad \text{and} \quad R_x = \frac{C_2 R_1}{C_3} \tag{28.34}$$

Usually, R_2 and R_3 are fixed and C_2 and C_3 are made variable. Schering bridges are frequently used in high-voltage applications with high-voltage capacitor C_3. They are also used as high-frequency bridges since the use of two variable adjustment capacitors are convenient for precise balancing.

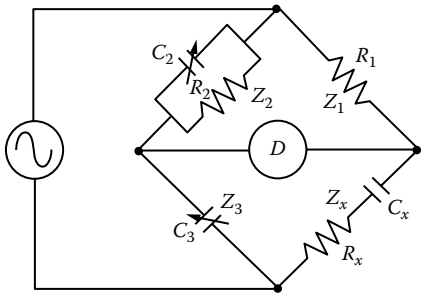

FIGURE 28.17 The Schering Bridge. This bridge is particularly useful for measuring the capacitance, associated dissipation factors, and the loss angles. The unknown capacitance is directly proportional to the known capacitance C_1. The Schering bridge is frequently used as a high-voltage bridge with a high-voltage capacitor as C_1.

Permeability and Hysteresis Measurement

Jeff P. Anderson
LTV Steel Corporation

Richard J. Blotzer
LTV Steel Corporation

Magnetic fields are typically conceptualized with so-called flux lines or lines of force. When such flux lines encounter any sort of matter, an interaction takes place in which the number of flux lines is either increased or decreased. The original magnetic field therefore becomes amplified or diminished in the body of matter as a result of the interaction. This is true whether the matter is a typical "magnetic" material, such as iron or nickel, or a so-called "nonmagnetic" material, such as copper or air.

The *magnetic permeability* of a substance is a numerical description of the extent to which that substance interacts with an applied magnetic field. In other words, permeability refers to the degree to which a substance can be magnetized.

Different substances possess varying degrees of magnetization. The aforementioned examples of strongly magnetic materials have the ability to strengthen an applied magnetic field by a factor of several thousand. Such highly magnetizable materials are called *ferromagnetic*. Certain other substances, such as Al, only marginally increase an applied magnetic field. Such weakly magnetizable materials are called *paramagnetic*. Still other substances, such as Cu and the rare gases, slightly weaken an applied magnetic field. Such "negatively magnetizable" substances are called *diamagnetic*.

In common parlance, diamagnetic and paramagnetic substances are often called *nonmagnetic*. However, as detailed in the following text, all substances are magnetic to some extent. Only empty space is truly nonmagnetic.

The term *hysteresis* has been used to describe many instances where an effect lags behind the cause. However, Ewing was apparently the first to use the term in science [1] when he applied it to the particular magnetic phenomenon displayed by ferromagnetic materials. Magnetic hysteresis occurs during the cyclical magnetization of a ferromagnet. The magnetization path created while increasing an externally applied field is not retraced on subsequent decrease (and even reversal) of the field. Some magnetization, known as *remanence*, remains in the ferromagnet after the external field has been removed. This remanence, if appreciable, allows for the permanent magnetization observed in common bar magnets.

TABLE 29.1 Conversion Factors between the mks and cgs Systems for Important Quantities in Magnetism

Quantity	mks	cgs
H, applied field	A/m	$=4\pi \times 10^{-3}$ Oe
B, flux density	Wb/m^2	$=10^4$ G
M, magnetization	Wb/m^2	$=10^4/4\pi$ emu/cm^3
κ, susceptibility	$Wb/(A \cdot m)$	$=16\ \pi^2 \times l0^{-7}$ emu/Oe $\cdot$ cm^3

29.1 Definition of Permeability

Let an externally applied field be described by the vector quantity H. This field may be produced by a solenoid or an electromagnet. Regardless of its source, H has units of ampere turns per meter (A/m). On passing through a body of interest, H magnetizes the body to a degree, M, formally defined as the magnetic moment per unit volume. The units of M are usually webers per square meter. A secondary coil (and associated electronics) is typically used to measure the combined effects of the applied field and the body's magnetization. This sum total flux-per-unit-area (flux density) is known as the induction, B, which typically has units of Wb/m^2, commonly referred to as a tesla (T). Because H, M, and B are usually parallel to one another, the vector notation can be dropped, so that

$$B = \mu_0 H + M \tag{29.1}$$

where μ_0 is the permeability of free space ($47\pi \times 10^{-7}$ Wb/A $\cdot$ m).

The absolute permeability, μ, of a magnetized body is defined as the induction achieved for a given strength of applied field, or

$$\mu = \frac{B}{H} \tag{29.2}$$

Often, the absolute permeability is normalized by μ_0 to result in the relative permeability, $\mu_r = (\mu/\mu_0)$. This relative permeability is numerically equal and physically equivalent to the cgs version of permeability. This, unfortunately, is still in common usage and often expressed in units of gauss per oersted (G/Oe), although the cgs permeability is actually dimensionless. Conversion factors between the mks and cgs systems are listed in Table 29.1 for the important quantities encountered.

29.2 Types of Material Magnetization

All substances fall into one of three magnetic groups: diamagnetic, paramagnetic, or ferromagnetic. Two important subclasses, antiferromagnetic and ferrimagnetic, will not be included here. The interested reader can find numerous discussions of these subclasses; for example, see [1].

29.2.1 Diamagnetism

Diamagnetic and paramagnetic (see next section) substances are usually characterized by their magnetic susceptibility rather than permeability. Susceptibility is derived by combining Equations 29.1 and 29.2, namely,

$$\mu_r = 1 + \frac{M}{\mu_0 H} = 1 + \frac{\kappa}{\mu_0} \tag{29.3}$$

where κ is the susceptibility with units of Wb/A $\cdot$ m. This so-called *volume susceptibility* is often converted to a mass susceptibility (χ) or a molar susceptibility (χ_M). Values for the latter are readily available for many pure substances and compounds [2]. Susceptibility is also often called "intrinsic permeability" [3].

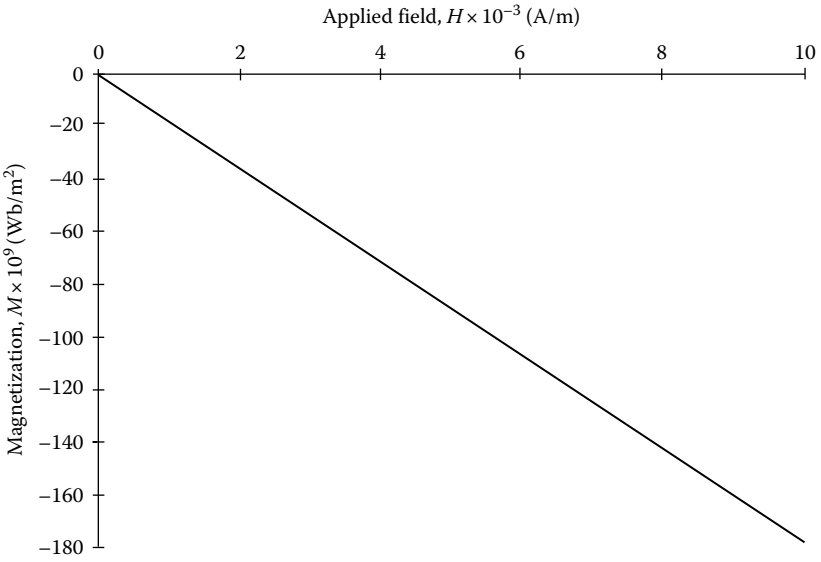

FIGURE 29.1 For diamagnetic substances, magnetization M is small and opposite the applied field H as in this schematic example for graphite ($\kappa = -1.78 \times 10^{-11}$ Wb/A · m).

In any atom, the orbiting and spinning electrons behave like tiny current loops. As with any charge in motion, a magnetic moment is associated with each electron. The strength of the moment is typically expressed in units of Bohr magnetons.

Diamagnetism represents the special case in which the moments contributed by all electrons cancel. The atom as a whole possesses a net zero magnetic moment. An applied field, however, can induce a moment in the diamagnetic material, and the induced moment opposes the applied field. The magnetization, M, in Equation 29.3 is therefore antiparallel to the applied field, H, and the susceptibility, κ, is negative. For diamagnetic materials, $\mu < 1$. Figure 29.1 shows a schematic M vs. H curve for graphite with $\kappa = -1.78 \times 10^{-11}$ Wb/A · m. Note that κ is a constant up to very high applied field values.

29.2.2 Paramagnetism

In a paramagnetic substance, the individual electronic moments do not cancel and the atom possesses a net nonzero moment. In an applied field, the weak diamagnetic response is dominated by the atom's tendency to align its moment parallel with the applied field's direction. Paramagnetic materials have relatively small positive values for κ, and $\mu > 1$.

Thermal energy retards a paramagnet's ability to align with an applied field. Over a considerable range of applied field and temperature, the paramagnetic susceptibility is constant. However, with very high applied fields and low temperatures, a paramagnetic material can be made to approach saturation—the condition of complete alignment with the field. This is illustrated in Figure 29.2 for potassium chromium alum, a paramagnetic salt. Even at a temperature as low as 1.30 K, an applied field in excess of about 3.8×10^6 A/m is necessary to approach saturation. (Note in Figure 29.2, that 1 Bohr magneton = 9.27×10^{-24} J/T.)

29.2.3 Ferromagnetism

Ferromagnetic substances are actually a subclass of paramagnetic substances. In both cases, the individual electronic moments do not cancel, and the atom has a net nonzero magnetic moment that tends to align itself parallel to an applied field. However, a ferromagnet is much less affected by the randomizing

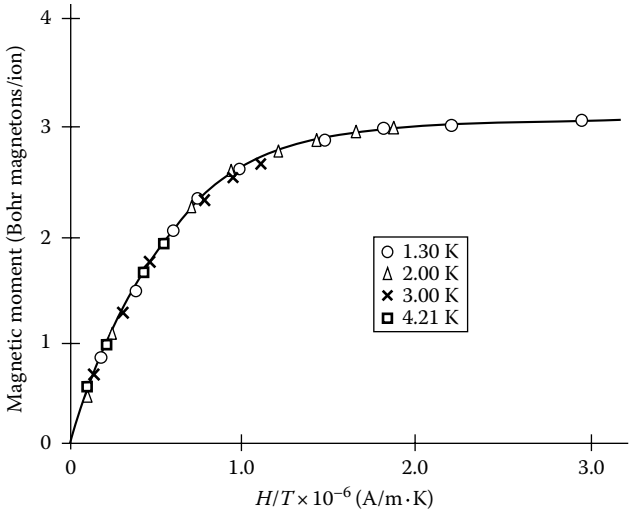

FIGURE 29.2 For paramagnetic substances, the susceptibility is constant over a wide range of applied field and temperature. However, at very high H and low T, saturation can be approached, as in this example for potassium chromium alum. (After Henry, W.E., *Phys. Rev.*, 88, 559, 1952.)

action of thermal energy compared to a paramagnet. This is because the individual atomic moments of a ferromagnet are coupled in rigid parallelism, even in the absence of an applied field.

With no applied field, a demagnetized ferromagnet is comprised of several magnetic domains. Within each domain, the individual atomic moments are parallel to one another, or coupled, and the domain has a net nonzero magnetization. However, the direction of this magnetization is generally opposed by a neighboring domain. The vector sum of all magnetizations among the domains is zero. This condition is called the *state of spontaneous magnetization*.

With an increasing applied field, domains with favorable magnetization directions, relative to the applied field direction, grow at the expense of the less favorably oriented domains. This process is schematically illustrated in Figure 29.3. The exchange forces responsible for the ferromagnetic coupling are explained by Heisenberg's quantum mechanical model [4]. Above a critical temperature known as the Curie point, the exchange forces disappear and the formerly ferromagnetic material behaves exactly like a paramagnet.

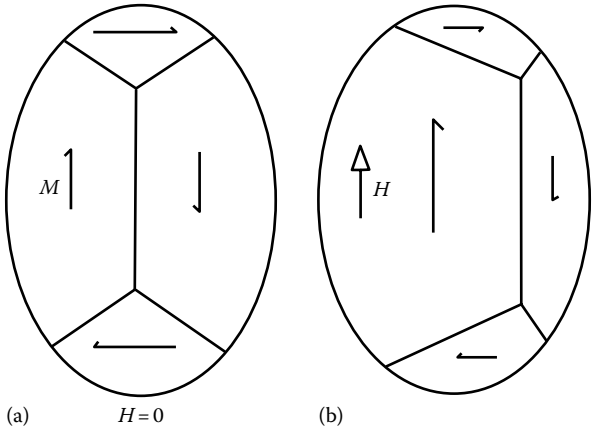

FIGURE 29.3 With no applied field, (a) a ferromagnet assumes spontaneous magnetization. With an applied field, (b) domains favorably oriented with H grow at the expense of other domains.

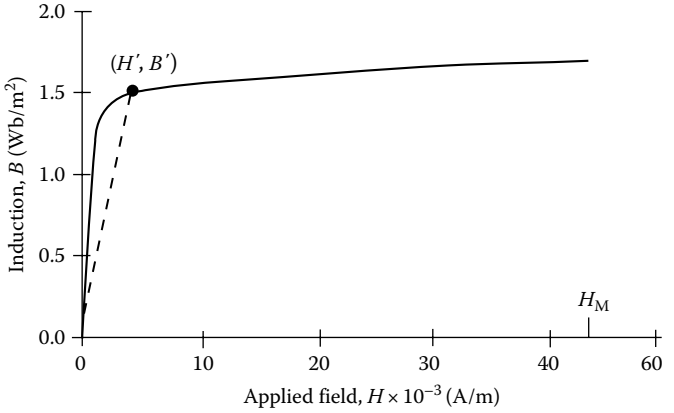

FIGURE 29.4 Magnetization (*B*–*H*) curve for a typical soft ferromagnet. Permeability at point (H', B') is the slope of the dashed line.

During magnetization, ferromagnets show very different characteristics from diamagnets and paramagnets. Figure 29.4 is a so-called *B*–*H* curve for a typical soft ferromagnet. Note that *B* is no longer linear with *H* except in the very low- and very high-field regions. Because of this, the permeability μ for a ferromagnet must always be specified at a certain applied field, *H*, or, more commonly, a certain achieved induction, *B*. Note that μ is the slope of the line connecting a point of interest on the *B*–*H* curve to the origin. It is not the slope of the curve itself, although this value, *dB*/*dH*, is called the *differential permeability* [3].

Another ferromagnetic characteristic evident in Figure 29.4 is *saturation*. Once the applied field has exceeded a certain (and relatively low) value, the slope of the magnetization curve assumes a constant value of unity. At this point, *M* in Equation 29.1 has reached a maximum value, and the ferromagnet is said to be saturated. For all practical purposes, all magnetic moments in the ferromagnet are aligned with the applied field at saturation. This maximum magnetization is often called the saturation induction, B_s [5]. Note that B_s is an intrinsic property—it does not include the applied field in its value.

29.3 Definition of Hysteresis

If *H* is decreased from H_M in Figure 29.4, *B* does not follow the original magnetization path in reverse. Even if *H* is repeatedly cycled from H_M to $-H_M$, *B* will follow a path on increasing *H* that is different from decreasing *H*. The cyclical *B*-*H* relationship for a typical soft ferromagnet is displayed by the hysteresis loops in Figure 29.5. Two loops are included: a minor loop inside a major loop generated by independent measurements. The two differ in the value of maximum applied field: H_M. for the minor loop was below saturation, while H_M for the major loop was near saturation. Both loops are symmetrical about the origin as a point of inversion since in each case $H_M = |-H_M|$.

Notice for the minor loop that when the applied field is reduced from H_M. to 0, the induction does not also decrease to zero. Instead, the induction assumes the value B_r, known as the *residual induction*. If the peak applied field exceeds the point of saturation, as for the major loop in Figure 29.5, B_r assumes a maximum value known as the *retentivity*, B_{rs}.

Note that B_r and B_{rs} are short-lived quantities observable only during cyclical magnetization conditions. When the applied field is removed, B_r rapidly decays to a value B_d, known as the *remanent induction*. B_d is a measure of the permanent magnetization of the ferromagnet. If the maximum applied field was in excess of saturation, B_{rs} rapidly decays to a maximum value of permanent magnetization, or *remanence*, B_{dm}.

The minor loop in Figure 29.5 shows that in order to reduce the induction *B* to zero, a reverse applied field, H_c, is needed. This is known as the *coercive force*. If the maximum applied field was in excess of saturation, the coercive force assumes a maximum value, H_{cs}, known as the *coercivity*. Note that H_c and H_{cs} are usually expressed as positive quantities, although they are negative fields relative to H'_M and H''_M.

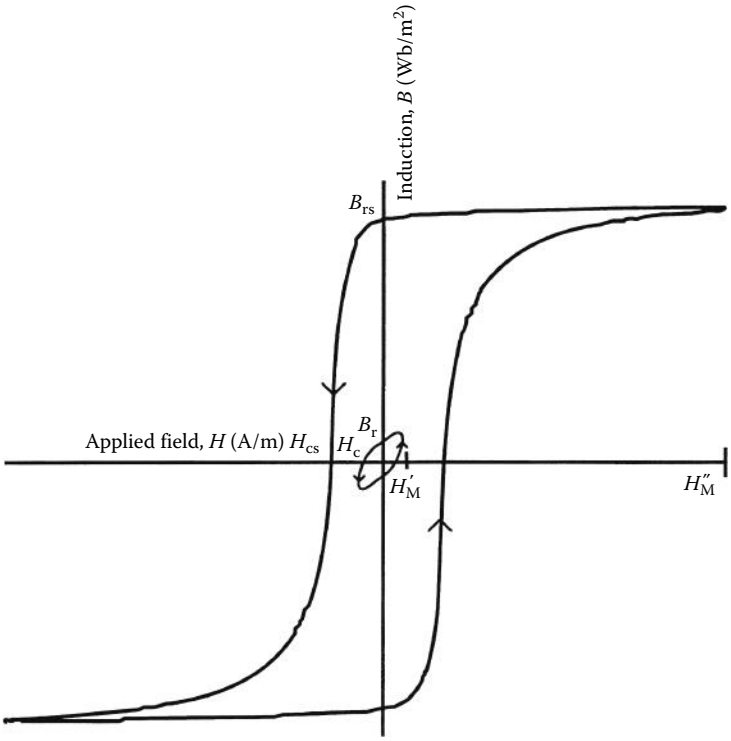

FIGURE 29.5 Major and minor dc hysteresis loops for a typical soft ferromagnet. Labeled points of interest are described in the text.

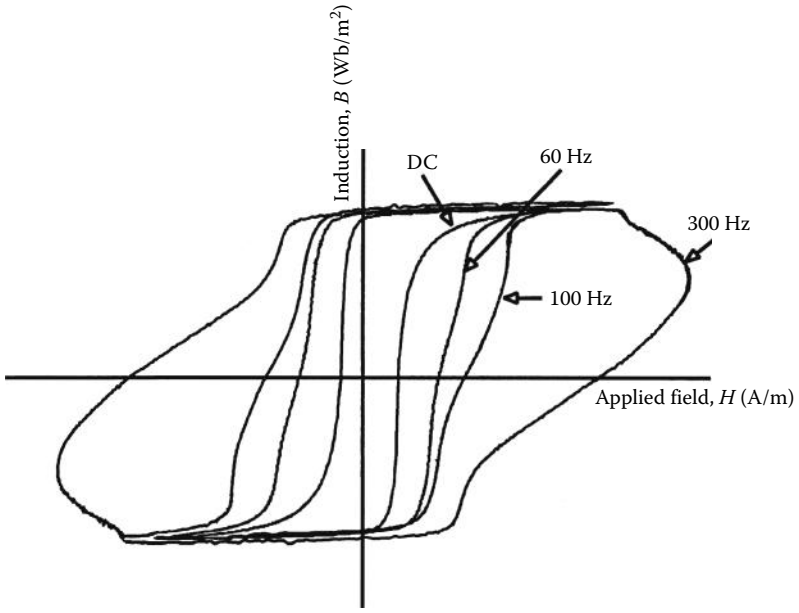

FIGURE 29.6 With increasing test frequency, coercivity for a soft ferromagnet also increases.

The hysteresis loops in Figure 29.5 are known as *direct current (dc) loops*. Typical sweep times for such loops range from 10 to 120 s. At faster sweep times, the coercivity will show frequency dependence, as shown experimentally in Figure 29.6. For soft magnetic materials, this dependence can be influenced by the metallurgical condition of the ferromagnet [6].

29.4 Core Loss

During alternating current (ac) magnetization, some of the input energy is converted to heat in ferromagnetic materials. This heat energy is called *core loss* and is classically comprised of three parts. The first, *hysteresis loss*, P_h, is proportional to the ac frequency, f, and the area of the (slow-sweep) dc hysteresis loop:

$$P_h = kf \int BdH \tag{29.4}$$

The second part is the *loss due to eddy current formation*, P_e. In magnetic testing of flat-rolled strips (e.g., the Epstein test; see next section), this core loss component is classically expressed as

$$P_e = \frac{(\pi Bft)^2}{6d\rho} \tag{29.5}$$

where

B is the peak induction
t is the strip thickness
d is the material density
ρ is the material resistivity

The sum total $P_h + P_e$ almost never equals the observed total core loss, P_t. The discrepancy chiefly originates from the assumptions made in the derivation of Equation 29.5. To account for the additional observed loss, an anomalous loss term, P_a, has often been included, so that

$$P_t = P_h + P_e + P_a \tag{29.6}$$

29.5 Measurement Methods

Reference [3] is a good source for the various accepted test methods for permeability and hysteresis in diamagnetic, paramagnetic, and ferromagnetic materials. Unfortunately, only a few of the instruments described there are available commercially. Examples of these are listed in Table 29.2.

The instruments in Table 29.2 include hysteresigraphs (LDJ models 3500, 5600, and 5500) and vibrating sample magnetometers (VSMs) (LDJ and Lakeshore Cryotronics VSM models). Also included are two Donart models of Epstein testers. The Epstein test is commonly used to characterize flat-rolled soft ferromagnets such as silicon electrical steels in sheet form. A recent alternative to the Epstein test is the single-sheet test method. The Soken instrument in Table 29.2 is an example of such a tester. This method requires much less sample volume than the Epstein test. It can also accommodate irregular sample geometries. However, the Soken instrument is not yet accepted by the American Society for Testing and Materials (ASTM) for reasons explained in the next section.

Note that all instruments in Table 29.2 can measure permeability (or susceptibility), but not all can provide hysteresis loop measurements. Diamagnetic and paramagnetic materials generally require VSM instruments unless one is prepared to construct their own specialty apparatus [3]. All instruments in Table 29.2 can measure ferromagnetic materials, although only a few can accommodate hard (i.e., permanently magnetizable) ferromagnets.

TABLE 29.2 Commercially Available Instruments for Measurement of Permeability and Hysteresis

Manufacturer	Model	Power	Material Type[a]	Ferromagnetic Type	Hysteresis Loop?	Core Loss?
LDJ	3500/5600	ac/dc	F	Soft and hard	Y	Y
Troy, MI	5500	dc	F	Soft and hard	Y	N
(810) 528-2202	VSM	dc	D, P, F	Soft and hard	Y	N
Lakeshore Cryotronics	VSM	dc	D, P, F	Soft and hard	Y	N
Westerville, OH	Susceptometer	ac	F	Soft and hard	N	N
(614) 891-2243	Magnetometer	dc	F	Soft and hard	N	N

Soken/Magnetech	DAC-BHW-2	ac	F	Soft	Y	Y
Racine, WI						
(501) 922-6899						

[a] D, diamagnetic; P, paramagnetic; F, ferromagnetic.

29.6 Validity of Measurements

For a ferromagnet under sinusoidal ac magnetization, the induction will show a waveform distortion (i.e., B is nonsinusoidal) once H_M exceeds the knee of the B–H curve in Figure 29.4. Brailsford [7] has discussed such waveform distortion in detail. With one exception, all ac instruments in Table 29.2 determine H from its sinusoidal waveform and B from its distorted waveform.

The single exception is the Soken instrument. Here, feedback amplification is employed to deliberately distort the H waveform in a way necessary to force a sinusoidal B waveform. In general, this will result in a smaller measured value for permeability compared to the case where feedback amplification is not used. Some suggest this to be the more precise method for permeability measurement, but the use of feedback amplification has prevented instruments such as the Soken from achieving ASTM acceptance to date.

Defining Terms

Hysteresis: A ferromagnetic phenomenon in which the magnetic induction B is out of phase with the magnetic driving force H.

Permeability: The extent to which a material can be magnetized.

Inductance Measurement

Michal Szyper
AGH University of Science and Technology and University of Mining and Metallurgy

Inductance is a property of all electrical conductors. It is a measurable quantity; therefore, it has a physical dimension, a measurement unit (the henry), as well as reference standards. It is found as *self-inductance L* of a single conductor and as *mutual inductance M* in the case of two or more conductors. Inductors can vary in construction, but windings in the form of coils are the most frequent. In this case, they have specific geometrical parameters: surface *A*, length *l*, and a number of turns of windings *N*. The path of magnetic flux can be specially shaped by magnetic cores. Figure 30.1 shows examples of different inductive elements of electrical circuits.

Figure 30.1a and b present windings with self-inductance made as a coreless coil (a) and wound on a ferromagnetic core that is the concentrator of the magnetic field (b). A transformer loaded by impedance Z_L and an electromagnet loaded by impedance related to eddy currents in the metal board, shown in Figure 30.1c and d, will have not only self-inductance of windings but also mutual inductance between windings (c) or between winding and eddy currents (d). Self-inductances and mutual inductances can be detected in busbars of electric power stations as shown in Figure 30.1e and also on tracks on printed circuit boards as in Figure 30.1f. Couplings between currents and electromagnetic fields can be made deliberately but can also be harmful, for example, due to energy losses caused by eddy currents or due to electromagnetic disturbances induced in the tracks of printed circuit boards. Inductors made as windings on ferromagnetic cores have numerous other applications: in electrical machines, transformers, reactors, relays, instrument transformers, as well as inductive sensors, magnetic field detectors, radio receiver antennas, components of power supplies for electronic systems, and other.

Inductive elements are characterized, apart from the inductance *L* and *M*, by the resistance *R* of their windings, which also represents active power losses in the core, and by the capacitance *C* between their windings. Inductive elements can be therefore described by the impedance *Z* (two-terminal network) or transmittance *T* (four-terminal network) whose numerical values are determined experimentally from the voltage and current measurements or by comparison with reference impedances. The models' parameters: self-inductances, mutual inductances, resistances, and capacitances are computed from the measurement results, based on a chosen circuit model (equivalent circuit).

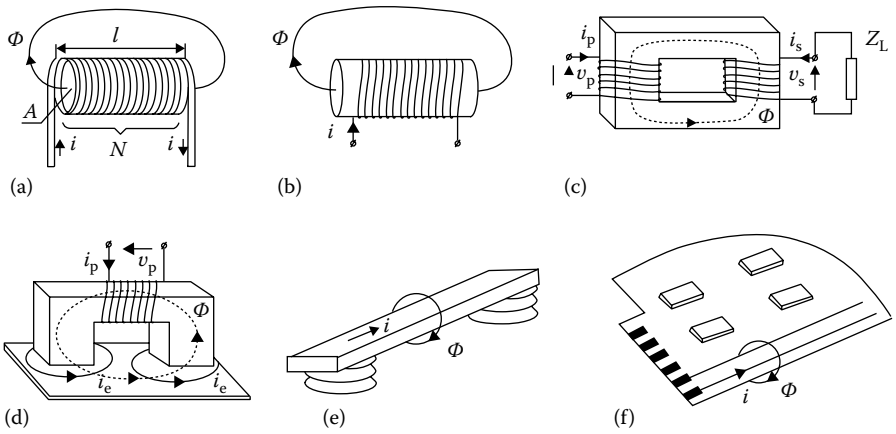

FIGURE 30.1 Examples of different inductive elements: (a) coreless coil, (b) coil with ferromagnetic concentrating core, (c) transformer, (d) electromagnet, (e) element of electrical power station busbars, and (f) printed circuit board with conductive tracks.

30.1 Definitions of Inductance

Inductance is a physical quantity measured in electric circuits in which current is changing in time. A time-varying electric current $i(t)$ produces a time-varying magnetic flux $\Phi(t)$ around the current-carrying conductors; thus, the current and the magnetic field are mutually coupled. The result of this coupling is the electromotive force, that is, the electric voltage $v_L(t)$ induced in these conductors according to Maxwell's law (Dorf and Svoboda 2003). The value of the voltage $v_L(t)$ and the form of its variability in time are thus dependent on the magnetic flux $\Phi(t)$ coupled with the current $i(t)$. In the simple case of a single current-carrying conductor placed in air, whose resistances and capacitances have been neglected as very small, these relations are

$$\Phi(t) = Li(t) \tag{30.1}$$

$$v_L(t) = \frac{d\Phi(t)}{dt} = L\frac{di(t)}{dt} \tag{30.2}$$

where L is the self-inductance of the conductor. The form of the Equation 30.2 and assumption of placing the conductor in air mean that the inductance L is ideal and it does not depend on neither the current nor time. In other words, regarding the inductance L of a current-carrying conductor, the electric circuit comprising this conductor is linear and stationary.

Using the Equation 30.2, the unit of self-inductance one henry (1 H) has been defined as a physical dimension of this quantity in the SI system (Dyer 2001, Tumanski 2006):

One henry (1 H) is the self-inductance of an electric conductor in which an electromotive force of one volt (1 V) is induced when the current in this conductor is uniformly changing at the rate one ampere (1 A) per second (1 s).

Apart from the self-inductance L of a single current-carrying conductor, also the mutual inductance M of two (or a larger number of) conductors is defined. Similarly, as in the case of the self-inductance, the mutual inductance is defined as the effect of coupling the windings by a magnetic flux passing through both windings and produced by the currents: primary $i_p(t)$ and secondary $i_s(t)$ in the primary and the secondary winding, respectively, as in Figure 30.1c. If we make the simplifying assumption about a linear relation between the flux $\Phi(t)$ and the current $i_p(t)$, assume the current $i_s(t) = 0$

(i.e., the secondary circuit is open), and neglect the resistances and capacitances, the mutual inductance between the primary and secondary winding can be defined as

$$v_s(t) = N_s \frac{d\Phi(t)}{dt} = k\sqrt{L_p L_s}\,\frac{di_p(t)}{dt} = M\frac{di_p(t)}{dt} \tag{30.3}$$

where $-1 \le k \le 1$ is the coupling coefficient between the primary and secondary winding. Its value depends on the windings design and, if the inductor has a magnetic core, on the core properties, and its sign depends on the windings direction. Self-inductances of the primary and secondary winding are denoted L_p and L_s, respectively, and the number of turns of the secondary winding is denoted N_s. The value $k \neq \pm 1$ means that the primary and secondary windings are not fully magnetically coupled; thus, a portion of the flux leaks out. Ferromagnetic cores significantly reduce the phenomenon of magnetic flux leakage but they can be a cause of the nonlinear relation between currents and the magnetic flux. The unit of mutual inductance is also the henry (1 H), defined similarly to the self-inductance unit (Dyer 2001, Tumanski 2006).

Since the use of a current test signal $i(t)$ or $i_p(t)$ uniformly (i.e., linearly) changing with time is inconvenient, usually sinusoidal test signals are employed for the inductance measurement: a current source signal $i(t) = I_m \sin\omega t$ or a voltage source signal $v(t) = V_m \sin\omega t$. For such case, and under formerly made simplifying assumptions, Equations 30.1 through 30.3 take the form

$$\Phi(t) = LI_m \sin\omega t \tag{30.4}$$

$$v_L(t) = \omega L I_m \cos\omega t = X_L(\omega) I_m \cos\omega t = V_{Lm} \cos\omega t \tag{30.5}$$

$$v_s(t) = \omega M I_{pm} \cos\omega t = T_{ps}(\omega) I_{pm} \cos\omega t = V_{sm} \cos\omega t \tag{30.6}$$

The reactance of a winding with self-inductance L, that is, a two-terminal network is denoted $X_L(\omega) = \omega L$. The *transmittance* between the secondary winding voltage $v_s(t)$ and the current $i_p(t)$ in the primary winding with mutual inductance M, that is, a four-terminal network, is denoted $T_{ps} = \omega M$.

Equations 30.1 through 30.6 indicate the method for measuring ideal self- and mutual inductances. It consists of determining the voltage and current signal values: the current signal rate of change and the voltage steady-state value for the first case, or the voltage and current amplitudes and frequency for the second case, and calculating the inductance from the quotient of these values. In such simple case, the use of a current source and an oscilloscope is sufficient. However, as mentioned in the introduction, inductive elements in electric circuits are characterized by resistances and capacitances, and relations between their currents and magnetic fluxes can be nonlinear. Expressions that represent actual properties of inductive elements are termed their models, and graphical representations of models are called equivalent circuits.

30.2 Models and Equivalent Circuits of Inductive Elements

Possibilities and methods of measuring the inductance of inductive elements depend on the form and properties of mathematical models we assign to them. Like in a case of any measurement, we only can measure phenomena, which we are able to describe mathematically. The representation error of actual properties of inductive elements models is always limited and its value can be selected. We choose the representation error value depending on the purpose, for which the model is intended, and then we measure its variables (currents and voltages) and calculate coefficients (inductances, resistances, and capacitances), that is, the values of the equivalent circuit components. The chosen model should take into account physical phenomena occurring in the measured inductive element that are necessary for obtaining the required accuracy of the measurement. In real inductive elements, aside from the

coupling between the current in conductors and the magnetic flux produced by this current and the voltage induction at the ends of these conductors, the following phenomena occur:

- Heat dissipation in resistances of the inductive element conductors.
- Heat dissipation in magnetic cores, on which windings having an inductance are wound, and in conductive elements in which eddy currents flow.
- The nonlinear and ambiguous relation between the current in a winding wound on a magnetic core and the magnetic flux produced in the core by this current termed the magnetization curve and the phenomenon of magnetic hysteresis.
- The phenomenon of electrical energy storing in stray (i.e., spatially distributed) self-capacitances of current-carrying conductors, for example, of individual turns of a winding with respect to each other or to shields and adjacent structures.
- The phenomenon of coupling of the magnetic flux produced the current in conductors with eddy currents induced by this current in adjacent conductive elements, like metallic components of sensors, shields, and metallic structures.
- The phenomenon of the increase in a conductor resistance with the frequency of the current in this conductor, termed the skin effect.
- The influence of external magnetic fields (i.e., not being produced by the current flowing in the windings) on the total magnetic flux coupled with these windings and, consequently, on the additive voltage from electromagnetic interferences (normal) induced by external magnetic fields in these windings.
- Spatial heterogeneity of magnetic flux density in magnetic core volume due to material properties and the core design (Craigen 2010).

These phenomena may, depending on the measurement conditions, considerably influence the measurement results and, consequently, their accuracy, that is, the inductance measurement errors. Therefore, if this influence is significant, they should be taken into account in the inductive elements models.

The following can be used as the models of inductive elements:

1. Operator algebraic equations, usually in the complex notation with the Fourier operator ($j\omega$) having the form of linear algebraic relations between the variables $I(j\omega)$, $V(j\omega)$, and $\Phi(j\omega)$ with coefficients $L(\omega)$, $M(\omega)$, $C(\omega)$, and $R(\omega)$ occurring in the determined impedances $Z(j\omega)$ or transmittances $T(j\omega)$ (Dyer 2001)
2. Linear or nonlinear differential equations and stationary or nonstationary differential equations with variables $i(t)$, $v(t)$, and $\Phi(t)$ and coefficients L, M, C, and R, or the corresponding integral operations (Dorf and Svoboda 2003)

A graphical representation of these models is equivalent circuits that have the form of electric circuits comprising L,C,R elements and represent the aforementioned physical phenomena with a given error.

Figure 30.2 shows basic equivalent circuits of typical inductive elements used in electric circuits. They are categorized according to the nature of their inductance (the self-inductance L and mutual inductance M), the frequency band (low frequencies LF, radio frequencies RF) and the presence (PMC) or absence (AMC) of ferromagnetic core. Equivalent circuits of coreless inductive elements for low frequencies (LF) comprise exclusively inductances and resistances connected in series, whereas for radio frequencies (RF), they also include capacitances connected in parallel with inductances and resistances. In the case of inductive elements having a magnetic core, their models and equivalent circuits are usually linearized. The method consists of determining the equivalent circuit parameters for the steady-state (e.g., nominal) values of the current amplitude and frequency. In such case, the magnetizing inductance $L\mu$ and, usually much smaller, leakage inductances L_d, L_{pd}, and L_{sd} are determined, as well as the resistances that represent active power losses in the core R_{Fe} and in windings R_{Cu}, R_{pCu}, and R_{sCu}.

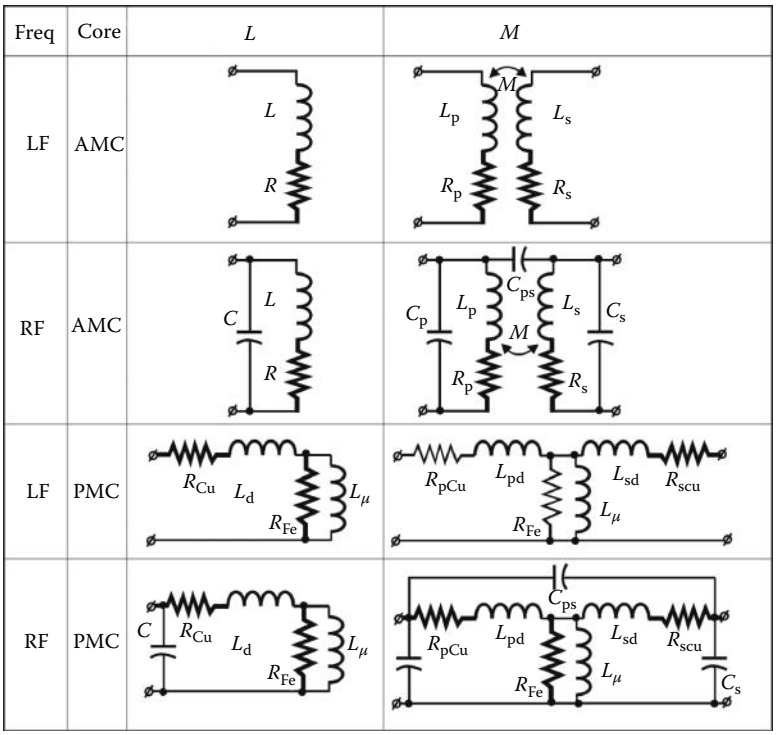

FIGURE 30.2 Basic equivalent circuits of inductive elements with self-inductance L, mutual inductance M for low (LF) and high (HF) frequencies, without ferromagnetic cores (AMC), and with ferromagnetic cores (PMC).

Since the calculation of *LCR* components' values in a complex equivalent circuit is complicated, appropriate computational tools, designed for solving electric circuits, are employed for this purpose.

In the complex number notation, the impedances and transmittances take the form

$$Z = R_Z + jX_Z = Z_m \exp(j\phi_Z), \quad Z_m = \sqrt{R_Z^2 + X_Z^2}, \quad \phi_Z = \arctan\frac{X_Z}{R_Z} \tag{30.7}$$

$$T = R_T + jX_T = T_m \exp(j\phi_T), \quad T_m = \sqrt{R_T^2 + X_T^2}, \quad \phi_T = \arctan\frac{X_T}{R_T} \tag{30.8}$$

The components R_Z, X_Z, and R_T, X_T of the impedance Z and the transmittance T are the algebraic functions of the determined values of *LCR* elements of equivalent circuits. Thus, by measuring the real and imaginary components, or moduli and phase angles of an impedance or transmittance, and comparing them with complex components of the functions representing equivalent circuits, we obtain algebraic equations systems whose solutions are the sought *LCR* elements values. For example, in the equivalent circuit denoted (L, LF, AMC) in Figure 30.2, from the measured impedance $Z = R_Z + jX_Z$, component values can be calculated: $L = \omega^{-1}X_Z$ and $R_L = R_Z$.

Linearization of models of inductive elements with ferromagnetic cores can however be the cause of considerably large errors in determination of inductance, whereas taking into consideration nonlinear relations between the measured inductances and currents requires the use of more complex models, for example, in the form of differential equation representing the inductive element with the voltage test signal $v(t)$:

$$L(i(t))\frac{di(t)}{dt} + i(t)\frac{dL(i(t))}{dt} + R_L(i(t))i(t) = v(t) \tag{30.9}$$

whose equivalent circuit is denoted (L, LF, PMC) in Figure 30.2. The measured values of the equivalent current-dependent self-inductance and the equivalent resistance are denoted $L(i(t))$ and $R_L(i(t))$, respectively. Steady-state $L(i)$ values can be determined from the relation $L(i) \approx \Delta\Phi(i)/\Delta i$ by measuring the magnetizing curve $\Phi(i)$. A shape of this curve depends not only on the amplitude of the current $i(t)$ but also on its frequency ω. The value of the resistance $R_L(i(t))$ also depends on the current amplitude and frequency. Where a dc component of the current in the inductive element (bias current) is applied, the inductance and resistance values depend also on this component value. Therefore, application of nonlinear models of inductive elements for determination of their variable coefficients is a difficult measuring task, usually solved by means of specialized measuring instruments (Agilent Handbook 2009). The variable coefficients of models having the form of Equation 30.9 can be determined by employing computational methods for model identification (Utsun 2009), for example, the tuned model method that is based on minimizing the difference between responses of the measured inductive element and its model to identical excitation with variable in time test signal.

30.3 Measurement Methods

Impedance (or transmittance) measurement methods for inductive elements used for determination of their inductance can be divided into three basic groups:

1. Current–voltage methods based on determination of the impedance (transmittance) and calculation of their equivalent circuit *LCR* components values from the measured current and voltage signal parameters, for example, amplitudes and phase angles in the case of sinusoidal signals, or from the measured parameters of the test signals of a different shape, for example, a step signal
2. Bridge and differential methods based on comparison of sinusoidal current and voltage signals of the measured (unknown) and the reference (known) impedances until a state of the signals equality is reached, that is, the approximate equality of the compared impedances with a given (small) error
3. Resonant methods based on the series or parallel connection of the measured inductive impedance with a variable (controlled) capacitive impedance, tuning resulting circuit to resonance at the given frequency of the excitation signal, and determination of the inductive reactance value from relations describing the state of resonance

30.3.1 Current–Voltage Methods

Current–voltage methods are presently a wide group of measurement methods employed in inductance measurements of all types of inductive elements. In these methods, periodic excitation signals are used within the frequency ranges from ca. 10 Hz to ca. 100 kHz (LF) and from ca. 100 kHz to ca. 1 GHz (RF), as well as in the range from ca. 1 GHz to ca. 100 GHz. Also, the current and voltage values are selected from a wide range, according to both the application and operating conditions of these elements. The accuracy of current–voltage methods is usually not very high and is contained within ca. 1% to ca. 10% of the measured impedance value. Simple current–voltage methods consist of the use of sinusoidal excitation and measuring the amplitudes or rms values and phase angles between currents and voltages in the measured inductance elements. In the case of inductive elements with large currents, and at low frequencies, the rms voltmeters and ammeters are used, as well as wattmeters applied for the measurement of active power losses in the measured element (Figure 30.3a). The "wattmeter" method can be used for measuring the equivalent inductances of nonlinear elements with cores, particularly those operated at the power network frequency (50 or 60 Hz). In the case of approximately linear elements and for higher frequencies, oscilloscopes are used in the *X*–*Y* mode, with both axes scaled in the current and voltage values, to allow determination of amplitudes of these signals and phase angles between them (Figure 30.3b). The orthogonal composition of the measured current and voltage signals, termed the

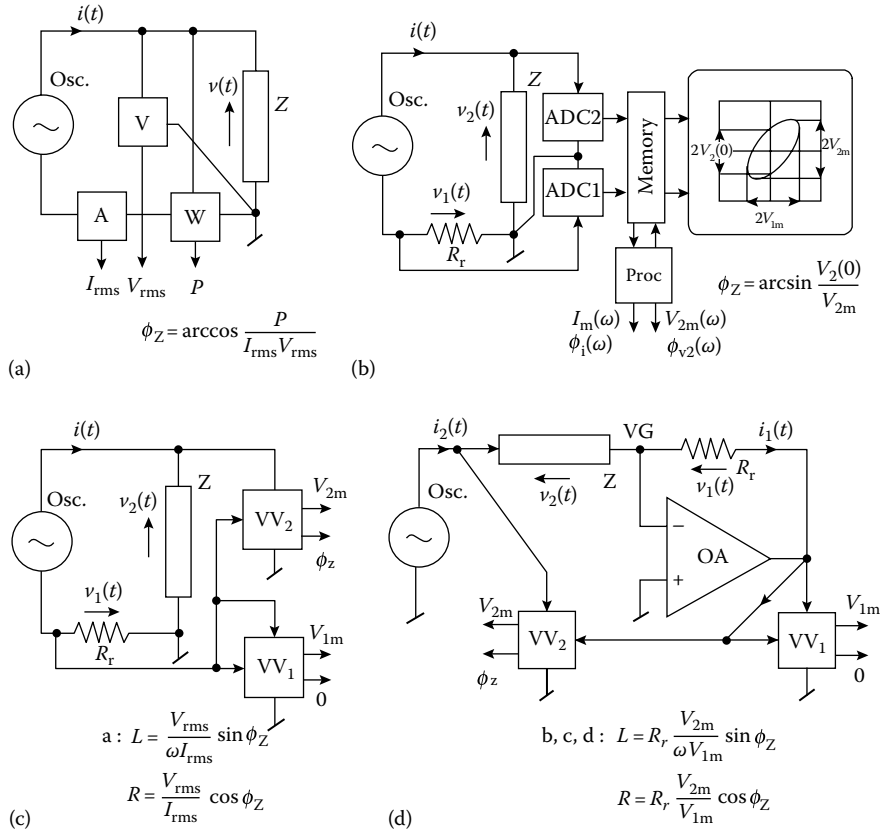

FIGURE 30.3 Circuit diagram for impedance measurement by current and voltage method: (a) the wattmeter method, (b) the oscilloscope method, (c) the concept of vector voltmeters method, and (d) the current-to-voltage conversion method using vector voltmeters.

"ellipse" method, allows observing the effects of the measured impedance nonlinearity, but the condition of its correct application is that transmittances of both oscilloscope channels are identical. Instead of using the "ellipse" method, the current and voltage waveforms can be stored in the oscilloscope memory using sufficiently fast sampling AD converters. On the stored signals, mathematical operations can be performed, for example, determination of their amplitude and phase spectra over the specified frequency band within an appropriate time window, from which the impedances or transmittances can be computed (NI Developer Zone [tutorial]).

Other conceptions of measuring systems employing current–voltage methods utilizing vector voltmeters are shown in Figure 30.3c and d. They consist of determining the modules and phase angles of the measured impedances or transmittances from the quotient of the voltage and current complex values from Equations 30.10 and 30.11 and computing the self- or mutual inductances basing on the assumed equivalent circuits:

$$Z = \frac{v_2}{i} = R_r \frac{v_2}{v_1} = R_r \frac{V_{2m} \exp(j\phi_2)}{V_{1m} \exp(j\phi_1)} = R_r \frac{V_{2m}}{V_{1m}} \exp j(\phi_2 - \phi_1) = Z_m \exp(j\phi_Z) \tag{30.10}$$

$$T = \frac{v_s}{i_p} = R_r \frac{v_s}{v_{pr}} = R_r \frac{V_{sm} \exp(j\phi_s)}{V_{prm} \exp(j\phi_{pr})} = R_r \frac{V_{sm}}{V_{prm}} \exp j(\phi_s - \phi_{pr}) = T_m \exp(j\phi_T) \tag{30.11}$$

The amplitudes of voltages across the measured impedance and transmittance are denoted V_{2m} and V_{sm}, the amplitudes of voltages proportional to the impedance and transmittance currents are denoted V_{1m} and V_{prm}, and Φ_2, Φ_1, Φ_s, Φ_{pr} denote the phase angles of these signals, respectively. The results of voltage measurements using vector voltmeters are amplitudes and phase angles with respect to the reference voltage phase angle. Since Equations 30.10 and 30.11 allow computing the differences between the results of the phase angle measurements, it is convenient to take one of the measured voltage signals as the reference voltage, with respect to which the other voltage phase angles will be determined as the value of the measured angle difference. In Figure 30.3c and d, it has been assumed that the reference voltage signal is the voltage across the resistor R_r. This voltage is proportional to the current but can be measured in different ways. The measuring system, shown in Figure 30.3c as the simplified conception of the measurement method, requires an appropriate choice of the reference point ("ground") common for both voltmeters, which may be difficult due to common-mode interference. The measuring system with current-to-voltage conversion shown in Figure 30.3d utilizes precise, wideband operational amplifiers (OAs). The node denoted VG is called "virtual ground point."

The vector voltmeter VV_1 measures the amplitude of the voltage drop $V_{1m} = R_r I_m$ caused by the test current $i_1(t) = i_2(t)$, and the result of phase angle measurement is $\Phi_1 = 0$. The vector voltmeter VV_2 measures the amplitude V_{2m} of the voltage drop $v_2(t)$ across the impedance Z and the phase angle $\Phi_2 = \Phi_Z$ between this voltage and the current. If the measurements are conducted at the radio frequencies, the capacitances of inductive elements should be taken into account, that is, the equivalent circuits denoted (L, RF, AMC) or (M, RF, AMC) in Figure 30.2 should be used. The measurements should be performed for the number of frequencies corresponding to the number of the necessary algebraic equations. The measuring system conception shown in Figure 30.3d is currently one of the most commonly employed to inductance measurement method.

A block diagram illustrating the principle of the vector voltmeter is shown in Figure 30.4a. The system consists of the multiplier or gated synchronous phase-sensitive detector (PSD) (Dyer 2001, Tumanski 2006) of the measured voltage v with the switching system of the phase of the reference voltage v_{dn}, integrator, digital voltmeter, and processor. The principle of vector voltmeter operation is based on determination of the magnitude V_m and phase angle ϕ of the measured voltage v in reference to voltage v_1, which is proportional to the current i. Assume that voltages v and v_{dn} are in the following forms:

$$v = V_m \sin(\omega t + \phi) = V_m(\sin\omega t \cos\phi + \cos\omega t \sin\phi) \tag{30.12}$$

$$v_{dn} = V_{md} \sin(\omega t + n\,\pi/2), \quad n = 0, 1, 2, 3 \tag{30.13}$$

Phase angle $n\pi/2$ of voltage v_{dn} can take values from the set $\{0, \pi/2, \pi, 3/2\,\pi\}$ by choosing the number n that gives the possibility of detecting the phase angle ϕ in all four quadrants of the Cartesian coordinate

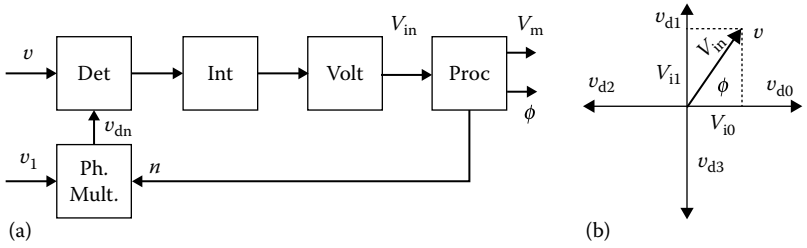

FIGURE 30.4 Block diagram (a) and phasor diagram (b) illustrating the principle of operation of a vector voltmeter. Block abbreviations: "Det," phase-sensitive amplitude detector; "Int," integrator; "Volt," voltmeter; "Proc," processor; and "Ph. mult," controlled phase multiplexer.

system, as is shown in Figure 30.4b. A multiplying synchronous phase detector multiplies voltages v and v_{dn}, and the integrator averages the multiplication result during time T_i:

$$V_{in} = \frac{1}{T_i}\int_0^{T_i} v\, v_{dn}\, dt \tag{30.14}$$

Averaging time $T_i = k\ T$, $k = 1, 2, 3, \ldots$ is a multiple of the period T of the measured voltage. From Equations 30.12 through 30.14, an example for $0 \le \phi \le \pi/2$ (e.g., $n = 0$ and $n = 1$), a pair of numbers is obtained:

$$V_{i0} = 0.5 V_m V_{md} \cos\phi, \quad V_{i1} = 0.5 V_m V_{md} \sin\phi \tag{30.15}$$

which are the values of the Cartesian coordinates of the measured voltage v. The module and phase angle of voltage are calculated from

$$V_m = \frac{2}{V_{md}}\sqrt{V_{i0}^2 + V_{i0}^2}, \quad \phi = \text{arctg}\frac{V_{i1}}{V_{i0}} \tag{30.16}$$

Both coordinates of the measured voltage v can be calculated in a similar way in the remaining quadrants of the Cartesian coordinate system. A vector voltmeter determines the measured voltage as vector (phasor) by measurement of its magnitude and angle as shown in Figure 30.4.

The current and voltage method of impedance or transmittance measurement is based on the measurement of voltages $v_1 = i\ R_r$ and v_2 or $v_{pr} = iR_r$ and v_s and the use of Equation 30.10 or 30.11. Calculation of the voltage measurement results and control of number n is performed by a processor. Errors in phase angle measurement of impedance when using vector voltmeters are within the range of 1% to 10% or between 10^{-5} and 10^{-3} rad, respectively, for a frequency equal to 1 GHz (information from websites). Advanced instruments for impedance and inductance measurements utilizing the vector current–voltage method are known as vector impedance meter or vector network analyzers.

Another method of comparative current/voltage type is a modernized version of the "three-voltmeter" method (Sydenham 1983). A diagram of a measurement system illustrating the principle of the method is shown in Figure 30.5a and b.

The method is based on the properties of an OA, in which output voltage v_2 is proportional to input voltage v_1 and to the ratio of the reference resistance R_r to measured impedance Z. The phasor

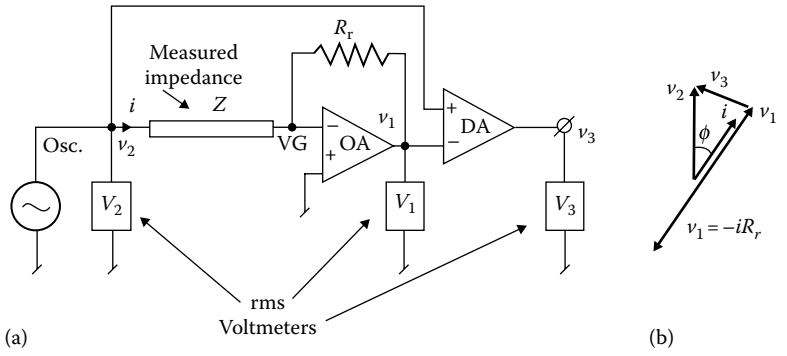

FIGURE 30.5 Block diagram (a) and phasor diagram (b) of the "three-voltmeter" method. Operational and differential amplifiers are represented by blocks "OA" and "DA."

difference v_3 of voltages v_1 and v_2 can be obtained using the differential amplifier (DA). The three voltages (as in Figure 30.5b) can be used for the module Z_m and phase ϕ calculation using relations

$$V_2 = i R_r = -\frac{R_r}{Z} v_1 \rightarrow Z_m = \frac{V_1}{V_2} R_r \tag{30.17}$$

$$v_3 = v_1 - v_2 \rightarrow \phi = \arccos \frac{V_1^2 + V_2^2 - V_3^2}{2V_1V_2} \tag{30.18}$$

where V_1, V_2, V_3 are the results of rms voltage measurements in the circuit. The advantage of the method lies in limiting the influence of stray capacitances as a result of attaching one of the terminals of the measured impedance to a point of "virtual ground." However, in order to obtain small measurement errors, particularly at high frequencies, wideband OAs and wideband rms voltmeters must be used.

Total errors of the inductance measurement, obtained by the current–voltage methods, depend on voltmeter errors, the amplifiers and resistance R_r errors, system factors (residual and leakage inductances, resistances, and capacitances), and the quality of approximation of the measured impedances by the equivalent circuit.

30.3.2 Bridge Methods

There is a variety of bridge methods for measuring inductances. Principles of operation and circuit diagrams of bridges are described in Helfrick and Cooper (2009), Dyer (2001), Tumanski (2006), and Sydenham (1983). The most common ac bridges for inductance measurements and the formulae for calculating measurement results are shown in Figure 30.6.

The procedure referred to as *bridge balancing* is based on a proper selection of the reference values of the bridge so as to reduce the differential voltage to zero (as referred to the output signal of the balance indicator). It can be done manually or automatically.

The condition of the balanced bridge $v_0 = 0$ leads to the following relation between the impedances of the bridge branches; one of them (e.g., Z_1) is the measured impedance:

$$Z_1Z_3 = Z_2Z_4 \rightarrow (R_1 + jX_1)(R_3 + jX_3) = (R_2 + jX_2)(R_4 + jX_4) \tag{30.19}$$

Putting Equation 30.19 into complex form and using expressions for the impedances of each branch, two algebraic equations are obtained by comparing the real and imaginary components. They are used to determine the values of the equivalent circuit elements of the measured impedance. In the simplest case, they are L and R elements connected in series. More complicated equivalent circuits need more equations to determine the equivalent circuit parameters. Additional equations can be obtained from measurements made at different frequencies.

In self-balancing bridges, vector voltmeters preceded by an amplifier of the out-of-balance voltage v_0 are used as "zero" detectors. The detector output is coupled with variable standard bridge components.

The Maxwell Wien bridge shown in Figure 30.6a is one of the most popular ac bridges. Its range of measurement values is large and the relative error of measurement is about 0.1% of the measured value. It is used in the wide frequency band of 20 Hz–1 MHz. The bridge is balanced by varying the R_2 and R_3 resistors or by varying R_3 and capacitor C_3. Some difficulties can be expected when balancing a bridge with inductors with high time constants.

The Hay bridge presented in Figure 30.6b is also used for measurement of inductors, particularly those with high time constants. The balance conditions of the bridge depend on the frequency value, so the frequency should be kept constant during the measurements, and the bridge supply voltage should

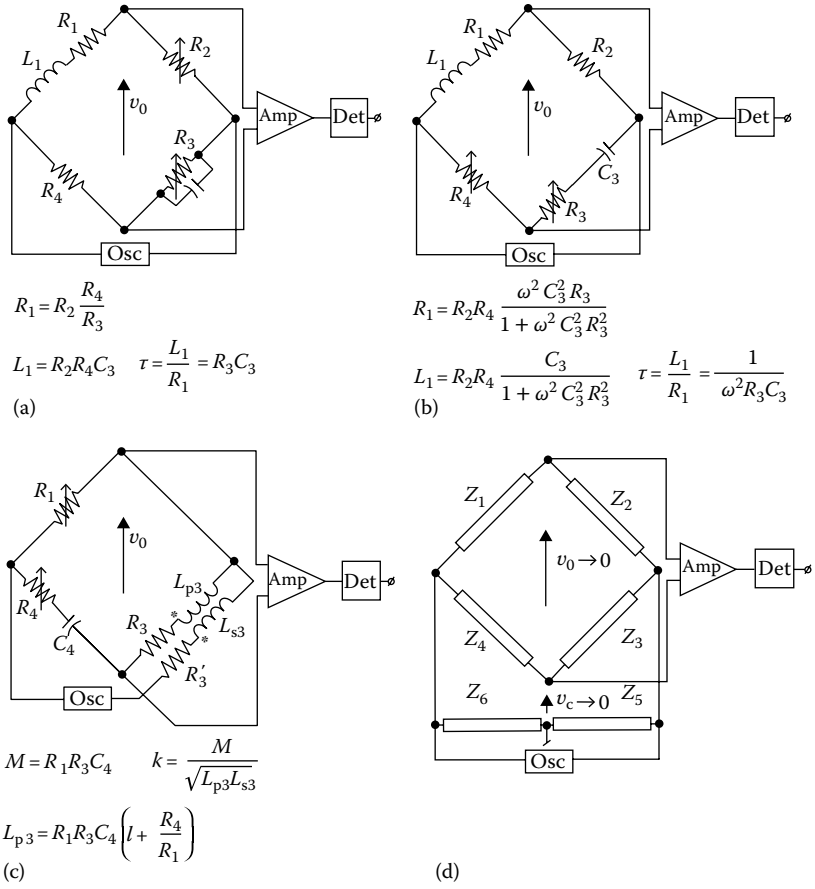

FIGURE 30.6 Bridge circuits used for inductance measurements: (a) Maxwell Wien bridge, (b) Hay bridge, (c) Carey Foster bridge, and (d) ac bridge with Wagner branch. Block abbreviations: Osc, oscillator; Amp, amplifier; Det, amplitude detector.

be free from harmonic distortions. The dependence of bridge balance conditions on frequency also limits the measurement ranges. The bridge is balanced by varying R_3 and R_4 resistors and by switching capacitor C_3.

Mutual inductance M of two windings with self-inductances L_p and L_s can be determined by Maxwell Wien or Hay bridges. For this, two inductance measurements have to be made for two possible combinations of the series connection of both coupled windings: one of them for the corresponding directions of the windings, and one for the opposite directions. Two values of inductances L_1 and L_2 are obtained as the result of the measurements:

$$L_1 = L_p + L_s + 2M, \quad L_2 = L_p + L_s - 2M \tag{30.20}$$

Mutual inductance is calculated from

$$M = 0.25(L_1 - L_2) \tag{30.21}$$

The Carey Foster bridge described in Figure 30.6c is used for mutual inductance measurement. The self-inductances of the primary and secondary windings can be determined by two consecutive measurements. The expressions presented in Figure 30.6c yield the magnetic coupling coefficient k.

The bridge can be used in a wide frequency range. The bridge can be balanced by varying R_1 and R_4 resistances and switching the remaining elements.

For correct measurements with ac bridges, it is essential to minimize the influence of harmful couplings among the bridge elements and connection wires, both between each other and to the environment. Elimination of parallel (common) and series (normal, electromagnetic) voltage distortions is necessary for high measurement resolution. These couplings are produced by the capacitances, inductances, and parasitic resistances of bridge elements to the environment and among themselves. Because of their appearance, they are called stray couplings. Series (electromagnetic, normal) voltage distortions are induced in the bridge circuit by varying common electromagnetic fields. Parallel (common) voltage distortions are caused by potential differences between the reference point of the supply voltage and the points of the out-of-balance voltage detector.

Magnetic shields applied to connection wires and bridge-balancing elements are the basic means of minimizing the influence of parasitic couplings and voltage distortions (Sydenham 1983). All the shields should be connected as a "star" connection, that is, at one point, and connected to one reference ("ground") point of the system. For these reasons, amplifiers with symmetric inputs are frequently used in an out-of-balance voltage detector of ac bridges, as they reject parallel voltage distortions well.

When each of the four nodes of the bridge has different stray impedances to the reference ground, an additional circuit called a Wagner branch is used (see Figure 30.6d). By varying impedances Z_5 and Z_6 in this circuit, voltage v_c can be reduced to zero; by varying the other impedances, voltage v_0 can also be reduced to zero. This way, the bridge becomes symmetrical in relation to the reference ground point and the influence of the stray impedances is minimized.

The total error of the inductance measurement results (when using bridge methods) depends on the following factors: the accuracy of the standards used as the bridge elements, mainly standard resistors and capacitors; errors of determining the frequency of the bridge-supplying voltage (if it appears in the expressions for the measured values); errors of the resolution of the zero detection systems (errors of state of balance); errors caused by the influence of residual and stray inductances; resistances and capacitances of the bridge elements and wiring; and the quality of approximation of the measured impedances in the equivalent circuit.

The errors of equivalent resistance measurements of inductive elements using bridge methods are higher than the errors of inductance measurements. The number of various existing ac bridge systems is very high. Often, the bridge system is built as a universal system that can be configured for different applications by switching elements. One of the designs of such a system is described in Helfrick and Cooper (2009). The example of an automatic bridge is given in Dyer (2001).

30.3.3 Differential Methods

Differential methods (Sydenham 1983) can be used to build fully automatic digital impedance meters (of real and imaginary components or module and phase components) that can measure inductive impedances. Differential methods are characterized by small errors, high resolution, and a wide frequency band and often utilize precise digital control and digital processing of the measurement results. The principle of differential methods is presented through the example of a measuring system with an inductive voltage divider (IVD) and a magnetic current comparator (MCC) (Figure 30.7). An IVD is a precise voltage transformer with several secondary winding taps that can be used to vary the secondary voltage in precisely known steps (Sydenham 1983). By combining several IVDs in parallel, it is possible to obtain a precise voltage division, usually in the decade system. The primary winding is supplied from a sinusoidal voltage source. An MCC is a precise differential transformer with two primary windings and a single secondary winding. The primary windings are connected in a differential way; that is, the magnetic fluxes produced by the currents in these windings subtract. The output voltage of the secondary winding depends on the current difference in the primary windings. MCCs are characterized by very high resolution and low error but are expensive. In systems in common use, precise control of

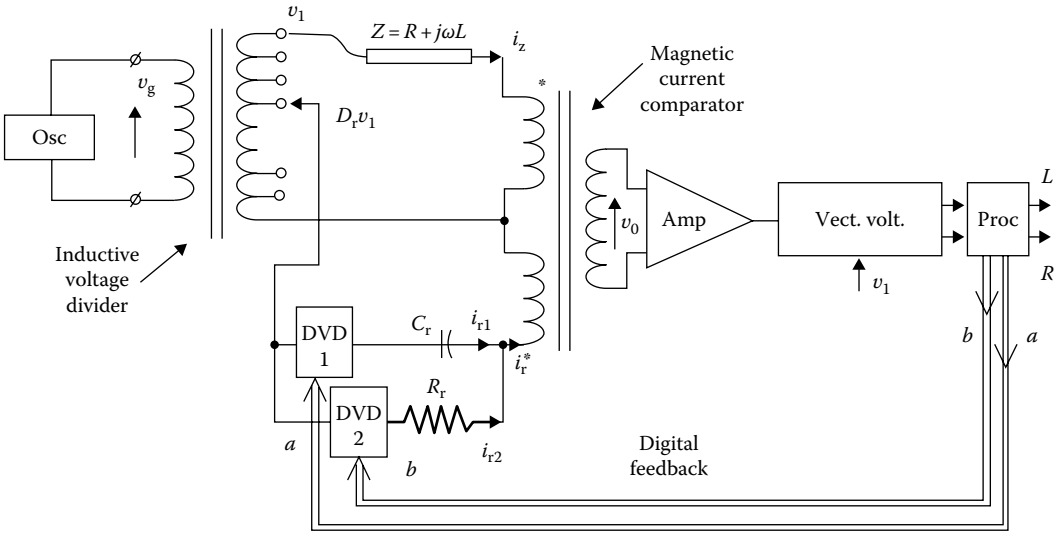

FIGURE 30.7 Scheme of the differential method. Block abbreviations: Osc, oscillator; Amp, amplifier; Vect. voltm, vector voltmeter; Proc, processor; DVD, digital voltage divider.

voltages (IVD) is provided by digitally controlled (sign and values) digital voltage dividers (DVDs), and the magnetic comparator is replaced by a DA.

The algorithms that enable calculation of L and R element values of the series equivalent circuit of an inductive impedance Z in a digital processor result from the mathematical model described in Figure 30.7. When the system is in a state of equilibrium, the following relations occur:

$$V_0 = 0 \rightarrow i_z - i_r = 0 \tag{30.22}$$

$$i_z = D_1 v_2 \frac{1}{R + j\omega L}, \quad i_r = v_r \left(\frac{b}{R_r} - aj\omega C_r \right) \tag{30.23}$$

where $0 < D_r \leq 1$ is the coefficient of v_1 voltage division and the values a and b are equivalent to the binary signals used by the processor to control DVD. Multiple digital-to-analog converters (DACs) are used as digitally controlled voltage dividers. They multiply voltage $D_r v_1$ by negative numbers ($-a$), which is needed in the case of using a standard capacitor C_r for measurements of inductance. After substituting Equation 30.23 into Equation 30.22 and equating the real and imaginary parts, the following formulae are obtained:

$$L = \frac{aR_r^2 C_r}{D_r \left(b^2 + a\omega^2 R_r^2 C_r^2 \right)} \tag{30.24}$$

$$R = \frac{bR_r}{D_r \left(b^2 + a\omega^2 R_r^2 C_r^2 \right)} \tag{30.25}$$

The length N of the code words $\{a_n\} \leftrightarrow a$ and $\{b_n\} \leftrightarrow b$, $n = 1, 2, \ldots, N$ determines the range and resolution of the measurement system; that is, the highest measurable inductance and resistance values and the lowest detectable values. The range can be chosen automatically by changing the division

coefficients D_r. Achieved accuracy is better than 0.1% in a very large range of impedances and in a sufficiently large frequency range. Measurements can be periodically repeated and their results can be stored and processed.

30.3.4 Resonance Methods

Resonance methods are a third group of methods of measuring inductance. They are based on application of a series or parallel resonance *LC* circuits as elements of either a bridge circuit or a two-port (four terminals) "T"-type network. Examples of both circuit applications are presented in Figure 30.8. In the bridge circuit shown in Figure 30.8a, which contains a series resonance circuit, the resonance state is obtained by varying the capacitor C_r, and then the bridge is balanced ($v_0 = 0$) using the bridge resistors. From the resonance and balance conditions, the following expressions are obtained:

$$L = \frac{1}{\omega^2 C_r}, \quad R = R_2 \frac{R_4}{R_3} \tag{30.26}$$

To calculate the values of the *LR* elements of the series equivalent circuit of the measured impedance, it is necessary to measure (or know) the angular frequency ω of the supply voltage. The frequency band is limited by the influence of unknown interturn capacitance value. In the "shunted T" network presented in Figure 30.8b, the state of balance (i.e., the minimal voltage v_0 value) is achieved by tuning the multiloop *LCR* circuit to parallel resonance. The circuit analysis (Sydenham 1983) is based on the "star-delta" transformation of the $C_rR_rC_r$ element loop and leads to the relations for *L* and *R* values:

$$L = \frac{2}{\omega^2 C_r}, \quad R = \frac{1}{\omega^2 C_r^2 R_r} \tag{30.27}$$

According to Sydenham (1983), a "double T" network can be used for inductive impedance measurements at high frequencies (up to 100 MHz).

In resonance methods, the quality factor *Q* and dissipation factor D are defined for the equivalent circuit of inductive elements. In the case of the equivalent circuit (L, LF, NMC) with inductance and resistance, it can be as follows:

$$Q = \frac{1}{D} = \frac{\omega L}{R} = \tau\omega \tag{30.28}$$

where parameter τ is a time constant. Connecting a variable capacitance *C* in parallel with this circuit and tuning the circuit to resonance, for $R \ll \omega L$ (e.g., $Q \gg 1$), the measured inductance can be computed from the measured resonant frequency in Equation 30.26.

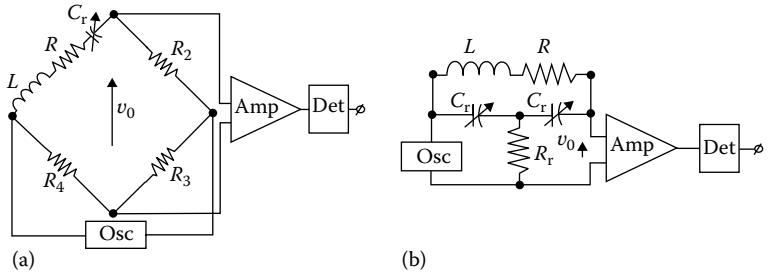

FIGURE 30.8 Circuits diagrams applied in resonance methods: (a) bridge circuit with series resonance circuit and (b) two-port "shunted T" type with parallel resonance circuit. Block abbreviations: Osc, oscillator; Amp, amplifier; Det, amplitude detector.

30.4 Instrumentation

Instruments used for inductance measurements can be categorized into several groups according to their application and metrological properties, mainly the test signal frequency band and the accuracy of measurement. The largest group are instruments for test measurements of *LCR* elements: *LCR* meters and *LCR* bridges, designed as built-in or self-contained digital multimeters, operating in the low and radio frequency band (Waltrip et al. 2005). The second group are advanced vector impedance meters, operating in the low and radio frequency band, and vector network analyzers, used for inductance measurements at high frequencies (Blaschke and Victory 2007). Into the third group can be classified instruments intended for building dedicated measuring systems, for example, for research purposes: vector voltmeters, selective signal detectors, precision differential systems (Dyer 2001), reference *LCR* elements (e.g., quantum Hall resistors [Bohacek 2004]) (NIST Calibration Services: Impedance Measurement), and sources of digitally synthesized analogue signals. Professional design of measuring instruments for inductance measurements reduces the influence of factors that give rise to measurement errors: residual and stray *LCR* parameters, inductive and capacitive couplings, normal-mode (electromagnetic) and common-mode interference, as well as other factors (Agilent Handbook 2009, Callegaro 2009). Operating manuals for such instruments provide necessary guidelines on measurement methods and conditions. More information can be found on the following websites:

Immittance Measurement

Achim Dreher
German Aerospace Center

Electronic circuits consist of numerous elements that can be lumped, distributed, or a combination of both. The components are regarded as *lumped* if their size is much smaller than the signal wavelength. This condition holds for resistors, inductors, capacitors, transformers, diodes, transistors, or similar devices operating in printed circuits at frequencies up to a few hundred megahertz or even higher in small integrated circuits. In the microwave or millimeter-wave region, the elements and their connecting transmission lines must be considered as *distributed*. While in lumped circuits a change of voltage or current at one single point immediately affects these quantities at all other points, in distributed circuits the propagation properties now have to be taken into account. The same holds for long connecting cables even at lower frequencies.

To describe the effect of any element within an electronic circuit or of the connection of different circuits, the *immittance* is used as a characteristic quantity. It simply provides a relation of sinusoidal voltage and current at the terminals of the element as a function of frequency. In practice, the single elements are interconnected to networks and the immittance also characterizes arbitrarily complicated networks considered as one port. Moreover, the elements themselves are not ideal. A resistor, for example, made of wound resistive wire, has parasitic components such as capacitance and inductance of winding and terminals. It must be represented by an equivalent circuit forming a complex network [1].

The word "immittance" was proposed by Bode [2] and is a combination of the words "impedance" and the reverse quantity called "admittance." These terms do not only occur in electrodynamics but wherever wave propagation takes place—in acoustics as well as in elasticity. The emphasis of this chapter is on lumped electronic networks and guided electromagnetic waves. Readers interested in more general propagation and scattering phenomena are referred to [3].

31.1 Definitions

Assume a stable linear and time-invariant (LTI) network with only one port. Linearity and time independence are generally met for combinations of passive elements but also for active devices with small-signal driving under constant physical conditions (temperature, humidity, dimensions, etc.). In the steady state, a voltage $v(t) = V_m \cos(\omega t + \varphi_v)$ with amplitude V_m varying harmonically with the angular frequency $\omega = 2\pi f$ that is applied to the terminal then only produces voltages and currents of the same frequency within the network (Figure 31.1). Using complex notation

$$v(t) = \mathrm{Re}\left\{Ve^{j\omega t}\right\} \quad \text{with } V = V_m e^{j\varphi_v} \tag{31.1}$$

the current flowing into the network is given by

$$i(t) = I_m \cos(\omega t + \varphi_i) = \mathrm{Re}\{Ie^{j\omega t}\} \quad \text{with } I = I_m e^{j\varphi_i} \tag{31.2}$$

The phasors V and I are time independent and can be represented in the complex plane (Figure 31.2). Relating voltage and current at the terminal, the network is uniquely described by means of a complex frequency-dependent quantity, the impedance Z:

$$Z = \frac{V}{I} = \frac{V_m}{I_m} e^{j(\varphi_v - \varphi_i)} = |Z|\, e^{j\varphi_z} \tag{31.3}$$

For a given frequency, an arbitrarily complex network within a circuit thus can be replaced by a single element without changing the electrical properties at the terminals. Sometimes it is more convenient to use the inverse of Z, the admittance Y:

$$Y = \frac{1}{Z} = \frac{1}{V} = |Y|\, e^{j\varphi_y} \quad \text{with } \varphi_y = \varphi_i - \varphi_v = -\varphi_z \tag{31.4}$$

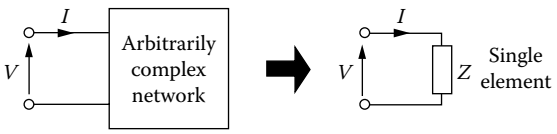

FIGURE 31.1 An arbitrarily complex network can be replaced by its impedance for a given frequency without changing the electrical properties at the terminal.

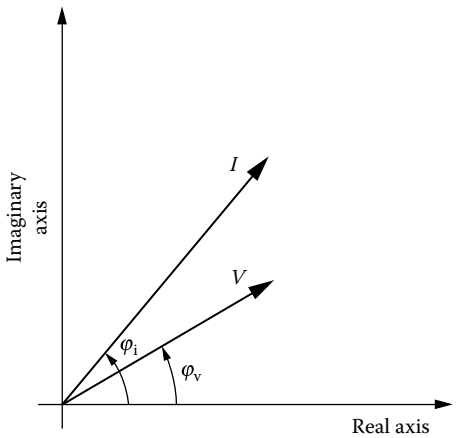

FIGURE 31.2 Voltage and current phasors in the complex plane.

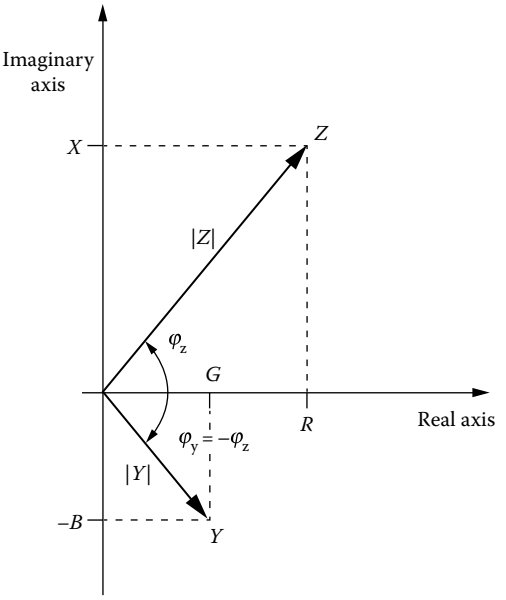

FIGURE 31.3 Representation of impedance and admittance in the complex plane showing the relations between rectangular and polar coordinates. Note that the units are different for each vector.

Both quantities are combined to form the word "immittance." Figure 31.3 shows their representation in the complex plane. Equations 31.3 and 31.4 give the definition in polar coordinates. In data sheets, they are often written as

$$|Z| \angle \varphi_z, \quad |Y| \angle \varphi_y \tag{31.5}$$

Using Euler's identity $e^{j\varphi} = \cos\varphi + j\sin\varphi$, one obtains in rectangular coordinates:

$$\begin{aligned} Z &= |Z|\cos\varphi_z + j|Z|\sin\varphi_z = R + jX \\ Y &= |Y|\cos\varphi_y + j|Y|\sin\varphi_y = G + jB \end{aligned} \tag{31.6}$$

From Figure 31.3, the following relations between rectangular and polar coordinate representation can be deduced immediately:

$$\begin{aligned} R &= |Z|\cos\varphi_z \;\; |Z| = \sqrt{R^2 + X^2} \quad G = |Y|\cos\varphi_y \quad |Y| = \sqrt{G^2 + B^2} \\ X &= |Z|\sin\varphi_z \;\; \varphi_z = \tan^{-1}\left(\frac{X}{R}\right) \quad B = |Y|\sin\varphi_y \quad \varphi_y = \tan^{-1}\left(\frac{B}{G}\right) \end{aligned} \tag{31.7}$$

The real parts are the resistance R and the conductance G. They indicate the losses within the network. The imaginary parts, which are termed reactance X and susceptance B, respectively, are a measure of the reactive energy stored in the network during one period. In general, all these quantities are frequency dependent.

Note that the correct sign of the imaginary parts must be used: the angle φ is in the range of $-180° < \varphi \leq 180°$ and $\varphi < 0$ always corresponds to $X, B < 0$.

For elements with low losses, the loss angle δ or loss factor D is often given instead of the phases φ_z and φ_y. They are always positive small quantities and tend to 0 for a lossless device:

$$D = \tan\delta = \tan\left(\frac{\pi}{2} - |\varphi_z|\right) = \tan\left(\frac{\pi}{2} - |\varphi_y|\right) = \left|\frac{R}{X}\right| = \left|\frac{G}{B}\right| \tag{31.8}$$

The inverse quantity is the quality factor $Q = 1/D$. It involves a ratio of stored electric energy to power dissipated:

$$Q = 2\pi \frac{\text{Energy stored}}{\text{Energy loss per period}} \tag{31.9}$$

A high Q indicates a nearly pure reactive component.

In high-power electronics, it is necessary to reduce losses on transmission lines and therefore avoid currents associated with reactive load components. To obtain a criterion for the application and efficiency of compensation techniques, a power factor is defined. From complex power representation,

$$P = VI^{\star} = |P|(\cos\varphi + j\sin\varphi) \tag{31.10}$$

(the asterisk, *, indicates the conjugate complex number) follows from Equations 31.3 and 31.4:

$$P = |I|^2 \quad Z = |I|^2|Z|(\cos\varphi_z + j\sin\varphi_z) = |V|^2 \quad Y^{\star} = |V|^2|Y|(\cos\varphi_y - j\sin\varphi_y) \tag{31.11}$$

and since the effective power is given by the real part of P,

$$P_{\text{eff}} = \text{Re}\{P\} = |P|\cos\varphi \tag{31.12}$$

the power factor is

$$\cos\varphi = \cos\varphi_z = \cos\varphi_y \tag{31.13}$$

In general, root mean square (rms) values are used for the phasors. Otherwise, a factor 1/2 has to be taken into account in Equations 31.10 and 31.11, since $|P| = 1/2V_mI_m$ for sinusoidal quantities.

It can also be seen from Equations 31.10 and 31.11 that the immittances are directly related to the apparent power:

$$|P| = |V||I| = |I|^2|Z| = |V|^2|Y| \tag{31.14}$$

31.2 Ideal Lumped Components

The immittances of the fundamental passive circuit elements are derived from their instantaneous voltage current relations using Equations 31.1 through 31.4 and the differentiation rules.

31.2.1 Resistances

From Equation 31.15

$$v(t) = Ri(t) \tag{31.15}$$

it follows $V = RI$ and thus $Z = R$ or $Y = G$. The immittance of a resistance is real and identical to its dc resistance or conductance.

31.2.2 Inductances

Voltage and current are related via the differential equation

$$v(t) = L\frac{\mathrm{d}i(t)}{\mathrm{d}t} \tag{31.16}$$

with inductance L, from which follows that $V = j\omega LI$ and

$$Z = j\omega L = jX_\mathrm{L}, \quad Y = \frac{1}{j\omega L} = -j\frac{1}{X_\mathrm{L}} = -jB_\mathrm{L} \tag{31.17}$$

31.2.3 Capacitances

From Equation 31.18

$$i(t) = C\frac{\mathrm{d}v(t)}{\mathrm{d}t} \tag{31.18}$$

with capacitance C, it follows that $I = j\omega CV$ and

$$Y = j\omega C = jB_\mathrm{C}, \quad Z = \frac{1}{j\omega C} = -j\frac{1}{B_\mathrm{C}} = -jX_\mathrm{C} \tag{31.19}$$

The immittance of ideal inductors and capacitors is purely imaginary with different signs according to the phase shift of ±90° between voltages and currents. A general element or network is therefore called inductive or capacitive at a given frequency corresponding to the sign of the imaginary part of its impedance. Note, however, that the frequency dependence can be much more complicated than for these ideal elements and the impedance can even change several times between capacitive and inductive characteristic.

31.3 Distributed Elements

At high frequencies, the size of the elements may no longer be small compared to the signal wavelength. Propagation effects must then be taken into account and the components can no longer be described by means of simple lumped equivalent circuits. If at all possible, they are replaced by transmission line circuits, which are easier to characterize; they realize the required electrical properties more exactly within a defined frequency range.

31.3.1 Transmission Lines

Assuming a simplifying transverse electromagnetic wave (TEM mode) with no field components in the propagation direction, voltages and currents can be uniquely defined and are given as solutions of the corresponding wave equations [4]:

$$\frac{\mathrm{d}^2V}{\mathrm{d}z^2} - \gamma^2 V = 0, \quad \frac{\mathrm{d}^2I}{\mathrm{d}z^2} - \gamma^2 I = 0 \tag{31.20}$$

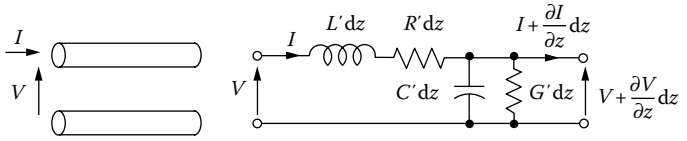

FIGURE 31.4 Equivalent circuit of a differential length of transmission line. The wave equations can be obtained by simply applying Kirchhoff's laws to voltages and currents.

They vary along the line in the z-direction according to

$$V(z) = V_0^+ e^{-\gamma z} + V_0^- e^{\gamma z}, \quad I(z) = I_0^+ e^{-\gamma z} + I_0^- e^{\gamma z} \tag{31.21}$$

These solutions are sums of forward ($e^{-\gamma z}$) and backward ($e^{\gamma z}$) traveling waves with amplitudes V_0^+, I_0^+ and V_0^-, I_0^- and a propagation constant

$$\gamma = \sqrt{(R' + j\omega L')(G' + j\omega C')} \tag{31.22}$$

The equivalent circuit of the transmission line is shown in Figure 31.4. The energy storage in the electric field is accounted for by the distributed shunt capacitance C' per unit length, while the effect of the magnetic field is represented by the series inductance L' per unit length. The series resistance R' per unit length and the shunt conductance G' per unit length represent the power losses in the conductors and in the dielectric, respectively. The amplitudes of voltage and current are related by means of the characteristic impedance Z_0:

$$Z_0 = \frac{V^+}{I^+} = -\frac{V^-}{I^-} = \sqrt{\frac{R' + j\omega L'}{G' + j\omega C'}} \tag{31.23}$$

Of special interest for the use within a network is the input impedance Z_{in} of the transmission line. It depends also on the termination Z_{L} at the other end of the line. For a transmission line of length l, it is given by

$$Z_{\text{in}} = Z_0 \frac{Z_{\text{L}} + Z_0 \tanh \gamma l}{Z_0 + Z_{\text{L}} \tanh \gamma l} \tag{31.24}$$

that is, a transmission line transforms the impedance Z_{L} into Z_{in} at the input.

A quantity more suitable to wave propagation and measurement at high frequencies is the reflection coefficient Γ. It is defined by the relation of the voltages associated with forward and backward traveling waves. At the end of the line, using $V(l) = Z_{\text{L}} I(l)$, one finds

$$\Gamma = \frac{V_0^- e^{\gamma l}}{V_0^+ e^{-\gamma l}} = \frac{Z_{\text{L}} - Z_0}{Z_{\text{L}} + Z_0} \tag{31.25}$$

For devices that support quasi or strong non-TEM waves like microstrip lines, hollow waveguides, and dielectric and optical waveguides, a voltage cannot be uniquely defined. That is why several definitions of the characteristic impedance Z_0 exist [5].

31.4 Interconnections and Graphical Representations

Since Kirchhoff's laws for voltages and currents also hold for complex quantities, the rules for series and parallel connections of resistances and susceptances in the dc case apply as well for immittances.
Series connection:

$$Z = \sum_i Z_i \quad \frac{1}{Y} = \sum_i \frac{1}{Y_i} \tag{31.26}$$

Parallel connection:

$$Y = \sum_i Y_i \quad \frac{1}{Z} = \sum_i \frac{1}{Z_i} \tag{31.27}$$

As an example, consider a simplified equivalent circuit of a wire-wound resistor with the nominal value R_0 including parasitic elements that represent the effects of windings and terminal (Figure 31.5). Gradually using the rules for series and parallel connection and the impedances for inductances (Equation 31.17) and capacitances (Equation 31.19), the impedance of the real resistor with parasitic elements as given leads to

$$Z = \frac{R_0 + j\omega L}{1 - \omega^2 LC + j\omega R_0} \tag{31.28}$$

The magnitude and phase of Z/R_0 as a function of ω/ω_0 are shown in Figure 31.6 with $\omega_0 = 1/\sqrt{LC}$ as the resonant frequency defined by the parasitic elements. The network is inductive for low ($\varphi_z > 0$) and capacitive for high frequencies. An alternative representation is to plot real and imaginary parts in the impedance plane with the frequency as parameter as indicated by the labels (Figure 31.7). This version, called the *locus*, is very suitable to see immittance changes caused by parameters like frequency or adjustable elements within the network. Note that both real and imaginary parts are parameter dependent and vary with frequency.

In high-frequency applications, one obtains the impedance more easily from the reflection coefficient. Rewriting Equation 31.25 in the form

$$\Gamma = \frac{\bar{Z}_L - 1}{\bar{Z}_L + 1} \quad \text{with} \quad \bar{Z}_L = \frac{Z_L}{Z_0} \tag{31.29}$$

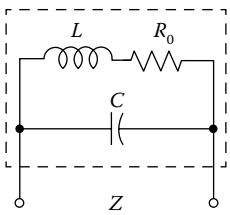

FIGURE 31.5 The simple equivalent circuit of a wire-wound resistor with nominal value R_0, inductance of the winding L, and capacitance of winding and terminal C. It is valid for a wide frequency range.

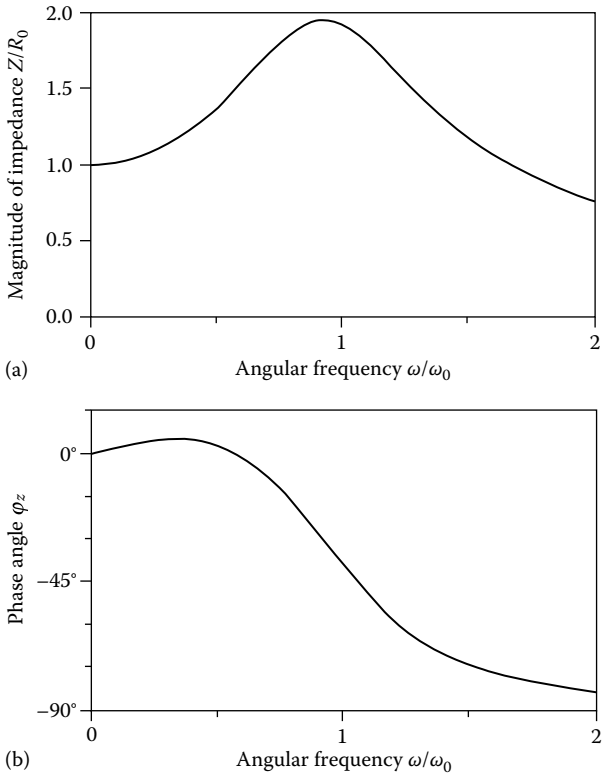

FIGURE 31.6 Normalized magnitude (a) and phase (b) of the impedance of a wire-wound resistor varying with frequency. ω_0 is the resonant frequency defined by the parasitic elements.

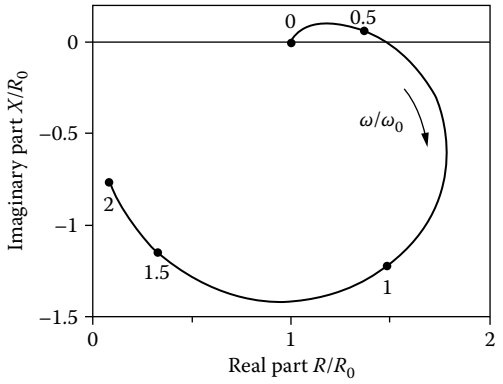

FIGURE 31.7 Normalized impedance of a wire-wound resistor in the complex plane. The arrow indicates the direction of increasing frequency.

defines a transformation of which the graphical representation has been called the Smith chart (Figure 31.8). It can be regarded as two coordinate systems lying one on top of the other. The reflection coefficient is given in polar coordinates around the center; the circles give the real and imaginary part of the associated impedance. The Smith chart is very useful for solving transmission line and waveguide impedance matching problems [6].

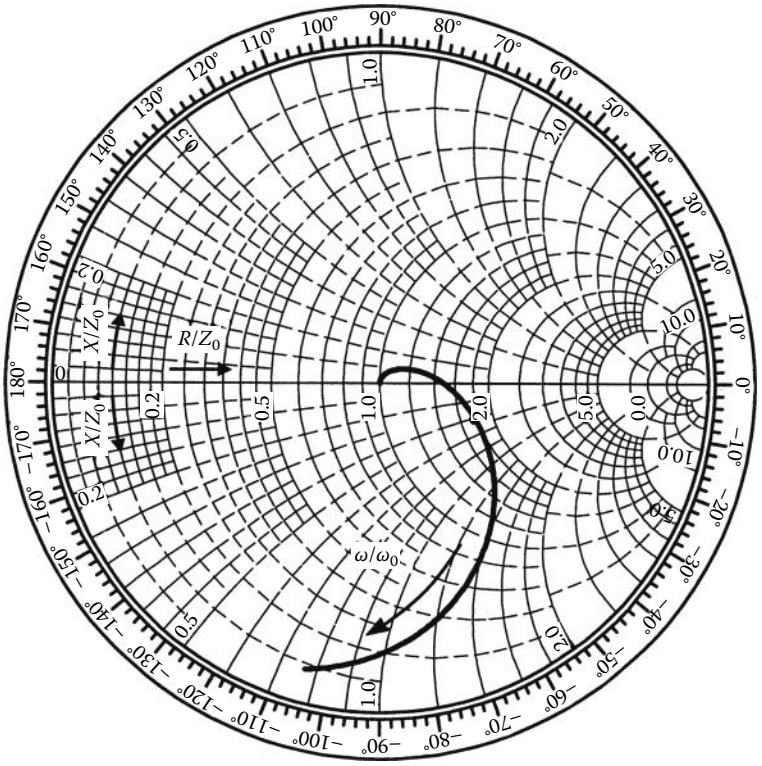

FIGURE 31.8 Smith chart representation of the impedance of a wire-wound resistor.

31.5 Measurement Techniques

Since immittances are complex quantities, one must determine two parameters: magnitude and phase or real and imaginary part, described as vector measurements. There exist several techniques depending on frequency range and required accuracy [7].

31.5.1 Current–Voltage Methods

A simple way to measure immittances follows directly from the defining Equation 31.3. Applying a well-known sinusoidal voltage to the terminal and measuring magnitude and phase of the current give the desired quantity (Figure 31.1). However, the internal impedance Z_A of the ammeter should be known exactly and the unknown impedance is then given by

$$Z = \frac{V}{I} - Z_A \tag{31.30}$$

In practical applications, impedances below 1000 Ω are measured by passing a predetermined current through the unknown device and measuring the voltage across it. Phase angle information is obtained by comparing the relative phase between voltage and current by means of a phase detector.

A variant on this method using only the better practicable voltage measurements is shown in Figure 31.9. The accurately known resistor R must be small compared to Z_x and to the internal resistance of V_2. One finds that

$$Z_x = \left(\frac{V_1}{V_2} - 1\right)R, \quad \text{or} \quad Z_x \approx \frac{V_1}{V_2}R \quad \text{if } R \ll |Z_x| \tag{31.31}$$

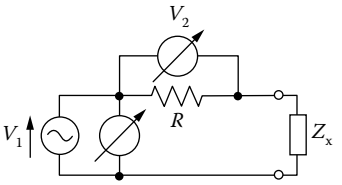

FIGURE 31.9 Determination of impedance Z_x by phase-sensitive voltage measurements, only using a well-known resistor R.

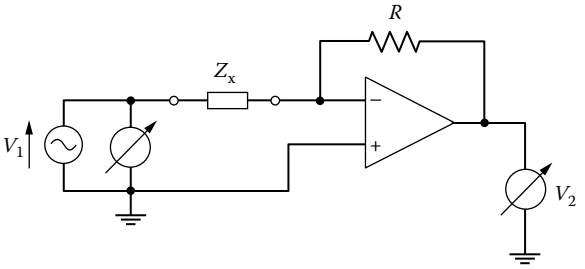

FIGURE 31.10 Impedance measurements with an inverting operational amplifier circuit. Its advantages are high input and low output resistance.

The measurement can be enhanced using an operational amplifier with high input and low output resistance in an inverting circuit (Figure 31.10). The unknown is then given by

$$Z_x = -\frac{V_1}{V_2}R \tag{31.32}$$

Practical implementations use operational amplifiers as part of an autobalancing bridge; see [7].

31.5.2 Bridge Methods

Alternating current bridges are low-cost standard laboratory devices to measure impedances over a wide frequency range from dc up to 300 MHz with very high precision (Figure 31.11). A comprehensive survey is given in [1]. Their main advantage is that only a zero indicator in the diagonal branch is necessary. In this case, the internal impedance does not influence the accuracy and the null can be detected with a high-sensitivity ac galvanometer as well as with headphones in the audio frequency range.

If the bridge is balanced, the unknown immittance is given by

$$Z_x = \frac{Z_1}{Z_3}Z_2 \quad \text{or} \quad Y_x = \frac{Z_3}{Z_1}Y_2 \tag{31.33}$$

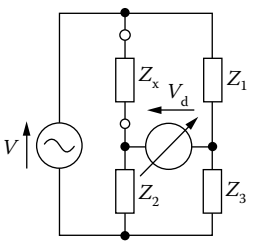

FIGURE 31.11 Impedance measurements by bridge methods. The bridge is balanced when the voltage V_d across the diagonal branch is adjusted to zero by tuning Z_1, Z_2, or Z_3.

Since the quantities are complex, Equation 31.33 involves the adjustment of two parameters: magnitude and phase

$$|Z_x| = \left|\frac{Z_1}{Z_3}\right| |Z_2|, \quad \varphi_x = \varphi_1 - \varphi_3 + \varphi_2 \tag{31.34}$$

or real and imaginary parts, respectively.

An important property of an impedance bridge is the sensitivity ε

$$\varepsilon = \left|\frac{\partial V_d}{\partial Z_x}\right| = V \frac{Z_2}{(Z_2 + Z_x)^2} \tag{31.35}$$

or (independent of Z_x)

$$\varepsilon = V \frac{Z_3^2}{Z_2 (Z_1 + Z_3)^2} \tag{31.36}$$

in the vicinity of zero crossing when the bridge is balanced.

The precision of the measurement not only depends on the exact zero adjustment, which can be enhanced by choosing the elements and the voltage according to Equation 31.36 to obtain a high sensitivity, but also on the realization of $Z_1 \ldots Z_3$. Mostly, these are connections of resistors and capacitors. Inductors are avoided because they always have a resistive component and it is difficult and expensive to manufacture inductors with exactly defined and reproducible electrical properties. There exist various types of bridges depending on how the elements are designed and interconnected. To choose the correct configuration, it must be known whether the unknown impedance is capacitive or inductive; otherwise, a zero adjustment is not always possible since the balancing condition cannot be fulfilled. Bridges are therefore principally used to measure capacitances and inductances as well as loss and quality factors of capacitors and coils. Since magnitude and phase conditions must be matched simultaneously, two elements must be tuned. To obtain a wide measurement range, the variable elements are designed as combinations of switchable and tunable capacitors and resistors. The sensitivity of the zero indicators can be changed for global search and final adjustment. Unfortunately, magnitude and phase cannot be adjusted independently of each other. If the balancing is performed by hand, a suitable strategy is to search the minimum voltage by tuning each element successively.

Frequently used bridges are the Wheatstone bridge (Figure 31.12) for the measurement of lossy capacitances and the Hay bridge (Figure 31.13) to determine inductivity and quality factor of coils. Because of its symmetrical structure, the balancing condition for the Wheatstone bridge is simply

$$R_x = \alpha R_1, \quad C_x = \alpha C_1, \quad \alpha = \frac{R_3}{R_2} \tag{31.37}$$

which is independent of frequency.

The measurement of a coil with the Hay bridge requires that

$$R_x + j\omega L_x = \frac{j\omega C_3 R_1 R_2}{1 + j\omega R_3 C_3} = \frac{\omega^2 C_3^2 R_1 R_2 R_3}{1 + (\omega R_3 C_3)^2} + j\omega \frac{C_3 R_1 R_2}{1 + (\omega R_3 C_3)^2} \tag{31.38}$$

from which the quality factor is obtained as

$$Q = \frac{\omega L_x}{R_x} = \frac{1}{\omega R_3 C_3} \tag{31.39}$$

The inductance of high-Q coils can be determined frequency independent since

$$L_x \approx R_1 R_2 C_3 \quad \text{if } (\omega R_3 C_3)^2 \ll 1 \tag{31.40}$$

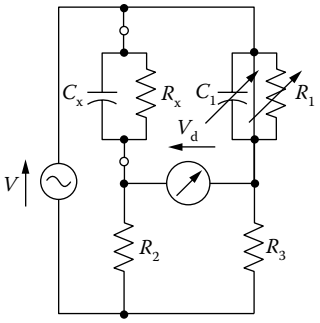

FIGURE 31.12 The Wheatstone bridge for the capacitance and dissipation factor measurement of capacitors. The balancing condition is frequency independent. The resistor R_1 and the capacitor C_1 must be tuned successively until the bridge is balanced.

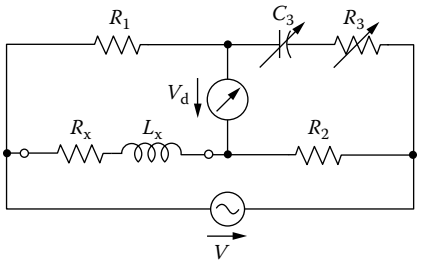

FIGURE 31.13 The Hay bridge for the measurement of the inductance and the quality factor of coils. If Q is sufficiently high, the inductance can be determined nearly frequency independent.

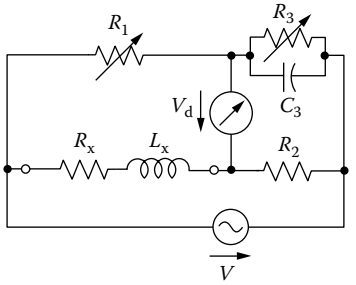

FIGURE 31.14 The Maxwell bridge with simple and frequency-independent balancing conditions. Despite these advantages, it is not recommended for high-Q coils because of a very large R_1 value.

A very interesting alternative is the Maxwell bridge (Figure 31.14), since it requires only resistors as variable elements, which can be manufactured with high precision. The balancing is frequency independent and leads to

$$R_x = \frac{R_1 R_2}{R_3}, \quad L_x = R_1 R_2 C_3, \quad Q = \omega C R_1 \tag{31.41}$$

Nevertheless, the Hay bridge is preferred for high-Q coils, because a very large value of R_1 is required for the Maxwell bridge leading to a disadvantageous balancing [8].

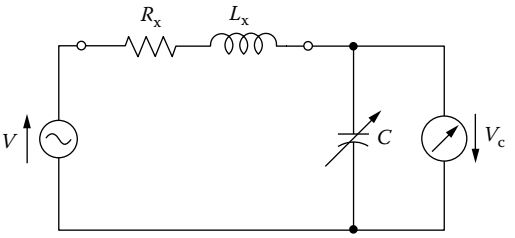

FIGURE 31.15 Coil as part of a resonance circuit to determine inductance and quality factor. The capacitor C is tuned to maximum voltage V_C.

31.5.3 Resonant Method

Using the coil as part of a resonance circuit as in Figure 31.15 and tuning C to maximum voltage, the quality factor can be measured directly as

$$Q = \left| \frac{V_{C,\max}}{V} \right| = \frac{1}{\omega R_x C} \tag{31.42}$$

The unknown inductance is then obtained from the test frequency by means of the resonance condition

$$L_x = \frac{1}{\omega^2 C} \tag{31.43}$$

If a capacitor with sufficiently low losses is used, Q values as high as 1000 can be measured.

31.5.4 Network Analysis Methods

31.5.4.1 Frequency Domain

In the case of distributed elements, measurements of currents and voltages depend on the position and are often not directly applicable to high-frequency devices like waveguides or microstrip lines. For that reason the determination of immittances is derived from measuring the reflection coefficient. Equation 31.24 shows the importance of defining a proper measurement plane. This is the cross section of the line or waveguide perpendicular to the direction of propagation at a definite length l_0, where the reflection coefficient has to be measured. It can then be transformed along the line toward load or source using this relation or the Smith chart. Exact microwave measurements are very sophisticated and need a lot of practical experience. Further details can be found in the literature [5,9–11].

Automated and precise immittance measurements over a wide frequency range are best carried out with a vector network analyzer [10]. Unfortunately, this is also the most expensive method. The principle of measurement is shown in Figure 31.16. A power divider splits the incident signal into a transmitted and a

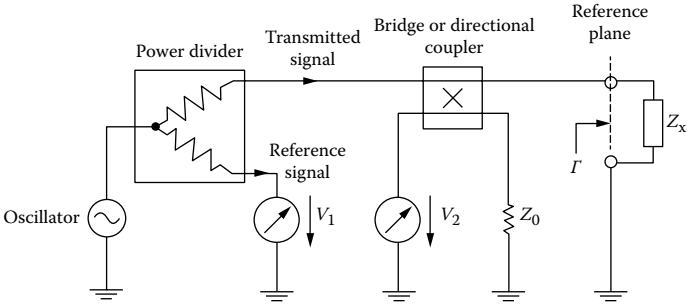

FIGURE 31.16 Schematic of network analyzer measurements. The voltage ratio V_2/V_1 of reflected wave and reference signal is proportional to the reflection coefficient Γ. The impedance Z_x can then be computed.

reference part. The directional bridge or coupler separates forward and backward traveling waves, and the reflected signal now appears in the branch with the phase-sensitive voltmeter V_2. Using a bridge with impedances matched to the line ($Z_1 = Z_2 = Z_3 = Z_0$), the voltage in the diagonal branch is given by (Figure 31.11)

$$V_d = \frac{Z_x - Z_0}{2(Z_x + Z_0)} V = V_2 \tag{31.44}$$

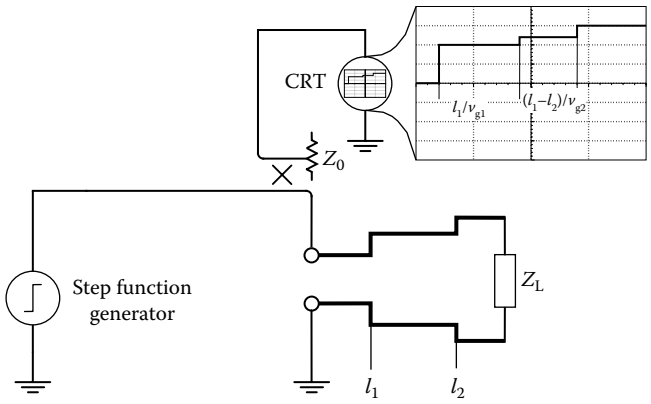

FIGURE 31.17 Detection and measurement of impedance steps on a line or waveguide with a TDR. Since phase information is usually not available, the characteristics and magnitudes of the impedances can only be estimated. Notice that the group or signal velocity v_g varies from step to step.

TABLE 31.1 Instruments for Immittance Measurements

Manufacturer	Model Number	Description
Agilent Technologies	4285A	Precision LCR Meter 75 kHz–30 MHz
Agilent Technologies	4287A	RF LCR Meter 1 MHz–3 GHz
Agilent Technologies	4294A	Precision Impedance Analyzer 40 Hz–110 MHz
Agilent Technologies	E4980A	Precision LCR Meter 20 Hz–2 MHz
Agilent Technologies	E5061B	Network Analyzer 5 Hz–3 GHz
Agilent Technologies	N9923A	FieldFox Handheld RF Vector Analyzer 2 MHz–4/6 GHz
Agilent Technologies	PNA Series	Vector Network Analyzers 300 kHz–1.05 THz
Anritsu	ME7828A	Vector Network Analyzer 70 kHz–110 GHz
Fluke	PM 6303A	Automatic RCL Meter
Fluke	PM 6306/6304	Automatic RCL Meter
Keithley	3321	LCZ Meter, 4 Test Frequencies to 100 kHz
Keithley	3322	LCZ Meter, 11 Test Frequencies to 100 kHz
Keithley	3330	LCZ Meter 20 Hz–200 kHz
QuadTech	1715 CE	LCR Meter 4 Test Frequencies to 10 kHz
QuadTech	1730 T	LCR Meter 7 Test Frequencies to 100 kHz
QuadTech	1910/1920 CE	LCR Meter 20 Hz–1 MHz
QuadTech	7600 Plus	LCR Meter 10 Hz–2 MHz
Rohde & Schwarz	ZVA Series	Vector Network Analyzer 300 kHz–80 GHz
SST	SR715/720	LCR Meter 10 kHz/100 kHz
Tinsley Precision Instruments	QJ Series	Portable Bridges (Wheatstone, Kelvin)
TTi	LCR400	Precision LCR Meter
Voltech	ATi	Precision Transformer Tester

and thus the reflection coefficient

$$\Gamma = \frac{Z_x - Z_0}{Z_x + Z_0} = \alpha \frac{V_2}{V_1} \tag{31.45}$$

is directly proportional to the voltage ratio.

Network analyzers use an automatic error correction to eliminate the effect of internal and external couplers and junctions. Because of that, a calibration procedure with standard terminations is necessary. These terminations must be manufactured very precisely, since they define the measurement plane and determine the overall measurement error.

31.5.4.2 Time Domain

It is often necessary to locate an impedance step, whether to find out the distance of a cable defect or to track down the origin of reflections within a connection. To this end, high-performance vector network analyzers have a Fourier transform procedure. But there also exist cheaper time-domain reflectometers (TDRs) [12]. They use an incident step or impulse signal (Figure 31.17) and the reflected signal is

separated by means of a directional coupler and displayed on an oscilloscope in the time domain. From the shape of the signal, the impedance step can be localized by means of the time delay:

$$l = \frac{1}{2} v_g t \tag{31.46}$$

with v_g as signal or group velocity on the line varying from step to step. Characteristic and magnitude of the impedance can only be estimated, since phase information is usually not available. TDR measurements are restricted to the localization of impedance steps and not to be recommended for exact measurements. Moreover, additional pulse deformations occur in dispersive waveguides.

31.6 Instrumentation and Manufacturers

A broad range of instrumentation for measuring immittance is available. Some of these instruments are included in Table 31.1. Table 31.2 provides the names and addresses of some companies that produce immittance-measuring instrumentation.

Defining Terms

Admittance (*Y*): The reciprocal of impedance.

Immittance: A response function for which one variable is a voltage and the other a current. Immittance is a general term for both impedance and admittance, used where the distinction is irrelevant.

Impedance (*Z*): The ratio of the phasor equivalent of a steady-state sine-wave voltage to the phasor equivalent of a steady-state sine-wave current. The real part is the *resistance*; the imaginary part is the *reactance*.

Phasor: A complex number, associated with sinusoidally varying electrical quantities, such that the absolute value (modulus) of the complex number corresponds to either the peak amplitude or root mean square (rms) value of the quantity and the phase (argument) to the phase angle at zero time. The term "phasor" can also be applied to impedance and related complex quantities that are not time dependent.

Reflection coefficient: At a given frequency, at a given point, and for a given mode of propagation, the ratio of voltage, current, or power of the reflected wave to the corresponding quantity of the incident wave.

Distortion Measurement

Michael F. Toner
Nortel Networks

Gordon W. Roberts
McGill University

A sine-wave signal will have only a single-frequency component in its spectrum, that is, the frequency of the tone. However, if the sine wave is transmitted through a system (such as an amplifier) having some nonlinearity, then the signal emerging from the output of the system will no longer be a pure sine wave. That is, the output signal will be a distorted representation of the input signal. Since only a pure sine wave can have a single component in its frequency spectrum, this situation implies that the output must have other frequencies in its spectral composition. In the case of *harmonic distortion*, the frequency spectrum of the distorted signal will consist of the fundamental (which is the same frequency as the input sine wave) plus harmonic frequency components that are at integer multiples of the fundamental frequency. Taken together, these will form a Fourier representation of the distorted output signal. This phenomenon can be described mathematically. Refer to Figure 32.1, which depicts a sine-wave input signal $x(t)$ at frequency f_1, applied to the input of a system $A(x)$, which has an output $y(t)$. Assume that system $A(x)$ has some nonlinearity. If the nonlinearity is severe enough, then the output $y(t)$ might have excessive harmonic distortion such that its shape no longer resembles the input sine wave. Consider the example where the system $A(x)$ is an audio amplifier and $x(t)$ is a voice signal. Severe distortion can result in a situation where the output signal $y(t)$ does not represent intelligible speech. The *total harmonic distortion* (THD) is a figure of merit that is indicative of the quality with which the system $A(x)$ can reproduce an input signal $x(t)$. The output signal $y(t)$ can be expressed as

$$y(t) = a_0 + \sum_{k=1}^{N} a_k \cos(2\pi k f_1 t + \theta_k) \tag{32.1}$$

where

a_k, $k = 0, 1, \ldots, N$ are the magnitudes of the Fourier coefficients
θ_k, $k = 0, 1, \ldots, N$ are the corresponding phases

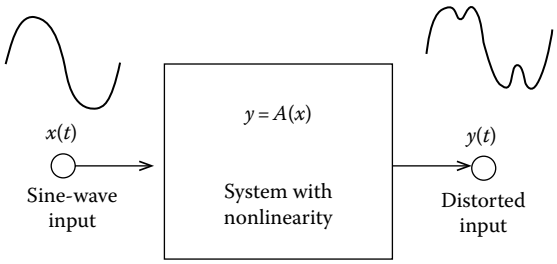

FIGURE 32.1 Any system with nonlinearity gives rise to distortion.

The THD is defined as the percentage ratio of the rms voltage of all harmonics components above the fundamental frequency to the rms voltage of the fundamental. Mathematically, the definition is written as

$$\text{THD} = \frac{\sqrt{\sum_{k=2}^{N} a_k^2}}{a_1} \times 100\% \tag{32.2}$$

If the system has good linearity (which implies low distortion), then the THD will be a smaller number than that for a system having poorer linearity (higher distortion). To provide the reader with some feeling for the order of magnitude of a realistic THD, a reasonable audio amplifier for an intercom system might have a THD of about 2% or less, while a high-quality sound system might have a THD of 0.01% or less. For the THD to be meaningful, the bandwidth of the system must be such that the fundamental and the harmonics will lie within the passband. Therefore, the THD is usually used in relation to low-pass systems or band-pass systems with a wide bandwidth. For example, an audio amplifier might have a 20 Hz to 20 kHz bandwidth, which means that a 1 kHz input sine wave could give rise to distortion up to the 20th harmonic (i.e., 20 kHz), which can lie within the passband of the amplifier. On the other hand, a sine wave applied to the input of a narrow-band system such as a radio frequency amplifier will give rise to harmonic frequencies that are outside the bandwidth of the amplifier. These kinds of narrow-band systems are best measured using *intermodulation distortion*, which is treated elsewhere in this handbook. For the rest of the discussion at hand, consider the example system illustrated in Figure 32.1 that shows an amplifier system $A(x)$ that is intended to be linear but has some undesired nonlinearities. Obviously, if a linear amplifier is the design objective, then the THD should be minimized.

32.1 Mathematical Background

Let $y = A(x)$ represent the input–output transfer characteristic of the system $A(x)$ in Figure 32.1 containing the nonlinearity. Expanding into a power series yields

$$A(x) = \sum_{k=0}^{\infty} c_k x^k = c_0 + c_1 x + c_2 x^2 + c_3 x^3 + \cdots \tag{32.3}$$

Let the input to the system be $x = \cos(2\pi f_0 t)$. Then the output will be

$$y = A(x) = c_0 + c_1 A_0 \cos(2\pi f_0 t) + c_2 A_0^2 \cos^2(2\pi f_0 t) + c_3 A_0^3 \cos^3(2\pi f_0 t) + \cdots \tag{32.4}$$

This can be simplified using the trigonometric relationships

$$\cos^2(\theta) = \frac{1}{2} - \frac{1}{2}\cos(2\theta) \tag{32.5}$$

$$\cos^3(\theta) = \frac{3}{4}\cos(\theta) + \frac{1}{4}\cos(3\theta) \tag{32.6}$$

$$\cos^4(\theta) = \frac{1}{8} - \frac{1}{2}\cos(2\theta) + \frac{1}{8}\cos(4\theta) \tag{32.7}$$

$$\cos^5(\theta) = \frac{5}{8}\cos(\theta) + \frac{5}{16}\cos(3\theta) + \frac{1}{16}\cos(5\theta) \tag{32.8}$$

and so on. Performing the appropriate substitutions and collecting terms results in an expression for the distorted signal $y(t)$ that is of the form shown in Equation 32.1. The THD can then be computed from Equation 32.2.

Closer inspection of Equations 32.6 and 32.8 reveals that a cosine wave raised to an odd power gives rise to only the fundamental and odd harmonics, with the highest harmonic corresponding to the highest power. A similar phenomenon is observed for a cosine raised to even powers; however, the result is only a dc component and even harmonics without any fundamental component. In fact, any nonlinear system that possesses an odd input–output transfer characteristic $A(x)$ (i.e., the function $A(x)$ is such that $-A(x) = A(-x)$) will give rise to odd harmonics only. Consider Figure 32.2, which illustrates an example of two-sided symmetrical clipping. It is an odd function. The application of a sine wave to its input will result in a waveform similar to that shown in Figure 32.3, which has only odd harmonics as shown in Figure 32.4. The majority of physical systems are neither odd nor even. (An even function is one that has the property $A(x) = A(-x)$; e.g., a full-wave rectifier.) Consider the enhancement N-type metal oxide semiconductors (NMOS) transistor illustrated in Figure 32.5, which

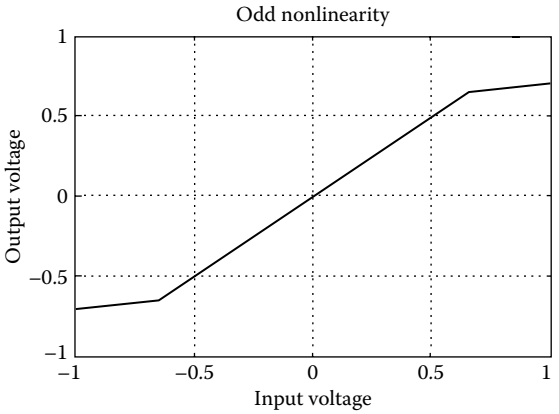

FIGURE 32.2 An off nonlinearity with $f(-x) = -f(x)$.

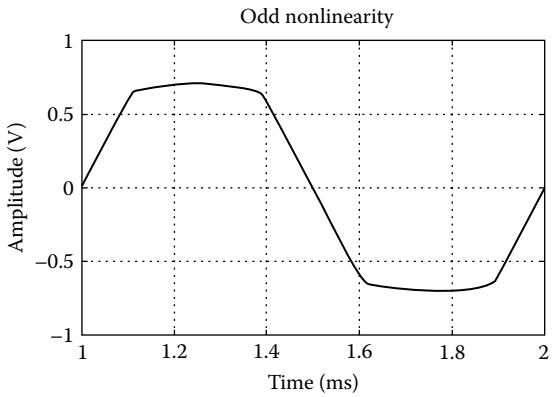

FIGURE 32.3 Distortion due to symmetrical two-sided clipping.

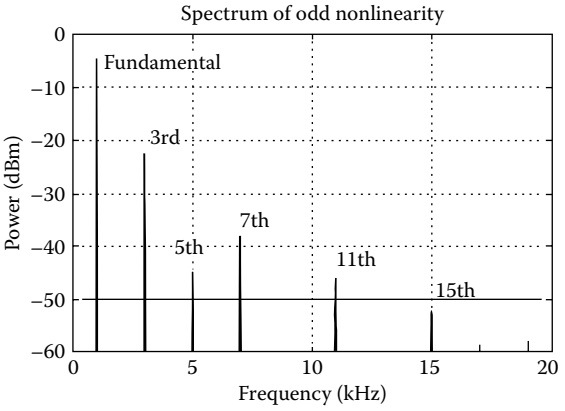

FIGURE 32.4 Frequency spectrum of signal distorted by symmetrical two-sided clipping.

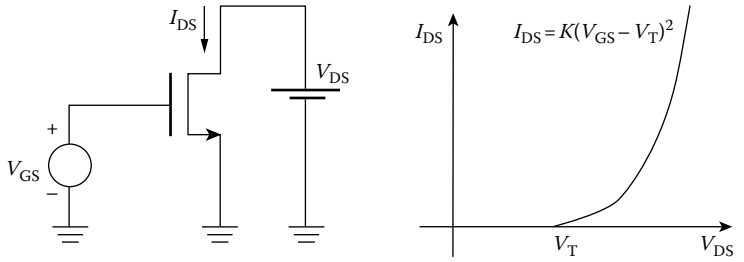

FIGURE 32.5 NMOS enhancement transistor is actually a nonlinear device. It is neither odd nor even in the strict sense.

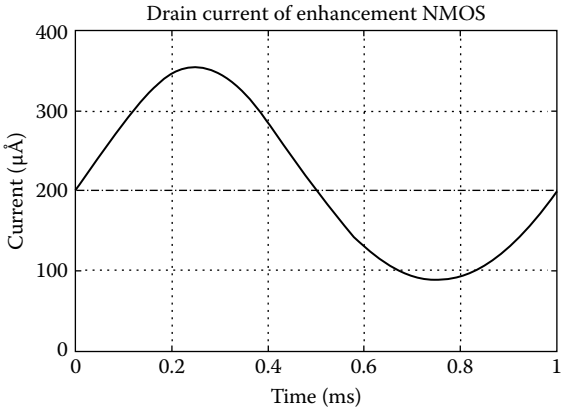

FIGURE 32.6 Showing how the drain current of the enhancement NMOS device is distorted.

has the square-law characteristic shown. Assume that the voltage V_{GS} consists of a dc bias plus a sine wave such that V_{GS} is always more positive than V_T (the threshold voltage). Then the current flowing in the drain of this NMOS transistor could have the appearance shown in Figure 32.6. It is observed that the drain current is distorted, since the positive-going side has a greater swing than the negative-going side. The equation for the drain current can be derived mathematically as follows. A MOS transistor operating in its saturation region can be approximated as a square-law device:

$$I_{DS} = \frac{\mu C_{ox}}{2}\frac{W}{L}(V_{GS} - V_T)^2 \tag{32.9}$$

If the gate of the *n*-channel enhancement MOSFET is driven by a voltage source consisting of a sine-wave generator in series with a dc bias, that is,

$$V_{GS} = V_B + A_0 \sin(2\pi f_0 t) \tag{32.10}$$

then the current in the drain can be written as

$$I_{DS} = \frac{\mu C_{ox}}{2}\frac{W}{L}\{[V_B + A_0 \sin(2\pi f_0 t)] - V_T\}^2 \tag{32.11}$$

Expanding and using the trigonometric relationship

$$\sin^2(\theta) = \frac{1}{2} - \frac{1}{2}\sin\left(2\theta + \frac{\pi}{2}\right) \tag{32.12}$$

Equation 32.11 can be rewritten as

$$I_{DS} = \frac{\mu C_{ox}}{2}\frac{W}{L}\left[(V_B - V_T)^2 + \frac{A_0^2}{2} + 2(V_B - V_T)A_0 \sin(2\pi f_0 t) + \frac{A_0^2}{2}\sin(4\pi f_0 t) + \frac{\pi}{2}\right] \tag{32.13}$$

which clearly shows the dc bias, the fundamental, and the second harmonic that are visible in the spectrum of the drain current I_{DS} in Figure 32.7. There is one odd harmonic (i.e., the fundamental) and two even harmonics (strictly counting the dc component and the second harmonic). This particular transfer characteristic is neither odd nor even. Finally, for an ideal square-law characteristic, the second harmonic is the highest frequency component generated in response to a sine-wave input. Another example of a transfer characteristic that is neither odd nor even is the single-sided clipping as shown in Figure 32.8, which gives rise to the distortion of Figure 32.9. One last example of an odd input–output transfer characteristic is symmetrical crossover distortion as depicted in Figure 32.10. The distorted output in response to a 1 kHz sine-wave input is shown in Figure 32.11. The spectrum of the output signal is shown in Figure 32.12. Note that only odd harmonics have been generated.

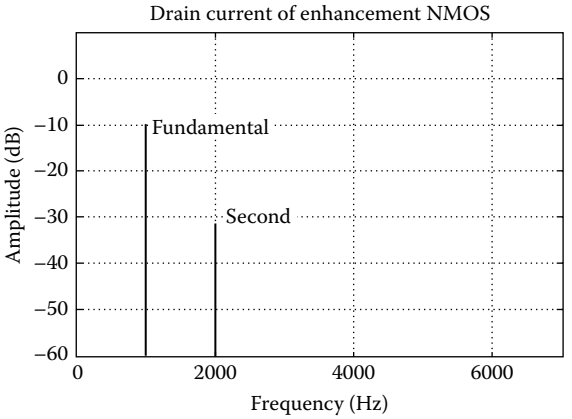

FIGURE 32.7 The drain current contains a dc bias, the fundamental, and the second harmonic only, for an ideal device.

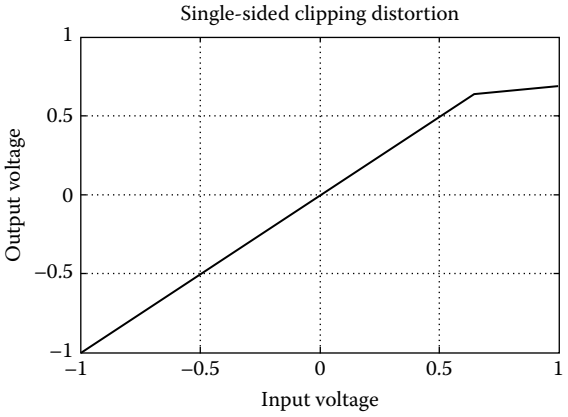

FIGURE 32.8 Single-sided clipping is neither even nor odd.

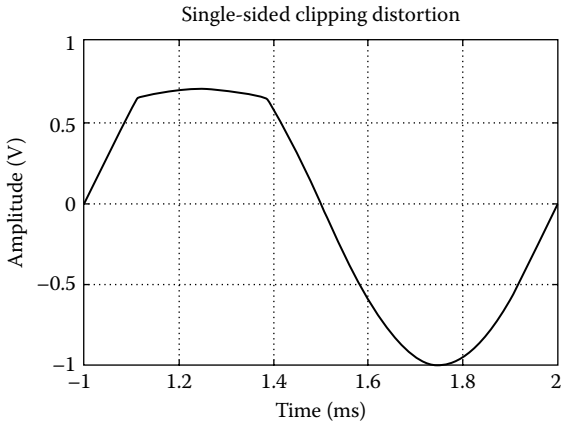

FIGURE 32.9 Distortion due to single-sided clipping.

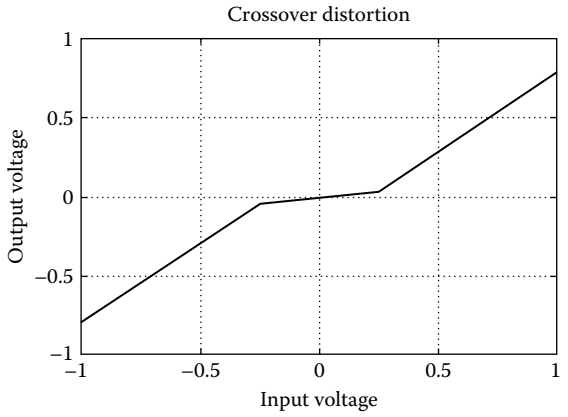

FIGURE 32.10 Symmetrical crossover distortion is odd.

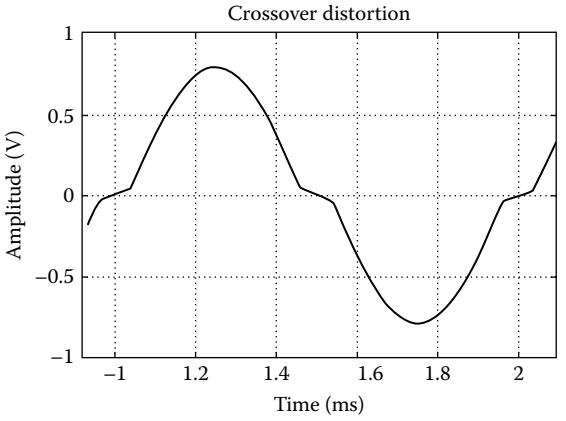

FIGURE 32.11 An example of crossover distortion.

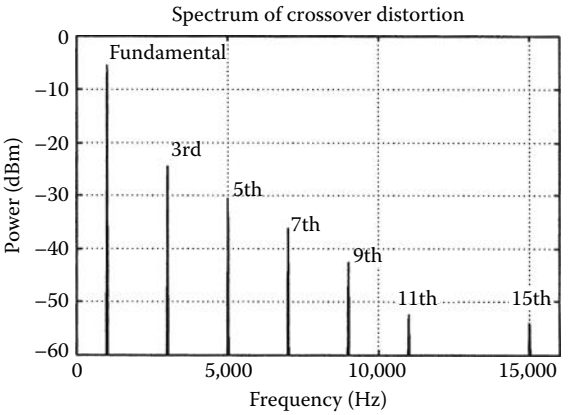

FIGURE 32.12 Symmetrical crossover distortion gives rise to odd harmonics.

To round out the discussion, consider a mathematical example wherein the harmonics are derived algebraically. Consider an input–output transfer function $f(x) = c_1x + c_3x^3 + c_5x^5$ that has only odd powers of x. If the input is a cosine $x = A_0\cos(2\pi f_0 t)$, then the output will be of the form

$$y(t) = f(x) = c_1A_0\cos(2\pi f_0 t) + c_3A_0^3\cos^3(2\pi f_0 t) + c_5A_0^5\cos^5(2\pi f_0 t) \tag{32.14}$$

This can be simplified using the trigonometric relationships given in Equations 32.5 through 32.8 with the following result:

$$y(t) = \left(c_1A_0 + \frac{3c_3A_0^3}{4} + \frac{5c_5A_0^5}{8}\right)\cos(2\pi f_0 t) + \left(\frac{c_3A_0^3}{4} + \frac{5c_5A_0^5}{16}\right)\cos(2\pi 3 f_0 t) + c_5A_0^5\cos^5(2\pi 5 f_0 t) \tag{32.15}$$

Clearly, only the fundamental plus the third and fifth harmonics are present. Should the exercise be repeated for an input–output transfer function consisting of only even powers of x, then only a dc offset plus even harmonics (not the fundamental) would be present in the output.

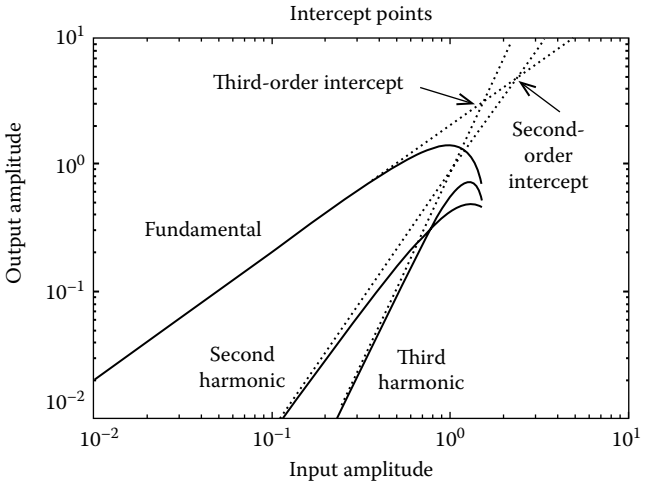

FIGURE 32.13 An example showing the IP2 and IP3 for a hypothetical system. Both axes are plotted on a logarithmic scale.

32.2 Intercept Points

It is often desirable to visualize how the various harmonics increase or decrease as the amplitude of the input sine wave $x(t)$ is changed. Consider the example of a signal applied to a nonlinear system $A(x)$ having single-sided clipping distortion as shown in Figure 32.8. The clipping becomes more severe as the amplitude of the input signal $x(t)$ increases in amplitude, so the distortion of the output signal $y(t)$ becomes worse. The *intercept point* (IP) is used to provide a figure of merit to quantify this phenomenon. Consider Figure 32.13, which shows an example of the power levels of the first three harmonics of the distorted output $y(t)$ of a hypothetical system $A(x)$ in response to a sine-wave input $x(t)$. It is convenient to plot both axes on a log scale. It can be seen that the power in the harmonics increases more quickly than the power in the fundamental. This is consistent with the observation of how clipping becomes worse as the amplitude increases. It is also consistent with the observation that, in the equations earlier, the higher harmonics will rapidly become more prominent because they are proportional to higher exponential powers of the input signal amplitude. The IP for a particular harmonic is the power level where the extrapolated line for that harmonic intersects with the extrapolated line for the fundamental. The second-order intercept is often abbreviated IP2, the third-order intercept abbreviated IP3, etc.

32.3 Measurement of the THD

32.3.1 Classical Method

The traditional method of measuring THD is shown in Figure 32.14. A sine-wave test stimulus $x(t)$ is applied to the input of the system $A(x)$ under test. The system output $y(t)$ is fed through a band-pass filter tuned to the frequency of the input stimulus to extract the signal. Its power p_1 can be measured

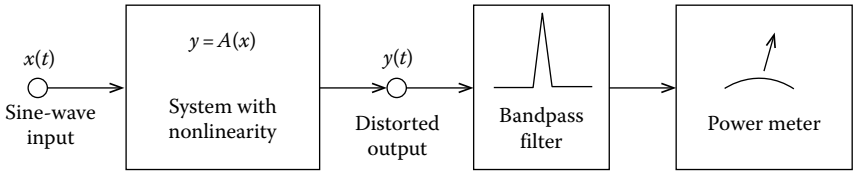

FIGURE 32.14 Illustrating the classical method of measuring THD.

with a power meter. The band-pass filter is then tuned to each of the desired harmonics in turn and the measurement is repeated to determine the required p_i. The THD is then calculated from

$$\text{THD} = \sqrt{\frac{\sum_{k=2}^{N} p_k}{p_1}} \times 100\% \tag{32.16}$$

In the case of an ordinary audio amplifier, nearly all of the power in the distorted output signal is contained in the first 10 or 11 harmonics. However, in more specialized applications, a much larger number of harmonics might need to be considered.

32.3.2 Spectrum Analyzer Method

THD measurements are often made with a spectrum analyzer using the setup shown in Figure 32.15. The readings for the power levels of each of the desired harmonic components in the frequency spectrum of the distorted signal $y(t)$ are collected from the spectrum analyzer, usually in units of dB. They are converted to linear units by means of the relationship

$$a_i = 10^{r_i/20} \tag{32.17}$$

where r_i is the reading for the ith component in dB. The THD is then computed from Equation 32.2. The spectrum analyzer method can be considered as an extension of the classical method described earlier, except that the spectrum analyzer itself is replacing both the band-pass filter and the power meter.

32.3.3 DSP Method

Digital signal processing (DSP) techniques have recently become popular for use in THD measurement. In this method, the distorted output $y(t)$ is digitized by a precision A/D converter and the samples are stored in the computer's memory as shown in Figure 32.16. One assumes that the samples have been collected with a uniform sample period T_s and that appropriate precautions have been taken with regard

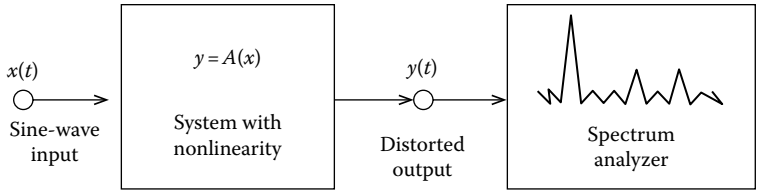

FIGURE 32.15 Illustrating measurement of THD using a spectrum analyzer.

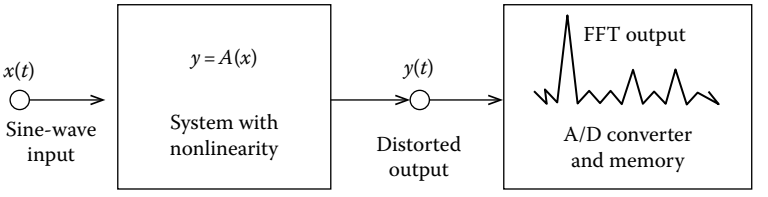

FIGURE 32.16 Illustrating the measurement of THD using FFT.

to the Nyquist criterion and aliasing. Let $y(n)$ refer to the nth stored sample. A fast Fourier transform (FFT) is executed on the stored data using the relationship

$$Y(k) = \sum_{n=0}^{N-1} y(n) e^{-j(2\pi/N)kn} \tag{32.18}$$

where N is the number of samples that have been captured. The frequency of the input test stimulus is chosen such that the sampling is coherent. Coherency in this context means that if N samples have been captured, then the input test stimulus is made to be a harmonic of the primitive frequency f_P, which is defined as

$$f_P = \frac{f_s}{N} = \frac{1}{T_s N} \tag{32.19}$$

One can view the primitive frequency f_P as the frequency of a sinusoidal signal whose period is exactly equal to the time interval formed by the N-points. Thus, the frequency of the test stimulus can be written as

$$f_0 = M \times f_P = M \times \frac{f_s}{N} = \frac{M}{N} \times f_s \tag{32.20}$$

where M and N are integers. To maximize the information content collected by a set of N-points, M and N are selected so that they have no common factors, that is, relatively prime. This ensures that every sample is taken at a different point on the periodic waveform. An example is provided in Figure 32.17, where $M = 3$ and $N = 32$. The FFT is executed on the distorted signal as per Equation 32.18, and then the THD is computed from

$$\text{THD} = \frac{\sqrt{\sum_{k=2}^{N} |Y(k \times M)|^2}}{|Y(M)|} \times 100\% \tag{32.21}$$

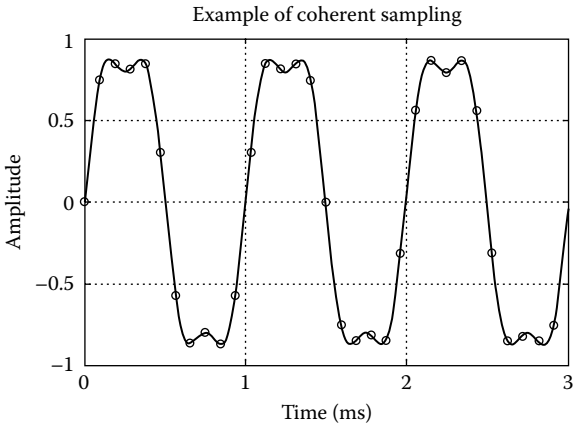

FIGURE 32.17 With coherent sampling, each sample occurs on a unique point of the signal.

32.4 Conclusions

The THD is a figure of merit for the quality of the transmission of a signal through a system having some nonlinearity. Its causes and some methods of measuring it have been discussed. Some simple mathematical examples have been presented. However, in real-world systems, it is generally quite difficult to extract all of the parameters c_k in the transfer characteristic. The examples were intended merely to assist the reader's understanding of the relationship between even and odd functions and the harmonics that arise in response to them.

Defining Terms

Distortion: The effect of corrupting a signal with undesired frequency components.

Fundamental: The lowest frequency component of a signal other than zero frequency.

Harmonic: Any frequency component of a signal that is an integer multiple of the fundamental frequency.

Nonlinearity: The deviation from the ideal of the transfer function, resulting in such effects as clipping or saturation of the signal.

Total harmonic distortion (THD): A numerical figure of merit of the quality of transmission of a signal, defined as the ratio of the power in all the harmonics to the power in the fundamental.

Noise Measurement

W. Marshall Leach, Jr.
Georgia Institute of Technology

This chapter describes the principal sources of electric noise and discusses methods for the measurement of noise. The notations for voltages and currents correspond to the following conventions: dc quantities are indicated by an uppercase letter with uppercase subscripts, for example, V_{BE}. Instantaneous small-signal ac quantities are indicated by a lowercase letter with lowercase subscripts, for example, v_n. The mean-square value of a variable is denoted by a bar over the square

of the variable, for example, $\overline{v_n^2}$, where the bar indicates an arithmetic average of an ensemble of functions. The root-mean-square or rms value is the square root of the mean-square value. Phasors are indicated by an uppercase letter and lower case subscripts, for example, V_n. Circuit symbols for independent sources are circular, symbols for controlled sources are diamond shaped, and symbols for noise sources are square. In the evaluation of noise equations, Boltzmann's constant is $k = 1.38 \times 10^{-23}$ J K^{-1} and the electronic charge is $q = 1.60 \times 10^{-19}$ C. The standard temperature is denoted by T_0 and is taken to be $T_0 = 290$ K. For this value, $4kT_0 = 1.60 \times 10^{-20}$ J and the thermal voltage is $V_T = kT_0/q = 0.025$ V.

33.1 Thermal Noise

Thermal noise or *Johnson noise* is generated by the random collision of charge carriers with a lattice under conditions of thermal equilibrium [1–7]. Thermal noise in a resistor can be modeled by a series voltage source or a parallel current source having the mean-square values:

$$\overline{v_t^2} = 4kTR\Delta f \tag{33.1}$$

$$\overline{i_t^2} = \frac{4kT\Delta f}{R} \tag{33.2}$$

where R is the resistance and Δf is the bandwidth in hertz (Hz) over which the noise is measured. The equation for $\overline{v_t^2}$ is commonly referred to as the *Nyquist formula*. Thermal noise in resistors is independent of the resistor composition.

The *crest factor* for thermal noise is the ratio of the peak value to the rms value. A common definition for the peak value is the level that is exceeded 0.01% of the time. The amplitude distribution of thermal noise is modeled by a Gaussian or normal probability density function. The probability that the instantaneous value exceeds 4 times the rms value is approximately 0.01%. Thus, the crest factor is approximately 4.

33.2 Spectral Density

The *spectral density* of a noise signal is defined as the mean-square value per unit bandwidth. For the thermal noise generated by a resistor, the voltage and current spectral densities, respectively, are given by

$$S_v(f) = 4kTR \tag{33.3}$$

$$S_i(f) = \frac{4kT}{R} \tag{33.4}$$

Because these are independent of frequency, thermal noise is said to have a uniform or flat distribution. Such noise is also called *white noise*. It is called this by analogy to white light, which also has a flat spectral density in the optical band.

33.3 Fluctuation–Dissipation Theorem

Consider any system in thermal equilibrium with its surroundings. If there is a mechanism for energy in a particular mode to leak out of that mode to the surroundings in the form of heat, then energy can leak back into that mode from the surrounding heat by the same mechanism. The fluctuation

dissipation theorem of quantum mechanics states that the average energy flow in each direction is the same. Otherwise, the system would not be in equilibrium.

Mathematically, the fluctuation dissipation theorem states, in general, that the generalized mean-square force $\overline{\mathfrak{F}^2}$ acting on a system in the frequency band from f_1 to f_2 is given by

$$\overline{\mathfrak{F}^2} = 4kT \int_{f_1}^{f_2} \mathrm{Re}[Z(f)]\mathrm{d}f \tag{33.5}$$

where

Re $[Z(f)]$ is the real part of the system impedance $Z(f)$
f is the frequency in hertz (Hz)

For a mechanical system, the generalized force is the mechanical force on the system and the impedance is force divided by velocity. For an electric system, the generalized force is the voltage and the impedance is the ratio of voltage to current.

Equation 33.1 is a statement of the fluctuation dissipation theorem for a resistor. The theorem can be used to calculate the mean-square thermal noise voltage generated by any two-terminal network containing resistors, capacitors, and inductors. Let $Z(f)$ be the complex impedance of the network. The mean-square open-circuit thermal noise voltage is given by

$$\overline{v_\mathrm{t}^2} = 4kT \int_{f_1}^{f_2} \mathrm{Re}[Z(f)]\mathrm{d}f \simeq 4kT\ \mathrm{Re}[Z(f)]\Delta f \tag{33.6}$$

where $\Delta f = f_2 - f_1$ and the approximation holds if Re $[Z(f)]$ is approximately constant over the band.

33.4 Equivalent Noise Resistance and Conductance

A mean-square noise voltage can be represented in terms of an *equivalent noise resistance* [8]. Let $\overline{v_\mathrm{n}^2}$ be the mean-square noise voltage in the band Δf. The noise resistance R_n is defined as the value of a resistor at the standard temperature T_0 = 290 K that generates the same noise. It is given by

$$R_\mathrm{n} = \frac{\overline{v_\mathrm{n}^2}}{4kT_0\Delta f} \tag{33.7}$$

A mean-square noise current can be represented in terms of an *equivalent noise conductance*. Let $\overline{i_\mathrm{n}^2}$ be the mean-square noise current in the band Δf. The noise conductance G_n is defined as the value of a conductance at the standard temperature that generates the same noise. It is given by

$$G_\mathrm{n} = \frac{\overline{i_0^2}}{4kT_0\Delta f} \tag{33.8}$$

33.5 Shot Noise

Shot noise is caused by the random emission of electrons and by the random passage of charge carriers across potential barriers [1–7]. The shot noise generated in a device is modeled by a parallel noise current source. The mean-square shot noise current in the frequency band Δf is given by

$$\overline{i_{\text{sh}}^2} = 2qI\Delta f \tag{33.9}$$

where I is the dc current through the device. This equation is commonly referred to as the *Schottky formula*. Like thermal noise, shot noise is white noise and has a crest formula of approximately 4.

33.6 Flicker Noise

The imperfect contact between two conducting materials causes the conductivity to fluctuate in the presence of a dc current [1–7]. This phenomenon generates what is called *flicker noise* or *contact noise*. It is modeled by a noise current source in parallel with the device. The mean-square flicker noise current in the frequency band Δf is given by

$$\overline{i_{\text{f}}^2} = \frac{K_{\text{f}} I^m \Delta f}{f^n} \tag{33.10}$$

where

K_{f} is the flicker noise coefficient
I is the dc current
m is the flicker noise exponent, and $n \approx 1$

Other names for flicker noise are *1/f noise* (read "one-over-f-noise"), *low-frequency noise*, and *pink noise*. The latter comes from the optical analog of pink light, which has a spectral density that increases at lower frequencies.

33.7 Excess Noise

In resistors, flicker noise is caused by the variable contact between particles of the resistive material and is called *excess noise*. Metal film resistors generate the least excess noise; carbon composition resistors generate the most, with carbon film resistors lying between the two. In modeling excess noise, the flicker noise exponent has the value $m = 2$. The mean-square excess noise current is often written as a function of the *noise index NI* as follows:

$$\overline{i_{\text{ex}}^2} = \frac{10^{NI/10}}{10^{12}\ln 10} \times \frac{I^2 \Delta f}{f} \tag{33.11}$$

where I is the dc current through the resistor. The noise index is defined as the number of μA of excess noise current in each decade of frequency per A of dc current through the resistor. An equivalent definition is the number of μV of excess noise voltage in each decade of frequency per volt of dc drop across the resistor. In this case, the mean-square excess noise voltage generated by the resistor is given by

$$\overline{v_{\text{ex}}^2} = \frac{10^{NI/10}}{10^{12}\ln 10} \times \frac{V^2 \Delta f}{f} \tag{33.12}$$

where $V = IR$ is the dc voltage across the resistor.

33.8 Burst Noise

Burst noise or *popcorn noise* is caused by a metallic impurity in a *pn* junction [4]. When amplified and reproduced by a loudspeaker, it sounds like corn popping. When viewed on an oscilloscope, it appears as fixed amplitude pulses of randomly varying width and repetition rate. The rate can vary from less than one pulse per minute to several hundred pulses per second. Typically, the amplitude of burst noise is 2–100 times that of the background thermal noise.

33.9 Partition Noise

Partition noise occurs when the charge carriers in a current have the possibility of dividing between two or more paths. The noise is generated in the resulting components of the current by the statistical process of partition [9]. Partition noise occurs in bipolar junction transistors (BJTs) where the current flowing from the emitter into the base can take one of two paths. The recombination of injected carriers in the base region corresponds to the current flow in one path. This current flows in the external base lead. The current carried to the collector corresponds to the current flow in the second path. Because the emitter current exhibits full shot noise, the base and collector currents also exhibit full shot noise. However, the base and collector noise currents are correlated because they have equal and opposite partition components. Partition noise in the BJT can be accounted for if all shot noise is referred to two uncorrelated shot noise current sources, one from base to emitter and the other form collector to emitter [10]. This noise model of the BJT is described here.

33.10 Generation–Recombination Noise

Generation–recombination noise is a semiconductor that is generated by the random fluctuation of free-carrier densities caused by spontaneous fluctuations in the generation, recombination, and trapping rates [7]. In BJTs, it occurs in the base region at low temperatures. The generation–recombination gives rise to fluctuations in the base-spreading resistances that are converted into a noise voltage due to the flow of a base current. In junction FETs, it occurs in the channel at low temperatures. Generation–recombination causes fluctuations of the carrier density in the channel, which gives rise to a noise voltage when a drain current flows. In silicon junction FETs, the effect occurs below 100 K. In germanium junction FETs, it occurs at lower temperatures. The effect does not occur in metal–oxide–semiconductor field-effect transistors (MOSFETs).

33.11 Noise Bandwidth

The *noise bandwidth* of a filter is the bandwidth of an ideal filter having a constant passband gain that passes the same rms noise voltage, where the input signal is white noise [1–7]. The filter and the ideal filter are assumed to have the same gains. Let $A_v(f)$ be the complex voltage gain transfer function of a filter, where f is the frequency in Hz. Its noise bandwidth B_n is given by

$$B_n = \frac{1}{A_{vo}^2} \int_0^\infty |A_v(f)|^2 \, df \tag{33.13}$$

where A_{vo} is the maximum value of $|A_v(f)|$. For a white noise input voltage with the spectral density $S_v(f)$, the mean-square noise voltage at the filter output is

$$\overline{v_{no}^2} = A_{vo}^2 S_v(f) B_n$$

TABLE 33.1 Noise Bandwidth B_n of Low-Pass Filters

Number of Poles	Slope (dB/dec)	Real Pole (B_n)		Butterworth (B_n)
1	20	$1.571\,f_0$	$1.571\,f_3$	$1.571\,f_3$
2	40	$0.785\,f_0$	$1.220\,f_3$	$1.111\,f_3$
3	60	$0.589\,f_0$	$1.155\,f_3$	$1.042\,f_3$
4	80	$0.491\,f_0$	$1.129\,f_3$	$1.026\,f_3$
5	100	$0.420\,f_0$	$1.114\,f_3$	$1.017\,f_3$

Two classes of low-pass filters are commonly used in making noise measurements. The first has n real poles, all with the same frequency, having the magnitude-squared transfer function given by

$$|A_v(f)|^2 = \frac{A_{vo}^2}{\left[1+(f/f_0)^2\right]^n} \tag{33.14}$$

where f_0 is the pole frequency. The second is an n-pole Butterworth filter having the magnitude-squared transfer function given by

$$|A_v(f)|^2 = \frac{A_{vo}^2}{1+(f/f_3)^{2n}} \tag{33.15}$$

where f_3 is the –3 dB frequency. Table 33.1 gives the noise bandwidths as a function of the number of poles n for $1 \le n \le 5$. For the real-pole filter, B_n is given as a function of both f_0 and f_3. For the Butterworth filter, B_n is given as a function of f_3.

33.12 Noise Bandwidth Measurement

The noise bandwidth of a filter can be measured with a white noise source with a known voltage spectral density $S_v(f)$. Let $\overline{v_n^2}$ be the mean-square noise output voltage from the filter when it is driven by the noise source. The noise bandwidth is given by

$$B_n = \frac{\overline{v_o^2}}{A_{vo}^2 S_v(f)} \tag{33.16}$$

If the spectral density of the source is not known, the noise bandwidth can be determined if another filter with a known noise bandwidth is available. With both filters driven simultaneously, let $\overline{v_{o1}^2}$ and $\overline{v_{o2}^2}$ be the two mean-square noise output voltages, B_{n1} and B_{n2} the two noise bandwidths, and A_{vo1} and A_{vo2} the two maximum gain magnitudes. The noise bandwidth B_{n2} is given by

$$B_{n2} = B_{n1}\left(\frac{\overline{v_{o2}^2}}{\overline{v_{o1}^2}}\right)\left(\frac{A_{vo1}}{A_{vo2}}\right)^2 \tag{33.17}$$

The white noise source should have output impedance that is low enough so that the loading effect of the filters does not change the spectral density of the source.

33.13 Spot Noise

Spot noise is the rms noise in a band divided by the square root of the noise bandwidth. For a noise voltage, it has the units $V/\sqrt{Hz}$, which is read "volts per root Hz." For a noise current, the units are $A/\sqrt{Hz}$. For white noise, the spot noise in any band is equal to the square root of the spectral density. Spot noise measurements are usually made with a band-pass filter having a bandwidth that is small enough so that the input spectral density is approximately constant over the filter bandwidth. The spot-noise voltage at a filter output is given by $\sqrt{(\overline{v_{no}^2}/B_n)}$, where $\overline{v_{no}^2}$ is the mean-square noise output voltage and B_n is the filter noise bandwidth. The spot-noise voltage at the filter input is obtained by dividing the output voltage by A_{vo}, where A_{vo} is the maximum value of $|A_v(f)|$.

A filter that is often used for spot-noise measurements is a second-order band-pass filter. The noise bandwidth is given by $B_n = \pi B_3/2$, where B_3 is the −3 dB bandwidth. A single-pole high-pass filter having a pole frequency f_1 cascaded with a single-pole low-pass filter having a pole frequency f_2 is a special case of band-pass filter having two real poles. Its noise bandwidth is given by $B_n = \pi(f_1 + f_2)/2$. The −3 dB bandwidth in this case is $f_1 + f_2$, not $f_2 - f_1$.

33.14 Addition of Noise Voltages

Consider the instantaneous voltage $v = v_n + i_n R$, where v_n is a noise voltage and i_n is a noise current. The mean-square voltage is calculated as follows:

$$\overline{v^2} = \overline{(v_n + i_n R)^2} = \overline{v_n^2} + 2\rho\sqrt{\overline{v_n^2}}\sqrt{\overline{i_n^2}}R + \overline{i_n^2}R^2 \tag{33.18}$$

where ρ is the *correlation coefficient* defined by

$$\rho = \frac{\overline{v_n i_n}}{\sqrt{\overline{v_n^2}}\sqrt{\overline{v_n^2}}} \tag{33.19}$$

For the case $\rho = 0$, the sources are said to be uncorrelated or independent. It can be shown that $-1 \le \rho \le 1$.

In ac analysis, noise signals are often represented by phasors. The square magnitude of the phasor represents the mean-square value at the frequency of analysis. Consider the phasor voltage $V = V_n + I_n Z$, where V_n is a noise phasor voltage, I_n is a noise phasor current, and $Z = R + jX$ is a complex impedance. The mean-square voltage is given by

$$\begin{aligned}\overline{v^2} &= \overline{(V_n + I_n R)(V_n^* + I_n^* Z_n^*)} \\ &= \overline{v_n^2} + 2\sqrt{\overline{v_n^2}}\sqrt{\overline{i_n^2}}\,\mathrm{Re}(\gamma Z^*) + \overline{i_n^2}\,|Z|^2\end{aligned} \tag{33.20}$$

where

* denotes the complex conjugate

γ is the complex *correlation coefficient* defined by

$$\gamma = \gamma_r + j\gamma_i = \frac{\overline{V_n I_n^*}}{\sqrt{\overline{v_n^2}}\sqrt{\overline{i_n^2}}} \tag{33.21}$$

It can be shown that $|\gamma| \le 1$.

Noise equations derived by phasor analysis can be converted easily into equations for real signals. However, the procedure generally cannot be done in reverse. For this reason, noise formulas derived by phasor analysis are the more general form.

33.15 Correlation Impedance and Admittance

The *correlation impedance* Z_γ and *correlation admittance* Y_γ between a noise phasor voltage V_n and a noise phasor current I_n are defined by [8]

$$Z_\gamma = R_\gamma + jX_\gamma = \gamma\sqrt{\frac{\overline{v_n^2}}{\overline{i_n^2}}} \tag{33.22}$$

$$Y_\gamma = G_\gamma + jB_\gamma = \gamma^*\sqrt{\frac{\overline{i_n^2}}{\overline{v_n^2}}} \tag{33.23}$$

where

$\overline{v_n^2}$ is the mean-square value of V_n
$\overline{i_n^2}$ is the mean-square value of I_n
γ is the complex correlation coefficient between V_n and I_n

With these definitions, it follows that $\overline{V_n I_n^*} = \overline{i_n^2} Z_\gamma = \overline{v_n^2}\ Y_\gamma^*$.

33.16 $v_n - i_n$ Amplifier Noise Model

The noise generated by an amplifier can be modeled by referring all internal noise sources to the input [1–7,11]. In order for the noise sources to be independent of the source impedance, two sources are required—a series voltage source and a shunt current source. In general, the sources are correlated.

Figure 33.1 shows the amplifier noise model, where V_s is the source voltage, $Z_s = R_s + jX_s$ is the source impedance, V_{ts} is the thermal noise voltage generated by R_s, $A_v = V_o/V_i$ is the complex voltage gain, and Z_i is the input impedance. The output voltage is given by

$$V_o = \frac{A_v Z_i}{Z_s + Z_i}(V_s + V_{ts} + V_n + I_n Z_s) \tag{33.24}$$

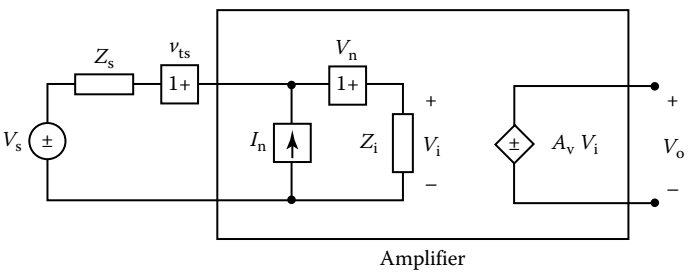

FIGURE 33.1 Amplifier $v_n - i_n$ noise model.

The *equivalent noise input voltage* is the voltage in series with V_s that generates the same noise voltage at the output as all noise sources in the circuit. It is given by $V_{ni} = V_{ts} + V_n + I_n Z_S$. The mean-square value is

$$\overline{v_{ni}^2} = 4kTR_sB_n + \overline{v_n^2} + 2\sqrt{\overline{v_n^2}}\sqrt{\overline{i_n^2}}\,\mathrm{Re}(\gamma Z_s^*) + \overline{i_n^2}\,|Z_s|^2 \tag{33.25}$$

where

B_n is the amplifier noise bandwidth

γ is the complex correlation between V_n and I_n

For $|Z_s|$ very small, $\overline{v_{ni}^2} \cong \overline{v_n^2}$ and γ is not important. Similarly, for $|Z_s|$ very large, $\overline{v_{ni}^2} \cong \overline{i_n^2}|Z_s|^2$ and γ is again not important.

When the source is represented by a Norton equivalent consisting of a source current i_s in parallel with source admittance $Y_s = G_s + jB_s$, the noise referred to the input must be represented by an *equivalent noise input current*. The mean-square value is given by

$$\overline{i_{ni}^2} = 4kTG_sB_n + \overline{v_n^2}\,|Y_s|^2 + 2\sqrt{\overline{v_n^2}}\sqrt{\overline{i_n^2}}\,\mathrm{Re}(\gamma Y_s) + \overline{i_n^2} \tag{33.26}$$

33.17 Measuring $\overline{V_{ni}^2}$, $\overline{V_n^2}$, and $\overline{i_n^2}$

For a given Z_s, the mean-square equivalent noise input voltage can be measured by setting $V_s = 0$ and measuring the mean-square noise output voltage $\overline{v_{no}^2}$. It follows that $\overline{v_{ni}^2}$ is given by

$$\overline{v_{ni}^2} = \frac{\overline{v_{no}^2}}{|A_v|^2} \times \left|1 + \frac{Z_s}{Z_i}\right|^2 \tag{33.27}$$

To measure $\overline{v_n^2}$ and $\overline{i_n^2}$, $\overline{v_{no}^2}$ is measured with $Z_s = 0$ and with Z_s replaced by a large-value resistor. It follows that $\overline{v_n^2}$ and $\overline{i_n^2}$ are then given by

$$\overline{v_n^2} = \frac{\overline{v_{no}^2}}{|A_v|^2} \quad \text{for } Z_s = 0 \tag{33.28}$$

$$\overline{i_n^2} = \left|\frac{1}{R_s} + \frac{1}{Z_i}\right|^2 \frac{\overline{v_{no}^2}}{|A_v|^2} \quad \text{for } Z_s = R_s \text{ and } R_s \text{ large} \tag{33.29}$$

33.18 Noise Temperature

The internal noise generated by an amplifier can be expressed as an equivalent *input-termination noise temperature* [12]. This is the temperature of the source resistance that generates a thermal noise voltage equal to the internal noise generated in the amplifier when referred to the input. The noise temperature T_n is given by

$$T_n = \frac{\overline{v_{ni}^2}}{4kR_sB_n} - T \tag{33.30}$$

where

$\overline{v_{ni}^2}$ is the mean-square equivalent input noise voltage in the band B_n

R_s is the real part of the source output impedance

T is the temperature of R_s

33.19 Noise Reduction with a Transformer

Let a transformer be connected between the source and the amplifier in Figure 33.1. Let n be the transformer turns ratio, R_1 the primary resistance, and R_2 the secondary resistance. The equivalent noise input voltage in series with the source voltage V_s has the mean-square value:

$$\overline{v_{ni}^2} = 4kT\left(R_s + R_1 + \frac{R_2}{n^2}\right)\Delta f + \frac{\overline{v_n^2}}{n^2}$$
$$+2\sqrt{\overline{v_n^2}}\sqrt{\overline{i_n^2}}\,\mathrm{Re}\left[\gamma\left(Z_s^* + R_1 + \frac{R_2}{n^2}\right)\right] + n^2\overline{i_n^2}\left|Z_s + R_1 + \frac{R_2}{n^2}\right|^2 \tag{33.31}$$

In general, $R_2/R_1 \propto n$, which makes it difficult to specify the value of n that minimizes $\overline{v_{ni}^2}$. For $R_1 + R_2/n^2 \ll |Z_s|$ it is minimized when

$$n^2 = \frac{1}{|Z_s|}\sqrt{\frac{\overline{v_n^2}}{\overline{i_n^2}}} \tag{33.32}$$

33.20 Signal-to-Noise Ratio

The *signal-to-noise ratio* of an amplifier is defined by

$$\mathrm{SNR} = \frac{\overline{v_{so}^2}}{\overline{v_{no}^2}} \tag{33.33}$$

where

$\overline{v_{so}^2}$ is the mean-square signal output voltage
$\overline{v_{no}^2}$ is the mean-square noise output voltage

The SNR is often expressed in dB with the equation $\mathrm{SNR} = 10\log(\overline{v_s^2}/\overline{v_{no}^2})$. In measuring the SNR, a filter should be used to limit the bandwidth of the output noise to the signal bandwidth of interest. An alternative definition of the SNR that is useful in making calculations is

$$\mathrm{SNR} = \frac{\overline{v_s^2}}{\overline{v_{ni}^2}} \tag{33.34}$$

where

$\overline{v_s^2}$ is the mean-square signal input voltage
$\overline{v_{ni}^2}$ is the mean-square equivalent noise input voltage

33.21 Noise Factor and Noise Figure

The *noise factor F* of an amplifier is defined by [1–8]

$$F = \frac{\overline{v_{no}^2}}{\overline{v_{nos}^2}} \tag{33.35}$$

where

$\overline{v_{no}^2}$ is the mean-square noise output voltage with the source voltage zeroed
$\overline{v_{nos}^2}$ is the mean-square noise output voltage considering the only source of noise to be the thermal noise generated by the source resistance R_s

The *noise figure* is the noise factor expressed in dB and is given by

$$\mathrm{NF} = 10\log F \tag{33.36}$$

For the $v_n - i_n$ amplifier noise model, the noise factor is given by

$$F = \frac{\overline{v_{ni}^2}}{4kTR_sB_n} = 1 + \frac{\overline{v_n^2} + 2\sqrt{\overline{v_n^2}}\sqrt{\overline{i_n^2}}\,\mathrm{Re}(\gamma Z_s^*) + \overline{i_n^2}|Z_s|^2}{4kTR_sB_n} \tag{33.37}$$

where B_n is the amplifier noise bandwidth. The value of Z_s that minimizes the noise figure is called the *optimum source impedance* and is given by

$$Z_{so} = R_{so} + jX_{so} = \left[\sqrt{1-\gamma_i^2} - j\gamma_i\right]\sqrt{\frac{\overline{v_n^2}}{\overline{i_n^2}}} \tag{33.38}$$

where $\gamma_i = \mathrm{Im}(\gamma)$. The corresponding value of F is denoted by F_0 and is given by

$$F_0 = 1 + \frac{\sqrt{\overline{v_n^2}}\sqrt{\overline{i_n^2}}}{2kTB_n}\left(\gamma_r + j\sqrt{1-\gamma_i^2}\right) \tag{33.39}$$

It follows that F can be expressed in terms of F_0 as follows:

$$F = F_0 + \frac{G_n}{R_{ns}}\left[(R_s - R_{so})^2 + (X_s - X_{so})^2\right] \tag{33.40}$$

where G_n is the noise conductance of I_n and R_{ns} is the noise resistance of the source. These are given by

$$G_n = \frac{\overline{i_n^2}}{4kT_0B_n} \tag{33.41}$$

$$R_{ns} = \frac{\overline{v_{ts}^2}}{4kT_0B_n} = \frac{T\ R_s}{T_0} \tag{33.42}$$

When the source is represented by a Norton equivalent consisting of a source current i_s in parallel with a source admittance $Y_s = G_s + jB_s$, the *optimum source admittance* is given by

$$Y_{so} = G_{so} + jB_{so} = \left[\sqrt{1-\gamma_i^2} + j\gamma_i\right]\sqrt{\frac{\overline{i_n^2}}{\overline{v_n^2}}} \tag{33.43}$$

which is the reciprocal of Z_{so}. The noise factor can be written as

$$F = F_0 + \frac{R_n}{G_{ns}}\left[(G_s - G_{so})^2 + (B_s - B_{so})^2\right] \tag{33.44}$$

where

R_n is the noise resistance of V_n
G_{ns} is the noise conductance of the source

These are given by

$$R_n = \frac{\overline{v_n^2}}{4kT_0B_n} \tag{33.45}$$

$$G_{ns} = \frac{\overline{i_{ts}^2}}{4kT_0B_n} = \frac{TG_s}{T_0} \tag{33.46}$$

33.22 Noise Factor Measurement

The noise factor can be measured with a calibrated white noise source driving the amplifier. The source output impedance must equal to the value of Z_s for which F is to be measured. The source temperature must be the standard temperature T_0. First, measure the amplifier noise output voltage over the band of interest with the source voltage set to zero. For the amplifier model of Figure 33.1, the mean-square value of this voltage is given by

$$\overline{v_{nol}^2} = \left|\frac{A_{vo}Z_i}{Z_s + Z_i}\right|^2 \left[4kT_0R_sB_n + \overline{v_n^2} + 2\sqrt{\overline{v_n^2}}\sqrt{\overline{i_n^2}}\,\mathrm{Re}(\gamma Z_s^*) + \overline{i_n^2}\,|\,Z_s\,|^2\right] \tag{33.47}$$

The source noise voltage is then increased until the output voltage increases by a factor r. The new mean-square output voltage can be written as

$$r^2\overline{v_{nol}^2} = \left|\frac{A_{vo}Z_i}{Z_s + Z_i}\right|^2 \left[(S_v(f) + 4kT_0R_s)B_n + \overline{v_n^2} + 2\sqrt{\overline{v_n^2}}\sqrt{\overline{i_n^2}}\,\mathrm{Re}(\gamma Z_s^*) + \overline{i_n^2}|Z_s|^2\right] \tag{33.48}$$

where $S_v(f)$ is the open-circuit voltage spectral density of the white noise source.

The aforementioned two equations can be solved for F to obtain

$$F = \frac{S_s(f)}{(r^2 - 1)4kT_0R_s} \tag{33.49}$$

A common value for r is $\sqrt{2}$. The gain and noise bandwidth of the amplifier are not needed for the calculation. If a resistive voltage divider is used between the noise source and the amplifier to attenuate the input signal, the source spectral density $S_s(f)$ is calculated or measured at the attenuator output with it disconnected from the amplifier input.

If the noise bandwidth of the amplifier is known, its noise factor can be determined by measuring the mean-square noise output voltage $\overline{v_{no}^2}$ with the source voltage set to zero. The noise factor is given by

$$F = \left|1 + \frac{Z_s}{Z_i}\right|^2 \frac{\overline{v_{no}^2}}{4kT_0R_sB_nA_{vo}^2} \tag{33.50}$$

This expression is often used with $B_n = \pi B_3/2$, where B_3 is the −3 dB bandwidth. Unless the amplifier has a first-order low-pass or a second-order band-pass frequency response characteristic, this is only an approximation.

33.23 Junction Diode Noise Model

When forward biased, a diode generates both shot noise and flicker noise [1–7]. The noise is modeled by a parallel current source having the mean-square value

$$\overline{i_n^2} = 2qI\Delta f + \frac{K_f I^m \Delta f}{f} \tag{33.51}$$

where I is the dc diode current. A plot of $\overline{i_n^2}$ versus f for a constant Δf exhibits a slope of –10 dB/decade for low frequencies and a slope of zero for higher frequencies.

Diodes are often used as noise sources in circuits. Specially processed zener diodes are marketed as solid-state noise diodes. The noise mechanism in these is called *avalanche noise*, which is associated with the diode reverse breakdown current. For a given breakdown current, avalanche noise is much greater than shot noise in the same current.

33.24 BJT Noise Model

Figure 33.2a shows the BJT noise model [1–7]. The base-spreading resistance r_x is modeled as an external resistor; v_{tx} is the thermal noise generated by r_x; i_{shb} and i_{fb}, respectively, are the shot noise and flicker noise in the base bias current I_B; and i_{shc} is the shot noise in the collector bias current I_C. The sources have the mean-square values of

$$\overline{v_{tx}^2} = 4kTr_x\Delta f \tag{33.52}$$

$$\overline{i_{shb}^2} = 2qI_B\Delta f \tag{33.53}$$

$$\overline{i_{fb}^2} = \frac{K_f I_B^m \Delta f}{f} \tag{33.54}$$

$$\overline{i_{shc}^2} = 2qI_C\Delta f \tag{33.55}$$

Let the resistances to signal ground seen looking out of the base and the emitter, respectively, be denoted by R_1 and R_2. The mean-square equivalent noise input voltages in series with the base or the emitter that generates the same collector noise current is given by

$$\overline{v_{ni}^2} = 4kT(R_1 + r_x + R_2)\Delta f + \left(2qI_B\Delta f + \frac{K_f I_B \Delta f}{f}\right)(R_1 + r_x + R_2)^2$$

$$+2qI_C\Delta f\left(\frac{R_1 + r_x + R_2}{\beta} + \frac{V_T}{I_C}\right)^2 \tag{33.56}$$

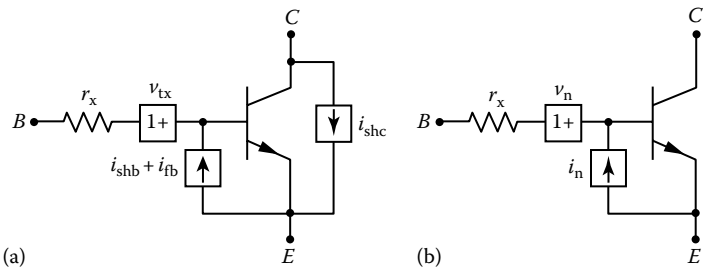

FIGURE 33.2 (a) BJT noise model and (b) BJT $v_n - i_n$ noise model.

At frequencies where flicker noise can be neglected, the value of I_C that minimizes $\overline{v_{ni}^2}$ is called the *optimum collector current*. It is given by

$$I_{C_{opt}} = \frac{V_T}{R_1 + r_x + R_2} \times \frac{\beta}{\sqrt{1+\beta}} \tag{33.57}$$

The corresponding value of $\overline{v_{ni}^2}$ is given by

$$\overline{v_{ni_{min}}^2} = 4kT(R_1 + r_x + R_2)\Delta f \times \frac{\sqrt{1+\beta}}{\sqrt{1+\beta}-1} \tag{33.58}$$

If N identical BJTs that are identically biased are connected in parallel, the equivalent noise input voltage is given by Equation 33.56 with r_x replaced with r_x/N, I_B replaced with NI_B, and I_C replaced with NI_C. In this case, R_1 and R_2, respectively, are the resistances to signal ground seen looking out of the parallel connected bases and the parallel connected emitters. For N fixed, the value of I_C that minimizes $\overline{v_{no}^2}$ is given by Equation 33.57 with R_1 replaced with NR_1 and R_2 replaced with NR_2. The corresponding value of $\overline{v_{ni_{min}}^2}$ is given by Equation 33.58 with r_x replaced with r_x/N. It follows that parallel connection of BJTs can be used to reduce the thermal noise of r_x, provided the devices are optimally biased.

The BJT $v_n - i_n$ noise model is given in Figure 33.2b, where r_x is a noiseless resistor, for its thermal noise is included in v_n. The mean-square values of v_n and i_n and the correlation coefficient are given by

$$\overline{v_n^2} = 4kTr_x\Delta f + 2kT\frac{V_T}{I_C}\Delta f \tag{33.59}$$

$$\overline{i_n^2} = 2qI_B\Delta f + \frac{K_f I_B^m \Delta f}{f} + \frac{2qI_C\Delta f}{\beta^2} \tag{33.60}$$

$$\rho = \frac{2kT\Delta f}{\beta\sqrt{\overline{v_n^2}}\sqrt{\overline{i_n^2}}} \tag{33.61}$$

where $\beta = I_C/I_B$ is the current gain. An alternative model puts r_x inside the BJT. For this model, the expressions for i_n and ρ are more complicated than the ones given here.

The $v_n - i_n$ noise model of Figure 33.1 does not have a noiseless resistor in series with its input. Before formulae that are derived for this model are applied to the BJT model of Figure 33.2b, the formulae must be modified to account for the noiseless r_x. For the common-emitter amplifier, for example, the source resistance R_s would be replaced in the expression for $\overline{v_{ni}^2}$ by $R_s + r_x$ in all occurrences except in terms that represent the thermal noise of R_s.

The value of the base-spreading resistance r_x depends on the method used to measure it. For noise calculations, r_x should be measured with a noise technique. A test circuit for measuring r_x is shown in Figure 33.3. The emitter bias current I_E and the collector bias voltage V_C are given by

$$I_E = \frac{-V_{BE} - V_{EE}}{R_E} \tag{33.62}$$

$$V_C = V_{CC} - \alpha I_E R_C \tag{33.63}$$

where $\alpha = \beta/(1 + \beta)$. Capacitors C_1 and C_2 should satisfy $C_1 >> I_E/(2\pi f V_T)$ and $C_2 >> 1/(2\pi f R_C)$, where f is the lowest frequency of interest. To minimize the noise contributed by R_C, R_F, and the op-amp, a

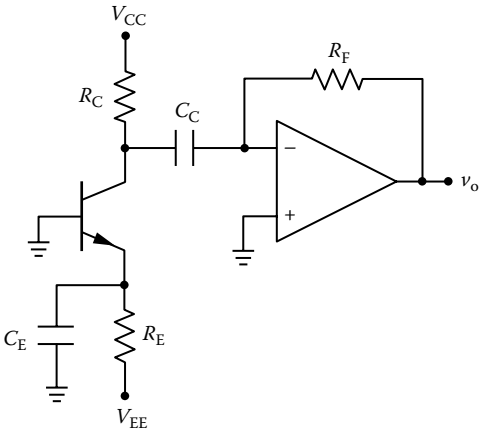

FIGURE 33.3 Test circuit for measuring r_x of a BJT.

low-noise op-amp should be used and R_F should be much larger than R_C. The power supply rails must be properly decoupled to minimize power supply noise.

To prevent flicker noise from affecting the data, the op-amp output voltage must be measured over a noise bandwidth where the spectral density is white. Denote the mean-square op-amp output voltage over the band B_n with the BJT in the circuit by $\overline{v_{no1}^2}$. Denote the mean-square voltage over the band B_n with the BJT removed by $\overline{v_{no2}^2}$. The base-spreading resistance r_x can be obtained by solving

$$r_x^2\left[\frac{A}{\beta^2}-2qI_BB_n\right]+r_x\left[\frac{2AV_T}{\beta I_C}-4kTB_n\right]+\frac{AV_T^2}{I_C^2}=0 \tag{33.64}$$

where

$$A=\frac{\overline{v_{no1}^2}-\overline{v_{no2}^2}}{R_F^2}-2qI_CB_n \tag{33.65}$$

The test circuit of Figure 33.3 can be used to measure the flicker noise coefficient K_f and the flicker noise exponent m. The plot of $(\overline{v_{no1}^2}-\overline{v_{no2}^2})$ versus frequency for a constant noise bandwidth Δf must be obtained, for example, with a signal analyzer. In the white noise range, the slope of the plot is zero. In the flicker noise range, the slope is −10 dB per decade. The lower frequency at which $(\overline{v_{no1}^2}-\overline{v_{no2}^2})$ is 3 dB greater than its value in the white noise range is the flicker noise corner frequency f_f. It can be shown that

$$K_fI_B^m=\frac{\left(\overline{v_{no1}^2}-\overline{v_{no2}^2}\right)f_f}{2R_F^2\Delta f}\times\left(\frac{r_x}{\beta}+\frac{V_T}{I_C}\right)^2 \tag{33.66}$$

By repeating the measurements for at least two values of I_C, this equation can be used to solve for both K_f and m. Unless I_C is large, the r_x/β term can usually be neglected compared to the V_T/I_C term. The value of the flicker noise exponent is usually in the range $1 < m < 3$ but is often taken as unity. If it is assumed that $m = 1$, the value of K_f can be calculated by making the measurements with only one value of I_C.

33.25 FET Noise Model

Figure 33.4a shows the MOSFET noise equivalent circuit, where i_{td} is the channel thermal noise current and i_{fd} is the channel flicker noise current [1–7]. The mean-square values of these currents are given by

$$\overline{i_{td}^2} = \frac{8kT\Delta f}{3g_m} \tag{33.67}$$

$$\overline{i_{fd}^2} = \frac{K_f \Delta f}{4KfL^2C_{ox}} \tag{33.68}$$

where

K is the transconductance parameter
$g_m = 2\sqrt{KI_D}$ is the transconductance
L is the effective length of the channel
C_{ox} is the gate oxide capacitance per unit area

Let the resistances to signal ground seen looking out of the gate and the source, respectively, be denoted by R_1 and R_2. The mean-square equivalent noise input voltage in series with either the gate or the source that generates the same drain noise current is given by

$$\overline{v_{ni}^2} = 4kT(R_1 + R_2)\Delta f + \frac{4kT\Delta f}{3\sqrt{KI_D}} + \frac{K_f \Delta f}{4KL^2C_{ox}f} \tag{33.69}$$

where it is assumed that the MOSFET bulk is connected to its source in the ac. If N identical MOSFETs that are identically biased are connected in parallel, the equivalent noise input voltage is given by Equation 33.69 with the exception that the second and third terms are divided by N.

The noise sources in Figure 33.4a can be reflected into a single source in series with the gate. The circuit is shown in Figure 33.4b. The mean-square value of v_n is given by

$$\overline{v_n^2} = \frac{8kT\Delta f}{3g_m} + \frac{K_f \Delta f}{4KfL^2C_{ox}} \tag{33.70}$$

The FET flicker noise coefficient K_f can be measured by replacing the BJT in Figure 33.3 with the FET. On a plot of $(\overline{v_{no1}^2} - \overline{v_{no2}^2})$ as a function of frequency for a constant noise bandwidth, the flicker noise corner frequency f_f is the lower frequency at which $(\overline{v_{no1}^2} - \overline{v_{no2}^2})$ is up 3 dB above the white noise level. A signal analyzer can be used to display this plot. The flicker noise coefficient is given by

$$K_f = \frac{32kTKf_fL^2C_{ox}}{3g_m} \tag{33.71}$$

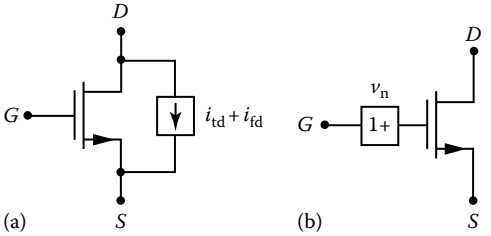

FIGURE 33.4 FET noise model: (a) current noise model and (b) voltage noise model.

The MOSFET circuits and equations also apply to the junction FET with the exception that the L^2 and C_{ox} terms are omitted from the formulae. This assumes that the junction FET gate-to-channel junction is reverse biased, which is the usual case. Otherwise, shot noise in the gate current must be modeled.

33.26 Operational Amplifier Noise Models

Variations of the $v_n - i_n$ amplifier noise model are used in specifying op-amp noise performance. The three most common models are given in Figure 33.5. In Figure 33.5b and c, v_n can be placed in series with either input [4,6]. In general, the sources in each model are correlated. In making calculations that use specified op-amp noise data, it is important to use the noise model for which the data apply.

33.27 Photodiode Detector Noise Model

Figure 33.6a shows the circuit symbol of a photodiode detector [4]. When reverse biased by a dc source, an incident light signal causes a signal current to flow in the diode. The diode small-signal noise model is shown in Figure 33.6b, where i_s is the signal current (proportional to the incident

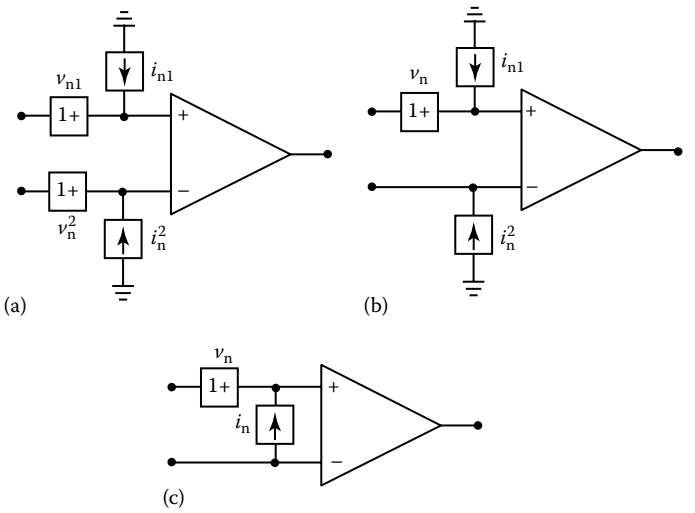

FIGURE 33.5 Op-amp noise models: (a) multiple noise currents and multiple noise voltage representation, (b) multiple noise currents and single voltage representation, and (c) single noise current and single noise voltage representation.

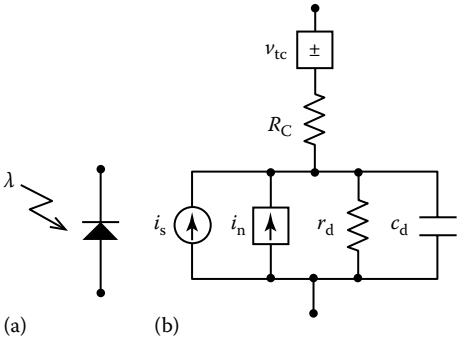

FIGURE 33.6 Photodiode noise model (a) photodiode symbol and (b) small-signal noise model of photodiode.

light intensity), i_n is the diode noise current, r_d is the small-signal resistance of the reverse-biased junction, c_d is the small-signal junction capacitance, r_c is the cell resistance (typically <50 Ω), and v_{tc} is the thermal noise voltage generated by r_c. The noise current i_n consists of three components: shot noise i_{sh}, flicker noise i_f, and carrier generation–recombination noise i_{gr}. The first three have the mean-square values

$$\overline{v_{tc}^2} = 4kTr_c\Delta f \tag{33.72}$$

$$\overline{i_{sh}^2} = 2qI_D\Delta f \tag{33.73}$$

$$\overline{i_f^2} = \frac{K_f I_D^m \Delta f}{f} \tag{33.74}$$

where I_D is the reverse-biased diode current. The carrier generation–recombination noise has a white spectral density up to a frequency determined by the carrier lifetime. Because the detector has a large output resistance, it should be used with amplifiers that exhibit a low input current noise.

33.28 Piezoelectric Transducer Noise Model

Figure 33.7a shows the circuit symbol of a piezoelectric transducer [4]. This transducer generates an electric voltage when a mechanical force is applied between two of its surfaces. An approximate equivalent circuit that is valid for frequencies near the transducer mechanical resonance is shown in Figure 33.7b. In this circuit, C_e represents the transducer electric capacitance, while C_s, L_s, and R_s are chosen to have a resonant frequency and quality factor numerically equal to those of the transducer mechanical resonance. The source v_s represents the signal voltage, which is proportional to the applied force. The source v_{ts} represents the thermal noise generated by R_s. It has a mean-square value of

$$\overline{v_{ts}^2} = 4kTR_s\Delta f \tag{33.75}$$

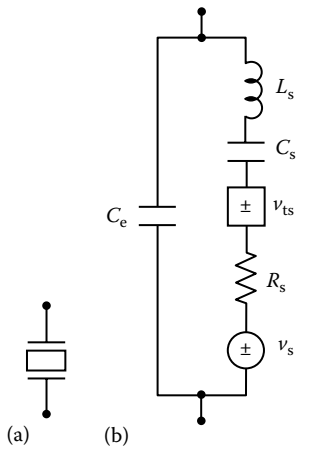

FIGURE 33.7 (a) Piezoelectric transducer symbol and (b) noise model of piezoelectric transducer.

This noise component is negligible in most applications.

The piezoelectric transducer has two resonant frequencies: short-circuit resonant frequency f_{sc} and an open-circuit resonant frequency f_{oc} given by

$$f_{sc} = \frac{1}{2\pi\sqrt{L_s C_s}} \tag{33.76}$$

$$f_{oc} = \frac{1}{2\pi\sqrt{L_1 C_1}} \tag{33.77}$$

where $C_1 = C_s C_e/(C_s + C_e)$. It is normally operated at the open-circuit resonant frequency where the transducer output impedance is very high. For this reason, it should be used with amplifiers that exhibit a low input current noise.

33.29 Parametric Amplifiers

A *parametric amplifier* is an amplifier that uses a time-varying reactance to produce amplification [13]. In low-noise microwave parametric amplifiers, a reverse-biased *pn* junction diode is used to realize a variable capacitance. Such diodes are called *varactors*, for variable reactance. The depletion capacitance of the reverse-biased junction is varied by simultaneously applying a signal current and a pump current at different frequencies. The nonlinear capacitance causes frequency mixing to occur between the signal frequency and the pump frequency. When the power generated by the frequency mixing exceeds the signal input power, the diode appears to have a negative resistance and signal amplification occurs. The only noise that is generated is the thermal noise of the effective series resistance of the diode, which is very small.

Figure 33.8 shows block diagram of a typical parametric amplifier. The varactor diode is placed in a resonant cavity. A circulator is used to isolate the diode from the input and output circuits. A pump signal is applied to the diode to cause its capacitance to vary at the pump frequency. The filter isolates the pump signal from the output circuit. The idler circuit is a resonant cavity that is coupled to the diode cavity to reduce the phase sensitivity. Let the signal frequency be f_s, the pump frequency be f_p, and the resonant frequency of the idler cavity be f_i. In cases where $f_p = f_s + f_i$, the varying capacitance of the diode looks like a negative resistance and the signal is amplified. If $f_i = f_s$, the amplifier is called a *degenerate* amplifier. This is the simplest form of the parametric amplifier and it requires the lowest

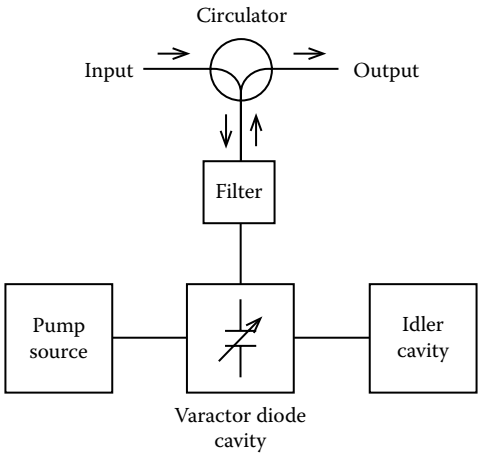

FIGURE 33.8 Block diagram of a typical parametric amplifier.

pump frequency and power to operate. For the *nondegenerate* amplifier, $f_p > 2f_s$. In both cases, the input and the output are at the same frequency. In the *upconverter* amplifier, $f_p = f_i - f_s$ and $f_p > 2f_s$. In this case, the varying capacitance of the diode looks like a positive resistance and the signal frequency output is not amplified. However, there is an output at the idler frequency that is amplified. Thus, the output frequency is higher than the input frequency. The conversion gain can be as high as the ratio of the output frequency to the input frequency.

33.30 Measuring Noise

A typical setup for measuring noise is shown in Figure 33.9. To prevent measurement errors caused by signals coupling in through the ground and power supply leads, the circuit under test and the test set must be properly grounded and good power supply decoupling must be used [6]. For measurement schemes requiring a sine-wave source, an internally shielded oscillator is preferred over a function generator. This is because function generators can introduce errors caused by radiated signals and signals coupled through the ground system.

When making measurements on a high-gain circuit, the input signal must often be attenuated. Attenuators that are built into sources might not be adequately shielded, so that errors can be introduced by radiated signals. These problems can be minimized if a shielded external attenuator is used between the source and the circuit under test. Such an attenuator is illustrated in Figure 33.9. When a high attenuation is required, a multistage attenuator is preferred. For proper frequency response, the attenuator might require frequency compensation [4]. Unless the load impedance on the attenuator is large compared to its output impedance, both the attenuation and the frequency compensation can be a function of the load impedance.

Figure 33.9 shows source impedance Z_s in series with the input to the circuit under test. This impedance is in series with the output impedance of the attenuator. It must be chosen so that the circuit under test has the desired source impedance termination for the noise measurements.

Because noise signals are small, a low-noise amplifier is often required to boost the noise level sufficiently so that it can be measured. Such an amplifier is shown in Figure 33.9. The noise generated by the amplifier will add to the measured noise. To correct for this, first measure the mean-square noise voltage with the amplifier input terminated in the output impedance of the circuit under test. Then subtract this from the

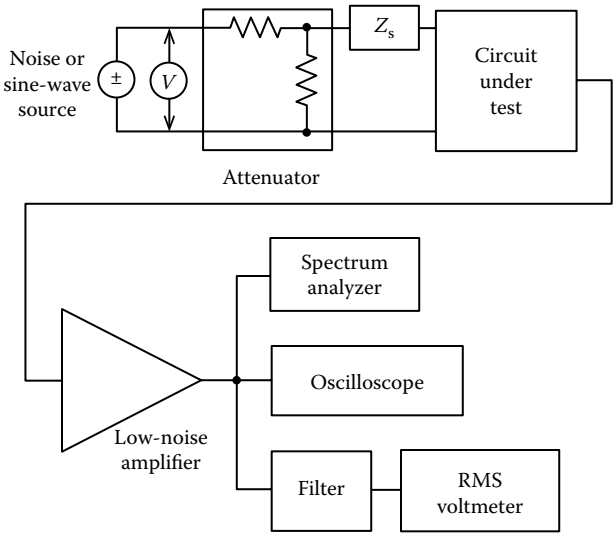

FIGURE 33.9 Noise measuring setup.

measured mean-square noise voltage with the circuit under test driving the amplifier. The difference is the mean-square noise due to the circuit. Ideally, the amplifier should have no effect on the measured noise.

The noise voltage over a band can be measured with either a spectrum analyzer or with a filter having a known noise bandwidth and a voltmeter. The noise can be referred to the input of the circuit under test by dividing by the total gain between its input and the measuring device. The measuring voltmeter should have a bandwidth that is at least 10 times the noise bandwidth of the filter. The *voltmeter crest factor* is the ratio of the peak input voltage to the full-scale rms meter reading at which the internal meter circuits overload. For a sine-wave signal, the minimum voltmeter crest factor is $\sqrt{2}$. For noise measurements, a higher crest factor is required. For Gaussian noise, a crest factor of 3 gives an error less than 1.5%. A crest factor of 4 gives an error less than 0.5%. To avoid overload on noise peaks caused by an inadequate crest factor, measurements should be made on the lower one-third to one-half of the voltmeter scale.

A true rms voltmeter is preferred over one that responds to the average rectified value of the input voltage but is calibrated to read rms. When the latter type of voltmeter is used to measure noise, the reading will be low. For Gaussian noise, the reading can be corrected by multiplying the measured voltage by 1.13. Noise voltages measured with a spectrum analyzer must also be corrected by the same factor if the spectrum analyzer responds to the average rectified value of the input voltage but is calibrated to read rms.

Noise measurements with a spectrum analyzer require knowledge of the noise bandwidth of the instrument. For a conventional analyzer, the bandwidth is proportional to frequency. When white noise is analyzed, the display exhibits a slope of +10 dB per decade. However, the measured voltage level at any frequency divided by the square root of the noise bandwidth of the analyzer is a constant equal to the spot-noise value of the input voltage at that frequency. Band-pass filters that have a bandwidth proportional to the center frequency are called *constant-Q filters*. For a second-order constant-*Q* filter, the noise bandwidth is given by $B_n = \pi f_0/2Q$, where f_0 is the center frequency and Q is the quality factor. The latter is given by $Q = f_0/B_3$, where B_3 is the –3 dB bandwidth. These equations are often used to estimate the noise bandwidth of band-pass filters that are not second order.

A second type of spectrum analyzer is called a *signal analyzer*. Such an instrument uses digital signal processing techniques to calculate the spectrum of the input signal as a discrete Fourier transform. The noise bandwidth of these instruments is a constant so that the display exhibits a slope of zero when white noise is the input signal.

Fairly accurate rms noise measurements can be made with an oscilloscope. A filter should be used to limit the noise bandwidth at its input. Although the procedure is subjective, the rms voltage can be estimated by dividing the observed peak-to-peak voltage by 6 [4]. One of the advantages of using the oscilloscope is that nonrandom noise that can affect the measurements can be identified, for example, a 60 Hz hum signal.

Another oscilloscope method is to display the noise simultaneously on both inputs of a dual-channel oscilloscope that is set in the dual-sweep mode. The two channels must be identically calibrated, and the sweep rate must be set low enough so that the displayed traces appear as bands. The vertical offset between the two bands is adjusted until the dark area between them just disappears. The rms noise voltage is then measured by grounding the two inputs and reading the vertical offset between the traces.

Defining Terms

Burst noise: Noise caused by a metallic impurity in a *pn* junction that sounds like corn popping when amplified and reproduced by a loudspeaker, also called *popcorn noise*.

Crest factor: The ratio of the peak value to the rms value.

Equivalent noise input current: The noise current in parallel with an amplifier input that generates the same noise voltage at its output as all noise sources in the amplifier.

Equivalent noise input voltage: The noise voltage in series with an amplifier input that generates the same noise voltage at its output as all noise sources in the amplifier.

Equivalent noise resistance (conductance): The value of a resistor (conductance) at the standard temperature T_0 = 290 K that generates the same mean-square noise voltage (current) as a source.

Excess noise: Flicker noise in resistors.

Flicker noise: Noise generated by the imperfect contact between two conducting materials causing the conductivity to fluctuate in the presence of a dc current, also called *contact noise*, *1/f noise*, and *pink noise*.

Generation–recombination noise: Noise generated in a semiconductor by the random fluctuation of free-carrier densities caused by spontaneous fluctuations in the generation, recombination, and trapping rates.

Noise bandwidth: The bandwidth of an ideal filter having a constant passband gain that passes the same rms noise voltage as a filter, where the input signal is white noise.

Noise factor: The ratio of the mean-square noise voltage at an amplifier output to the mean-square noise voltage at the amplifier output considering the thermal noise of the input termination to be the only source of noise.

Noise figure: The noise factor expressed in dB.

Noise index: The number of μA of excess noise current in each decade of frequency per A of dc current through a resistor. Also, the amount of μV of excess noise voltage in each decade of frequency per V of dc voltage across a resistor.

Noise temperature: The internal noise generated by an amplifier expressed as an equivalent input-termination noise temperature.

Nyquist formula: Expression for the mean-square thermal noise voltage generated by a resistor.

Optimum source impedance (admittance): The complex source impedance (admittance) that minimizes the noise factor.

Parametric amplifier: An amplifier that uses a time-varying reactance to produce amplification.

Partition noise: Noise generated by the statistical process of partition when the charge carriers in a current have the possibility of dividing between two or more paths.

Shot noise: Noise caused by the random emission of electrons and by the random passage of charge carriers across potential barriers.

Schottky formula: Expression for the mean-square shot noise current.

Signal-to-noise ratio: The ratio of the mean-square signal voltage to the mean-square noise voltage at an amplifier output.

Spectral density: The mean-square value per unit bandwidth of a noise signal.

Spot noise: The rms noise in a band, divided by the square root of the noise bandwidth.

Thermal noise: Noise generated by the random collision of charge carriers with a lattice under conditions of thermal equilibrium, also called *Johnson noise*.

Varactor diode: A diode used as a variable capacitance.

Voltmeter crest factor: The ratio of the peak input voltage to the full-scale rms meter reading at which the internal meter circuits overload.

White noise: Noise that has a spectral density that is flat, that is, not a function of frequency.

Microwave measurements cover the frequency range from 0.5 to about 20 GHz. Frequencies from 30 to 300 GHz are often referred to as mm waves. In the following, the most important measurements are described.

34.1 Power Measurement

The exact microwave power measurement is in demand for development, fabrication, and installation of modern telecommunication networks. It is essential for attenuation, insertion, and return loss measurements, as well as for noise measurement and six-port network analysis. This chapter gives a brief overview about the basics of microwave power measurement. Detailed information about this subject can be found in [1–4]. Power detectors usually consist of a sensor that transfers the microwave signal into a dc or low-frequency signal and a power meter to read out the measured power levels. The sensor includes load impedance for the microwave source (Figure 34.1).

First, several power definitions need to be clarified:

- *Conjugate available power* (P_{CA}): The maximum available power a signal generator can transmit. This power is delivered by the generator if the load impedance is equal to the complex conjugate of the generator's source impedance. Since measurement techniques often require different lengths of waveguides or coaxial lines, the conjugate available power can be achieved only by tuning.

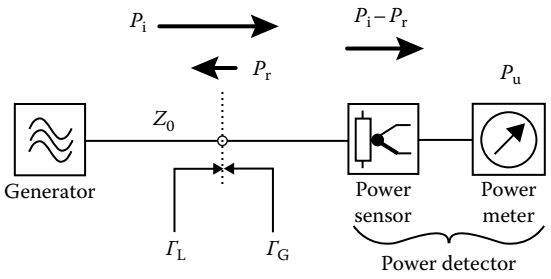

FIGURE 34.1 Setup of a power measurement in load configuration.

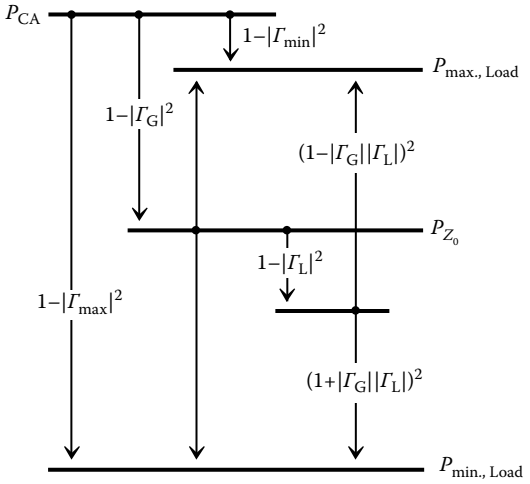

FIGURE 34.2 Relationships between conjugate power P_{CA}, Z_0 available power P_{Z0}, and the power levels available in the load of the power sensor.

- Z_0 *available power* (P_{Z0}): The power that is transferred via a coaxial line of characteristic impedance Z_0 into a load impedance Z_L equal to Z_0, while the generator has the impedance Z_G. Consequently, the available power level is reduced due to generator mismatch: $P_{Z0} = P_{CA}(1 - |\Gamma_G|^2)$, where Γ_G is the reflection coefficient of the generator. Figure 34.2 shows the relationships between P_{CA}, P_{Z0}, and the maximum and minimum power levels that can be measured in the load of a power sensor.
- *Average power* (P_{av}): The result of an averaging over many periods of the lowest modulation frequency of a modulated signal $P(t)$ (Figure 34.3).
- *Envelope power* ($P_e(t)$): The power averaged over the period of the carrier frequency.
- *Peak envelope power* (PEP): The maximum of $P_e(t)$.
- *Pulse power* (P_p): Defined for pulsed signals. If the pulse width τ and the repetition frequency $1/T$ are known, P_p is given by the measured average power:

$$P_p = P_{av}\frac{T}{\tau}$$

34.1.1 Measurement Errors and Uncertainties

Measurement errors occur due to mismatch as well as inside the power sensor and in the power meter. After correcting for these errors, the measurement uncertainties remain. Typically 75% of the total uncertainty belongs to mismatch and the smallest part is due to the power meter. The uncertainties and

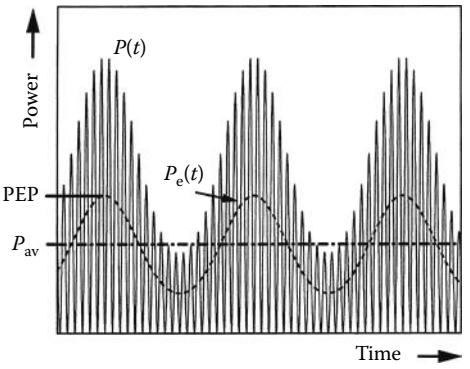

FIGURE 34.3 Power definitions for modulated signals.

errors can be power dependent, frequency dependent, or independent of both. Of course, the *total uncertainty* must be calculated from the different uncertainties u_i as the root sum of the squares: rss = $\sqrt{\sum u_i^2}$, provided that the errors are all independent. A pessimistic error definition is the *worst-case uncertainty*, which simply sums up all extreme values of the independent errors.

Mismatch errors occur due to the fact that neither the generator (G), the line, nor the load (L) exhibits exactly the characteristic impedance Z_0. Using the modulus of the reflection coefficient $|\Gamma|$, the available power of the generator P_G can be expressed as [3]

$$P_G = P_L \frac{\left|1 - \Gamma_G \Gamma_L\right|^2}{(1 - \left|\Gamma_G\right|^2)(1 - \left|\Gamma_L\right|^2)} \tag{34.1}$$

The reflection coefficients can also be expressed in terms of the voltage standing wave ratio (VSWR):

$$\left|\Gamma\right| = \frac{\text{VSWR} - 1}{\text{VSWR} + 1} = \frac{Z_L - Z_0}{Z_L + Z_0} \tag{34.2}$$

As mentioned, the knowledge of Z_0 available power P_{Z0} is sufficient in most applications. Then the ratio between the Z_0 available power and the absorbed power is given by

$$\frac{Pz_0}{P_i - P_r} = \frac{\left|1 - \Gamma_G \Gamma_L\right|^2}{1 - \left|\Gamma_L\right|^2} \tag{34.3}$$

where the subscripts "i" and "r" denote the incident and reflected power, respectively. Expressing Equation 34.3 in dB gives the Z_0 *mismatch loss*, while the term –10 log(1 – $|\Gamma_L|^2$) is called the *mismatch loss*, which accounts for reflected power from the load only.

Since the reflection coefficients are seldom known completely but only their magnitudes are known, a *mismatch uncertainty* is defined as

$$M_u = \left\{(1 \pm \left|\Gamma_G\right\|\Gamma_L\right|)^2 - 1\right\} 100\% \tag{34.4}$$

Conversion errors are due to the specific characteristics of the individual power sensor. The conversion efficiency is frequently dependent and a *calibration factor* (CF) is defined for each power detector:

$$\text{CF} = \frac{P_u}{P_i} \tag{34.5}$$

where

P_u is the uncorrected power

P_i is the actual incident power (Figure 34.1)

Sometimes, also the *effective efficiency* η_e is used:

$$\eta_e = \frac{P_u}{P_i - P_r} \tag{34.6}$$

Both quantities are related via the reflection coefficient of the load of the power sensor:

$$CF = \eta_e(1 - |\Gamma_L|^2) \tag{34.7}$$

The CF is used to correct for efficiency loss and it also accounts for the mismatch loss. Still a remaining CF *uncertainty* has to be taken into account. It is specified for each sensor. The calibration data are usually traceable to a national bureau of standards. Power sensors under test can be compared to the standards using high directivity couplers or power splitters [2].

The next described errors are due to the electronics inside the power meter.

Some power meters exhibit an internal reference oscillator to verify and adjust for the sensitivity of the diode or thermocouple sensor. The *reference power uncertainty* is specified by the manufacturer. Since this reference has its own reflection coefficient, it is related to a *reference oscillator mismatch uncertainty*.

Instrumentation uncertainty depends on the circuit limitations of the power meter and is specified by the manufacturer.

The ±1 *count error* is for digital output and can be expressed by the relative power reading of the last significant digit.

Autozero can be used on all measurement ranges. Zero setting immediately prior to the measurement can reduce *drift errors* when measuring in the lower ranges. Still *zero set errors* remain due to noise during the zero-setting operation. This error can be very serious for measurement of low power levels [5]. *Zero carryover* is caused by ADC quantization errors in the zero readings for all measurement ranges except the most sensitive one. ADC quantization also causes a *power quantization error*. If very low power levels have to be measured, averaging can reduce random noise at the expense of measurement speed.

34.1.2 Power Sensors

A large variety of power sensors is available for the frequency range from dc up to 110 GHz and for minimum detectable power levels as low as 100 pW. The sensors differ in measurement principle, and hence, the correct choice depends on the application. A detailed description of power sensors is given in [2,3]. Thermal sensors transform the absorbed microwave power into heat that is measured with temperature-sensitive elements:

- *Calorimeters* measure the heat absorbed in a fluid (e.g., water) of well-known specific heat. Applying the substitution principle, their precision can be enhanced. Because of their high stability, they are used in the National Institute of Standards. The manufacturer usually references the sensors to these standards.
- *Bolometers* and *thermistors* [3] make use of the temperature-dependent resistivity change of a resistive load, which is highly nonlinear. Hence, dc power substitution is used to keep the load at constant temperature. The substituted dc power is the measurement. Self-balancing bridges are used for this purpose but need careful ambient temperature compensation. The effective efficiency of bolometers is known very exactly. However, they have only relatively small dynamic range (typical 10 μW–10 mW). Currently, liquid nitrogen-cooled, high-temperature superconducting bolometers with extremely high sensitivity of several thousand volts per watt are used [6]. A comprehensive overview of bolometers is given in [7].

- *Thermocouple sensors* are based on microwave power conversion into heat via matched load impedance. Its temperature is controlled by thermocouples utilizing the thermoelectric effect in thin films or semiconductors [8]. One has to distinguish between realizations where the thermocouple itself represents the load impedance [3] and galvanically decoupled thermocouples [9]. The main advantages of the latter sensors are the better flatness of the response from dc to microwave and a lower voltage standing wave ratio (VSWR). The design of such sensors is simple and a silicon micromachining technique can be applied to enhance the sensitivity [10]. The lowest measurable power levels are 1 μW.

Thermal sensors are well suited to absolute power measurement, especially with respect to their high linearity. Their drawback is the relatively long response time (>10 ms), which limits these sensors to the measurement of average power. The high speed of Schottky diodes predestines them for the measurement of peak power, envelope power, and peak envelope power (PEP):

- *Diode sensors* consist of Schottky barrier diodes that are zero biased and work in the square-law part of their *I–V* characteristics. For low power levels (<–20 dBm), these devices are very linear in response and measure the average power correctly. Still, diode sensors exhibit non-quadratic contributions [11], which can be important to account for when accurate measurement is required. Minimum detectable power is –70 dBm where the signal level is of the order of 50 nV and requires sophisticated amplification. The diode sensor is part of the sensors described later.
- *Peak power sensors* are specially designed for peak power measurements and account for measurement errors due to waveform and power level, although any diode detector can be used for this purpose if the peak voltages are ≤1 V.
- *Peak envelope analyzers* are designed to detect the envelope power. This is not possible with a simple diode sensor because the electronic setup of the diode must be different.
- *Feedthrough power sensors* are used to measure microwave power in transmission configuration. They have minor losses of approximately 0.5 dB and a limited bandwidth of typically 0.1–1 GHz. The limiting device in these systems is a directional coupler with power splitters. Such a measurement can also be implemented with discrete elements. The characteristic figure of merit of these devices is the *directivity* (a_D), relating the read incident power P_i to the read reflected power P_r in case of reflection free load ($\Gamma_L = 0$):

$$a_D = 10 \log \frac{P_i}{P_r} \text{ dB} \tag{34.8}$$

The directivity should be as high as possible.

The previously mentioned power sensors are discrete devices. The maturity in microwave monolithic integrated circuit (MMIC) design and fabrication allows the integrated realization of diode power sensors, for example, in an integrated six-port reflectometer [12]. Activities to fabricate thermal power sensors integrable to MMIC typical processes [13] can presently be implemented on commercial processes, such as the Philips Lemeill high electron mobility transistor (HEMT) processes with additional postmicromachining [14].

34.1.3 Commercially Available Power Measurement Systems

A collection of different power sensors and corresponding measurement units is shown in Table 34.1. All power meters have general purpose interface bus (GPIB) interfaces for easy use in automated measurement.

TABLE 34.1 Available Commercial Power Sensors and Power Meters

Supplier	Power Sensor* Power Meter	Frequency Range	Dynamic Range	VSWR	Remark
Power sensors in matched load configuration and related power meter					
Hewlett-Packard	HP8478B	10 MHz–18 GHz	—	1.1–1.75	Thermistor
Rohde & Schwarz	NRV-Z52	dc–26.5 GHz	1 μW–100 mW	1.11–1.22	Thermocouple, up to 30 W available
Marconi	6913/6914S	10 MHz–26.5/46 GHz	1 μW–100 mW	1.1–1.4/3.6	Thermocouple, up to 3 W available
Boonton	51100(9E)	10 MHz–18 GHz	10–100 μW	1.18–1.28	Thermocouple
Hewlett-Packard	HP8485A	50 MHz–26.5 GHz	1 μW–100 mW	1.10–1.25	Thermocouple
	HP8487A	50 MHz–50 GHz	1 μW–100 mW	1.10–1.50	Thermocouple
	HPR/Q/W8486A	26.5–40/33–50/ 75–110 GHz	1 μW–100 mW	1.4/1.5/1.08	Rectangular waveguide, thermocouple
Rohde & Schwarz	NRV-Z6	50 MHz–26.5 GHz	1 nW–20 mW	1.2–1.4	Diode
Marconi	6923/6924S	10 MHz–26.5/ 46 GHz	0.1 nW/ 0.1–10 μW	1.12–1.5/3.6	Diode
Hewlett-Packard	HP8487D	50 MHz–50 GHz	0.1 nW–10 μW	1.15–1.89	Diode
Rohde & Schwarz	*NRVS/D	dc–26.5 GHz	0.4 nW–30 W	—	One/two channel
Boonton	*4230A	l0 kHz–l00 GHz	0.1 nW–25 W	—	—
Marconi	*6960B	30 kHz–46 GHz	0.1 nW–30 W	—	—
	*6970	30 kHz–46 GHz	0.1 nW–30 W	—	Hand portable
Hewlett-Packard	*HP437B	100 kHz–110 GHz	0.07 nW–25 W	—	—
Power analyzer					
Hewlett-Packard	HP84812/13/14A	500 MHz–18/26.5/40 GHz	0.6 μW–100 mW	1.25–1.60	Resolution 100 ps

34.2 Frequency Measurement

Frequency measurement in the microwave regime is usually part of a more complex measurement procedure, for example, determining the scattering parameters and filter characteristics of a device under test (DUT). If one is only interested in frequency or a higher accuracy is required, one must use direct frequency measurement systems.

Two different techniques can be distinguished. The rather old-fashioned way is to use mechanically tunable resonators, the so-called *wave meters*. These are not explained in detail here. *Digital frequency counters* are an alternative and are now the state of the art (Table 34.2).

The digital frequency counter measurement system is based on the principle of counting the zero crossovers of a continuous sinusoidal signal. At low frequencies, this method can be used directly, whereas in the microwave region, direct digital counters are not available because of their limited bandwidth. Thus, a modified measurement system must be used.

The standard digital frequency counter usually consists of a mixer, a local oscillator (frequency f_0) in the lower-frequency regime, several multipliers, and the digital counter. The principal measurement technique is shown in Figure 34.4.

An extremely stable local oscillator (quartz oscillator) is used to provide the reference signal used in the measurement system. This signal is multiplied by a factor of N and mixed with the RF signal of the DUT. The IF in the low-frequency range can be easily counted, and, thus, the frequency of the signal f_s can be calculated according to the following equation:

$$f_s = f_{IF} + Nf_0 \tag{34.9}$$

For this method, an extremely stable low-frequency oscillator (often temperature controlled) must be provided, and in order to allow a sufficient bandwidth, a high number of multipliers must be implemented in this system.

TABLE 34.2 Digital Microwave Frequency Counter

Supplier	Counter	Frequency Range	Resolution (Hz)	Sensitivity	Remark	–Price $US

HewlettPackard	HP5352B	40(46) GHz	1	–30 dBm	—	11,800

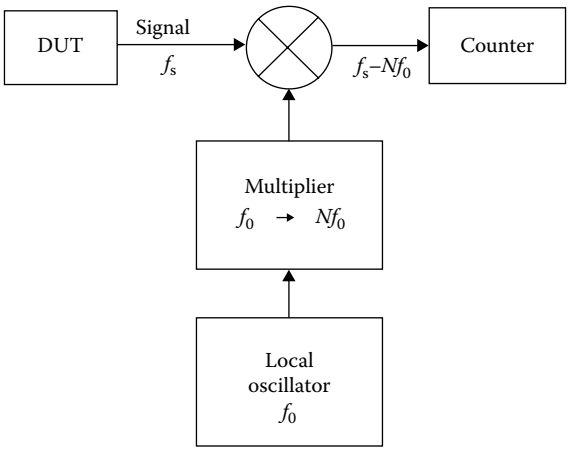

FIGURE 34.4 Block diagram of a digital frequency counter.

A pulsed oscillator with extremely short risetime can circumvent this problem. In the frequency domain, this signal is given by spectral lines at $f = if_0$, where f_0 denotes the fundamental frequency of the pulses. Using a band-pass filter, a single frequency can be separated and transferred to the mixer.

34.3 Spectrum Analysis

The expression spectrum analysis subsumes the measurements that are performed to obtain the Fourier transformation $S(f)$ of a given signal $s(t)$. The Fourier transformation of $s(t)$ in the frequency domain is defined by the following equation:

$$S(f) = \int_{-\infty}^{+\infty} s(t) e^{-j2\pi ft} dt \tag{34.10}$$

In practice, the lower and upper bounds of the integral are limited by a finite measurement time that must be fixed by the user:

For the analysis of an unknown spectrum, different methods can be distinguished:

- *Wave analyzers and selective voltmeters*: These devices utilize a tunable filter for frequency-selective measurements.
- *Spectrum analyzers* rely on the principle of heterodyne mixing with subsequent band-pass filtering.
- Calculation of the spectrum using a *fast Fourier transformation* (FET). This method can be employed only for lower frequencies, since a digital-to-analog converter is needed. For microwave frequencies, the calculation of the spectrum using the fast Fourier transform (FFT) is, therefore, difficult to realize.

Since the spectrum analyzer is most suitable for microwave frequencies, it will be described in detail in the following. Brief introductions into the spectrum analyzer measurement techniques are given in [15,16].

34.3.1 Spectrum Analyzer

The spectrum analyzer is most suitable for the analysis of microwave signals. It is a general-purpose instrument for measurements in the frequency domain and provides the user with the amplitude, power, or noise density of a signal depicted versus the frequency. The frequency scale is in most cases linear; the vertical axes can be either linear or logarithmic. Spectrum analyzers are available from a few hertz up to more than 100 GHz. They give a quick overview of the spectral power distribution of a signal. Spectrum analyzers have a large dynamic range, a resolution bandwidth of a few hertz, and a reasonable frequency resolution.

The spectrum analyzer is suitable for the following measurements:

- *Measurement of absolute and relative frequency:* Frequency drift (unstabilized oscillators), spectral purity, and frequency of harmonics.
- *Absolute and relative amplitude:* Gain of frequency multipliers, harmonics of periodic signals, intermodulation (IM) distortion, and harmonic distortion.
- Scalar network analysis (if equipped with a tracking generator): Frequency response of amplifiers and filters.
- Electromagnetic interference (EMI) measurements: Broadband spectra.
- Measurements of modulated signals: AM, FM, or PM.
- *Noise:* Many spectrum analyzers can be used for noise measurements of active devices.
- *Phase noise:* Phase noise of oscillators can be analyzed with spectrum analyzers [17].

34.3.2 Spectrum Analyzer Setup

The spectrum analyzer is basically an electronically tunable filter that allows the measurement of the amplitude, power, or noise at a certain frequency. Using the example shown in Figure 34.5, the principle of operation can be explained as follows.

The tunable filter used to separate the frequencies to be measured is realized using a chain of mixers and intermediate frequency (IF) amplifiers. In this case, three mixers convert a given input signal frequency f_s to the IF passband of the last IF amplifier. At least one of the oscillators is tunable (voltage-controlled oscillator, VCO) in order to scan the input frequency f_s. Sometimes, more than one tunable oscillator is used.

The first mixer and the following IF amplifier with a band-pass center frequency of 1.95 GHz in the given example selects the input frequency to be analyzed according to

$$f_s = f_{ol} - 1.95\ \text{GHz} \tag{34.11}$$

The input frequency for the spectrum analyzer shown in Figure 34.4 can be due to the scan of the frequency of the tunable oscillator f_{ol}, between 50 MHz and 2.05 GHz. However, the image frequency f_{is} will also be mixed to the IF:

$$f_{is} = f_{ol} + 1.95\ \text{GHz} \tag{34.12}$$

Since f_{is} is in the range of 3.95–5.95 GHz, a band-pass filter with a cutoff frequency of 3 GHz is used at the input to reject the image frequency.

Because it is difficult to realize a narrow band-pass at 1.95 GHz, the signal is converted to a lower frequency in the megahertz range. At these frequencies, stable quartz filters with high-quality factors can be employed. In principle, the RF frequency could be mixed down to the last IF section in one step. However, in such an arrangement, it would be difficult to suppress the image frequencies. In any case, the image frequency of each stage should be rejected by the preceding IF amplifier as shown in Figure 34.6 for the second stage of the given example.

The last IF amplifier is very important for the performance of the complete system. In nearly all spectrum analyzers, its bandwidth—the so-called resolution bandwidth—can be adjusted in steps. For separation of closely spaced spectral components, the bandwidth should be very small. Most spectrum analyzers offer a minimum bandwidth of a few hertz. On the other hand, larger bandwidths are needed, since for a narrow IF filter, only a slow scan speed can be allowed (see succeeding text), and therefore, the measurement over several frequency decades would result in a large sweep time. The shape of the IF filter is important for the capability of the spectrum analyzer to separate close spectral components. The performance of the IF filter is described by the shape factor. It is defined by the ratio of the 60 dB

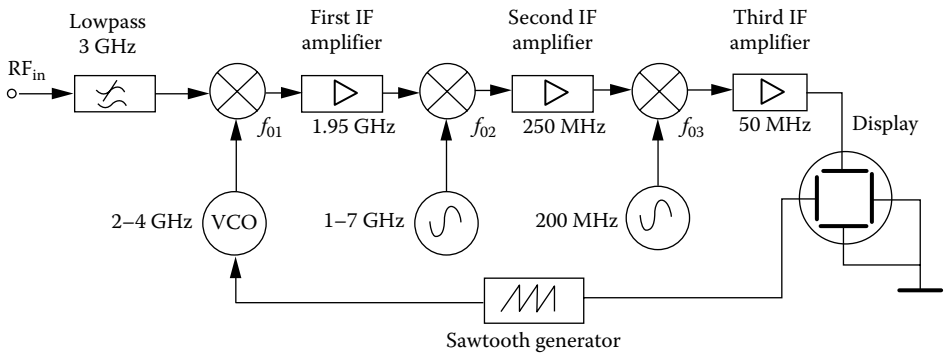

FIGURE 34.5 Simplified setup of a spectrum analyzer.

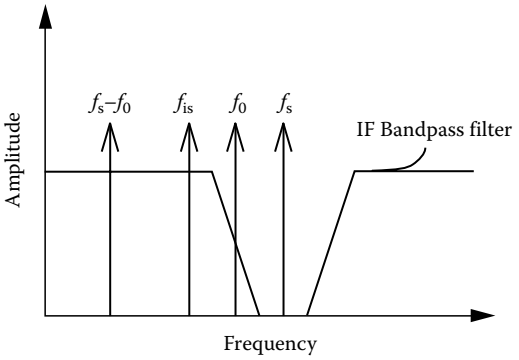

FIGURE 34.6 Example for the blocking of the image frequency by the IF filter in an arrangement according to Figure 34.5.

to the 3 dB bandwidth of the IF filter. The IF filter can be switched between the linear and logarithmic amplifications. This is performed numerically in most cases.

A sawtooth generator produces the control voltage for the voltage controlled oscillator (VCO) and the *x*-deflection voltage of the screen. A significant error is introduced in the frequency scale by a not-ideal voltage-to-frequency characteristic of the VCO. Therefore, in many cases, synthesizers with a quartz-stabilized phase-locked loop [18] are used.

The detector has to be sensitive to either the amplitude, the power, or the noise $(\text{mV}\sqrt{\text{Hz}^{-1}})$. In modern spectrum analyzer, digital signal processing is used for this purpose.

It is important to note that there are restrictions on the minimum sweep time T_s. In order to avoid settling errors of the narrow band-pass IF amplifier with bandwidth B, the scan time should be for a frequency span S larger than [19,20]

$$T_s > 20\frac{S}{B^2} \tag{34.13}$$

Most of the spectrum analyzers control the scan time automatically according to this equation.

34.3.3 Harmonic Mixing

For higher frequencies, the harmonic mixing technique is widely used. If the first 3 GHz low-pass filter in Figure 34.5 is omitted and the VCO produces harmonics, a larger number of input frequencies are converted to the passband of the spectrum analyzer. For the example shown, the possible input signals are depicted in Figure 34.7 versus the VCO frequency according to

$$f_s = nf_{01} \pm 1.95 \text{ GHz} \tag{34.14}$$

The notation of the numbers in the figure is the harmonic number n and the plus or the minus sign in the earlier equation. For a frequency $f_{ol} = 3$ GHz of the VCO, the following frequencies will appear at the same frequency location on the screen: 1.05 GHz (1–), 4.95 GHz (1+), 4.05 GHz (2–), 7.95 GHz (2+), 7.05 GHz (3–), and 10.95 GHz (3+). A tracking preselection filter (see succeeding text), which is scanned with the VCO, can select one of these harmonics.

For further extension of the frequency in the upper mm-wave range, external mixers are used. With such an arrangement, frequencies higher than 500 GHz can be measured. Additionally, the equipment for mixing of signals in the optical range is offered by some companies.

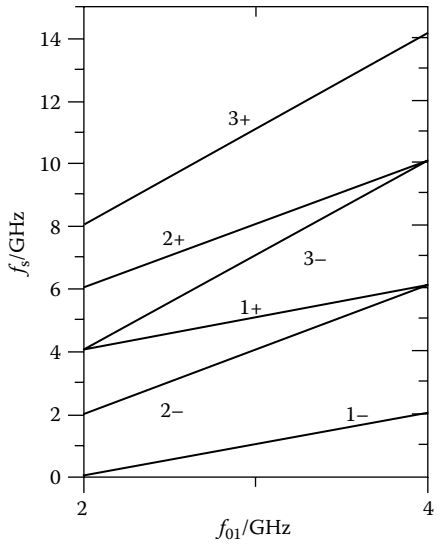

FIGURE 34.7 Measured RF frequency f_s versus the frequency of the VCO f_{01}. Parameters are n and the plus or the minus sign in Equation 34.4.

34.3.4 Tracking Preselection

For small input signals, the spectrum analyzer can be considered a linear device. However, if the input level increases, harmonics and IM products are generated due to the nonlinearities of a mixer. These products result in spurious signals on the screen of the spectrum analyzer. In addition, image frequencies will appear on the screen, as demonstrated earlier. To avoid these spurious responses, a tracking preselection filter is employed at the input of the spectrum analyzer. A tracking preselection filter is an electronically tuned band-pass filter usually realized using a yttrium iron garnet (YIG) filter.

34.3.5 Tracking Generator

Spectrum analyzers are often equipped with a tracking generator. The principle is shown in Figure 34.8. A local oscillator, with a frequency exactly on the center frequency of the IF amplifier, is mixed by an

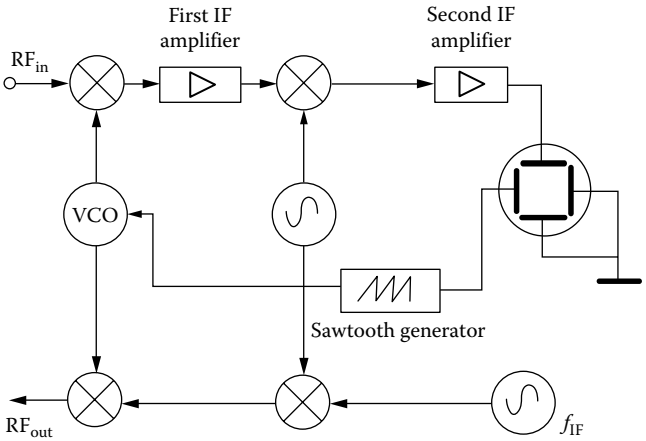

FIGURE 34.8 Principle of a tracking generator, which delivers at the port RF_{out} a signal that is precisely in the passband of the spectrum analyzer.

identical setup as in the analyzer path. Using the same local oscillator as in the analyzer path ensures that the frequency of the tracking generator follows precisely the center frequency of the swept window of the analyzed frequency band.

The tracking generator can be used for network analysis. If the tracking frequency is used as an input signal of a two-port, the amplitude of the output can be measured with the spectrum analyzer. Such a network analyzer has the advantage of being sensitive only in a very narrow band. Thus, third-order IM products and noise are suppressed. However, only scalar measurements can be performed.

34.3.6 Commercially Available Spectrum Analyzers

A number of commercially available, general-purpose spectrum analyzers for the microwave and mm-wave range are listed in Table 34.3. Only a small number of spectrum analyzers available on the market are presented. Most of the companies offer special equipment for production quality control. These spectrum analyzers can be computer controlled for fixed measurement routines. On request, spectrum analyzers with special options like fixed frequency operation, multichannel operation, support of external mixers, integrated frequency counters, and digital storage are available.

Typical specifications of microwave spectrum analyzers include

- The frequency span is several gigahertz.
- With external mixers, the upper frequency limit can be extended to more than 100 GHz.
- The frequency accuracy is between 10^{-5} and 10^{-7}.

TABLE 34.3 Commercially Available Spectrum Analyzers

Company/Model	Frequency Range	Min. Res. Bandw.	Amplitude Accuracy	Remarks
Anritsu				
MS2602A	100 Hz–8.5 GHz	—	1.1 dB	—
Avantek				
3365	100 Hz–8 GHz	10 Hz	—	Portable, tracking
3371	100 Hz–26.5 GHz	10 Hz	—	Portable, tracking
R3272	9 kHz–26.5 GHz	300 Hz	1 dB	External mixer 325 GHz
Hewlett-Packard

HP8596E	9 kHz–12.8 GHz	30 Hz	2.7 dB	—
HP8593E	9 kHz–22 GHz	30 Hz	2.7 dB	—
HP8564E	9 kHz–40 GHz	1 Hz	3 dB	—
HP8565E	9 kHz–50 GHz	1 Hz	3 dB	—
Marconi				
2370	30 Hz–1.25 GHz	5 Hz	5 Hz	With frequency extender
2383	30 Hz–4.2 GHz	3 Hz	1 dB	Tracking
Rohde & Schwarz				
FSEA30	20 Hz–3.5 GHz	1 Hz	1 dB	—
FSEB30	20 Hz–7 GHz	1 Hz	1 dB	—
FSEM30	20 Hz–26.5 GHz	1 Hz	1 dB	External mixer 110 GHz
Tektronix				
2714	9 kHz–1.8 GHz	300 Hz	2 dB	AM/FM demodulation 50 Ω/75 Ω
2784	100 Hz–40 GHz	3 Hz	1.5 dB	Counter 1.2 THz, external mixer 325 GHz

- The resolution bandwidth (i.e., the effective bandwidth of the narrow IF filter) can be adjusted in steps between 1 Hz and a few megahertz.
- The resolution bandwidth shape factor is typically 10:1.
- The amplitude accuracy is about 1 dB.
- The noise floor is at about –140 dBm.

34.4 Cavity Modes and Cavity *Q*

Cavities are used in a variety of applications. For example, they can be used to construct filters, and they serve as those elements in microwave generators (e.g., klystrons) that determine the operating frequency. Cavities can also be applied in order to measure the frequency or the wavelength of microwaves (wavemeter). The most important parameters of a cavity are its resonant frequency and its *Q*-factor. The latter determines the sharpness of the resonance or, in case of filters, the bandwidth of the passband.

A cavity can be defined as a volume that is almost completely surrounded by a metallic surface. At one or two positions, coupling elements are applied to the metal surface in order to connect the cavity to other circuit elements. In the case of one coupling element, one speaks of a single-ended cavity, whereas a transmission cavity has two coupling elements. The coupling elements are usually small compared to the dimensions of the cavity. The inside of the cavity is filled with dielectric material (e.g., air: $\varepsilon_r = 1$).

Cavities are used as resonators for microwave applications. Therefore, they are comparable to low-frequency resonant circuits consisting of an inductance *L* and a capacitance *C*. In the low-frequency range, lumped elements (inductors and capacitors) are used, which are small in comparison with the wavelength. In contrast, cavities are distributed elements with dimensions comparable to the wavelength. This results in comparatively small losses. Since cavities are distributed elements, it is in general no longer possible to determine *L* and *C* directly. Instead of *L* and *C*, the resonant frequency $f_0 = \omega_0/2\pi$ is the most important property of a cavity.

Neither lumped elements nor cavities are completely lossless. One must take into account the finite conductivities of the materials, resulting in a resistance *R* when analyzing resonant circuits. For cavities, however, *R* cannot be determined directly due to the same reasons that hold for *L* and *C*. Therefore, a different parameter, the *Q*-factor *Q*, plays a similar role for cavities. *Q* is proportional to the stored electric and magnetic energy *W*, divided by the power loss *P*:

$$Q = \frac{\omega_0 W}{P} \tag{34.15}$$

Although cavities are distributed elements, one is able to show that their behavior near resonance can be described by a simple parallel resonant circuit consisting of *R*, *L*, and *C* if the reference plane is chosen appropriately. Therefore, the basic properties of such a parallel resonant circuit are analyzed in the following.

Assume that the losses are small $Q << 1$, which is desirable in practice. Therefore, the resistance *R* of the parallel resonant circuit is comparatively large. In this case, the resonant frequency does not depend on *R* in a first-order approximation:

$$\omega_0 \approx \frac{1}{\sqrt{LC}} \tag{34.16}$$

In Equation 34.15, which is applied to the analyzed parallel resonant circuit, one obtains

$$Q \approx \frac{R}{\omega_0 L} \approx R\sqrt{\frac{C}{L}} \tag{34.17}$$

One can characterize the width of a resonance curve by those angular frequencies $\omega_1 = 2\pi f_1$ and $\omega_2 = 2\pi f_2$ where the power has decreased to one-half of its maximum value (–3 dB). The impedance

has then decreased to $1/\sqrt{2} \approx 70.7\%$ of its maximum value. This enables calculation of the angular frequencies ω_1 and ω_2:

$$\omega_1 \approx \omega_0 - \frac{1}{2RC}, \quad \omega_2 \approx \omega_0 + \frac{1}{2RC} \tag{34.18}$$

Using these relations, one can easily derive the following equation, which is equivalent to Equation 34.17:

$$Q \approx \frac{\omega_0}{\omega_2 - \omega_1} \approx \frac{f_0}{f_2 - f_1} \tag{34.19}$$

This expression shows that Q is a symbol for the sharpness of resonance. Furthermore, it leads to the first principle as to how the Q-factor can be measured. This principle, which is often referred to as the band-pass method, is based on the measurement of a resonance curve. For example, one can measure the reflection coefficient S_{11} with a network analyzer. From this curve, the 3 dB bandwidth $\Delta f = f_2 - f_1$ and the resonant frequency $f_0 = (f_1 + f_2)/2$ can be easily determined. The application of Equation 34.19 yields the desired Q.

A second principle used to measure the Q-factor is based on the transient behavior of the cavity after excitation with a pulse. In this case, the energy decays exponentially, and the time constant of the decay is proportional to Q^{-1}. This can again be shown by analyzing the equivalent parallel resonant circuit. Up until now, all signals were time harmonic, which enabled a solution by complex quantities. This time, the corresponding differential equation must be solved. One can easily show that the amplitude of the voltage is proportional to $e^{-\omega_0 t/2Q}$, which means a $e^{-\omega_0 t/2Q}$ dependency of the energy exists. Measuring the decay time constant, therefore, enables one to determine the Q-factor.

The Q, defined here, is the unloaded Q of the cavity; that is, no further resistance is connected to the cavity. Sometimes it is desirable to determine the loaded Q (Q_L), which takes into account such resistances. Detailed information about the loaded Q can be found in [21–23]. Although the Q-factor is not influenced by the coupling structure if it is lossless, the coupling structure is of great importance. Further information about coupling parameters is presented in [21–23]. Detailed descriptions of measurement methods based on the previously mentioned principles can also be found in [21,22].

Up to now, all analyses were based on the equivalent resonant circuit. There are many other effects that can be explained by this analogy. For example, the energy in both the cavity and in its equivalent circuit oscillates between the magnetic and electric fields. Some properties of cavities, however, can only be seen by examining the electric and magnetic fields themselves. These are governed by Maxwell's equations.

A solution of Maxwell's equations (which can be very complicated for a given cavity) shows that all cavities have an infinite number of resonant frequencies. This could not be seen by analyzing the equivalent parallel resonant circuit. A description of the cavity by a discrete parallel resonant circuit is only valid in the vicinity of *one* of these resonant frequencies.

Furthermore, different modes can exist that have the same resonant frequency. This phenomenon is called *degeneration*. If the resonator will operate at such a frequency, where degenerate modes exist, one has to take care that the companion mode is suppressed. This can be accomplished by an appropriate choice of the positions of the coupling elements.

Even if the desired mode does not have any companion mode, one should take care that no other mode exists in the operating range of the cavity (this can be accomplished with a mode chart [22,23]); otherwise, these modes must be damped sufficiently in order to be sure that an observed resonance corresponds to the desired mode.

34.5 Scattering Parameter Measurements

Scattering parameters describe multiple-port structures in terms of wave variables. The introduction of scattering parameters (*S*-parameters) arises naturally in microwave circuits and systems, due to the lack of a unique definition for currents and voltages at these frequencies. Most circuits and systems at high frequencies are efficiently described in terms of *S*-parameters.

This section describes the fundamentals and properties of *S*-parameters, together with network analysis based on *S*-parameter calculations and measurements. Measurement procedures are outlined and the most frequently used systems for *S*-parameter measurement are described. Finally, information on hardware required for the experimental determination of *S*-parameters is provided, together with the corresponding suppliers.

34.5.1 Introduction and Fundamentals

At high frequencies, the wave variables are a natural extension of the voltages and currents at port terminals. In electric systems where the voltages and currents cannot be uniquely defined, the power flow in a waveguide can be described via wave variables. Whenever a transverse electromagnetic (TEM) mode of wave propagation cannot be assumed, the currents and voltages are dependent on the integration path. This situation is encountered in all rectangular, circular, and passive waveguide structures, even in the case of lossless wave propagation. It is also true for all guiding structures if losses are to be considered along the path of wave propagation [24–27]. For the case of wave propagation along a transmission line, the wave variables a and b are defined as follows:

$$\begin{aligned} a(z) &= \frac{1}{2}\left(\frac{U(z)}{\sqrt{Z_0}} + I(z)\sqrt{Z_0}\right) \\ &= \frac{U_+}{\sqrt{Z_0}} = I_+\sqrt{Z_0} \\ b(z) &= \frac{1}{2}\left(\frac{U(z)}{\sqrt{Z_0}} - I(z)\sqrt{Z_0}\right) \\ &= \frac{U_-}{\sqrt{Z_0}} = I_-\sqrt{Z_0} \end{aligned} \tag{34.20}$$

The propagation is along the z-direction. The characteristic impedance of the transmission line is Z_0, and $U(z)$ and $I(z)$ are the voltage and current, respectively, at location z along the line. The variables $a(z)$ and $b(z)$ are the complex amplitudes of the modes on the line. The voltage U_+ and U_- and the currents I_+ and I_- denote the voltage and current amplitudes, respectively, in forward and reverse direction. The wave variables are related to the power in the following form:

$$\begin{aligned} P_+ &= \frac{1}{2}\frac{|U_+|^2}{Z_0} = \frac{1}{2}|I_+|^2 Z_0 = \frac{1}{2}|a(z)|^2 \\ P_- &= \frac{1}{2}\frac{|U_-|^2}{Z_0} = \frac{1}{2}|I_-|^2 Z_0 = \frac{1}{2}|b(z)|^2 \end{aligned} \tag{34.21}$$

In Equation 34.21, it is assumed that the system is excited by a pure sinusoid and that the characteristic impedance is purely real. The wave variables have the dimensions of $\sqrt{W}$.

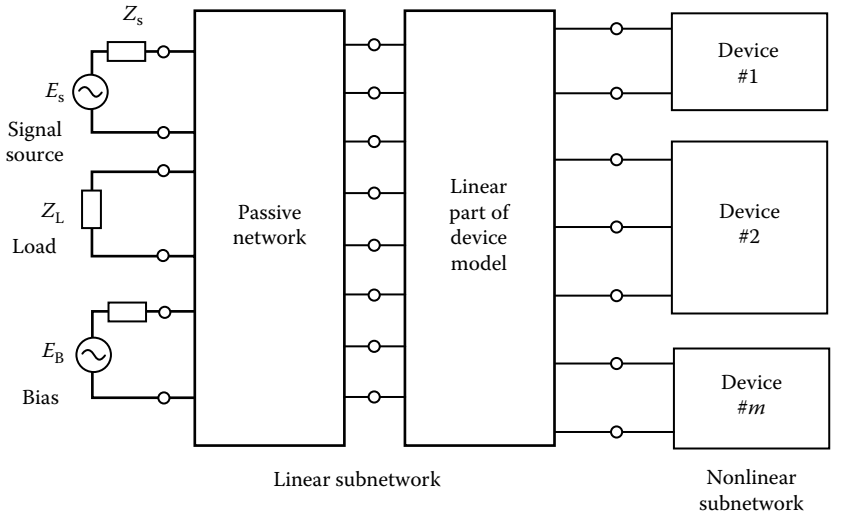

FIGURE 34.9 Schematic illustration of application of wave variables to nonlinear circuits.

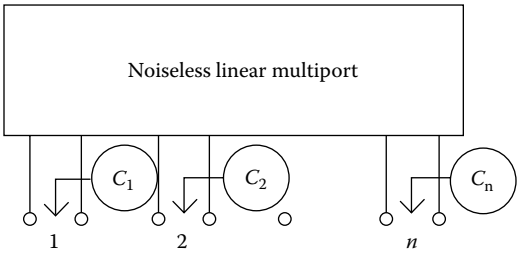

FIGURE 34.10 Schematic illustration of application of wave variables to noisy circuits.

Strictly speaking, wave variables and *S*-parameters can only be applied to linear networks. This is important because many publications are devoted to the so-called large-signal *S*-parameter measurements. The interpretation of such results is not simple, and great care must be employed in the correct determination of the characteristic impedance of the system [26]. In the case of analysis of large-signal or nonlinear circuits, two methods exist to introduce the wave variables:

- Volterra series representation [28]
- Harmonic-balance method [26]

Both methods transform the nonlinear circuit into a number of linear circuits at different frequencies and then change the terminal voltages and currents into wave variables. This situation is sketched in Figure 34.9. Particular attention must be paid to the definition of the characteristic impedance, which can vary between different frequencies. An in-depth treatment of wave variables can be found in [26].

A further utilization of wave variables can be found in the noise analysis of microwave circuits. According to Figure 34.10, a noisy multiport can be analyzed by an associated noiseless two-port with the according noise sources c_i at the corresponding ports of the circuit.

34.5.2 Calculations and Analysis with *S*-Parameters

The characterization of multiports with *S*-parameters requires embedding of the multiport into a system consisting of a signal source with characteristic impedance and appropriate terminations of all ports.

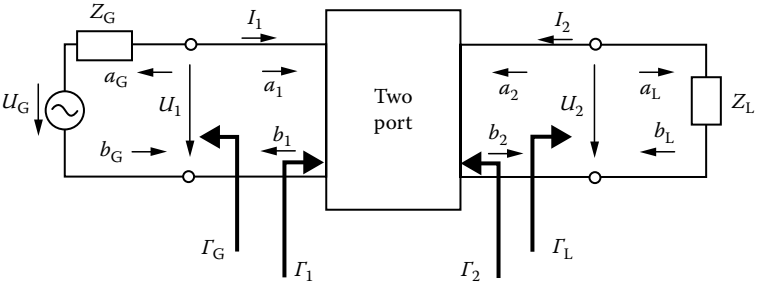

FIGURE 34.11 Two-port network indicating the wave variables and the scattering parameters. The subscripts G and L indicate the generator and the load, respectively.

This situation is shown in Figure 34.11. The outgoing wave parameters b are reflections at the corresponding ports. The wave variables are related to the scattering parameters of a two-port in the following manner:

$$\begin{pmatrix} b_1 \\ b_2 \end{pmatrix} = (S)\begin{pmatrix} a_1 \\ a_2 \end{pmatrix} = \begin{pmatrix} S_{11} & S_{12} \\ S_{21} & S_{22} \end{pmatrix}\begin{pmatrix} a_1 \\ a_2 \end{pmatrix} \tag{34.22}$$

For the determination of the individual scattering matrix elements, all ports of the network must be terminated in their characteristic impedance. The impedances at the corresponding ports need not be equal for all ports. The S-parameters are, in general, complex and are defined with respect to reference planes. These reference planes can be the network terminals but could also been shifted to other locations in the circuit if this is desirable. The scattering matrix can be transformed into all circuit representations. Table 34.4 indicates the conversion formulae between the S-parameters and Z Y h parameters for arbitrary characteristic impedances. Additional conversion methods can be found in [29].

The scattering parameters in the case of a noisy two-port as indicated schematically in Figure 34.10 are defined as [26]

$$\begin{pmatrix} b_1 \\ b_2 \end{pmatrix} = \begin{pmatrix} S_{11} & S_{12} \\ S_{21} & S_{22} \end{pmatrix}\begin{pmatrix} a_1 \\ a_2 \end{pmatrix} + \begin{pmatrix} c_1 \\ c_2 \end{pmatrix} \tag{34.23}$$

The noise wave sources c_1 and c_2 represent the noise generated in the circuit and are therefore complex variables varying with time. They are characterized by a correlation matrix C_s as follows:

$$C_s = \overline{\begin{pmatrix} c_1 \\ c_2 \end{pmatrix}\begin{pmatrix} c_1 \\ c_2 \end{pmatrix}^H} = \begin{pmatrix} \overline{|c_1|^2} & \overline{c_1 c_2^*} \\ \overline{c_2 c_1^*} & \overline{|c_2|^2} \end{pmatrix} \tag{34.24}$$

where

bar ($\bar{}$) indicates time averaging
$(\cdot)^H$ denotes the Hermitian conjugate
* stands for the complex conjugate

$S_{21} = \dfrac{2X_{21}\sqrt{R_{01}R_{02}}}{(X_{11} + Z_{01})(X_{22} + Z_{02}) - X_{12}X_{21}}$	$X_{21} = \dfrac{2S_{21}\sqrt{R_{01}R_{02}}}{(1 - S_{11})(1 - S_{22}) - S_{12}S_{21}}$
$S_{22} = \dfrac{(X_{11} + Z_{01})(X_{22} - Z_{02}^{\star}) - X_{12}X_{21}}{(X_{11} + Z_{01})(X_{22} + Z_{02}) - X_{12}X_{21}}$	$X_{22} = \dfrac{(1 - S_{11})(Z_{02}^{\star} + S_{22}Z_{02}) - S_{12}S_{21}Z_{02}}{(1 - S_{11})(1 - S_{22}) - S_{12}S_{21}}$
$S_{11} = \dfrac{(1 - Y_{11}Z_{01}^{\star})(1 + Y_{22}Z_{02}) + Y_{12}Y_{21}Z_{01}^{\star}Z_{02}}{(1 + Y_{11}Z_{01})(1 + Y_{22}Z_{02}) - Y_{12}Y_{21}Z_{01}Z_{02}}$	$Y_{11} = \dfrac{(1 - S_{11})(Z_{02}^{\star} + S_{22}Z_{02}) + S_{12}S_{21}Z_{02}}{(Z_{01}^{\star} + S_{11}Z_{01})(Z_{02}^{\star} + S_{22}Z_{02}) - S_{12}S_{21}Z_{01}Z_{02}}$
$S_{12} = \dfrac{-2Y_{12}\sqrt{R_{01}R_{02}}}{(1 + Y_{11}Z_{01})(1 + Y_{22}Z_{02}) - Y_{12}Y_{21}Z_{01}Z_{02}}$	$Y_{12} = \dfrac{-2S_{12}\sqrt{R_{01}R_{02}}}{(Z_{01}^{\star} + S_{11}Z_{01})(Z_{02}^{\star} + S_{22}Z_{02}) - S_{12}S_{21}Z_{01}Z_{02}}$
$S_{21} = \dfrac{-2Y_{21}\sqrt{R_{01}R_{02}}}{(1 + Y_{11}Z_{01})(1 + Y_{22}Z_{02}) - Y_{12}Y_{21}Z_{01}Z_{02}}$	$Y_{21} = \dfrac{-2S_{21}\sqrt{R_{01}R_{02}}}{(Z_{01}^{\star} + S_{11}Z_{01})(Z_{02}^{\star} + S_{22}Z_{02}) - S_{12}S_{21}Z_{01}Z_{02}}$
$S_{22} = \dfrac{(1 + Y_{11}Y_{11})(1 - Y_{22}Z_{02}^{\star}) + Y_{12}Y_{21}Z_{01}Z_{02}^{\star}}{(1 + Y_{11}Z_{01})(1 + Y_{22}Z_{02}) - Y_{12}Y_{21}Z_{01}Z_{02}}$	$Y_{22} = \dfrac{(Z_{01}^{\star} + S_{11}Z_{01})(1 - S_{22}) - S_{12}S_{21}Z_{01}}{(Z_{01}^{\star} + S_{11}Z_{01})(Z_{02}^{\star} + S_{22}Z_{02}) - S_{12}S_{21}Z_{01}Z_{02}}$
$S_{11} + \dfrac{(h_{11} - Z_{01}^{\star})(1 + h_{22}Z_{02}) - h_{12}h_{21}Z_{02}}{(h_{11} + Z_{01})(1 + h_{22}Z_{02}) - h_{12}h_{21}Z_{02}}$	$h_{11} = \dfrac{(Z_{01}^{\star} + S_{11}Z_{01})(Z_{02}^{\star} + S_{22}Z_{02}) + S_{12}S_{21}Z_{01}Z_{02}}{(1 - S_{11})(Z_{02}^{\star} + S_{22}Z_{02}) - S_{12}S_{21}Z_{02}}$
$S_{12} = \dfrac{2h_{12}\sqrt{R_{01}R_{02}}}{(h_{11} + Z_{01})(1 + h_{22}Z_{02}) - h_{12}h_{21}Z_{02}}$	$h_{12} = \dfrac{2S_{12}\sqrt{R_{01}R_{02}}}{(1 - S_{11})(Z_{02}^{\star} + S_{22}Z_{02}) - S_{12}S_{21}Z_{02}}$
$S_{21} = \dfrac{-2h_{21}\sqrt{R_{01}R_{02}}}{(h_{11} + Z_{01})(1 + h_{22}Z_{02}) - h_{12}h_{21}Z_{02}}$	$h_{21} = \dfrac{-2S_{21}\sqrt{R_{01}R_{02}}}{(1 - S_{11})(Z_{02}^{\star} + S_{22}Z_{02}) - S_{12}S_{21}Z_{02}}$
$S_{22} = \dfrac{(h_{11} + Z_{01})(h_{22} - Z_{02}^{\star}) - h_{12}h_{21}Z_{02}^{\star}}{(h_{11} + Z_{01})(h_{22}Z_{02}) - h_{12}h_{21}Z_{02}}$	$h_{22} = \dfrac{(1 - S_{11})(1 - S_{22})S - S_{12}S_{21}}{(1 - S_{11})(Z_{02}^{\star}) - S_{12}S_{21}Z_{02}}$

For the calculation of the cascade connection of two networks, it is desirable to convert the *S*-parameters to *T* parameters defined in the following way:

$$\begin{pmatrix} b_1 \\ a_1 \end{pmatrix} = \begin{pmatrix} T_{11} & T_{12} \\ T_{21} & T_{22} \end{pmatrix} \cdot \begin{pmatrix} a_2 \\ b_2 \end{pmatrix} \tag{34.25}$$

The conversion between *S*-parameters and *T* parameters is given in the following:

$$T_{11} = S_{12} - \frac{S_{11}S_{22}}{S_{21}} \tag{34.26}$$

$$T_{12} = \frac{S_{11}}{S_{21}} \tag{34.27}$$

$$T_{21} = -\frac{S_{22}}{S_{21}} \tag{34.28}$$

$$T_{22} = \frac{1}{S_{21}} \tag{34.29}$$

It should be emphasized that different definitions of the *T* parameters exist in the literature [2,24–27,30]. Power gain, mismatch, insertion loss, etc., can be efficiently described with the help of scattering parameters [2,30].

34.5.3 Measurement of *S*-Parameters

Network analyzers are generally used for the measurement of *S*-parameters. A schematic configuration of a network analyzer is indicated in Figure 34.12. The network analyzer consists of two structures to separate the signals and a heterodyne receiver. According to the definitions, the measurement is performed in two steps as indicated in Figure 34.13. Different error models are employed for the calibration of the network analyzer. The most simple is the one-port error model, which consists of contributions due to directivity, source mismatch, and frequency response. A flow diagram is illustrated in Figure 34.14.

For the characterization of active and passive two-ports, a more sophisticated error model is required. The signal flow graphs of the full two-port model are drawn in Figure 34.15. To determine the *S*-parameters of the DUT, a de-embedding procedure is required [31–43]. The two-port

error model is then divided into two error adapters and the actual DUT, as depicted in Figure 34.16. The example shown makes reference to the so-called "through, reflect, line (TRL)" calibration procedure. This name abbreviates the three calibration standards utilized in this method: a *through* standard with zero length, a *reflecting* standard, and a *line* standard. This method cannot be applied to on-wafer measurements at low frequencies, due to the excessive line length required for a broadband measurement. Other error correction methods are summarized in Table 34.5 [44]. In addition to the measurements given in the table, a known reference impedance and port 1 to port 2 connections are required. Furthermore, at higher frequencies (above ≈ 15 GHz), a calibration measurement of the

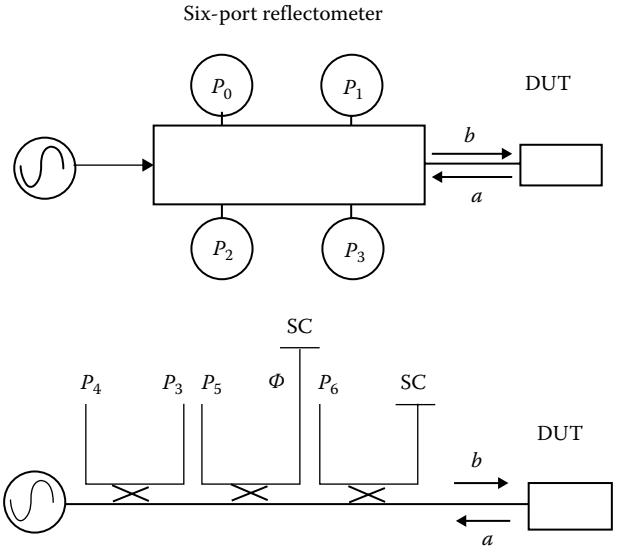

FIGURE 34.16 A network analyzer based on a six-port reflectometer and a possible realization using three couplers and four power detectors, two short circuits (SC), and one phase shifter (Φ).

TABLE 34.5 Summary of Different Calibration Methods

TOSL	Through standard (T) with known length; fulfills four conditions	Three known reflections (OSL) on port 1; fulfills three conditions	Three known reflections (OSL) on port 2; fulfills three conditions
TRL and LRL	Through or line standard (T) or (L) with known length; fulfills four conditions	Unknown equal reflection standard (R) on port 1 and port 2; fulfills one condition	Line (L) with known S_{11} and S_{22}; fulfills two conditions
TRM and LRM	Through or line standard (T) or (L) with known length; fulfills four conditions	Unknown equal reflection standard (R) on port 1 and port 2; fulfills one condition	Known match (M) on port 1 and port 2; fulfills two conditions
TXYZ and LXYZ	Through or line standard (T) or (L) with known length; fulfills four conditions	Three known reflection standards (XYZ) on port 1 or port 2; fulfills three conditions	—
UXYZ	Unknown line standard (U) with $S_{11} = S_{21}$; fulfills one condition	Three known reflection standards (XYZ) on port 1; fulfills three conditions	Three known reflection standards (XYZ) on port 2; fulfills three conditions

isolation should be performed. For this purpose, both ports are terminated by their characteristic impedances and a transmission measurement is performed. This measurement determines the values of C_F and C_R in the calibration flow diagram (see Figure 34.14).

Another possibility for performing vector network measurement is based on multiport reflectometers [45]. The advantage of such systems is the reduced complexity of the network analyzer receiver. A possible realization of a reflectometer structure is the so-called *six-port reflectometer*. The reflectometer consists of three couplers and four power sensors. No frequency conversion is required, which simplifies the test equipment.

34.5.4 Commercially Available Network Analyzers

Table 34.6 shows some of the current suppliers for network analysis. The frequency range is 10 Hz up to 800 GHz.

TABLE 34.6 Companies Supplying Network Analyzers for *S*-Parameter Measurements

	Frequency			
Company	Minimum	Maximum (GHz)	Method	Cal. Methods
Hewlett-Packard HP 8510	45 MHz	110	Heterodyne	SOLT, TLR, LRL, LRM, TRM
Wiltron	45 MHz	110	Heterodyne	SOLT, TLR, LRL, LRM, TRM
Rhode & Schwarz	10 Hz	4	Heterodyne	SOLT, TLR, LTL, LRM, TRM
AB Millimeterique	2 GHz	800	Heterodyne	TLR, LRL, proprietary

Q Factor Measurement

Albert D. Helfrick
Embry–Riddle Aeronautical University

Q factor is a method of characterizing the rate of dissipation of energy from an oscillating system [1]. *Q* is defined as 2π times the energy stored in a resonant system divided by the energy dissipated per cycle. The term system used in this context refers to any type of resonance: mechanical, electric, nuclear, etc. For the purposes of this *handbook*, *Q* will be that of an electric circuit. Also, for the discussion of *Q*, very low values of *Q*, typically less than 10, will not be considered as these low values of *Q* produce highly damped oscillations that are more exponential than oscillatory and the concept of *Q* does not fit.

A common interpretation of *Q* is quality factor that explains the use of the letter, *Q*, but this is misleading. A component that has a high *Q* is not always beneficial and may not be of high quality. In many circuits, a component requires a specific value of *Q* rather than "higher is better." In other cases, a high *Q* is an advantage.

The *Q* factors encountered in common circuit components range from a low of about 50 for many inductors to nearly 1 million found in high-quality quartz crystals. *Q* can be applied to a resonant circuit or to capacitors and inductors. When *Q* is applied to a component, such as an inductor, the *Q* would be that obtained if the inductor were used in a resonant circuit with a capacitor that dissipates no energy. In this case, the value of *Q* depends on the frequency.

For most *LC* resonant circuits, the losses in the inductor dominate and the *Q* of the inductor is, essentially, the *Q* of the circuit. It is easy to make very low-loss capacitors even in the ultra high frequency (UHF) region. On the other hand, varactor diodes have considerably more loss than fixed capacitors, and a varactor can play a more significant role in setting the circuit *Q*.

35.1 Basic Calculation of *Q*

Figure 35.1 shows a simple resonant circuit. The capacitor can store energy in the electric field and the inductor in the magnetic field. The circuit oscillates with the energy transferring between the two elements. For the ideal elements shown, this continues forever. Since the definition of *Q* has the energy lost per cycle in the denominator—which is zero—the result is an infinite *Q*.

In practice, circuit elements are not perfect and the energy initially contained within this circuit would be lost by the circuit and the oscillations would decrease in amplitude as the energy diminished.

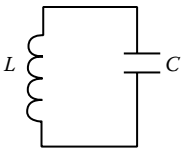

FIGURE 35.1 A simple resonant circuit with no loss elements.

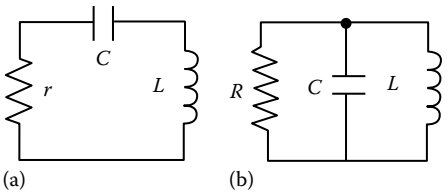

FIGURE 35.2 Resonant circuits: (a) A simple series resonant circuit with the equivalent resistance and (b) a parallel resonant circuit with a parallel equivalent resistance. For the same *Q* circuit, the values of the resistors are not the same.

Energy loss in a circuit is represented by that in a resistor, which can be included in one of two ways. The first way is shown in Figure 35.2a, where the resistor is in series with the capacitor and inductor. A second representation is a parallel resistor as shown in Figure 35.2b.

To derive the relationship between the circuit element values and the *Q* of the circuit, either the current or voltage of the circuit can be used in the equations. Current is the obvious choice for a series circuit, while voltage is the common thread for the parallel circuit. Assume that the amplitude of the current through the series circuit of Figure 35.2a is given by

$$i(t) = I(t)\cos(2\pi f_0 t) \tag{35.1}$$

where f_0 = resonant frequency

$$f_0 = \frac{1}{2\pi\sqrt{LC}} \tag{35.2}$$

and $I(t)$ is the amplitude, which is decreasing in some unspecified fashion. The circuit's peak current occurs when the cosine function is equal to 1 and all of the energy is contained in the inductor and is equal to $(1/2)LI^2(t)$.

Assume that a relatively high *Q* is present in this circuit and that $I(t)$ changes by only a slight amount during the time of one cycle. During this cycle, the peak current is $I(t)$, and the rms value of the current is $(0.707)I(t)$. Therefore, the energy dissipated in one cycle is $(0.5)I^2(t)r/f_0$. Substituting these values in the definition of *Q* yields

$$Q = 2\pi\frac{(1/2)(LI^2(t))}{(1/2)(rI^2(t)/f_0)} = \frac{2\pi f_0 L}{r} = \frac{X_L}{r} \tag{35.3}$$

where X_L is the reactance of the inductor. The same procedure can be used with the parallel resonant circuit of Figure 35.2b using voltage equations to obtain the relationship between a parallel resistance and *Q*, which is

$$Q = \frac{R}{X_L} \tag{35.4}$$

It is very important to understand the nature of the circuit resistance in Figure 35.2a and b. This resistance represents all of the losses in the resonant circuit. These losses are from a variety of sources, such as

the resistance of the wire to make an inductor or the leakage current of a capacitor. It can also represent the deliberate addition of resistors to set the *Q* of the circuit to a specific value. The resistance shown in the circuits of Figure 35.2 represents the equivalent resistance of all of the energy losses. This resistance cannot be measured with an ohmmeter as the value of the equivalent resistor is a function of frequency and other variables such as signal level. Some of the loss in a resonant circuit is due to radiation, which is a function of frequency. The resistance of conductors is mostly due to skin effect, which increases with increasing frequency. The losses in the ferromagnetic materials used for making some inductors are nonlinear; thus, the equivalent resistance is not only a function of frequency but of signal level.

Most resonant circuits are not stand-alone circuits as shown in Figure 35.2 but are a part of other circuits where there are sources and loads. These additional resistances further remove energy from the resonant circuit. The *Q* of a resonant circuit when there are sources and loads is called the *loaded Q*. In most applications of resonant circuits, the *Q* of the resonance is set by the external loads rather than the capacitor and inductor that form the resonance.

35.2 Bandwidth and *Q*

The *bandwidth* of a resonant circuit is a measure of how well a resonant circuit responds to driving signals of a frequency near the resonant frequency and is a function of *Q*. The relationship between the 3 dB bandwidth and *Q* will be derived.

Applying a driving signal to a resonant circuit can overcome the losses of the circuit and cause the resonant circuit to oscillate indefinitely. As an example of this, consider the voltage generator in the series resonant circuit shown in Figure 35.3.

When the frequency of the voltage source is equal to the resonant frequency of the circuit, the equivalent impedance of the series resonant circuit is the resistance of the circuit and the current in the circuit, simply *E*/*r*.

At frequencies higher or lower than the resonant frequency, the impedance of the circuit is greater because the net reactance is not zero and the circuit current will be less than at resonance.

At what frequency will the circuit current be 3 dB less than at resonance? This frequency is where the circuit impedance is 1.414 that of the impedance at resonance. This is the frequency where the reactive part of the impedance is equal to the real part. This situation occurs at two frequencies. Below the resonant frequency, the net reactance is capacitive and is equal to *r*, while at a second frequency above the resonant frequency, the reactance is inductive and equal to *r*. This can be represented by two equations for the two frequencies:

$$\text{For } f_1 > f_0, \quad |X_L - X_C| = 2\pi f_1 L - \frac{1}{2\pi f_1 C} = \frac{(f_1 - f_0)^2 - 1}{2\pi f_1 C} = r$$

$$\left(\frac{f_1}{f_0}\right)^2 - \frac{1}{Q}\left(\frac{f_1}{f_0}\right) - 1 = 0 \quad \left(\frac{f_1}{f_0}\right) = \frac{1}{2Q} \pm \sqrt{\frac{1}{4Q^2}} + 1 \tag{35.5}$$

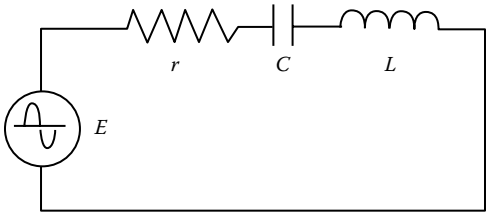

FIGURE 35.3 A series resonant circuit showing a driving source.

$$\text{For } f_2 < f_0, \quad |X_L - X_C| = \frac{1}{2\pi f_2 C} - 2\pi f_2 L = \frac{-(f_1 - f_0)^2 - 1}{2\pi f_2 C} = r$$

$$\left(\frac{f_2}{f_0}\right)^2 + \frac{1}{Q}\left(\frac{f_2}{f_0}\right) - 1 = 0 \quad \left(\frac{f_2}{f_0}\right) = \frac{1}{2Q} \pm \sqrt{\frac{1}{4Q^2}} + 1 \tag{35.6}$$

$$(f_1 - f_2) = \frac{f_0}{Q} = \text{bandwidth}$$

35.2.1 Measuring *Q*

There are a number of methods of measuring *Q* using a variety of bridges, several of which are described in [2]. One method of measuring a capacitive or inductive *Q* is to place the component in a resonant circuit. When the *Q* to be measured of a device that is, in itself, a resonant circuit such as quartz crystal, similar techniques are used except the device's own resonance is used for the measurement. Circuit voltages or currents are measured at the resonance frequency and the *Q* is determined.

35.3 *Q*-Meter

One simple and very popular method of measuring *Q* is with a device called, appropriately, the *Q*-meter. Consider the resonant circuit in Figure 35.4 for measuring the *Q* of inductors. This circuit has a very low-loss capacitor of known value and a constant voltage source.

The usual components measured by the *Q*-meter are inductors. It was previously mentioned that inductors are the weak link in resonant circuits, and the *Q* of a circuit is usually set by the inductor. The *Q*-meter can measure capacitance and capacitor *Q*. In this theoretical circuit, the circuit resistance is the equivalent series resistance (ESR) of the inductor under test. This is due to the fact the variable capacitor is assumed to be lossless, the generator has zero resistance, and the voltmeter does not appreciably load the circuit. In a real circuit, it is not possible to achieve this situation, but the instrument is designed to approach this goal.

To measure the *Q* of an inductor using the *Q*-meter, the generator is set to the desired frequency, while the variable capacitor tunes the circuit to resonance as indicated by the peak reading of the voltmeter. At resonance, the impedance of the circuit is simply the ESR of the inductor. This sets the current of the circuit as

$$I = \frac{E}{R_X} \tag{35.7}$$

where

E is the generator voltage

R_X is the equivalent resistance of the inductor

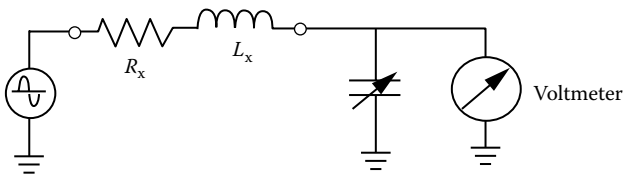

FIGURE 35.4 The basic circuit of a *Q*-meter showing the signal source, the inductor under test, and the voltmeter.

Because the circuit is at resonance, the voltages of the two reactances are equal and of opposite phase. Those voltages are

$$V = IX_C \quad \text{or} \quad V = IX_L \tag{35.8}$$

where

X_C is the capacitive reactance
X_L is the inductive reactance, which are numerically equal at resonance

Substituting the relationship of the circuit current, the result is

$$V = \frac{EX_L}{R_X} = \frac{EX_C}{R_X} = EQ \tag{35.9}$$

Therefore, the voltage across the reactances is equal to Q times the applied voltage. If, as an example, the voltage source were 1 V, the voltmeter would read Q directly. Q values of several hundred are common, and therefore, voltages of several hundred volts could be measured. Modern circuits do not typically encounter voltages of this magnitude, and many components cannot withstand this potential. Therefore, most Q-meters use a much smaller source voltage, typically 20 mV.

If the frequency of the source and the circuit capacitance are known, it is possible to calculate the inductance of the unknown.

35.4 Other *Q* Measuring Techniques

There are very few Q-meters being manufactured today, although there are thousands of old Q-meters still in use. Because the Q-meter was the only accepted method of measuring Q for so many years, it will take decades before alternative methodologies overtake the Q-meter.

Measuring Q without a Q-meter involves a variety of *RLC* measuring instruments that measure the vector impedance and calculate Q. The calculated Q value is not as valid as that determined with a Q-meter unless the *RLC* meter is capable of measuring Q at the desired frequency. Only the more sophisticated, and expensive, *RLC* meters allow the use of any test frequency. Despite the new sophisticated *RLC* measuring instruments, there is an adapter for one model *RLC* instrument that allows the classic Q-meter-style measurement to be made.

Because vector impedance measurement is covered elsewhere in this handbook, the remainder of this section will be devoted to measurements using the Q-meter.

35.5 Measuring Parameters Other than *Q*

In addition to Q, the Q-meter can be used to measure inductance, the Q or dissipation factor of a capacitor, and the distributed capacitance, C_d, of an inductor.

If an inductor with capacitance C_d is placed in the Q-meter circuit, the total circuit capacitance includes both the Q-meter's capacitance and the additional C_d. Therefore, when resonance is achieved, the actual resonating capacitance is more than what is indicated on the Q-meter capacitor's dial. If C_d is not included in the calculation of inductance, the resulting value would be too large.

In many applications, the actual inductance is not the important parameter to be measured by the Q-meter. The actual parameter being determined is "what capacitance is required to resonate the particular inductor at a specific frequency," regardless of C_d.

In other applications, such as inductors that are to be used in wide-range oscillators, where C_d will limit the tuning range, C_d is an important parameter.

The *Q*-meter can be used to determine C_d, which will also allow for an accurate calculation of inductance. Determining C_d is a matter of resonating the inductor under test at more than one frequency.

To understand how the two-frequency measurement will allow the determination of C_d, assume that an inductor is resonated at a frequency f_1. The relationship between the applied frequency, f_1, and the capacitor of the *Q*-meter to obtain resonance is

$$f_1 = \frac{1}{2\pi\sqrt{L(C_1 + C_d)}} \tag{35.10}$$

where C_1 is the capacitance set on the *Q*-meter.

Resonating the same inductor at a second, higher, frequency, f_2, requires a *Q*-meter capacitance of C_2, such that

$$f_2 = \frac{1}{2\pi\sqrt{L(C_2 + C_d)}} \tag{35.11}$$

This implies that C_2 is a smaller capacitance than C_1. Using these two equations and solving for C_d, the following result is obtained:

$$C_d = \frac{C_2 f_2^2 - C_1 f_1^2}{f_1^2 - f_2^2} \tag{35.12}$$

A convenient relationship between f_1 and f_2 is to set $f_2 = 1.414\, f_1$. With frequencies thus related, the distributed capacitance is

$$C_d = C_1 - 2C_2 \tag{35.13}$$

C_d causes errors in the measurement of *Q* because of current through the C_d. The *Q* measured by the *Q*-meter is called the "effective *Q*." Since large inductors with significant C_d are no longer in common use because of the use of active filters, the distinction between effective *Q* and real *Q* is seldom considered. For additional information about effective *Q* and distributed capacitance, see [3].

To measure capacitors on the *Q*-meter, a relatively high-*Q* inductor is connected to the inductance terminals on the *Q*-meter and resonated with *Q*-meter's internal calibrated capacitor. The capacitor to be measured is connected to the instrument's capacitor terminals, which are in parallel with the internal variable capacitor. This increases the circuit capacitance. The *Q*-meter variable capacitor is adjusted to regain resonance, which requires that the capacitance be reduced by an amount equal to the unknown capacitor.

The *Q* of the capacitor can be measured. The addition of the capacitor reduces the circuit *Q* because of the additional loss introduced by the capacitor. In the description of the *Q*-meter, the *Q*-meter's variable capacitor is assumed to have no loss.

Measuring the *Q* of a capacitor using the *Q*-meter is seldom done. This is because most capacitors have very high-*Q* values, usually significantly higher than the test inductor and the *Q*-meter's internal capacitor. Therefore, the addition of a high-*Q* unknown capacitor makes an imperceptible difference in the overall circuit *Q* making it very difficult to obtain an accurate *Q* measurement. There are special cases, such as measuring the *Q* of a capacitive transducer or a varactor diode, where low *Q* values are encountered and the *Q*-meter can be used successfully.

For best results, the *Q* of the inductor must be considerably greater than that of the unknown capacitor, and the unknown capacitance must be considerably greater than the internal capacitance. If these criteria are met, the *Q* of the unknown capacitor can be read from the *Q*-meter. If these criteria are compromised, corrections can be made but the equations become complex and the accuracy degrades.

Most *Q*-meters provide measurement ranges to about 500 or to 1000. This is sufficient for measuring inductors, which was the main purpose of the *Q*-meter. For measuring high-*Q* devices such as ceramic resonators with *Q* values greater than 1000 or for quartz resonators with *Q* values extending into the hundreds of thousands, the *Q*-meter technique is insufficient. A high-*Q* circuit implies very little energy loss, and the energy that must be removed to make a measurement must be very small if *Q* is to be measured accurately.

35.6 Measuring High-*Q* Capacitors

The original intent of the *Q*-meter was primarily for measuring the *Q* of inductors since it was the *Q* of the inductor that set the bandwidth of most tuned circuits at radio frequencies (RFs). The *Q* of a capacitor was usually much higher than the inductor in a resonant circuit and only inductors were typically measured. The *Q* of a capacitor has several other names such as dissipation factor, loss tangent, or ESR. The resistive part of a capacitor's impedance has become increasingly more important for power supplies and circuits where capacitors could experience significant currents and a capacitor with a high dissipation factor or low *Q* wastes energy and could be destroyed by internal heating.

The technique described using a *Q*-meter with a calibrated inductor for making capacitor measurements is very limited by the *Q* of the resonating inductor and particularly difficult where the capacitor to be measured is a high capacitance value and high *Q*.

Modern circuits do not rely as much on high-*Q* inductors as in the past. Signal filtering once done at intermediate and audio frequencies, IF and AF, is done routinely with digital signal processing. RF filtering is still required, but new applications extend into UHF and microwave frequencies where conventional wire-wound coils are not used. The need for wire-wound inductors and their measurements is diminishing.

As the need for high-*Q* inductors diminishes, high-*Q* capacitors are becoming in more demand as the use of switching power supplies increases. When describing capacitors for power supplies, ESR is the preferred term. But ESR = X_c/Q.

Modern switching power supplies operate at RF frequencies and therefore use components that would be suitable for RF circuits and therefore require RF style measurements.

Another factor in the increasing need for high-*Q* capacitors is the use of solid-state amplifiers for RF. High-powered vacuum tube amplifiers used resonant circuits that were high voltage and lower current when compared to the same power level for transistor amplifiers. These higher currents increase the heating of a capacitor due to the ESR. Capacitors used for filters usually required a high *Q* because of the large circulating currents, but in a transistor power amplifier, high-*Q* capacitors are also required for coupling and bypassing, applications not usually associated with high *Q*.

With the demise of the *Q*-meter, vector network analyzers were used to measure capacitor and inductor parameters. It is difficult to obtain accurate *Q* measurement for ultrahigh-*Q* capacitors using a vector network analyzer because of the large disparity between the real and imaginary part of the capacitor's impedance. This requires the network analyzer to accurately separate the real and imaginary parts and to have the ability to resolve small fractions of a dB.

Modern ultralow ESR chip capacitors can have *Q* factors well into the thousands. The classic *Q*-meter, when measuring inductors, could handle *Q* factors from less than 100 to perhaps as high as 1000 with accuracy. A very important factor when using resonance as a method of measuring *Q* of either inductors or capacitors is the *Q* of the resonating element. When measuring the *Q* of inductors in the classic *Q*-meter, the *Q* of the resonating capacitor, using an air dielectric, had sufficiently high *Q* to measure moderately high Q_s for inductors. Using resonance techniques for measuring the *Q* of ultralow ESR capacitors demands an inductor of extremely high *Q*. This need can be met with a section of coaxial transmission line.

A typical transmission line section used for measuring *Q* is on the order of a meter or two in length. One end is short-circuited, while the other is open circuited. To ensure low loss, air is used as the

dielectric, and the inner, conducting, surfaces are gold or silver plated to decrease skin effect resistance. At the open-circuited end, a sleeve extends the outer conductor of the transmission line, called a choke section, to minimize radiation from the end of the transmission line. At the shorted end of the transmission line, there is the ability to insert a leadless component usually involving a jackscrew-like clamping device.

The transmission line section is more than just an inductor but a resonant circuit. The measurement techniques call for the characterization of the transmission line in terms of resonant frequency and bandwidth. The transmission line will resonate at odd multiples of one-quarter of its wavelength. Since the dielectric is air, the resonant frequencies will be $(n/4)(3E8/d)$ where d is the length of the line and n is an odd integer.

To determine resonance and the bandwidth of the transmission line section, a signal generator is loosely coupled into the transmission line section with a loop, and the RF energy is sampled, also loosely coupled with either a capacitive probe or another loop. It is important that the coupling be very loose to prevent energy from being lost to the signal source or the sensor. Another important reason to limit the power coupled to the measurement is that very high Q_s are involved, which implies high circulating currents. The heating of the capacitor under test can skew the measurements for some capacitors. The arrangement is similar to a cavity filter but with a very high amount of insertion loss. Insertion losses of 40–60 dB are not uncommon. Typical source/detector combinations are a signal generator and a sensitive RF millivoltmeter or a spectrum analyzer. Another excellent source/detector pair is a spectrum analyzer with a tracking generator or a scalar, or vector, network analyzer. The limitations of the vector network analyzer are removed from the measurement technique as there is no need to separate the real and imaginary parts in the described technique.

The transmission line is resonated and the resonant frequency and the bandwidth of the line are determined. It is not necessary to use only the 3 dB bandwidth and the 6 dB or other values may be used. The bandwidth is used to calculate the Q of the resonator, and the calculation must reflect the measurement points used.

The capacitor under test is inserted in the shorted end of the transmission line and the resonant frequency and bandwidth are measured again. The addition of the capacitor will change the resonant frequency of the transmission line because of the capacitance being placed in series with the center conductor of the transmission line. The bandwidth of the transmission line will be wider because of the capacitor's ESR.

Using the before and after values, the value and Q of the capacitor under test can be determined. This technique is the basis behind ANSI/EIA RS 483, Effective Series Resistance (ESR) and Capacitance of Multilayer Ceramic Capacitors at High Frequencies, standard.

The Q-meter relied on causing resonance in a circuit to determine the capacitance or inductance and the attendant Q. The transmission line technique also relies on resonance. The classic Q-meter may be a thing of the past, but the techniques that defined the Q-meter live on.

Defining Terms

Bandwidth: A measurement of the amount of frequency spectrum occupied by a signal or the equivalent spectrum covered by a circuit that passes a finite band of frequencies. There are a number of methods of defining bandwidth depending on the nature of the spectrum. Relative to resonant circuits, the bandwidth is measured between the –3 dB points of the passband.

Distributed capacitance: The amount of capacitance added to an inductor typically from the capacitance due to adjacent wires in a solenoid-type inductor. The distributed capacitance is given as a single capacitance figure for a specific inductor and can be defined as the equivalent capacitance across the entire coil. This would also allow the inductor to have a self-resonant frequency where the inductor resonates with the distributed capacitance with no external capacitance.

Effective inductance: Due to distributed capacitance, less capacitance than that calculated from an inductance value is required to resonate a circuit. If the actual capacitance required to resonate a circuit is used to calculate an inductance value, the resulting inductance value will be higher than the theoretical inductance value. This higher value is called the "effective inductance." The actual inductor cannot be considered as a pure inductance of a value equal to the effective inductance because the real inductor has a resonant frequency that a pure inductance does not.

***Q*:** A measurement of the rate of energy loss in a resonant circuit.

***Q*-meter:** An instrument for measuring *Q* factor by resonating the circuit and measuring the voltage across the reactances.

RF: radio frequencies: Any frequency above about 10 kHz extending to the upper limits of the radio spectrum. Generally, radio frequencies are distinguished from power generation frequencies such as 50, 60, or 400 Hz and above the range of human hearing or 20 kHz.

EMI and EMC Test Methods

Jeffrey P. Mills
Illinois Institute of Technology

36.1 Introduction

Electric and magnetic fields must be measured for a variety of reasons. A radio or TV broadcast station is licensed to provide reliable coverage over a specified geographic area, and any properly operating receiver must pick up the signal and properly respond to it. This can be assured only if the broadcast signal is of a guaranteed minimum strength. Also, the signal must not be so strong that it interferes with a distant station sharing the same frequency. The broadcast field must be measured over its geographic area of coverage to be sure that it satisfies both criteria.

Many electric devices unintentionally radiate electromagnetic fields. Examples include

- Oscillators in superheterodyne radio or TV receivers
- Digital logic circuits
- Switching contacts, particularly if unsuppressed
- Automotive ignition systems

Stray fields (*emissions*) from these devices can interfere with other devices or even with the radiating device itself. This process is known as *electromagnetic interference*, commonly abbreviated EMI. The interference between two devices is known as *intersystem EMI*, whereas if a device interferes with itself, it is *intrasystem EMI*. Intrasystem EMI is usually easy to spot because the device itself does not operate correctly. Intersystem EMI is usually more difficult to isolate. Its result might be a simple annoyance, such as noise on a radio and TV receiver caused by an electric vacuum cleaner or a power drill. It could, however, be much more serious; a portable radio receiver might affect aircraft navigation or critical communications.

It is also possible for a device to be susceptible to fields intentionally generated by a licensed transmitter such as a broadcast or mobile-radio transmitter. Examples include

- Public-address systems
- Music (high-fidelity) systems
- Telephone lines and instruments
- Digital logic circuits

Again, the result may be only an annoyance, or it could be much more serious; aircraft control surfaces have been observed to move uncontrollably due to strong electromagnetic fields. Since the fields themselves cannot be eliminated in these cases, the devices must be made immune to electromagnetic fields.

In the previously mentioned cases, the interference is usually through electric and/or magnetic fields in space, so the process is known as *radiated coupling*. Another coupling path exists if two devices share the same power source. One device may generate undesired high-frequency voltages on its power leads, which then appear on the power leads of the other. The second device may then malfunction because of this high-frequency voltage. This is known as *conducted coupling*. So we must consider both radiated and conducted noise.

It is not practical to eliminate all interfering fields completely, so a compromise must be reached. A stray field will not cause EMI if it is very weak compared with the desired field, which might be the field of a broadcast signal. The permissible strength of the stray field depends on the strength of the desired field; the stronger the desired field, the more stray field can be tolerated. It also depends on the device that is being interfered with (the *victim*); some receivers can reject undesired signals better than others. Since there are many combinations of interference sources and victims, a worst-case scenario is sought that will protect most real-life situations. This occurs where the weakest legal radio or TV signal (in its licensed area of coverage) is received by the poorest available receiver.

The maximum stray field strength that causes no EMI for this worst-case scenario is incorporated into government regulations. The field actually radiated by every device must then be measured to be sure that it does not exceed this level at the nearest practical distance from it, usually 10 or 30 m. To specify and measure these field strengths accurately, the nature of electric and magnetic fields must be understood.

Unlike most electrical engineering topics, EMI control is not very precise because of the complexity of practical hardware. It is virtually impossible to predict interference more precisely than within a factor of three, and usually the margin of error is even worse. Measurements can vary significantly between two supposedly identical samples, due to slight variations in physical dimensions. If one measures the EMI resulting from two different designs, the design that exhibits less EMI is probably better, but not always. An engineer can often judge if an EMI problem exists, but one must never rely on the accuracy normally expected in other branches of electrical engineering.

36.2 Nature of Electric and Magnetic Fields

An electric field is generated by a distribution of electric charge. If the distribution changes with time, then so will the electric field. A magnetic field may be generated by a permanent magnet or by an electric current. If the permanent magnet or the current path moves or if the current magnitude varies with time, the magnetic field will vary with time. A time-varying electric field creates a magnetic field, and conversely.

Electric fields, designated E, are normally expressed in volts per meter (V/m). Magnetic fields are designated H and expressed in amperes per meter (A/m). More often, magnetic fields are perceived as magnetic flux densities, which are designated B and expressed in webers per square meter (W/m^2), also known as *teslas* (T). A non-SI unit, sometimes found in older literature, is the *gauss*, equal to 10^{-4} T. Of course, any unit may be preceded by a scaling prefix such as micro or pico. In free space, B is equal to $\mu_0 H$, where μ_0 is equal to 0.4π (approximately 1.257) μT m/A (equivalent to μH/m).

Near a time-varying electric field source such as a charge distribution, the magnetic field is relatively weak, but it becomes stronger when observed from farther away. At a great enough distance, the ratio of E to H approaches $\sqrt{\mu/\varepsilon}$, which in free space is equal to 120π (approximately 377) Ω. For a sinusoidal function of time with a frequency f, this occurs at any distance that is large compared with $\lambda/2\pi$ (approximately $\lambda/6$). Here, λ is the wavelength corresponding to f, equal to $3 \times 10^8/f$ m if f is specified in hertz. Distances much greater than $\lambda/2\pi$ are considered to be in the *far-field region*; nearer distances are in the *near-field region*. For a nonsinusoidal function of time, each Fourier frequency component must be considered separately, and the far-field region begins closer to the source for its higher-frequency components.

Near a time-varying magnetic field source such as a current loop, the electric field is weak, becoming stronger when observed from a greater distance. At distances that are large compared with $\lambda/2\pi$ (the far-field region), the ratio of E to H again approaches $120\pi\ \Omega$.

Since $H = \sqrt{\varepsilon/\mu}E$ and $B = \mu H = \sqrt{\mu\varepsilon}E$ in the far-field region for either type of source, only E or B must be measured, and the other can easily be calculated from it. In free space, $\sqrt{\mu/\varepsilon} \approx 10^{-8}/3\,\mathrm{T\cdot m/V}$ (equivalent to s/m), so if E is expressed in volts per meter, $B \approx 3.33E$ nT. By choice of a suitable antenna, either field can be measured. Far-field strengths are normally specified in terms of the E field, no matter whether the E or B field is measured.

Alternatively, the far-field strength may be specified in terms of *power density*, expressed in watts per square meter. This denotes the amount of radiated power passing through each square meter of a surface perpendicular to the direction away from the source. The *peak* power density P is equal to EH, and, for a sinusoidal source, the *average* power density is half this value. For a nonsinusoidal source, each frequency component must be considered separately, and the total average power is the sum of the average powers for all frequencies. Since $H = \sqrt{\varepsilon/\mu}E$, it follows that $P = E^2/377\ \Omega$.

In regions other than the far field, the ratio of E to H varies greatly, approaching infinity for an electric field source or zero for a magnetic field source. A source may generate both electric and magnetic fields; for example, a charge moving between two electrodes causes a current to flow between them. Then the ratio of E to H may be any value at all. Therefore, at distances less than $\lambda/2\pi$ from a field source, both the E and B fields must be measured separately.

In the far-field region, both the electric and magnetic fields are perpendicular to the direction that an electromagnetic wave is propagating, and they are also perpendicular to each other. This still usually allows the fields to be oriented at many different angles with respect to the surface of the Earth. The direction of the electric field is called the *polarization* of the wave, which may be vertical, horizontal, or somewhere between. Or the wave may be *elliptically polarized*, which results from two waves that are not exactly in phase, one polarized vertically and the other horizontally. If the waves are equal in magnitude and exactly 90° out of phase, the wave is *circularly* polarized. To account for all these cases, all fields must be checked separately for vertically and horizontally polarized waves.

36.3 Measurement Antennas

Most electronic components and instruments are designed to respond to voltages or currents, not fields. To measure field strength, it is necessary to convert its effect to a voltage or a current. This is achieved by an antenna. Although many antennas are simple conductor shapes, they must be analyzed carefully if accurate quantitative measurements are desired.

A straight conductor immersed in a time-varying electric field will develop a current in it. If the conductor material is linear (the usual case), the current will be proportional to the applied electric field, so their ratio will be constant. This ratio, however, depends greatly on the geometric dimensions of the conductor and the frequency of the electric field. It must be known to calibrate the antenna.

Similarly, a closed conductive loop immersed in a time-varying magnetic field will develop a current in it. Again, if the conductor is linear, the ratio of the current to the magnetic field strength is constant but depends on the dimensions of the loop and the frequency of the magnetic field.

The easiest way to calibrate an antenna is to immerse it in a known electric or magnetic field and measure the current or voltage at the antenna terminals. The principal problem is generating the known field. To find its strength, one must use a "standard" antenna for which the current-to-field ratio can be calculated.

To calculate the required ratio, Maxwell's equations must be solved subject to the boundary conditions of the antenna conductor. For most antennas, an exact closed-form solution is impossible. However, for a sinusoidally varying field encountering a straight cylindrical conductor called a *dipole antenna*, such a solution is possible, though difficult [1]. Once the solution is obtained, the required ratio becomes a simple expression if the antenna is *resonant* or *tuned*. This occurs for a precise length that

is slightly less than one-half the wavelength, λ, of the time-varying field. Obviously, the antenna will be resonant at only one frequency, so the ratio will be valid only for a field varying sinusoidally at that frequency. For nonsinusoidal fields, each Fourier frequency component must be measured separately, and the antenna length must be changed as different frequencies are measured. To simplify changing its length, two telescoping rods, mounted end to end, are normally used to make the dipole antenna. The measuring instrument is connected between these two rods via a transmission line.

For a given frequency, at any point on the antenna, there is a certain current I flowing in it, and there is also a certain voltage V on it with respect to ground. The ratio of these phasors, V/I, is known as the *driving-point impedance*. The precise resonant antenna length is that for which V and I are exactly in phase, that is, for which the driving-point impedance is purely real. As mentioned earlier, this length is slightly less than half the wavelength, λ, and it also depends on the thickness of the telescoping rods [1, pp. 547–548]. For a rod thickness of $\lambda/400$, the resonant length is 0.476λ. The driving-point impedance of a dipole antenna of these dimensions is 64 Ω. If a voltage-measuring instrument such as a radio receiver or spectrum analyzer is connected to the antenna terminals via a transmission line and is properly matched to the 64 Ω impedance, the measured voltage V_m will be equal to $0.148\lambda E$, where E is the applied field strength and λ is the wavelength at the frequency being measured. The ratio V_m/E, equal to 0.148λ, is known as the effective length (l_e) of the antenna, since it relates the field strength in volts per meter to the measured terminal voltage in volts. Obviously, it is not equal to the physical antenna length but is instead approximately one-third of that value. With this ratio known, the electric field strength E that causes a certain terminal voltage V_m can easily be calculated.

To simplify calculations, E is often expressed in decibels with respect to a reference field of 1 μV/m and is designated E_d. Similarly, V_m is expressed in decibels with respect to a reference voltage of 1 μV and is designated V_d. The antenna factor (AF) is defined as the effective length expressed in negative decibels, or $AF = -20 \log(l_e)$. Then the multiplication becomes an addition, that is, $E_d = V_d + AF$.

The aforementioned AF assumes that the antenna is perfectly matched to the receiver, which implies maximum power transfer. A mismatch would change the AF. Therefore, since the antenna driving-point impedance usually is not equal to the receiver input impedance, a matching circuit must be inserted between the antenna and receiver. Another essential consideration is antenna balance. Most receivers and spectrum analyzers have one input terminal grounded. If this grounded terminal is connected to one of the dipole antenna terminals, the impedances connected to the two antenna terminals will be unequal with respect to ground. This also will upset the AF, since one side of the antenna will not be properly matched to the receiver. To prevent this, a balanced-to-unbalanced (*balun*) network must be inserted between the antenna and the receiver. Such a circuit provides a high impedance *with respect to ground* for both input terminals while providing the correct input impedance (such as 64 Ω) *between* its input terminals. Normally, a single network provides both the matching and balancing functions.

Unfortunately, unless the dipole antenna is precisely the correct length, its AF is much more complicated. Even if the frequency being measured differs only a few percent from the antenna resonant frequency, the AF becomes unpredictable and the driving-point impedance becomes complex. Thus, the electric field cannot be easily calculated from the measured terminal voltage. To achieve the simple AF described earlier, the frequencies must be measured one at a time and the dipole antenna length properly adjusted for each frequency. It is impossible to sweep the spectrum rapidly, as when using a spectrum analyzer, unless the antenna length can somehow be varied also. This leads to mechanical difficulties and is usually impractical.

Other types of antennas, however, are less sensitive to frequency. Examples are the biconical antenna and the log-periodic antenna. A biconical antenna can perform acceptably over a range of 20–300 MHz, and a log-periodic antenna is useful from 300 to 1000 MHz. Their AFs are relatively constant, usually varying by no more than 20 dB, over their useful frequency ranges. The AFs are usually too difficult to calculate, but they may easily be measured simply by observing the terminal voltage resulting from a sinusoidally varying field of known strength. The known field is first measured using a tuned dipole

antenna, for which the AF can be calculated. The AF is measured in this manner at several frequencies throughout its useful range, and the results are plotted for use with the antenna.

Unlike the tuned dipole, the biconical and log-periodic antennas do not exhibit constant driving-point impedances over their useful frequency range. Since the receiver input impedance cannot be made to follow the variation of driving-point impedance with frequency, an exact match is impossible. This affects the AF just as it would for a mismatched tuned dipole. To compensate for this, the AF must be measured with the antenna terminated into a known impedance, which must then be used for all measurements made with that antenna. Then the mismatch is accounted for in the AF itself. The mismatch does cause the antenna to reradiate the received signal, but this effect may be minimized by performing the measurements in an open-field site, which will be discussed later.

Tuned dipole, biconical, and log-periodic antennas are *linearly polarized* antennas because they respond to only one polarization component of a propagating wave. If the antenna is oriented horizontally, only the horizontally polarized component of the wave will affect it. Similarly, only the vertically polarized component will affect a vertically oriented antenna. Thus, with two measurements, any linearly polarized antenna will detect any type of field polarization. Other types of antennas, such as the spiral antenna, are designed to detect a circularly polarized wave. They will detect vertically and horizontally polarized waves, but they could miss a wave that is circularly polarized in the reverse direction (e.g., counterclockwise instead of clockwise). Consequently, circularly polarized antennas are forbidden for many types of field measurements.

All antennas discussed earlier respond to the electric field, E. As mentioned earlier, in the far-field region, the magnetic field, B, is simply 3.33 nT times the value of E expressed in volts per meter. In any other region, however, B is not so simply related to E and must be measured separately, using an antenna that responds to magnetic fields. A circular loop or coil of wire is such an antenna. The loop is cut at one point, and the radio receiver or spectrum analyzer is connected between its two ends. For quantitative measurements, its AF must be known. The factor can be measured by immersing the antenna in a known magnetic field and measuring its terminal voltage. To find the known magnetic field strength, the electric field is first measured, in the far-field region, using a tuned dipole antenna for which the factor is known. The magnetic field is then 3.33 nT times this value expressed in volts per meter. With the magnetic field thus determined, the AF of the loop may be calculated, as required.

36.4 Measurement Environment

A major difficulty with electromagnetic field measurements is repeatability of results. Electromagnetic fields are affected by any materials in their vicinity, even by poor conductors and dielectrics. The measurement environment must therefore be carefully defined, and similar environments must be used for all comparable measurements.

The ideal environment would be one where (1) the only electromagnetic field source is the equipment under test (EUT) and (2) there is no "foreign" material at all that could affect the fields being measured. Unfortunately, the only natural location where this could be achieved is in outer space, since the Earth itself affects electromagnetic fields. Since this is impractical, attempts are made to simulate this environment on Earth.

A large outdoor open area simulates a hemisphere of free space. Such a test site is appropriately called an *open-field site*. If the conductivity, permittivity, and permeability of the Earth were constant, every open-field site would have the same effect on the electromagnetic fields radiating from the EUT. The Earth's parameters do vary, however. To compensate for this variation, a large conductive floor, or ground plane, is laid under the EUT. This causes all electromagnetic waves to be totally reflected from the ground plane, so that the Earth's properties have no effect. The ground plane must be large enough so that it appears infinite with respect to the EUT and the associated test equipment. Acceptable dimensions are $1.73d \times 2d$, where d is the distance between the measurement antenna and the EUT, normally 3 or 10 m. Radiated emissions must be measured in all directions from the EUT

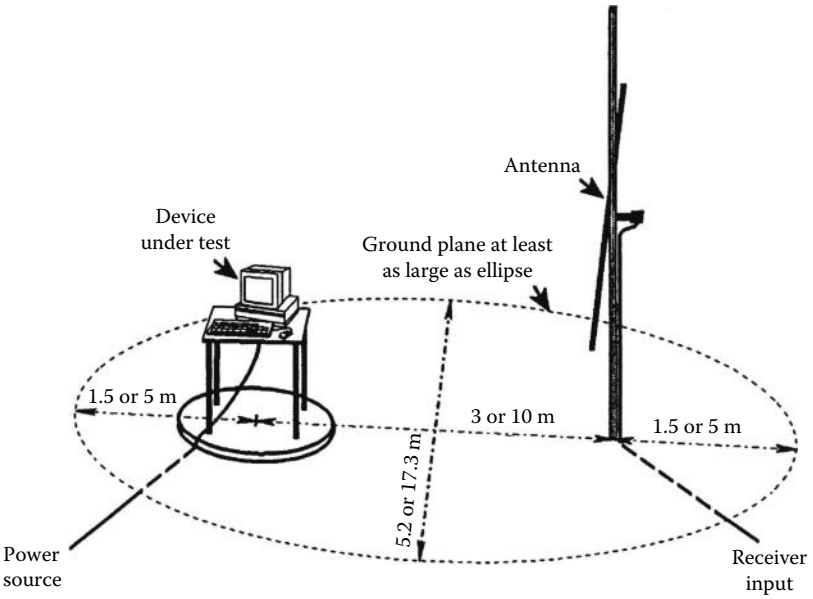

FIGURE 36.1 An open-field test site. Power and antenna cables are run under the ground plane so that they will not affect measured fields. The area outlined by the ellipse must be free of everything except the device under test, the table on which it rests, and the measuring antenna. To facilitate measuring radiation in all directions from the device, it is placed on a turntable. By rotating it during testing and simultaneously varying the height of the receiving antenna, the direction of maximum radiation is found.

and at various angles of inclination. This is most easily achieved by placing the EUT on a turntable, which is then rotated during the test. To allow measurement at various inclination angles, the receiving antenna height must be varied, and this is accomplished by mounting it on a halyard. A typical open-field site appears in Figure 36.1.

An open-field site provides repeatable data only if there are no nearby trees or structures that could cause undesirable reflections. Before it can be reliably used, it must be tested. This is done by generating a known electromagnetic field and measuring it. The field is normally generated by a radio-frequency oscillator driving a tuned dipole antenna, for which the radiation can be calculated ([2]: pp. 237–238). This radiation is then measured as though it were generated by a typical device being tested. The ratio of the voltage at the transmitting antenna terminals to that at the receiving antenna terminals is known as the *site attenuation*. If the site attenuation is within 3 dB of its calculated value, the test site is deemed acceptable.

Although an open-field site eliminates reflections, external field sources, such as licensed transmitters, still cause problems. Since electromagnetic radiation can travel thousands of miles, no open-field site will be completely free of electromagnetic fields. To eliminate the effects of these stray sources, testing must be performed inside a shielded enclosure. There, however, severe reflections occur, and measurements become inaccurate and unrepeatable.

An ideal test environment would be a shielded enclosure lined with material that does not reflect electromagnetic waves. Such an enclosure is called an *anechoic chamber*, with the understanding that the name refers to *electromagnetic* echoes. Until recently, such chambers were not practical except at very high frequencies, but improvements are constantly being made. Such an enclosure is acceptable for testing if it meets the site-attenuation requirements of a true open field. The site attenuation must be measured at several points inside the chamber, to assure that the proximity of the chamber walls has no effect. Unfortunately, such chambers are at present very expensive.

Another type of test chamber is the *transverse electromagnetic (TEM) cell*. This consists of an enlarged section of waveguide, in which the electromagnetic fields can be accurately predicted [3,4]. They are suitable only for testing small devices at relatively low frequencies. The TEM cell can be no larger than a wavelength at the frequency being tested. For example, to test at 200 MHz, the cell could be no larger than 1.5 m, or 5 ft, and the device itself must not exceed $\frac{1}{6}$ of this value, or 10 in. For small devices, however, the TEM cell is very accurate and is unaffected by stray field sources.

If a suitable anechoic chamber is not available, a device may be tested in an ordinary shielded enclosure to learn what frequencies it emits. The field strengths will be inaccurate due to the internal reflections. Then the device is tested in a true open-field site, and the suspected frequencies are measured quantitatively. Any field that exceeds the acceptable limits is then observed while the device is shut off. If it does not disappear, it is obviously not being generated by the EUT. This procedure is acceptable, although not as simple as testing inside an anechoic chamber.

Preliminary measurements may even be performed in an ordinary room. They will not be comparable with similar measurements made anywhere else, because of the effects of nearby conductors and dielectrics. Here, also, the device must be shut off to decide if any emissions are from stray external sources instead of from the EUT. This procedure provides a rough estimate of the emissions from the EUT, and it usually saves time during any later testing at a true open-field site. The various measurement methods appear in Table 36.1.

Permissible emission levels appear in the *Code of Federal Regulations* [5]. These rules assume open-field measurements, which are the most accurate possible. Even there, variations of ±6 dB are typical. Therefore, a manufacturer should allow a safety factor when performing measurements intended to assure compliance with government regulations. Otherwise, a device may pass when tested by the manufacturer but fail if later tested by the government using a supposedly identical test procedure. Since the government's measurements then prevail, the manufacturer's integrity could be questioned.

Further details on measurement techniques are available in Refs. [2,6].

TABLE 36.1 Comparison of EMI Measurement Methods

Method	Equipment Required	Space Required	Accuracy	Outside Influence	Cost	Comments
Ordinary room	Antenna and receiver	3 or 10 m radius around EUT	Medium, affected by structure, ±20 dB	May be severe, depending on location	Minimum	Usually acceptable for preliminary tests
Shielded room	Shielded room, antenna, and receiver	4–6 m radius around EUT	Poor, ±30–40 dB due to reflections	Usually none	Moderate	Use for preliminary tests in noisy areas
TEM cell	TEM cell and receiver	1–3 m^3	Very good, ±10 dB	Usually none	Moderate	Unusable for large EUT due to high-order modes
Open field	Antenna and receiver	17 × 20 m open field with no nearby structures	Excellent, usually ±6 dB	May be severe, depending on location	High, due to logistics of site (power, weather, etc.)	Standard test method
Shielded anechoic chamber	Anechoic chamber, antenna, and receiver	6–15 m radius around EUT	Very good, ±10 dB	Usually none	Very high	Use for accurate tests in noisy areas

Defining Terms

Antenna factor: Its effective length expressed in negative decibels.

Balun: An interface device used to isolate a dipole or other balanced antenna from the effects of a receiver having one grounded terminal.

Conducted coupling: Coupling due to voltages imposed on a shared power source.

Dipole antenna: An antenna consisting of two collinear rods with the feed line connected between them.

Driving-point impedance: The ratio of voltage to current at the driving point (normally the center) of an antenna.

Effective length: The ratio of the voltage observed at the driving point of an antenna to the strength of its received electric field.

Electromagnetic compatibility (EMC): The capability of two or more electric devices to operate simultaneously without mutual interference.

Electromagnetic interference (EMI): Any undesired effect of one electric device upon another due to radiated electromagnetic fields or due to voltages imposed on a shared power source.

Elliptical polarization: Polarization of an electromagnetic wave consisting of two perpendicular electric fields of differing phase.

Emissions: Fields or conducted voltages generated by an electric device.

Far-field region: Any location that is much farther than $\lambda/2\pi$ from an electric or magnetic field source, where λ is the wavelength at the frequency of concern.

Intersystem EMI: EMI between two or more systems.

Intrasystem EMI: EMI between two or more parts of the same system.

Near-field region: Any location that is much nearer than $\lambda/2\pi$ to an electric or magnetic field source, where λ is the wavelength at the frequency of concern.

Open-field site: A test location free of any conductors that would affect electromagnetic fields and taint the results.

Polarization: The direction of the electric field, E, of an electromagnetic wave.

Power density: Radiated power per unit of cross-sectional area.

Radiated coupling: Coupling due to radiated electric, magnetic, or electromagnetic fields.

Site attenuation: A measure of the degree to which electromagnetic fields at a test site are disturbed by environmental irregularities, obtained by comparing calculations with measured experimental results.

Susceptibility: The degree to which an electric device is affected by externally generated fields or conducted voltages.

Transverse electromagnetic (TEM) cell: A relatively small test chamber in which fields can be accurately controlled by its geometric properties.

Permittivity Measurement

University of Wisconsin–Milwaukee

37.1 Introduction

Dielectric materials possess relatively few free charge carriers. Most of the charge carriers are bound and cannot participate in conduction. However, these bound charges can be displaced by applying an external electric field. In such cases, the atom or molecule forms an electric dipole that maintains an electric field. Consequently, each volume element of the material behaves as an electric dipole. The dipole field tends to oppose the applied field. Dielectric materials that exhibit nonzero distribution of such bound charge separations are said to be *polarized*. The volume density of polarization $\vec{P}$ describes the volume density of those electric dipoles. When a material is linear and isotropic in nature, the polarization density is related to applied electric field intensity, $\vec{E}$, as follows:

$$\vec{P} = \varepsilon_0 \chi_e \vec{E} \tag{37.1}$$

where

ε_0 (=8.854 × 10^{-12} F m^{-1}) is the permittivity of free space
χ_e is called the electric susceptibility of the material

The electric flux density, or displacement, $\vec{D}$ is defined as follows:

$$\vec{D} = \varepsilon_0 \vec{E} + \vec{P} = \varepsilon_0 (1 + \chi_0)\vec{E} = \varepsilon_0 \varepsilon_r \vec{E} = \varepsilon \vec{E} \tag{37.2}$$

where

ε is called the permittivity of the material
ε_r is its relative permittivity or dielectric constant

Electric flux density is expressed in coulombs per meter (C m^{-1}).

Equation 37.2 represents a relation between the electric flux density and electric field intensity in frequency domain. It will hold well in time domain only if the permittivity is independent of frequency. A material is called *dispersive* if its characteristics are frequency dependent. The product of Equation 37.2 in frequency domain will be replaced by a convolution integral for the time-domain fields.

Assuming that the fields are time harmonic as $e^{j\omega t}$, the generalized Ampere's law can be expressed in phasor form as follows:

$$\nabla \times \vec{H} = \vec{J}^{\,e} + \vec{J} + j\omega\vec{D} \tag{37.3}$$

where

H is the magnetic field intensity in A m^{-1}
J^e is the current-source density in A m^{-2}
J is the conduction current density in A m^{-2}
the last term represents the displacement current density
J^e will be zero for a source-free region

The conduction current density is related to the electric field intensity through Ohm's law as follows:

$$\vec{J} = \sigma\vec{E} \tag{37.4}$$

where σ is the conductivity of material in S m^{-1}.

From Equations 37.2 through 37.4, one obtains

$$\nabla \times \vec{H} = \vec{J}^{\,e} + \sigma\vec{E} + j\omega\varepsilon\vec{E} \tag{37.5}$$

Conduction current represents the loss of power. There is another source of loss in dielectric materials. When a time-harmonic electric field is applied, the dipoles flip back and forth constantly. Because the charge carriers have finite mass, the field must do work to move them and they might not respond instantaneously. This means that the polarization vector will lag behind the applied electric field. This factor shows up at high frequencies. Therefore, Equation 37.5 is modified as follows:

$$\nabla \times \vec{H} = \vec{J}^{\,e} + \sigma\vec{E} + \omega k''\vec{E} + j\omega\varepsilon\vec{E} = \vec{J}^{\,e} + j\omega\left(\varepsilon - j\frac{\sigma + \omega k''}{\omega}\right)\vec{E} = \vec{J}^{\,e} + j\omega\varepsilon^{*}\vec{E} \tag{37.6}$$

The complex relative permittivity of a material is defined as follows:

$$\varepsilon_r^{*} = \frac{\varepsilon^{*}}{\varepsilon_0} = \frac{1}{\varepsilon_0}\left(\varepsilon - j\frac{\sigma + \omega k''}{\omega}\right) = \varepsilon_r' - j\varepsilon_r'' = \varepsilon_r(1 - j\tan\delta) \tag{37.7}$$

where ε_r' and ε_r'' represent real and imaginary parts of the complex relative permittivity. The imaginary part is zero for a lossless material. The term tanδ is called the *loss tangent*. It represents the tangent of angle between the displacement phasor and total current, as shown in Figure 37.1. Thus, it will be close to zero for a low-loss material.

Dispersion characteristics of a large class of materials can be represented by the following empirical equation of Cole–Cole:

$$\varepsilon_r^{*} = \varepsilon_\infty + \frac{\varepsilon_s - \varepsilon_\infty}{1 + (j\omega\tau)^{1-\alpha}} \tag{37.8}$$

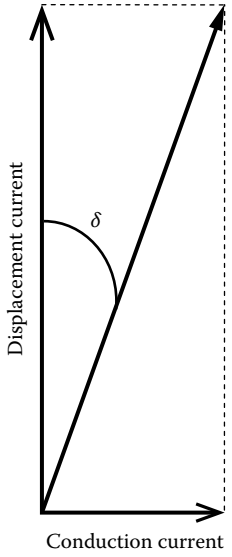

FIGURE 37.1 A phasor diagram representing displacement and loss currents.

where

ε_∞ and ε_s are the relative permittivities of material at infinite and zero frequencies, respectively
ω is the signal frequency in radians per second
τ is the characteristic relaxation time in seconds

For α equal to zero, Equation 37.8 reduces to the Debye equation. Dispersion parameters for a few liquids are given in Table 37.1.

Complex permittivity of a material is determined using lumped circuits at low frequencies, and distributed circuits or free-space reflection and transmission of waves at high frequencies. Capacitance and dissipation factor of a lumped capacitor are measured using a bridge or a resonant circuit. The complex permittivity is calculated from these data. Complex permittivities for some substances are presented in Table 37.2.

At high frequencies, the sample is placed inside a transmission line or a resonant cavity. Propagation constants of the transmission line or resonant frequency and quality factor of the cavity resonator are used to calculate the complex permittivity. Propagation characteristics of electromagnetic waves are influenced by the complex permittivity of that medium. Therefore, a material can be characterized by monitoring the reflected and transmitted wave characteristics as well.

37.2 Measurement of Complex Permittivity at Low Frequencies

A parallel-plate capacitor is used to determine the complex permittivity of dielectric sheets [1,2]. For a separation d between the plates of area A in vacuum, the capacitance is given by

$$C_0 = 8.854\frac{A}{d}\ \text{pF} \tag{37.9}$$

where all dimensions are measured in meters. If the two plates have different areas, then the smaller one is used to determine C_0. Further, it is assumed that the field distribution is uniform and perpendicular to the plates. Obviously, the fringing fields along the edges do not satisfy this condition. The guard electrodes, as shown in Figure 37.2, are used to ensure that the field distribution is close to the assumed condition. For best results, the width of the guard electrode must be at least $2d$, and the unguarded plate must extend to outer edge of the guard electrode. Further, the gap between the guarded and guard electrodes must be as small as possible.

The radius of guarded electrode is r_1, and the inner radius of guard electrode is r_2. It is assumed that $R - r_2 \geq 2d$. The area A for this parallel-plate capacitor is πr^2, where r is defined as follows:

$$r = r_1 + \Delta \tag{37.10}$$

$$\Delta = \frac{1}{2}(r_2 - r_1) - \frac{2d}{\pi}\ln\left(\cosh\frac{\pi(r_2 - r_1)}{4d}\right) = \frac{1}{2}(r_2 - r_1) - 1.4659d\ln\left(\cosh 0.7854\frac{r_2 - r_1}{d}\right) \tag{37.11}$$

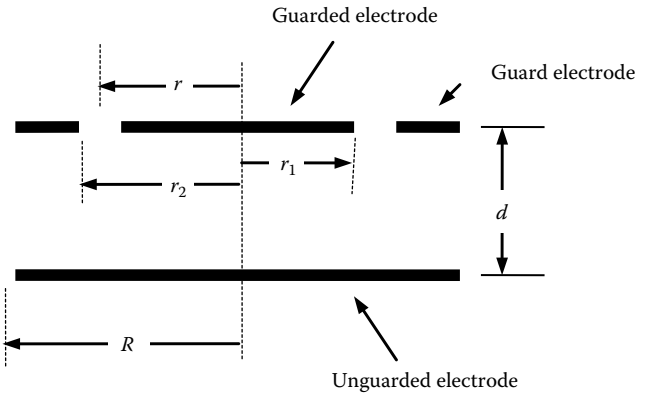

FIGURE 37.2 Geometry of a guarded capacitor.

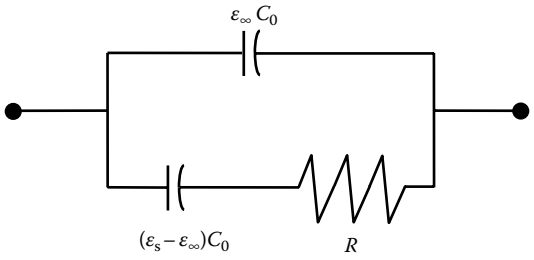

FIGURE 37.3 Equivalent circuit of a parallel-plate capacitor based on the Debye model.

Using the Debye model (i.e., $\alpha = 0$ in Equation 37.8), an equivalent circuit for a dielectric-filled parallel-plate capacitor can be drawn as shown in Figure 37.3. If a step voltage V is applied to it, then the current I can be found as follows [2]:

$$I = \varepsilon_\infty C_0 V\delta(t) + \frac{VC_0(\varepsilon_0 - \varepsilon_\infty)}{\tau}\exp\left(-\frac{t}{\tau}\right) \tag{37.12}$$

where $\tau = RC_0(\varepsilon_0 - \varepsilon_\infty)$.

The first term in Equation 37.12 represents the charging current of capacitor $\varepsilon_\infty C_0$ in the upper branch. This current is not measured because it disappears instantaneously. In practice, it needs to be bypassed at short times to protect the detector from overloading or burning. The second term of Equation 37.12 represents the current charging the lower branch of the equivalent circuit. The time constant, τ, is determined following the decay characteristics of this current. Further, the resistance R can be found after extrapolating this current–time curve to $t = 0$. The discharging current characteristics are used to remove V at $t = 0$.

A typical circuit arrangement for the characterization of dielectric materials using a step voltage is shown in Figure 37.4. A standard resistor R_1 of either 10 GΩ or 1 TΩ is connected between the guarded electrode and the load resistor R_2. A feedback circuit is used that forces the voltage drop across R_1 equal in magnitude but opposite in polarity to that of across R_2. It works as follows. Suppose that the node between capacitor and R_1 has a voltage V_1 with respect to ground. It is amplified but reversed in polarity by the amplifier. Therefore, the current through R_1 will change. This process continues until the input to the amplifier is zero. The junction between R_1 and the capacitor will then be at the ground potential. Thus, the meter M measures voltage across R_2 that is negative of the voltage across R_1. Since R_1 is known, the current through it can be calculated. This current also flows through the sample. S_1 is used to switch from charging to discharging mode, while S_2 is used to provide a path for surge currents.

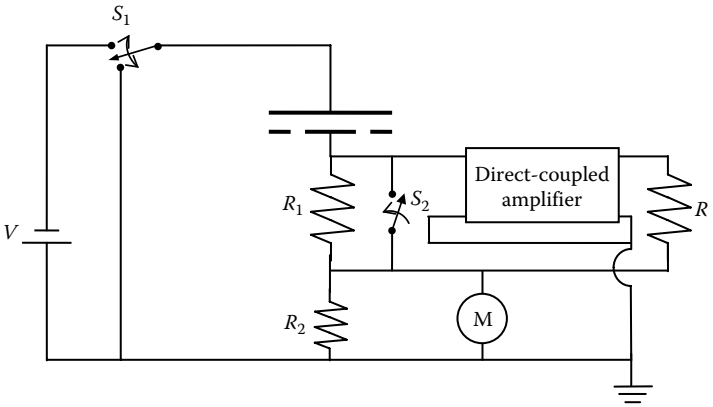

FIGURE 37.4 Circuit arrangement for the characterization of dielectric materials using a step voltage.

Capacitance and dissipation factor of the dielectric-loaded parallel-plate capacitor are used in the medium frequency range to determine the complex permittivity of materials. A substitution method is generally employed in a Schering bridge circuit for this measurement.

In the Schering bridge shown in Figure 37.5, assume that the capacitor C_v is disconnected for the time being and the capacitor C_s contains the dielectric sample. In the case of a lossy dielectric sample, it can be modeled as an ideal capacitor C_x in series with a resistor R_x. The bridge is balanced by adjusting C_d and R_c. An analysis of this circuit under the balanced condition produces the following relations:

$$R_x = \frac{C_d R_c}{C_T} \tag{37.13}$$

and

$$C_x = \frac{C_T R_d}{R_c} \tag{37.14}$$

Quality factor Q of a series RC circuit is defined as the tangent of its phase angle, while the inverse of Q is known as the dissipation factor D. Hence,

$$Q = \frac{X_x}{R_x} = \frac{1}{\omega C_x R_x} = \frac{1}{D} \tag{37.15}$$

For a fixed R_d, the capacitor C_d can be calibrated directly in terms of dissipation factor. Similarly, the resistor R_c can be used to determine C_x. However, an adjustable resistor limits the frequency range. A substitution method is preferred for precision measurement of C_x at higher frequencies. In this technique, a calibrated precision capacitor C_v is connected in parallel with C_s as shown in Figure 37.5, and the bridge is balanced. Assume that the settings of two capacitors at this condition are C_{d1} and C_{v1}. The capacitor C_s is then removed, and the bridge is balanced again. Let the new settings of these capacitors be C_{d2} and C_{v2}, respectively. Equivalent circuit parameters of the dielectric-loaded capacitor C_s are then found as follows:

$$C_x = C_{v2} - C_{v1} \tag{37.16}$$

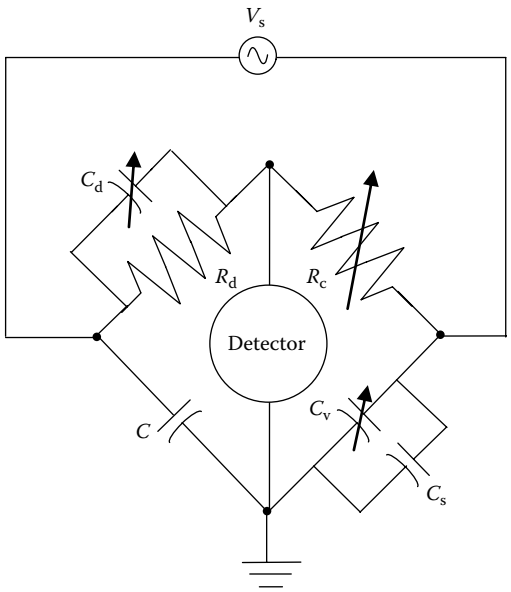

FIGURE 37.5 Schering bridge.

$$D_x = \frac{C_{v2}}{C_x}\delta D \tag{37.17}$$

where

$$\delta D = \omega R_d (C_{d1} - C_{d2})$$

Complex permittivity of the specimen is calculated from these data as follows:

$$\varepsilon_r' = \frac{C_x}{C_0} \tag{37.18}$$

and

$$\varepsilon_r'' = \frac{C_x D_x}{C_0} \tag{37.19}$$

Thus far, a series *RC* circuit equivalent model is used for the dielectric-loaded capacitor. As illustrated in Figure 37.6, an equivalent parallel *RC* model can also be obtained for it. The following equations can be used to switch back and forth between these two equivalent models:

$$G_p = \frac{R_s}{R_s^2 + \left(1/\omega^2 C_s^2\right)} = \frac{1}{R_s}\left(\frac{1}{1+Q^2}\right) \tag{37.20}$$

$$C_p = \frac{C_s}{1+(\omega R_s C_s)^2} = \frac{C_s}{1+D^2} \tag{37.21}$$

$$R_s = \frac{G_p}{G_p^2 + \omega^2 C_p^2} = \frac{1}{G_p}\left(\frac{1}{1+Q^2}\right) \tag{37.22}$$

$$C_s = \frac{G_p^2 + \omega^2 C_p^2}{\omega^2 C_p} = C_p(1+D^2) \tag{37.23}$$

and

$$Q = \frac{1}{D} = \frac{\omega C_p}{G_p} = \frac{1}{\omega R_s C_s} \tag{37.24}$$

Proper shielding and grounding arrangements are needed for a reliable measurement, especially at higher frequencies. Grounding and edge capacitances of the sample holder need to be taken into account for improved accuracy. Further, a guard point needs to be obtained that may require balancing in some cases. An inductive-ratio-arm capacitance bridge can be another alternative to consider for such application [1].

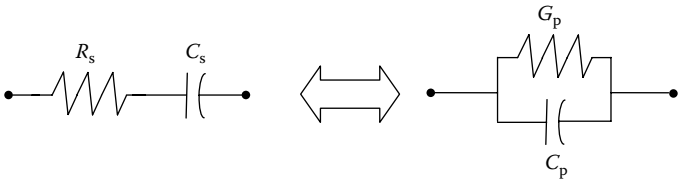

FIGURE 37.6 Series and parallel equivalent circuits of a dielectric-loaded capacitor.

37.3 Measurement of Complex Permittivity Using Distributed Circuits

Measurement techniques based on the lumped circuits are limited up to the lower end of the very high frequency (VHF) band. Characterization of materials at microwave frequencies requires the distributed circuits. A number of techniques have been developed on the basis of wave reflection and transmission characteristics inside a transmission line or in free space. Some other methods employ a resonant cavity that is loaded with the sample. Cavity parameters are measured, and the material characteristics are deduced from that. A number of these techniques, described in [3,4], can be used for a sheet material. These techniques require cutting a piece of sample to be placed inside a transmission line or a cavity. In case of liquid or powder samples, a so-called modified infinite sample method can be used. In this technique, a waveguide termination is filled completely with the sample, as shown in Figure 37.7. Since a tapered termination is embedded in the sample, the wave incident on it will be dissipated with negligible reflection, and it will look like the sample is extending to infinity. The impedance at its input port will depend on the electric properties of filling sample. Its voltage standing wave ratio (VSWR) S and location of first minimum d from the load plane are measured using a slotted line. The complex permittivity of sample is then calculated as follows [5]:

$$\varepsilon_r' = \left(\frac{\lambda}{\lambda_c}\right)^2 + \frac{[1-(\lambda/\lambda_c)^2]\times[S^2\sec^4(\beta d)-(1-S^2)^2\tan^2(\beta d)]}{[1+S^2\tan^2(\beta d)]^2} \tag{37.25}$$

and

$$\varepsilon_r'' = \frac{[1-(\lambda/\lambda_c)^2]\times[2S(1-S^2)^2\sec^4(\beta d)\tan(\beta d)]}{[1+S^2\tan^2(\beta d)]^2} \tag{37.26}$$

where

λ is the free-space wavelength
λ_c is the cutoff wavelength for the mode of propagation in empty guide
β is the propagation constant in the feeding guide

It is assumed that the waveguide supports TE_{10} mode only.

37.3.1 Resonant Cavity Method

A cavity resonator can be used to determine the complex permittivity of materials at microwave frequencies. If a cavity can be filled completely with the sample, then the following procedure can be used.

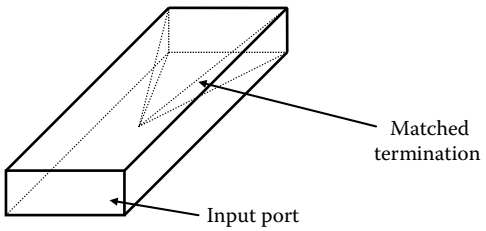

FIGURE 37.7 A waveguide termination filled with liquid or powder sample.

Measure the resonant frequency f_1 and the quality factor Q_1 of an empty cavity. Next, fill that cavity with the sample material and measure its new resonant frequency f_2 and quality factor Q_2. The dielectric parameters of the sample are then calculated from the following formulae [3]:

$$\varepsilon_r = \left(\frac{f_1}{f_2}\right)^2 \tag{37.27}$$

and

$$\tan\delta = \frac{1}{Q_2} - \frac{1}{Q_1}\sqrt{\frac{f_1}{f_2}} \tag{37.28}$$

On the other hand, a cavity perturbation technique will be useful for smaller samples [4]. If the sample is available in a circular cylindrical form, then it may be placed inside a TE_{101} rectangular cavity through the center of its broad face where the electric field is the maximum. Its resonant frequency and quality factor with and without the sample are then measured. Complex permittivity of the sample is calculated as follows:

$$\varepsilon_r' = 1 + \frac{1}{2}\frac{f_1 - f_2}{f_2}\frac{V}{v} \tag{37.29}$$

and

$$\varepsilon_r'' = \frac{V}{4v}\frac{Q_2 - Q_1}{Q_1 Q_2} \tag{37.30}$$

where V and v are cavity and sample volumes, respectively.

Similarly, for a small spherical sample of radius r that is placed in a uniform field at the center of the rectangular cavity, the dielectric parameters are as follows:

$$\varepsilon_r' = \frac{abd}{8\pi r^3}\frac{f_1 - f_2}{f_2} \tag{37.31}$$

and

$$\varepsilon_r'' = \frac{abd}{16\pi r^3}\left(\frac{Q_2 - Q_1}{Q_1 Q_2}\right) \tag{37.32}$$

where a, b, and d are the width, height, and length of the rectangular cavity, respectively. For best accuracy in cavity perturbation method, the shift in frequency $(f_1 - f_2)$ must be very small.

37.3.2 Free-Space Method for Measurement of Complex Permittivity

When a plane electromagnetic wave is incident on a dielectric interface, its reflection and transmission depend on the contrast in the dielectric parameters. Many researchers have used it for determining the complex permittivity of dielectric materials placed in free space. An automatic network analyzer and phase-corrected horn antennas can be used for such measurements [6]. The system is calibrated using the TRL (through, reflect, and line) technique. A time-domain gating is used to minimize the error due to multiple reflections. The sample of thickness d is placed in front of a conducting

plane, and its reflection coefficient S_{11} is measured. A theoretical expression for this reflection coefficient is found as follows:

$$S_{11} = \frac{jZ_{\mathrm{d}} \tan(\beta_{\mathrm{d}} d) - 1}{jZ_{\mathrm{d}} \tan(\beta_{\mathrm{d}} d) + 1} \tag{37.33}$$

where

$$Z_{\mathrm{d}} = \frac{1}{\sqrt{\varepsilon_r^{\star}}} \tag{37.34}$$

$$\beta_{\mathrm{d}} = \frac{2\pi}{\lambda}\sqrt{\varepsilon_{\mathrm{r}}^{\star}} \tag{37.35}$$

λ is the free-space wavelength of electromagnetic signal.

Equation 37.33 is solved for $\varepsilon_{\mathrm{r}}^{\star}$ after substituting the measured S_{11}. Since it represents a nonlinear relation, an iterative numerical procedure can be used.

37.3.3 Electric Probe Method for Determining the Dielectric Properties of Materials

Coaxial line-excited short electric probes have been used for the in situ determination of dielectric properties. The procedure requires an accurate measurement of the input impedance of the in situ probe and its mathematical model that is dependent on the electric characteristics of the surrounding medium. The procedure is complex, and therefore, there are a number of models reported in the literature for simplification. In one of these techniques, it is assumed that the electric probe is immersed in the medium under test and a coaxial line of inner and outer radii a and b, respectively, feeds this probe from behind the ground plane, as illustrated in Figure 37.8 [7]. The medium has conductivity σ S/m and the dielectric constant ε_{r}. Further, the opening $(b - a)$ is much smaller than the probe radius a, and the probe length λ is smaller than a quarter wavelength. The so-called induced EMF method provides an expression for the input impedance Z_{in} of this probe as follows:

$$Z_{\mathrm{in}} = \frac{j\omega\mu_0}{4\pi\beta_{\mathrm{d}} \sin(\beta_{\mathrm{d}}\ell)} \int_0^{\ell} \sin\{\beta_{\mathrm{d}}(\ell - z)\} f(z) dz \tag{37.36}$$

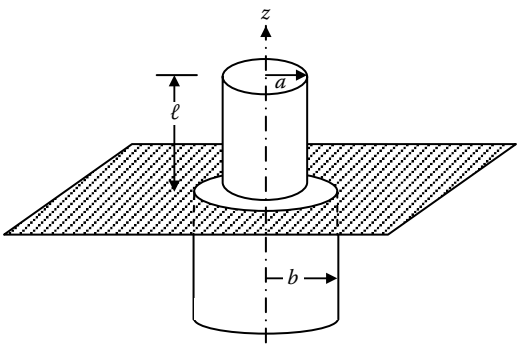

FIGURE 37.8 A coaxial line-excited short electric probe on the ground plane.

where

$$f(z) = \frac{e^{-j\beta_d r_1}}{r_1} + \frac{e^{-j\beta_d r_2}}{r_2} - 2\cos(\beta_d \ell) \cdot \frac{e^{-j\beta_d r}}{r} \tag{37.37}$$

$$r_1 = \sqrt{(\ell - z)^2 + a^2} \tag{37.38}$$

$$r_2 = \sqrt{(\ell + z)^2 + a^2} \tag{37.39}$$

$$r = \sqrt{z^2 + a^2} \tag{37.40}$$

$$\frac{\omega\mu_0}{\beta_d} = \sqrt{\frac{\mu_0}{\varepsilon^*}} = \eta = \text{Intrinsic impedance of the medium} \tag{37.41}$$

$$\varepsilon^* = \varepsilon_0\left(\varepsilon_r - j\frac{\sigma}{\omega\varepsilon_0}\right) \tag{37.42}$$

$$\beta_d^2 = \omega^2\mu_0\varepsilon^* \tag{37.43}$$

Since the input impedance Z_{in} is known precisely after measurement, Equation 37.36 can be solved numerically for complex β_d using a root-finding routine. The material characteristics are then determined from Equations 37.42 and 37.43.

37.3.4 Nondestructive Method for Measuring the Complex Permittivity of Materials

Most of the techniques described thus far require cutting and placing a part of sample in the test fixture. Sometimes, it may not be permissible to do so. Further, the dielectric parameters can change in that process. It is especially important in the case of a biological specimen to perform in vivo measurements. In one such technique, an open-ended coaxial line is placed in close contact with the sample, and its input reflection coefficient is measured using an automatic network analyzer [8,9]. As recommended by the manufacturers, the network analyzer is calibrated initially using an open-circuit, a short-circuit, and a matched load. The reference plane is then moved to the measuring end of the coaxial line using short circuit.

Assume that a and b are inner and outer radii of the coaxial line, respectively. ω is the angular frequency; μ_0 and ε_0 are the permeability and permittivity of the free space, respectively; $k = \omega\sqrt{\mu_0\varepsilon_0\varepsilon_r^*}$ is the wavenumber in material medium. Admittance of the coaxial aperture in contact with material medium is as follows:

$$Y_L = \frac{2}{\int_a^b E_\rho(\rho', 0)d\rho'} - \frac{2\pi}{\left[\sqrt{(\mu_0/\varepsilon_0\varepsilon_1)}\ln(b/a)\right]} \tag{37.44}$$

where $E_\rho(\rho', 0)$ is radial electric field intensity over the aperture. It is evaluated from the following integral equation:

$$\frac{1}{\pi\rho} + j\omega\varepsilon_1\varepsilon_o\int_a^b E_\rho(\rho', 0)K_c(\rho, \rho')\rho' d\rho' = \frac{j\omega\varepsilon_r^*\varepsilon_0}{\pi}\int_a^b E_\rho(\rho', 0)\rho' d\rho' \int_0^\pi \cos(\phi')\frac{\exp(-jkr)}{r}d\phi' \tag{37.45}$$

where

$$r = \sqrt{\rho^2 + \rho'^2 - 2\rho\rho'}\cos(\phi') \tag{37.46}$$

$$K_c(\rho, \rho') = j\sum_{n=0}^{\infty} \frac{\phi_n(\rho)\phi_n(\rho')}{A_n^2 \beta_n} \tag{37.47}$$

$$\phi_n = Y_0(\gamma_n a)J_1(\gamma_n \rho) - J_0(\gamma_n a)Y_1(\gamma_n \rho) \tag{37.48}$$

$$\beta_n = \begin{cases} \sqrt{k_1^2 - \gamma_n^2} & k_1 > \gamma_n \\ -j\sqrt{\gamma_n^2 - k_1^2} & k_1 < \gamma_n \end{cases} \tag{37.49}$$

$$A_n^2 = \frac{2}{\pi^2 \gamma_n^2}\left[\frac{J_0^2(\gamma_n a)}{J_0^2(\gamma_n b)} - 1\right] \quad n > 0; \quad A_0^2 = \ln\left(\frac{b}{a}\right) \tag{37.50}$$

The eigenvalues λ_n are solutions to the following characteristic equation:

$$J_0(\gamma_n b)Y_0(\gamma_n a) = J_0(\gamma_n a)Y_0(\gamma_n b) \tag{37.51}$$

where

J_n and Y_n are Bessel functions of the first and second kind of order n, respectively
ε_1 is the dielectric constant of the insulator
k_1 is wavenumber inside the coaxial line

Equation 37.45 is solved numerically using the method of moments. A numerical root-finding procedure, such as Muller's method, is used to solve Equation 37.44 for the complex wavenumber k. Complex permittivity, in turn, is determined from the following relation:

$$\varepsilon_r^* = \frac{k^2}{\omega^2 \mu_0 \varepsilon_0} \tag{37.52}$$

A relatively much simpler method may be used if the coaxial aperture of the probe is electrically small such that there is negligible radiation. This technique requires four standard media to calibrate the system. For example, water, open circuit, short circuit, and methanol are used to find calibration constants. Further, it does not require precise value of reflection coefficient (or input impedance), and therefore, there is no need to calibrate the automatic network analyzer to manufacturer's standards. The procedure may be summarized as follows.

With open end of the probe in free space, its reflection parameter R_1 is recorded. The probe is then dipped in distilled water and then in methanol, and the corresponding reflection parameters are recorded as R_2 and R_4. With a conductive foil tightly pressed on the aperture, the reflection parameter

R_3 is recorded. Note that the magnitudes of reflection parameters may be larger than unity sometimes because this setup is not calibrated for measuring the reflection coefficients. Now, a coefficient χ is determined to find the equivalent admittance parameters at the opening as follows:

$$\chi = \frac{(1+\Lambda)\varepsilon_{r4}^{\star} - \varepsilon_{r1}^{\star} - \Lambda\varepsilon_{r2}^{\star}}{\varepsilon_{r1}^{\star 2} + \Lambda\varepsilon_{r2}^{\star 2} - (1+\Lambda)\varepsilon_{r4}^{\star 2}} \tag{37.53}$$

where $\varepsilon_{r1}^{\star}$, $\varepsilon_{r2}^{\star}$, and $\varepsilon_{r4}^{\star}$ are the complex relative permittivities of free space (~1), water, and methanol, respectively, at the measurement frequency, and

$$\Lambda = \frac{(R_4 - R_1)\cdot(R_3 - R_2)}{(R_4 - R_2)\cdot(R_1 - R_3)} \tag{37.54}$$

A dimensionless equivalent admittance parameter y_n of the aperture with the nth medium is found as follows:

$$y_n = \varepsilon_{rn}^{\star} + \chi\varepsilon_{rn}^{\star 2} \tag{37.55}$$

Now with the test-sample terminating the coaxial aperture, reflection parameter R_s is recorded, and it is used to find the coefficient ξ as follows:

$$\xi = \frac{(R_s - R_1)\cdot(R_3 - R_2)}{(R_s - R_2)\cdot(R_1 - R_3)} \tag{37.56}$$

Using Equation 37.55, the admittance parameters y_1 and y_2 for the free space and water, respectively, are computed. The admittance parameter y_s for the sample is then found as follows:

$$y_s = \frac{y_1 - y_2\xi}{1-\xi} \tag{37.57}$$

The complex relative permittivity $\varepsilon_{rs}^{\star}$ of the sample can now be determined via Equation 37.55 as follows:

$$\varepsilon_{rs}^{\star} = \frac{-1 \pm \sqrt{1 + 4y_s\chi}}{2\chi} \tag{37.58}$$

Only one of these two values found for $\varepsilon_{rs}^{\star}$ will have positive real part and negative imaginary part. The other solution is not physically possible and, hence, can be thrown.

Note: The relevant ASTM standards and a list of manufacturers are included at the end of the text.

Defining Terms

Conduction current density: Current per unit area caused by conduction of charge carriers.

Dielectric constant: A dimensionless constant that represents the permittivity of a material relative to the permittivity of free space.

Displacement current density: It represents the time rate of change of electric flux density.

Dissipation factor: It is the inverse of the quality factor.

Electric dipole: A pair of equal and opposite electric charges separated by a small distance.

Electric flux density: A fundamental electric field quantity that is related to volume density of free charges. It is also known as the electric displacement.

Electric polarization density: The average electric dipole moment per unit volume.

Electric susceptibility: A dimensionless parameter that relates the polarization density in a material with electric field intensity.

Frequency domain field: A phasor quantity (a complex function in general) that depends on space coordinates. The time dependency is assumed to be sinusoidal.

Isotropic material: A material in which the electric polarization has the same direction as the applied electric field.

Loss tangent: A ratio of the imaginary part to the real part of the complex permittivity of a material.

Quality factor: A dimensionless quantity that represents the time average energy stored in an electric circuit relative to energy dissipated in one period.

Reflection coefficient: Defined as a ratio of reflected phasor voltage to that of incident phasor voltage at a point in the circuit.

Relaxation time: It represents the time taken by a charge placed inside a material volume to decay to about 37% of its initial value.

Time-domain field: A field expressed as a function of time. It is a real function that is dependent on time and space coordinates.

Voltage standing wave ratio (VSWR): Defined as a ratio of maximum voltage to the minimum voltage on a transmission line.

Electric-Field Strength

David A. Hill
National Institute of Standards and Technology

Motohisa Kanda
National Institute of Standards and Technology

Electric-field strength is defined as the ratio of the force on a positive test charge at rest to the magnitude of the test charge in the limit as the magnitude of the test charge approaches zero. The units of electric-field strength are volts per meter (V m^{-1}). Electric charges and currents are sources of electric and magnetic fields, and Maxwell's equations [1] provide the mathematical relationships between electromagnetic (EM) fields and sources.

The electric field at a point in space is a vector defined by components along three orthogonal axes. For example, in a rectangular coordinate system, the electric field $\vec{E}$ can be written as

$$\vec{E} = \hat{x}E_x + \hat{y}E_y + \hat{z}E_z \tag{38.1}$$

where
$\hat{x}, \hat{y}$, and $\hat{z}$ are unit vectors
E_x, E_y, and E_z are scalar components

For electrostatic fields, the components are real scalars that are independent of time. For steady-state, time-harmonic fields, the components are complex phasors that repetition dependent, $e^{j\omega t}$, are suppressed.

38.1 Electrostatic Fields

Electrostatic fields are present throughout the atmosphere, and there are strong electrostatic fields near high-voltage dc power lines. The commonly used electrostatic field meters generate an ac signal by periodic conductor motion (either rotation or vibration). This ac signal is proportional to the electric-field strength, and field-meter calibration is performed in a known electrostatic field.

38.1.1 Field Mills

Field mills (also called generating voltmeters) determine electric-field strength by measuring modulated, capacitively induced charges or currents on metal electrodes. Two types of field mills—the shutter type and the cylindrical type—are described in the technical literature [2]. The shutter type is more common; a simplified version is shown in Figure 38.1. The sensing electrode is periodically exposed to and shielded from the electric field by a grounded, rotating shutter. The charge q_s induced on the sensing electrode and the current i_s between the sensing electrodes and grounds are both proportional to the electric-field strength E normal to the electrode:

$$q_s(t) = \varepsilon_0 E a_s(t) \quad \text{and} \quad i_s(t) = \varepsilon_0 E \frac{da_s(t)}{dt} \tag{38.2}$$

where

ε_0 is the permittivity of free space [1]
$a_s(t)$ is the effective exposed area of the sensing electrode at time t

Thus, the field strength can be determined by measuring the induced charge or current (or voltage across the impedance Z). If the induced signal is rectified by a phase-sensitive detector (relative to the shutter motion), the dc output signal will indicate both the polarity and magnitude of the electric field [3].

Shutter-type field mills are typically operated at the ground or at a ground plane, but a cylindrical field mill can be used to measure the electric field at points removed from a ground plane. A cylindrical field mill consists of two half-cylinder sensing electrodes as shown in Figure 38.2. Charges induced on the two sensing electrodes are varied periodically by rotating the sensing electrodes about the cylinder axis at a constant angular frequency ω_c. The charge q_c induced on a half cylinder of length L and the current i_c between the half cylinders are given by

$$q_c = 4\varepsilon_0 r_c L E \sin \omega_c t \quad \text{and} \quad i_c = 4\varepsilon_0 r_c L E \omega_c \cos \omega_c t \tag{38.3}$$

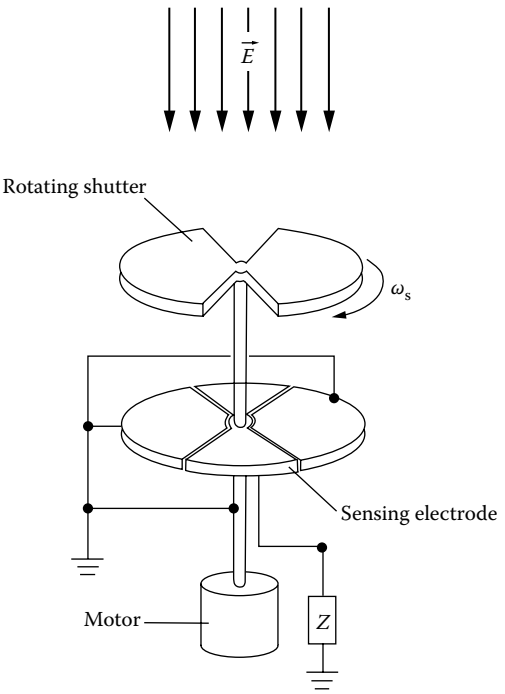

FIGURE 38.1 Shutter-type electric-field mill for measurement of the polarity and magnitude of an electrostatic field.

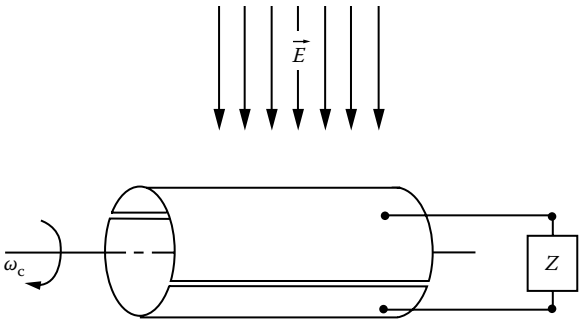

FIGURE 38.2 Cylindrical field mill for measurement of electrostatic field strength.

where r_c is the cylinder radius. Equation 38.3 is based on the 2D solution for a conducting cylinder in an electric field and neglects end effects for finite L. Equation 38.3 shows that the electric-field strength E can be determined from a measurement of the induced charge or current.

A third type of electric-field meter uses a vibrating plate [4] to generate an ac signal that is proportional to the electric-field strength. With any type of electric-field strength meter, the observer should be at a sufficient distance from the measurement location to avoid perturbing the electric field.

38.1.2 Calibration Field

A known uniform field for meter calibration can be produced between a pair of parallel plates [2]. If a potential difference V is applied between a pair of plates with a separation d_p, the field strength away from the plate edges is V/d_p. The plate dimensions should be much larger than d_p to provide an adequate region of uniform field. Also, d_p should be much larger than the field-meter dimensions so that the charge distribution on the plates is not disturbed. The parallel plates can be metal sheets or tightly stretched metal screens.

The field meter should be located in the type of environment in which it will be used. Shutter-type field mills that are intended to be located at a ground plane should be located at one of the plates. Cylindrical field mills that are not intended to be used at a ground plane should be located in the center of the region between the plates.

For simplicity, only field mills and calibration in the absence of space charge were mentioned. However, near power lines or in the upper atmosphere [5], the effects of space charge can be significant and require modifications in field mill design. A field mill for use in a space charge region and a calibration system with space charge are described in [6].

38.2 ELF and ULF Electric Fields

In this section, measurement techniques for extremely low frequency (ELF, 3 Hz to 3 kHz) and ultralow frequency (ULF, below 3 Hz) electric fields are considered. Natural ELF fields are produced by thunderstorms, and natural ULF fields are produced by micropulsations in the Earth's magnetic field [7]. Geophysicists make use of these natural fields in the magnetotelluric method for remote sensing of the Earth's crust [8]. AC power lines are dominant sources of fields at 50 or 60 Hz and their harmonics.

An ac electric-field strength meter [9] includes two essential parts: (1) an antenna and (2) a detector (receiver). Other possible features are a transmission line or optical link, frequency-selective circuits, amplifying and attenuating circuits, an indicating device, and a nonconducting handle. The antenna characteristics can be calculated for simple geometries or determined by calibration. For example,

linear antennas are often characterized by their effective length L_{eff} [10], which determines the open-circuit voltage V_{oc} induced at the antenna terminals:

$$V_{oc} = L_{eff} E_{inc} \tag{38.4}$$

where E_{inc} is the component of the incident electric field parallel to the axis of the linear antenna. The detector could respond to the terminal voltage or current or to the power delivered to the load.

38.2.1 Natural Horizontal Electric Field at the Earth's Surface

Magnetotelluric sounding of the Earth's crust requires measurement of the horizontal electric and magnetic fields at the Earth's surface [8]. The magnetic field is measured with a horizontal axis loop, and the electric field is measured with a horizontal wire antenna as shown in Figure 38.3. The antenna wire is insulated since it lies on the ground, but it is grounded at its end points. Nonpolarizing grounding electrodes should be used to avoid polarization potentials between the electrodes and the ground.

Since the natural electric-field strength to be measured is on the order of 1 μV m^{-1}, the antenna length L_h needs to be on the order of 1 km to produce a measurable voltage. Since the effective length of a grounded antenna is equal to the physical length ($L_{eff} = L_h$), the horizontal component E_h of the electric field parallel to the antenna is equal to the open-circuit voltage divided by the antenna length:

$$E_h = \frac{V_{oc}}{L_h} \tag{38.5}$$

The frequencies used in typical magnetotelluric sounding range from approximately 0.1 mHz to 10 Hz. If both horizontal components of the electric field are needed, a second orthogonal antenna is required.

38.2.2 Free-Body Electric-Field Meters

ELF electric fields in residential and industrial settings are most conveniently measured with free-body field meters [11,12], which measure the steady-state current or charge oscillating between two-halves of a conducting body in free space. (Ground reference meters [13] are also available for measuring the electric field normal to the ground or some other conducting surface.) Geometries for free-body electric-field meters are shown in Figure 38.4. Commercial field meters are usually rectangular in shape, and typical dimensions are on the order of 10 cm. A large dynamic range (1 V m^{-1} to 30 kV m^{-1}) is required to cover the various field sources (ac power lines, video display terminals, mass transportation systems, etc.) of interest. (Electro-optic field meters with less sensitivity are described in [12].) A long, nonconducting handle is normally attached perpendicular to the field-meter axis for use in measurement surveys.

The charge Q on half of the field meter is proportional to the incident electric field E along the meter axis:

$$Q = A\varepsilon_0 E \tag{38.6}$$

where

ε_0 is the permittivity of free space [1]
A is a constant proportional to the surface area

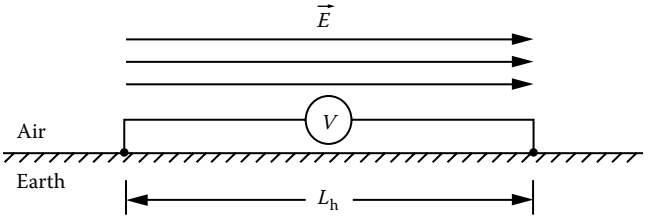

FIGURE 38.3 Grounded horizontal antenna for measurement of the horizontal component of the electric field.

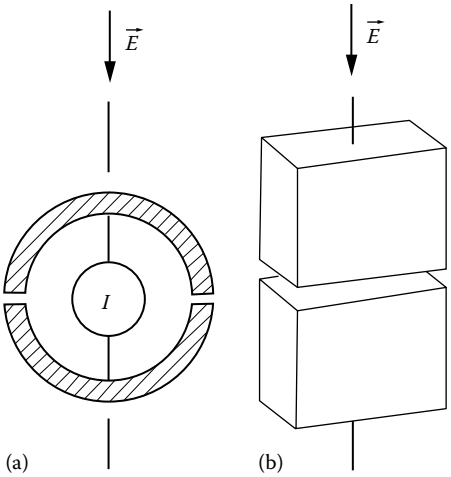

FIGURE 38.4 Electric-field meters for measurement of the axial component of the electric field: (a) spherical geometry and (b) rectangular geometry.

For the spherical geometry in Figure 38.4a, $A = 3\pi a^2$, where a is the sphere's radius. Since the current I between the two-halves is equal to the time derivative of the charge, for time-harmonic fields, it can be written as

$$I = j\omega A\varepsilon_0 E \tag{38.7}$$

This allows E to be determined from the measured current. For commercial field meters that are not spherical, the constant A needs to be determined by calibration. A known calibration field can be generated between a pair of parallel plates where the plates are sufficiently large compared to the separation to produce a uniform field with small edge effects. This technique produces a well-characterized field with an uncertainty of less than 0.5% [11]. However, the presence of harmonic frequencies can cause less accurate meter readings in field surveys.

38.3 Radio-Frequency and Microwave Techniques

38.3.1 Dipole Antennas

A thin, linear dipole antenna of length L is shown in Figure 38.5. Its effective length is approximately [10]

$$L_{\text{eff}} = \frac{\lambda}{\pi}\tan\left(\frac{\pi L}{2\lambda}\right) \tag{38.8}$$

where λ is the free-space wavelength. Resonant half-wave dipoles ($L = \lambda/2$) have an effective length of $L_{\text{eff}} = 2L/\pi$ and are of convenient length for frequencies from 30 to 1000 MHz. The physical length of a dipole at resonance is actually slightly shorter than $\lambda/2$ to account for the effect of a finite length-to-diameter ratio. Resonant dipoles are used as standard receiving antennas to establish a known standard field in the *standard antenna method* [9]. Commercial antennas and field meters are calibrated in such standard fields.

For $L < \lambda/2$, Equation 38.8 must be used to determine L_{eff}. For very short dipoles ($L/\lambda \ll 1$), the current distribution is approximately linear, and the effective length is approximately one-half the physical length ($L_{\text{eff}} \approx L/2$). Short dipoles are frequently used as electric-field probes.

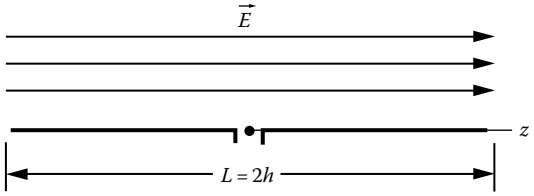

FIGURE 38.5 Dipole antenna for measurement of the axial component of the electric field.

38.3.2 Aperture Antennas

Aperture antennas are commonly used for receiving and transmitting at microwave frequencies (above 1 GHz). As receiving antennas, they are conveniently characterized by their on-axis gain g or effective area A_{eff}. Effective area is defined as the ratio of the received power P_{r} to the incident power density S_{inc} and can also be written in terms of the gain [9]:

$$A_{\text{eff}} = \frac{P_{\text{r}}}{S_{\text{inc}}} = \frac{g\lambda^2}{4\pi} \tag{38.9}$$

Equation 38.9 applies to the case where the incident field is polarization matched to the receiving antenna. The incident power density in a plane wave is $S_{\text{inc}} = E^2/\eta_0$, where E is the rms electric-field strength and η_0 is the impedance of free space (≈377 Ω). Thus, the electric-field strength can be determined from the received power:

$$E = \sqrt{\frac{P_{\text{r}}\eta_0}{A_{\text{eff}}}} = \lambda^{-1}\sqrt{\frac{4\pi\eta_0 P_{\text{r}}}{g}} \tag{38.10}$$

In general, the gain can be measured using the two-antenna method [9]. For a pyramidal horn antenna as shown in Figure 38.6, the gain can be calculated accurately from [14]

$$g = \frac{32ab}{\pi\lambda^2} R_{\text{E}} R_{\text{H}} \tag{38.11}$$

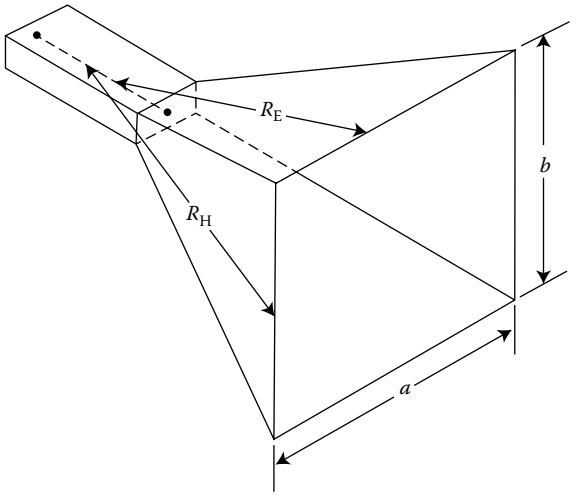

FIGURE 38.6 Pyramidal horn for measuring power density or electric-field strength.

where R_E and R_H are gain reduction factors due to the *E* and *H* plane flare of the horn. The gain reduction factors are

$$R_E = \frac{C^2(w) + S^2(w)}{w^2} \quad \text{and} \quad R_H = \frac{\pi^2\{[C(u) - C(v)]^2 + [S(u) - S(v)]^2\}}{4(u - v)^2} \tag{38.12}$$

where

$$w = \frac{b}{\sqrt{2\lambda l_E}} \quad \text{and} \quad \left.\begin{matrix} u \\ v \end{matrix}\right\} = \frac{\sqrt{\lambda l_H/2}}{a} \pm \frac{a}{\sqrt{2\lambda l_H}}$$

The Fresnel integrals *C* and *S* are expressed as [15]

$$C(w) = \int_0^w \cos\left(\frac{\pi}{2}t^2\right)dt \quad \text{and} \quad S(w) = \int_0^w \sin\left(\frac{\pi}{2}t^2\right)dt \tag{38.13}$$

Well-characterized aperture antennas are also used to generate standard fields [16] for calibrating commercial antennas and field strength meters. This method of calibration is called the *standard field method* [9]. The electric-field strength *E* at a distance *d* from the transmitting antenna is

$$E = \frac{\sqrt{\eta_0 P_{del} g/(4\pi)}}{d} \tag{38.14}$$

where P_{del} is the net power delivered to the transmitting antenna and is typically measured with a directional coupler [16]. The gain *g* for a pyramidal horn can be calculated from Equation 38.11. The National Institute of Standards and Technology (NIST)* uses rectangular open-ended waveguides from 200 to 500 MHz and a series of pyramidal horns from 500 MHz to 40 GHz to generate standard fields in an anechoic chamber [16]. The uncertainty of the field strength is less than 1 dB over the entire frequency range of 200 MHz–40 GHz.

38.4 Three-Loop Antenna System

Electronic equipment can emit unintentional EM radiation that can interfere with other electronic equipment. If the radiating source is electrically small (as is a video display terminal), then it can be characterized by equivalent electric and magnetic dipole moments. The three-loop antenna system (TLAS), shown in Figure 38.7, consists of three orthogonal loop antennas that are terminated at diametrically opposite points. The unique feature of loop antennas with double terminations [17] is that they can measure both electric and magnetic fields. For electromagnetic interference (EMI) applications, a device under test (DUT) is placed at the center of the TLAS. On the basis of six terminal measurements, the TLAS determines three equivalent electric dipole components and three equivalent magnetic dipole moments of the DUT and hence its radiation characteristics.

Here, the theory [18] is summarized for one of the three loops. The DUT in Figure 38.7 is replaced by an electric dipole moment $\vec{m}_e$ and a magnetic dipole moment $\vec{m}_m$ both located at the origin of the coordinate system. The dipole moments can be written in terms of their rectangular components:

$$\vec{m}_e = \hat{x}m_{ex} + \hat{y}m_{ey} + \hat{z}m_{ex} \quad \text{and} \quad \vec{m}_m = \hat{x}m_{mx} + \hat{y}m_{my} + \hat{z}m_{mz} \tag{38.15}$$

The loop in the *xy* plane has radius r_0 and has impedance loads Z_{xy} located at the intersections with the *x*-axis ($\phi = 0, \pi$).

* Contribution of the NIST, not subject to copyright in the United States.

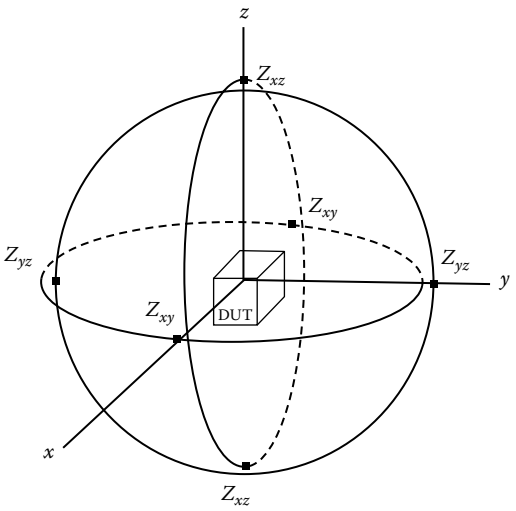

FIGURE 38.7 Geometry of the TLAS and the DUT.

The solution for the current induced in the loop is based on Fourier series analysis [19]. The incident azimuthal electric-field $E_{\phi}^{\mathrm{i}}(\phi)$ tangent to the loop is

$$E_{\phi}^{\mathrm{i}}(\phi) = A_0 + A_1 \cos\phi + B_1 \sin\phi \tag{38.16}$$

where

$A_0 = m_{\mathrm{m}x} G_{\mathrm{m}}$

$A_1 = m_{\mathrm{e}y} G_{\mathrm{e}}$

$B_1 = -m_{\mathrm{e}x} G_{\mathrm{e}}$

$$G_{\mathrm{m}} = \frac{\eta_0}{4\pi}\left(\frac{k^2}{r_0} - \frac{jk}{r_0^2}\right)e^{-jkr_0}$$

$$G_{\mathrm{e}} = \frac{-\eta_0}{4\pi}\left(\frac{jk}{r_0} + \frac{1}{r_0^2} + \frac{1}{jkr_0^2}\right)e^{-jkr_0}$$

$k = 2\pi/\lambda$ is the free-space wave number

An approximate solution [17] for the loop current $I(\phi)$ yields the following results for the load currents $I(0)$ and $i(\pi)$:

$$\begin{aligned} I(0) &= 2\pi r_0\left(\frac{m_{\mathrm{m}z} G_{\mathrm{m}} Y_0}{1 + 2Y_0 Z_{xy}} + \frac{m_{\mathrm{e}y} G_{\mathrm{e}} Y_1}{1 + 2Y_1 Z_{xy}}\right) \\ I(\pi) &= 2\pi r_0\left(\frac{m_{\mathrm{m}z} G_{\mathrm{m}} Y_0}{1 + 2Y_0 Z_{xy}} - \frac{m_{\mathrm{e}y} G_{\mathrm{e}} Y_1}{1 + Y_1 Z_{xy}}\right) \end{aligned} \tag{38.17}$$

where Y_0 and Y_1 are the admittances for the constant and cos ϕ currents [17].

One can solve Equation 38.17 for the magnetic and electric dipole components:

$$m_{mz} = \frac{I_\Sigma(1+2Y_0Z_{xy})}{2\pi r_0 G_m Y_0} \quad \text{and} \quad m_{ey} = \frac{I_\Delta(1+2Y_1Z_{xy})}{2\pi r_0 G_e Y_1} \tag{38.18}$$

where

$I_\Sigma = [I(0) + I(\pi)]/2$

$I_\Delta = [I(0) - I(\pi)]/2$

Thus, the sum current I_Σ can be used to measure the magnetic dipole moment, and the difference current I_Δ can be used to measure the electric dipole moment. The four remaining dipole components can be obtained in an analogous manner. The loop in the *xz* plane can be used to measure m_{my} and m_{ex}, and the loop in the *yz* plane can be used to measure m_{mx} and m_{ez}.

The total power P_T radiated by the source can be written in terms of the magnitudes of the six dipole components:

$$P_T = \frac{2\pi\eta_0}{3\lambda^2}\left[|m_{ex}|^2 + |m_{ey}|^2 + |m_{ez}|^2 + k^2\left(|m_{mx}|^2 + |m_{my}|^2 + |m_{mz}|^2\right)\right] \tag{38.19}$$

The expression for the power pattern is more complicated and involves the amplitudes and phases of the dipole moments [20]. The TLAS has been constructed with 1 m diameter loops and successfully tested from 3 kHz to 100 MHz [21]. It is currently being used to measure radiation from video display terminals and other inadvertent radiators.

38.5 Broadband Dipole Antennas

The EM environment continues to grow more severe and more complex as the number of radiating sources increases. Broadband antennas are used to characterize the electromagnetic (EM) environment over a wide frequency range. For electric-field measurements, electrically short dipole antennas with high capacitive input impedance are used with a capacitive load, such as a field-effect transistor (FET). The transfer function *S* of frequency *f* is defined as the ratio of the output voltage V_L of the antenna to the incident electric field E_i [22]:

$$S(f) = \frac{V_L(f)}{E_i(f)} = \frac{h\alpha/2}{1 + C/C_a} \tag{38.20}$$

where

$$C_a = \frac{4\pi h}{c\eta_0(\Omega_a - 2 - \ln 4)}$$

$$\alpha = \frac{\Omega_a - 1}{\Omega_a - 2 + \ln 4}$$

Ω_a is the antenna thickness factor and is equal to $2\ln(2h/r_a)$

r_a is the antenna radius

C is the load capacitance

C_a is the antenna capacitance

h is half the physical length of the dipole antenna, as shown in Figure 38.5

c is the free-space speed of light

Since the input impedance of an electrically short dipole is predominantly a capacitive reactance, a very broadband frequency response can be achieved with a high-impedance capacitive load. However, given the present state of the art, it is not possible to build a balanced, high-input impedance FET with high common-mode rejection above 400 MHz. For this reason, it is more common practice to use a high-frequency, beam-lead Schottky-barrier diode with a very small junction capacitance (less than 0.1 pF) and very high junction resistance (greater than several M3) for frequencies above 400 MHz.

The relationship between the time-dependent diode current $i_d(t)$ and voltage $v_d(t)$ is

$$i_d(t) = I_s[e^{\alpha_d v_d(t)} - 1] \tag{38.21}$$

where I_s and α_d are constants of the diode. For very small incident fields $E_i(t)$, the output detected dc voltage v_0 is

$$\begin{aligned} v_0 &= \frac{-b_d^2}{2\alpha_d}\left\langle \tilde{v}_i^2 \right\rangle \\ v_i &= E_i L_e \end{aligned} \tag{38.22}$$

where

$\tilde{v}_i(t) = v_i(t) - \langle v_i \rangle$

$b_d = \dfrac{C_a \alpha_d}{C_a + C_d}$

C_a is the dipole capacitance

C_d is the diode capacitance

L_e is the effective length of the dipole antenna

$\langle\rangle$ indicates time average

Thus, the dc detected voltage is frequency independent and is directly proportional to the average of $(E_i - \langle E_i \rangle)^2$.

For large incident fields $E_i(t)$, the output detected dc voltage is

$$v_0 = -\frac{b_d \tilde{V}_i}{\alpha_d} \tag{38.23}$$

where $\tilde{V}_i$ is the peak value of $v_i(t)$. Consequently, for a large incident field, v_0 is also frequency independent and is directly proportional to the peak field.

Conventional dipole antennas support a standing-wave current distribution; thus, the useful frequency range of this kind of dipole is usually limited by its natural resonant frequency. In order to suppress this resonance, a resistively loaded dipole (traveling-wave dipole) has been developed. If the internal impedance per unit length $Z_l(z)$ as function of the axial coordinate z (measured from the center of the dipole) has the form

$$Z_l(z) = \frac{60\psi}{h - |z|} \tag{38.24}$$

then the current distribution $I_z(z)$ along the dipole is that of a traveling wave. Its form is

$$I_z(z) = \frac{V_0}{60\psi(1 - j/kh)}\left[1 - \frac{|z|}{h}\right]e^{-jk|z|} \tag{38.25}$$

where

$2h$ is the total physical length of the dipole

V_0 is the driving voltage

$$\psi = 2\left[\sinh^{-1}\frac{h}{a_d} - C(2ka_d, 2kh) - jS(2ka_d, 2kh)\right] + \frac{j}{kh}(1 - e^{-j2kh}) \tag{38.26}$$

$C(x, y)$ and $S(x, y)$ are generalized cosine and sine integrals

a_d is the dipole radius

This type of resistively tapered dipole has a fairly flat frequency response from 100 kHz to 18 GHz [23].

Defining Terms

Antenna: A device designed to radiate or to receive time-varying EM waves.

Aperture antenna: An antenna that radiates or receives EM waves through an open area.

Dipole antenna: A straight wire antenna with a center feed used for reception or radiation of EM waves.

Electric-field strength: The ratio of the force on a positive test charge to the magnitude of the test charge in the limit as the magnitude of the test charge approaches zero.

Electrostatic field: An electric field that does not vary with time.

Field mill: A device used to measure an electrostatic field.

Microwaves: EM waves at frequencies above 1 GHz.

Power density: The time average of the Poynting vector.

Magnetic Field Measurement

Robert L. Fagaly
Quasar Federal Systems

Steven A. Macintyre
Macintyre Electronic Design

Magnetic field strength is measured using a variety of different technologies. Each technique has unique properties that make it more suitable for particular applications. These applications can range from simply sensing the presence or change in the field to the precise measurements of a magnetic field's scalar and vector properties. A very good and exhaustive fundamental description of both mechanical and electrical means for sensing magnetic fields can be found in Lion [1]; less detailed but more up-to-date surveys of magnetic sensor technologies can be found in [2,3]. It is not possible to adequately describe all of these technologies in the space available in a handbook. This chapter concentrates on sensors that are commonly used in magnetic field measuring instruments.

As shown in Figure 39.1, magnetic field sensors can be divided into vector component and scalar magnitude types. The vector types can be further divided into sensors that are used to measure low fields (<1 mT) and high fields (>1 mT). Instruments that measure low fields are commonly called *magnetometers*. High-field instruments are usually called *gaussmeters*.

The induction coil and fluxgate magnetometers are the most widely used vector measuring instruments. They are rugged, reliable, and relatively less expensive than the other low-field vector measuring instruments. The fiber-optic magnetometer is the most recently developed low-field instrument. Although it currently has about the same sensitivity as a fluxgate magnetometer, its potential for better performance is large. The optical fiber magnetometer has not yet left the laboratory, but work on making it more rugged and field worthy is under way. The superconducting quantum interference device (SQUID) magnetometers are the most sensitive of all magnetic field measuring instruments. These sensors operate at temperatures near absolute zero and require special thermal control systems. This makes the SQUID-based magnetometer more expensive, less rugged, and less reliable.

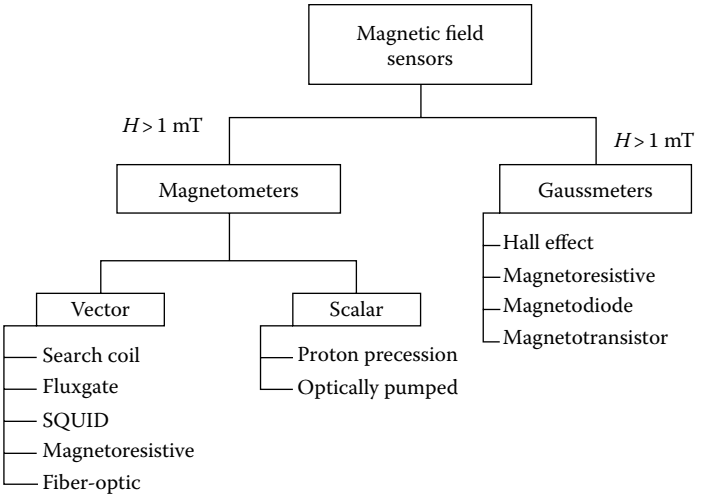

FIGURE 39.1 Magnetic field sensors are divided into two categories based on their field strengths and measurement range: magnetometers measure low fields and gaussmeters measure high fields.

TABLE 39.1 Field Strength Instrument Characteristics

Instrument	Range (mT)	Resolution (nT)	Bandwidth (Hz)	Comment
Induction coil	10^{-10}–10^{6}	Variable	10^{-1}–10^{6}	Cannot measure static fields
Fluxgate	10^{-4}–0.5	0.1	dc to 2×10^{3}	General-purpose vector magnetometer
SQUID	10^{-9}–0.1	10^{-4}	dc to 5	Highest sensitivity magnetometer
Hall effect	$0.1–3 \times 10^{4}$	100	dc to 10^{8}	Best for fields above 1 T
Magnetoresistance	10^{-3}–5	10	dc to 10^{7}	Good for midrange applications
Proton precession	0.02–0.1	0.05	dc to 2	General-purpose scalar magnetometer
Optically pumped	0.01–0.1	0.005	dc to 5	Highest-resolution scalar magnetometer

The Hall effect device is the oldest and most common high-field vector sensor used in gaussmeters. It is especially useful for measuring extremely high fields (>1 T). The magnetoresistive sensors cover the middle ground between the low- and high-field sensors. Anisotropic magnetoresistors (AMR) are currently being used in many applications, including magnetometers. The recent discovery of the giant magnetoresistive (GMR) effect, with its 10-fold improvement in sensitivity, promises to be a good competitor for the traditional fluxgate magnetometer in medium-sensitivity applications.

The proton (nuclear) precession magnetometer is the most popular instrument for measuring the scalar magnetic field strength. Its major applications are in geological exploration and aerial mapping of the geomagnetic field. Since its operating principle is based on fundamental atomic constants, it is also used as the primary standard for calibrating magnetometers. The proton precession magnetometer has a very low sampling rate, on the order of one to three samples per second, so it cannot measure fast changes in the magnetic field. The optically pumped magnetometer operates at a higher sampling rate and is capable of higher sensitivities than the proton precession magnetometer, but it is more expensive and not as rugged and reliable.

Table 39.1 lists various magnetic field strength instruments and their characteristics.

39.1 Magnetic Field Fundamentals

An understanding of the nature of magnetic fields is necessary in order to understand the techniques used for measuring magnetic field strength. The most familiar source of a magnetic field is the bar magnet. The field it produces is shown in Figure 39.2. Magnetic field is a vector quantity; that is, it has

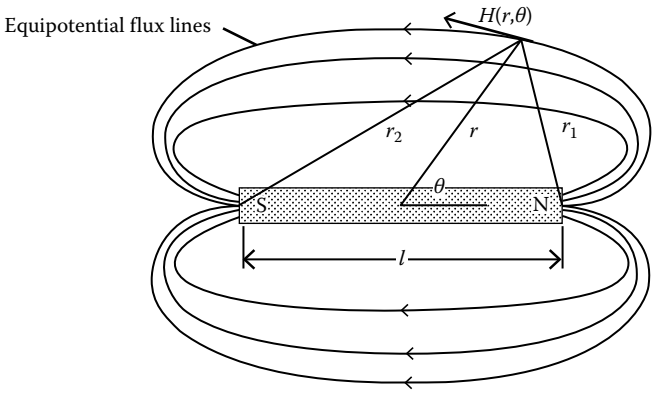

FIGURE 39.2 Magnets produce magnetic fields. A magnetic field is a vector quantity with both magnitude and direction properties.

both a magnitude and a direction. The field of a bar magnet or any other magnetized object, when measured at a distance much greater than its longest dimension, is described by Equation 39.1:

$$\vec{H} = \frac{3(\vec{m} \times \hat{a}_r)\hat{a}_r - \vec{m}}{r^3} \tag{39.1}$$

where

$\hat{a}_r$ is a unit vector along r
r is the distance between the magnetic field source and the measurement point
$\vec{m}$ is called the magnetic dipole moment

The derivation of this equation can be found in many textbooks on electromagnetics. This is a very convenient equation for estimating the field produced by many magnetized objects.

The strength or intensity of a magnetized object depends on the density of its volume-distributed moments. This intensity is called its magnetization M, which is defined as the moments per unit volume:

$$\vec{M} = \frac{\vec{m}}{\text{Volume}} \tag{39.2}$$

Like magnetic field, magnetization is a vector quantity. Magnetization is a material property that can arise from internal magnetic sources as well as be induced by an external magnetic field.

There is a third magnetic vector $\vec{B}$ called magnetic induction or flux density. In free space, magnetic field and magnetic induction are proportional to one another by a constant factor μ_0:

$$\vec{B} = \mu_0 \vec{H} \tag{39.3}$$

Things are different in matter. Equation 39.4 describes the relationship among the magnetic field, magnetic induction, and magnetization vectors in matter:

$$\vec{B} = \mu_0(\vec{H} + \vec{M}) \tag{39.4}$$

In this case, the magnetic induction and the magnetic field vectors do not necessarily have the same direction. Some materials have anisotropic magnetic properties that make these two vectors point in

different directions. The magnetization vector can consist of permanent and induced magnetization components. The permanent magnetization vector does not depend on the presence of an external field. The induced magnetization vector does depend on an external magnetic field and only exists while the inducing field is present.

Magnetic materials can be loosely classified as magnetically "soft" or magnetically "hard." In a magnetically hard material, the permanent magnetization component dominates (a magnet is an example). Magnetization in a soft magnetic material is largely induced and is described by the following equation:

$$\vec{M} = \chi \vec{H} \tag{39.5}$$

where χ is called the material's magnetic susceptibility. In an isotropic material (magnetic properties are not direction dependent), χ is a scalar quantity, and the magnetization and field vectors are proportional and aligned. In anisotropic material (magnetic properties depend on direction), χ is a tensor represented by a 3×3 matrix; therefore, the magnetization vector magnitude and direction depend on the direction and strength of the inducing field. As a result, the magnetization vector will not always align with the magnetization inducing field vectors. Equation 39.5 can be modified for magnetically "soft" material to the following:

$$\vec{B} = \mu_0(1 + \chi)\vec{H} = \mu_0 \mu \vec{H} \tag{39.6}$$

where μ is called the relative permeability of the material.

A magnetized object with a magnetic moment $\vec{m}$ will experience torque $\vec{T}$ in the presence of a uniform magnetic field $\vec{H}$. Equation 39.7 expresses this relationship:

$$\vec{T} = \vec{m} \times \vec{H} \tag{39.7}$$

Torque is the cross-product of the magnetic moment and field vectors. The magnitude equation is

$$T = mH\sin\theta \tag{39.8}$$

where θ is the angle between the direction of $\vec{m}$ and $\vec{H}$.

There is an intimate relationship between electric and magnetic fields. Oersted discovered that passing a current through a wire near a compass causes the compass needle to rotate. The compass was the first magnetic field strength sensor. Faraday found that he could produce an electric voltage at the terminals of a loop of wire if he moved a magnet near it. This led to the induction or search coil sensor.

Magnetic fields are produced by the flow of electric charge (i.e., electric currents). In effect, a magnetic field is a velocity-transformed electric field (through a Lorentz transformation). Current flowing through a straight wire, a loop of wire, or a solenoid will also produce a magnetic field as illustrated in Figure 39.3.

Units are always a problem when dealing with magnetic fields. The Gaussian centimeter, gram, and second (cgs) system of units was favored for many years. Since $\mu_0 = 1$ in the cgs system, magnetic field and flux density have the same numeric value in air, and their units (oersted for field and gauss for flux density) are often indiscriminately interchanged. This has led to great confusion. The cgs system has now been replaced by the International System of Units (SI). The SI system uses, among others, the meter (m), kilogram (kg), second (s), and ampere (A) as the fundamental units. Payne [4] gives a very good explanation of the differences between these systems of units as they relate to magnetic fields. Table 39.2 summarizes the relationships between the two systems of units.

The SI system of units is used throughout this chapter.

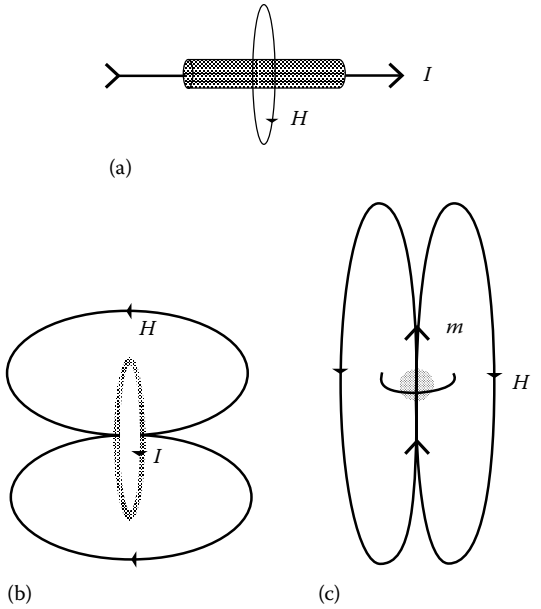

FIGURE 39.3 Magnetic fields are also produced by electric currents: (a) Straight wire, (b) loop of wire, and (c) spinning proton.

TABLE 39.2 Factors for Converting from cgs to SI Magnetic Field Units

Description	Symbol	SI Unit	Gaussian cgs Unit	Multiply By
Magnetic induction	B	Tesla	gauss	10^4
Magnetic field strength	H	A m^{-1}	oersted (oe)	$4\pi \times 10^{-3}$
Magnetization	M	A m^{-1}	emu m^3	10^{-3}
Magnetic dipole moment	m	A m^2	emu	10^3
Magnetic flux	ϕ	Weber (Wb)	maxwell	10^8
Magnetic pole strength	p	A m	emu	
Permeability of free space	μ_0	H m^{-1}	$4\pi \times 10^{-7}$	1

39.2 Low-Field Vector Magnetometers

39.2.1 Induction Coil Magnetometer

The induction or search coil, which is one of the simplest magnetic field sensing devices, is based on Faraday's law. This law states that if a loop of wire is subjected to a changing magnetic flux, ϕ, through the area enclosed by the loop, then a voltage will be induced in the loop that is proportional to the rate of change of the flux:

$$e(t) = -\frac{d\phi}{dt} \tag{39.9}$$

Since magnetic induction $\vec{B}$ is flux density, then a loop with cross-sectional area $\vec{A}$ will have a terminal voltage:

$$e(t) = -\frac{d(\vec{B} \cdot \vec{A})}{dt} \tag{39.10}$$

for spatially uniform magnetic induction fields.

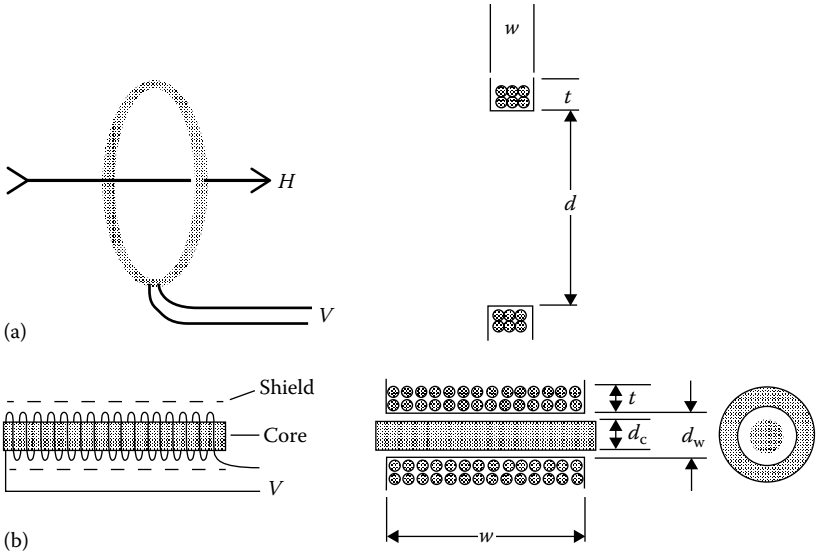

FIGURE 39.4 Induction or search coil sensors consist of a loop of wire (or a solenoid), which may or may not surround a ferromagnetic core: (a) Air-core loop antenna and (b) solenoid induction coil antenna with ferromagnetic core.

Equation 39.10 states that a temporal change in $\vec{B}$ or the mechanical orientation of $\vec{A}$ relative to $\vec{B}$ will produce a terminal voltage. If the coil remains fixed with respect to $\vec{B}$, then static fields cannot be detected, but if the loop is rotated or the magnitude of $\vec{A}$ is changed, then it is possible to measure a static field. The relationship described by Equation 39.10 is exploited in many magnetic field measuring instruments (see [1]).

Figure 39.4 shows the two most common induction coil configurations for measuring field strength: the air-core loop antenna and the rod antenna. The operating principle is the same for both configurations. Substituting $\mu_0\mu_e H(t)$ for B in Equation 39.10 and assuming the loop is stationary with respect to the field vector, the terminal voltage becomes

$$e(t) = -\mu_0\mu_e nA\frac{dH(t)}{dt} \tag{39.11}$$

where

n is the number of turns in the coil

μ_e is the effective relative permeability of the core

The core of a rod antenna is normally constructed of magnetically "soft" material so one can assume that the flux density in the core is induced by an external magnetic field and, therefore, the substitution earlier is valid. With an air (no) core, the effective relative permeability is one. The effective permeability of an induction coil that contains a core is usually much greater than one and is strongly dependent on the shape of the core and, to some extent, on the configuration of the winding.

Taking the Laplace transform of Equation 39.11 and dividing both sides by H, one obtains the following transfer function $T(s)$ for an induction coil antenna:

$$T(s) = -\mu_0\mu_e nAs = -Ks \text{ VmA}^{-1} \tag{39.12}$$

where $E(s) = T(s)\,H(s)$, $E(s)$ and $H(s)$ are the Laplace transforms of e(t) and $H(t)$, and s is the Laplace transform operator. Inspection of Equation 39.12 reveals that the magnitude of the coil voltage is proportional

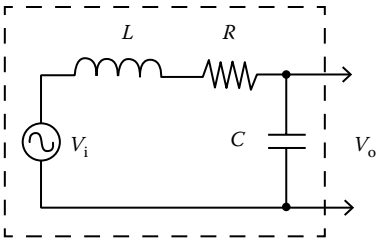

FIGURE 39.5 The induction coil equivalent circuit is a frequency-dependent voltage source in series with an inductor, resistor, and lumped capacitor.

to both the magnitude and frequency of the magnetic field being measured. The coil constant or sensitivity of the loop antenna is

$$K = \mu_0 \mu_e nA \text{ VsmA}^{-1} \tag{39.13}$$

Figure 39.5 is the equivalent circuit for an induction coil antenna. The actual voltage measured at the terminals of the loop is modified by the inductance L, resistance R, and the distributed stray and shield capacitances represented by the lumped capacitor C. These circuit parameters depend on the geometry of the core, coil, and winding.

The electrostatic shield made of nonmagnetic material shown in Figure 39.4 is an important element in the design of an induction coil. It prevents coupling of electric fields into the coil, thereby assuring that the signal seen at the coil terminals is only that due to a magnetic field. The shield should not be placed too close to the winding since it contributes to coil capacitance and noise.

39.2.2 Air-Core Loop Antenna

The air-core loop antenna consists of a circular or rectangular loop containing one or more turns of wire and no magnetic core. The diameter of the loop is usually much greater than the dimensions of the winding cross section. The sensitivity of a circular loop antenna with a winding inside diameter d and rectangular cross section is approximately

$$K = \mu_0 n\pi \frac{d^2}{4}\left[1 + 2\left(\frac{t}{d}\right) + \frac{3}{4}\left(\frac{t}{d}\right)^2\right] \tag{39.14}$$

where

t is the thickness of the winding
n is the number of turns

The resistance of the coil is

$$R = 4n\frac{d}{d_w^2}\left(1 + \frac{t}{d}\right)\rho\,\Omega \tag{39.15}$$

where

d_w is the diameter of the bare wire
ρ is its resistivity in Ω m (1.7×10^{-8} Ω m for copper)

The inductance of the coil is more difficult to compute since it depends heavily on the geometry of the coil. Those who are interested in computing very accurate inductance values for a wide variety of coil

shapes should consult [5]. Equation 39.16 is a general expression that gives a good approximation for the inductance of a circular air-core coil:

$$L = \mu_0 n^2 \pi \left(\frac{\bar{d}}{2}\right)^2 \frac{k}{w} \text{ H} \tag{39.16}$$

where
- w is the width of the winding
- $\bar{d}$ is the average diameter
- k is Nagaoka's constant

$$k = \frac{1}{1 + 0.45(\bar{d}/w) + 0.64(t/\bar{d}) + 0.84(t/w)} \tag{39.17}$$

The distributed capacitance of the coil contributes the most to the overall antenna capacitance. The parasitic capacitances can usually be ignored. Equation 39.18 can be used to estimate the distributed capacitance of a coil:

$$C_\text{d} = \left[\frac{\varepsilon_\text{w}\varepsilon_1}{\varepsilon_\text{w} t_1 + \varepsilon_1 t_\text{w}}\right]\left[\frac{0.018544\,\bar{d}w\,(n_1 - 1)}{n_1^2}\right] \tag{39.18}$$

where
- ε_w is the dielectric constant of the wire insulation
- ε_1 is the dielectric constant of the interlayer insulation if any
- t_w is the thickness of the wire insulation
- t_1 is the thickness of the interlayer insulation
- n_1 is the number of layers

Adding a second layer to a single-layer coil significantly increases the capacitance, but as the number of layers increases, the capacitance decreases.

The air-core loop antenna is particularly useful for measuring magnetic fields with frequencies from 100 Hz to several megahertz. Because it has a linear response to magnetic field strength, it has virtually no intermodulation distortion. On the negative side, the size of the sensor can get quite large for applications that require high sensitivities at low frequencies.

39.2.3 Rod Antenna

The rod antenna is a good alternative to an air-core loop antenna. It is smaller in size than a loop antenna with the same sensitivity, and it can be designed to operate at lower frequencies. Unfortunately, its response to magnetic field strength can be nonlinear and the core adds noise.

Figure 39.4b is a typical configuration for a rod antenna. It is basically a solenoid with a magnetic core. The core can have a circular or rectangular cross section and can be made from a ferrite, a nickel–iron alloy, an amorphous metal glass alloy, or some other material with high relative permeability. The winding can be wound directly on the core or on a form through which the core is inserted. Insulation is sometimes placed between layers of the winding to reduce distributed capacitance. An electrostatic shield is placed around the winding to attenuate any electric field coupling into the signal. The shield has a gap that runs the length of the winding. This prevents circulating currents in the shield from attenuating the magnetic field within the coil.

The most common rod antenna configuration is a core with a circular cross section and a tightly coupled winding that runs most of the length of the core. The sensitivity of the rod antenna is computed by substituting μ_e in Equation 39.13 with the following:

$$\mu_e = 1 + \left(\frac{d_c}{d+t}\right)^2 (\bar{\mu} - 1) \tag{39.19}$$

where

d_c is the core diameter

$\bar{\mu}$ is the core average effective permeability

The core effective or apparent permeability depends on its geometry and initial permeability, as well as the winding length relative to the core length. A rod becomes magnetized when a magnetic field is applied to it. In response, a magnetic field is created within the rod that opposes the externally applied field and reduces the flux density. The demagnetizing field is proportional to the magnetization and the net field H in the core is

$$H = H' - NM \tag{39.20}$$

where

H' is the applied external field

N is the demagnetizing factor

M is the magnetization

The apparent relative permeability of a core is the ratio of the flux density B in the middle of the core to the flux density in air:

$$\frac{B}{\mu_0 H'} = \mu_a = \frac{\mu_i}{1 + N(\mu_i - 1)} \tag{39.21}$$

where μ_i is the initial relative permeability of the core material. Initial relative permeability is the slope of the B–H magnetization curve near-zero applied field for a closed magnetic path.

The value of N is shape dependent. As the length-to-diameter ratio m of a rod increases, N decreases and the apparent relative permeability approaches the initial permeability. Table 39.3, which is

HyMu "80"	4.2 Mo, 80 Ni, 15 Fe	Carpenter	50,000	200,000
2826MB	NiFe-based amorphous alloy	Allied signal	100,000	800,000

Note: μ_i is the slope of the magnetization curve at the origin; μ_{max} is the maximum incremental slope of the magnetization curve.

reproduced from [6], lists demagnetizing factors for a rod, prolate ellipsoid (cigar shape), and oblate ellipsoid (disk shape).

Equation 39.22 can be used to approximate the value of N for cylindrical rods with $m > 10$ and $\mu_i > 1000$:

$$N = \frac{2.01 \times \log_{10} m - 0.46}{m^2} \tag{39.22}$$

The apparent permeability of a rod with a small m and large μ_i is almost exclusively determined by m alone. Table 39.4 lists the magnetic properties of several ferromagnetic materials that can be used to construct a core.

Bozorth [7] found that the apparent permeability of a rod is not constant throughout the length of the rod. It reaches a maximum at the center of the rod and continuously drops in value until the ends of the rod are reached. The variation in permeability can be approximated by

$$\mu(l) = \mu_a \left[1 - F\left(\frac{l}{l_0} \right)^2 \right] \tag{39.23}$$

where

l is the distance from the center of the rod to the measurement point
l_0 is the half length of the rod
F is a constant that varies from 0.72 to 0.96

The average permeability seen by the coil is the integral of Equation 39.23 over the length of the coil:

$$\bar{\mu} = \mu_a \left[1 - F\left(\frac{l_w}{l_c} \right)^2 \right] \tag{39.24}$$

where

l_w is the length of the winding
l_c is the length of the core

Equation 39.24 is substituted into Equation 39.19 to compute the rod's effective relative permeability that is used in Equation 39.13 to compute sensitivity.

The inductance of the rod antenna can be computed using the following equations:

$$L = \frac{\mu_0 \mu_e n^2 \pi (d+t)^2 l_w}{4 l_c} \tag{39.25}$$

$$\mu_e = 1 + \left(\frac{d_c}{d+t}\right)^2 \left[\mu_a f\left(\frac{l_w}{l_c}\right) - 1\right] \tag{39.26}$$

$$f\left(\frac{l_w}{l_c}\right) = 1.9088 - 0.8672\left(\frac{l_w}{l_c}\right) - 1.1217\left(\frac{l_w}{l_c}\right)^2 + 0.8263\left(\frac{l_w}{l_c}\right)^3 \tag{39.27}$$

The function $f(l_w/l_c)$ accounts for the variation in flux density from the middle of the winding to its ends and assumes the winding is centered about the middle of the core.

Equations 39.15 and 39.16 can be used to compute the resistance and capacitance of a rod antenna.

39.2.4 Signal Conditioning

To be useful, the induction coil signal must be conditioned using either a voltage or a current amplifier. Figure 39.6 illustrates the circuit configurations for both of these signal conditioning methods. The voltage amplifier can have either a single-ended or differential input and it can be tuned or untuned. The signal output of the voltage amplifier is proportional to the magnitude and frequency of the field for frequencies well below resonance. Its output will peak at the resonant frequency of the coil or at the tuning frequency. Because its output signal depends on both the frequency and strength of the magnetic field, the voltage amplifier is more suited to narrow band or tuned frequency applications.

In the current amplifier configuration, the induction coil terminals are connected to a virtual ground. As long as the product of the amplifier forward gain and the coil ohmic resistance is much greater than

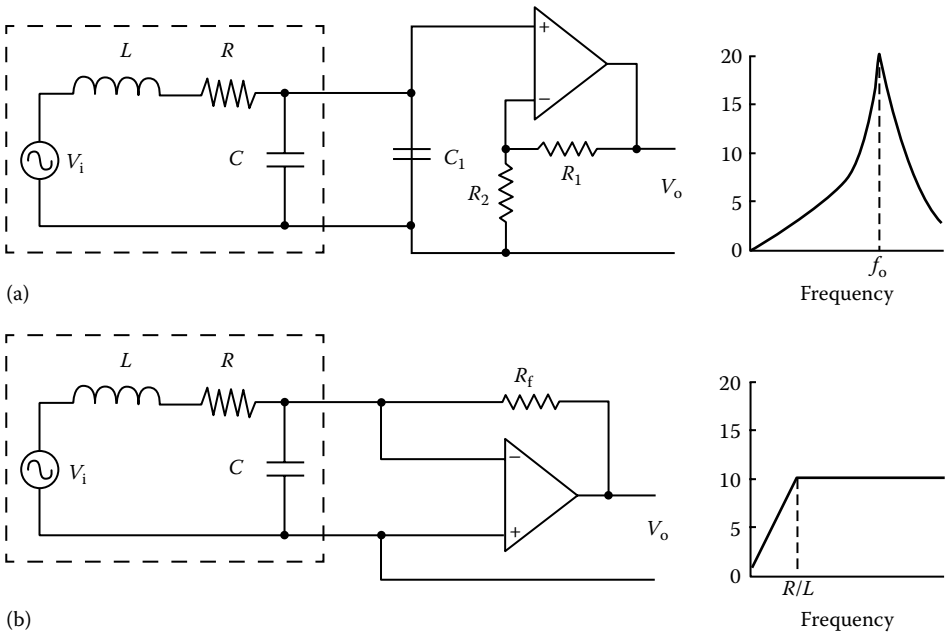

FIGURE 39.6 (a) The amplitude of a voltage-amplified induction coil signal is proportional to the frequency and strength of the field, (b) the amplitude of a current-amplified induction coil signal is only proportional to field strength beyond its L/R corner frequency.

the feedback resistor, the output signal magnitude is independent of the frequency of the magnetic field beyond the R/L (rad s^{-1}) corner of the coil. This remains true up to the coil's resonant frequency. For this reason, the current amplifier configuration is particularly suited to broadband magnetic field strength measurements. The current amplifier configuration minimizes intermodulation distortion in induction coils with magnetic cores. The current flowing through the coil produces a magnetic field that opposes the ambient field. This keeps the net field in the core near zero and in a linear region of the B–H curve.

Current amplifier–based induction coil magnetometers have been built that have a flat frequency response from 10 Hz to over 200 kHz. Some magnetometers designed for geophysical exploration applications have low-frequency corners that extend down to 0.1 Hz. For further information on this subject, refer to [8,9].

39.2.5 Fluxgate Magnetometer

The fluxgate magnetometer has been and is the workhorse of magnetic field strength instruments both on Earth and in space. It is rugged, reliable, physically small, and requires very little power to operate. These characteristics, along with its ability to measure the vector components of magnetic fields over a 0.1 nT^{-1} mT range from dc to several kHz, make it a very versatile instrument. Geologists use them for exploration and geophysicists use them to study the geomagnetic field (about 20–75 μT on Earth's surface). Satellite engineers use them to determine and control the attitude of spacecraft, scientists use them in their research, and the military uses them in many applications, including mine detection, vehicle detection, and target recognition. Some airport security systems use them to detect weapons.

39.2.6 Fluxgate

The heart of the magnetometer is the *fluxgate*. It is the transducer that converts a magnetic field into an electric voltage. There are many different fluxgate configurations. Two of the more popular ones are shown in Figure 39.7. A very comprehensive explanation of the fluxgate principle and the different fluxgate configurations is given in [10].

The ring-core fluxgate is constructed from a thin ribbon of easily saturable ferromagnetic material, such as 4–79 permalloy wrapped around a bobbin to form a ring or toroid. As shown in Figure 39.8, an alternating current is applied through a coil that is wound about the toroid. This creates a magnetic field that circulates around the magnetic core. This magnetic field causes the flux in the ferrous material to periodically saturate first clockwise and then counterclockwise. A pickup (signal) winding is wrapped around the outside of the toroid. While the ferrous material is between saturation extremes, it maintains an average permeability much greater than that of air. When the core is in saturation, the core permeability becomes equal to that of air. If there is no component of magnetic field along the axis of the signal winding, the flux change seen by the winding is zero. If, on the other hand, a field component is present along the signal winding axis, then each time the ferrous material goes from one saturation extreme to the other, the flux within the core will change from a low level to a high level. According to Faraday's law, a changing flux will produce a voltage at the terminals of the signal winding that is proportional to the rate of change of flux. For dc and low-frequency magnetic fields, the signal winding voltage is

$$e(t) = nA\frac{d(\mu_0\mu_e H)}{dt} = nA\mu_0 H\frac{d\mu_e(t)}{dt} \tag{39.28}$$

where

H is the component of the magnetic field being measured
n is the number of turns on the signal winding
A is the cross-sectional area of the signal winding
$\mu_e(t)$ is the effective relative permeability of the core

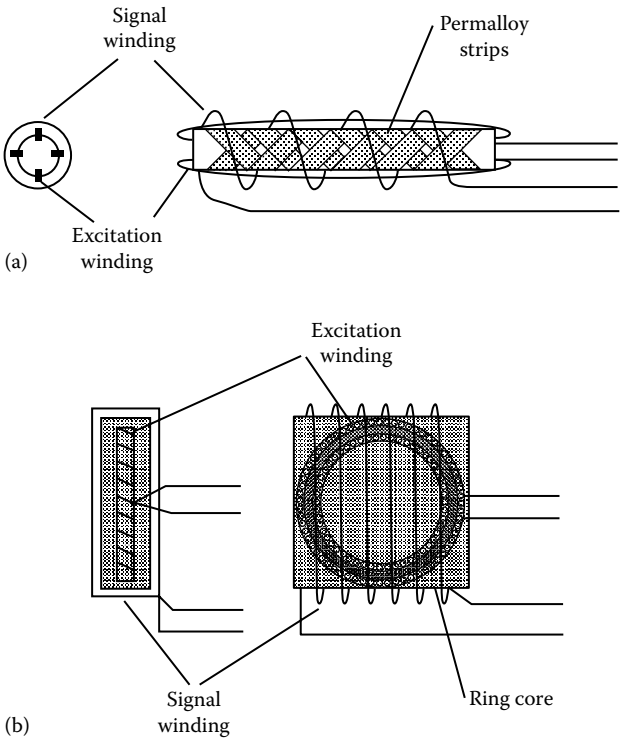

FIGURE 39.7 In Schonstedt (a) and ring-core and (b) fluxgate sensors, the excitation field is at right angles to the signal winding axis. This configuration minimizes coupling between the excitation field and the signal winding.

As the core permeability alternates from a low value to a high value, it produces a voltage pulse at the signal winding output that has amplitude proportional to the magnitude of the external magnetic field and a phase indicating the direction of the field. The frequency of the signal is twice the excitation frequency since the saturation-to-saturation transition occurs twice each excitation period.

The discussion about effective permeability in the induction coil section applies here as well. Readers can consult [10,13,14] for comprehensive discussions about fluxgate effective permeability and signal characteristics as they relate to excitation field levels, excitation waveforms, and winding geometry.

39.2.7 Signal Conditioning

The signal from the fluxgate is an amplitude-modulated suppressed carrier signal that is synchronous with the second harmonic of the excitation signal. In a simple low-power magnetometer, this signal is converted to the base band using a synchronous demodulator, filtered, and presented as the final output. Example circuits are given in [11,12]. The accuracy of magnetometers that use this open-loop architecture is limited by the linearity of the core's magnetization curve and is about 5% for Earth's field (60 μT) applications.

More precise and stable magnetometers use magnetic field feedback rather than the open-loop structure described earlier. A simplified schematic of a typical second harmonic field feedback fluxgate magnetometer is shown in Figure 39.9. The circuitry to the left of the fluxgate is called the excitation circuit. It consists of an oscillator tuned to twice the excitation frequency, a flip-flop that divides the oscillator frequency by two, and a power amplifier driven by the flip-flop and, in turn, provides the excitation current to the excitation winding.

The circuitry to the right of the fluxgate is called the signal channel circuit. It amplifies the output from the fluxgate signal winding, synchronously demodulates the ac signal using the oscillator signal

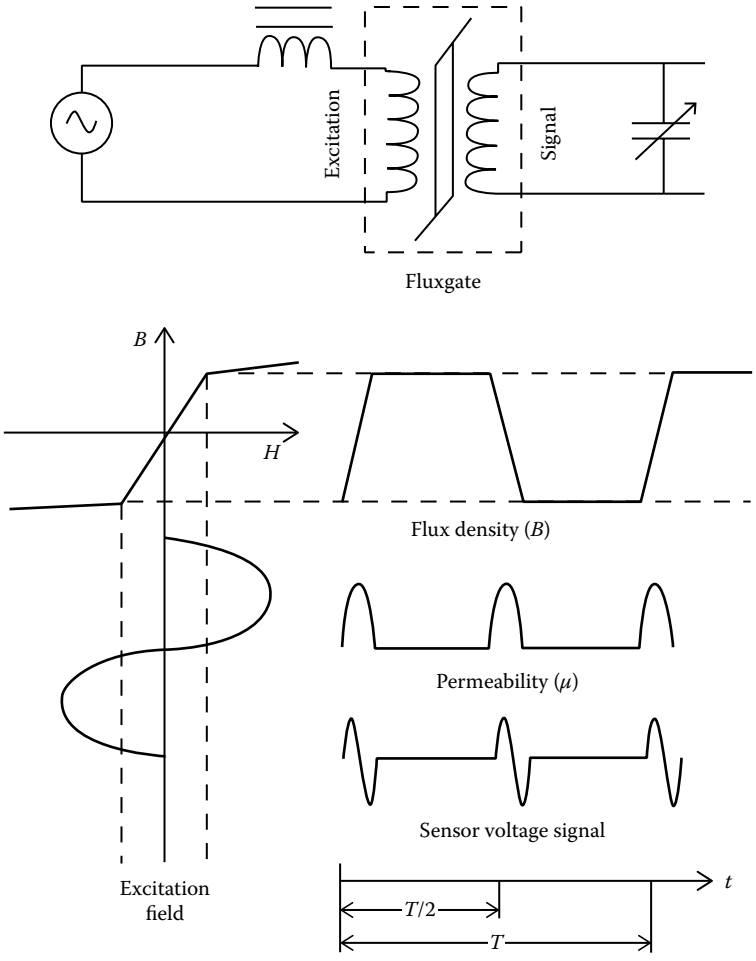

FIGURE 39.8 The excitation field of a fluxgate magnetometer alternately drives the core into positive or negative saturation, causing the core's effective permeability to switch between 1 and a large value twice each cycle.

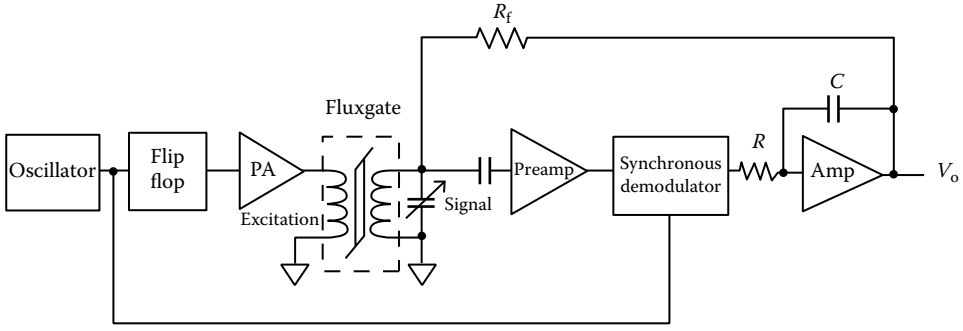

FIGURE 39.9 Typical circuit configurations for a field feedback fluxgate magnetometer. The sensor output is ac amplified, synchronously demodulated, and filtered. A magnetic field that nulls the ambient field at the sensor is produced by connecting the resistor R_f, between the output and the signal winding.

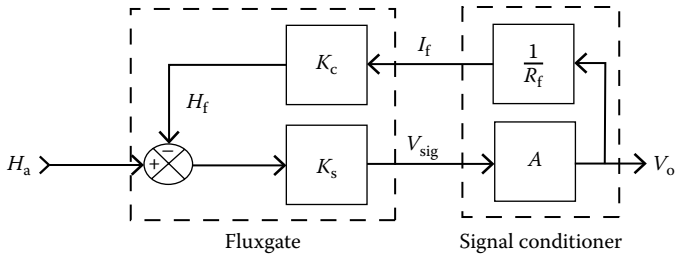

FIGURE 39.10 Block diagram of a field feedback fluxgate magnetometer. K_c is the current-to-field constant for the coil. K_s is the field-to-voltage transduction constant for the sensor. The feedback field H_f opposes the ambient field H_a, thus keeping the net sensor field very small.

as a reference, integrates and amplifies the base band output, and then feeds back the output through a resistor to the signal winding. The feed-back signal produces a magnetic field inside the sensor that opposes the external field. This keeps the field inside the sensor near zero and in a linear portion of the magnetization curve of the ferromagnetic core.

The flow diagram for the magnetometer is given in Figure 39.10. The external field H_a is opposed by the feedback field H_f, and the difference is converted into a voltage signal (K_s represents the transfer function from field to voltage). This signal is amplified (A), and the amplified signal is converted into a current I_f and then into the feedback field (K_c represents the transfer function from current to field). The overall transfer function for the magnetometer is

$$\frac{V_0}{H_a} = \frac{AK_s}{1 + (K_c AK_s / R_f)} \tag{39.29}$$

The amplifier gain is normally very high such that the second term in the denominator is much larger than one, and Equation 39.29 reduces to

$$\frac{V_0}{H_a} = \frac{R_f}{K_c} \tag{39.30}$$

Under these circumstances, the transfer function becomes almost completely determined by the ratio of R_f (the feedback resistor) to K_c (the current-to-field coil constant of the sensor winding). Both of these constants can be very well controlled. The consequence of this circuit topology is a highly stable and accurate magnetometer that is insensitive to circuit component variations with temperature or time. An accuracy of 1% over a temperature range of –80°C to 80°C is easily achievable. Accuracy and stability can be improved using a current feedback circuit, like the one described in [13] that compensates for the resistance of the signal winding or by using a separate feedback winding and a high-quality voltage-to-current converter instead of a simple feedback resistor.

39.2.8 SQUID Magnetometer

Brian D. Josephson in 1962, while a graduate student at Cambridge University, predicted that superconducting current could flow between two superconductors that are separated by a thin insulation layer. The magnitude of the superconductor (critical) current through this "Josephson junction" is affected by the presence of a magnetic field and forms the basis for the SQUID magnetometer.

Magnetometers based on the SQUID are currently the most sensitive instruments available for measuring magnetic field strength. In many cases, SQUID instrumentation offers the ability to make measurements where no other methodology is possible. Sensitivities below 1 fT/√Hz have

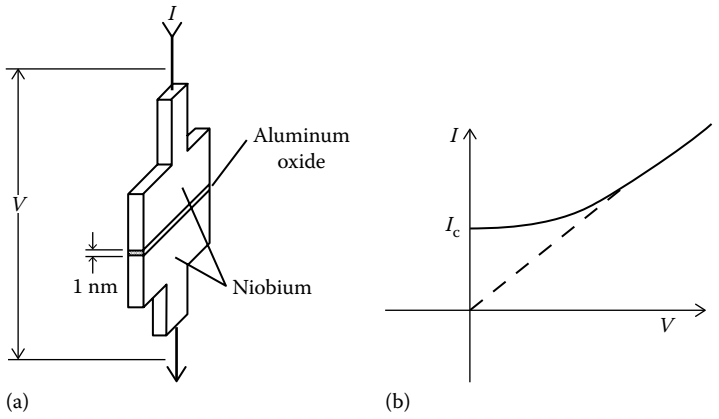

FIGURE 39.11 The Josephson junction in (a) consists of a superconductor such as niobium separated by a thin insulation layer. The voltage (V) versus current (I) curve in (b) shows that a superconducting current flows through the junction with zero volts across the junction.

been achieved. The superconducting nature of SQUID devices allows for flat frequency and phase response from dc to GHz frequencies. Chapters 5 and 14 in this book describe the principles behind SQUID devices and applications including laboratory instrumentation, nondestructive test and evaluation, geophysics, and medicine.

Figure 39.11 illustrates the general structure of a Josephson junction and the voltage–current (V–I) relationship. Two superconductors (e.g., niobium) are separated by a very thin insulating layer (e.g., aluminum oxide). The thickness of this layer is typically 1 nm. When the temperature of the junction is reduced to below 4.2 K (–269°C), a superconductor current will flow in the junction with 0 V across the junction. The magnitude of this current, called the critical current I_c, is a periodic function of the magnetic flux present in the junction. Its maximum magnitude occurs for flux values equal to $n\phi_0$ where ϕ_0 is one flux quantum (2 fW), and its minimum magnitude occurs for flux values equal to $(n + (1/2))\phi_0$. The period is one flux quantum. This phenomenon is called the "dc Josephson effect" and is only one of the "Josephson effects."

Magnetometers based on the SQUID are currently the most sensitive instruments available for measuring magnetic field strength. SQUID magnetometers measure the change in the magnetic field from some arbitrary field level; they do not intrinsically measure the absolute value of the field. Biomedical research is one of the more important applications of SQUID magnetometers. SQUID magnetometers and gradiometers (measure spatial variation in the magnetic field) have the high sensitivities needed to measure the weak magnetic fields generated by the body [15]. Other application areas include paleomagnetics (measuring remanent magnetism in rocks) and magnetotellurics (Earth resistivity measurements). Descriptions of these applications as well as the general theory of SQUIDs can be found in [16]. Clark [17], one of the pioneers in SQUID magnetometers, provides a good contemporary overview of SQUID technology and applications.

A dc SQUID magnetometer uses two Josephson junctions in the two legs of a toroid as shown in Figure 39.12a. The toroid is biased with a constant current that exceeds the maximum critical current of the junctions. When the flux through the toroid is an integral multiple of ϕ_0, the voltage across the junctions is determined by the intersection of I_b and the $n\phi_0$ $V - I$ curve (point A). As the flux increases, the critical current decreases. The V–I curve and thus the intersection point move to the right (the junction voltage increases). The critical current reaches a minimum when the flux has increased by $(1/2)\phi_0$ and the junction voltage is at its maximum (point B). As the flux continues to increase, the critical current increases back toward its maximum value and the junction voltage decreases. Thus, the period of the flux cycle is ϕ_0.

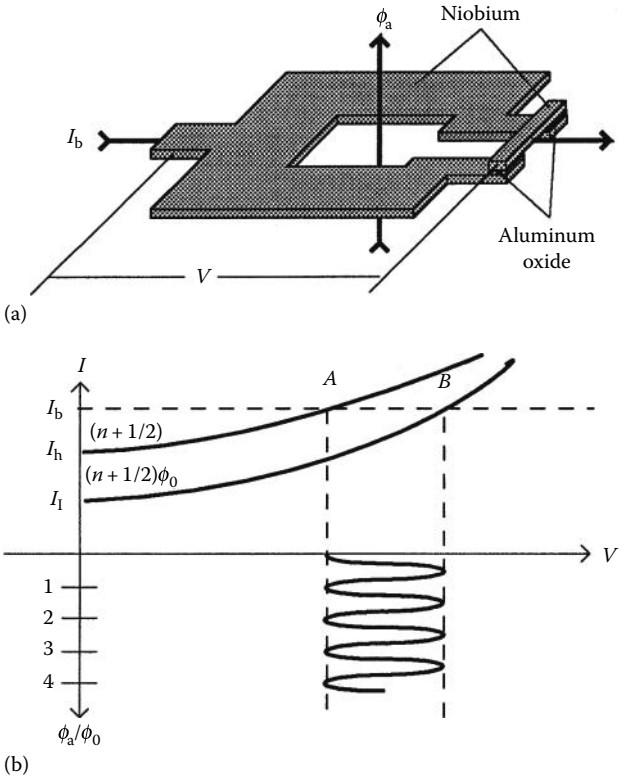

FIGURE 39.12 Use of a dc SQUID to measure magnetic flux. The dc SQUID in (a) consists of a superconductor loop and two Josephson junctions with a bias current that is greater than the maximum critical current I_h. The V–I curve in (b) illustrates how the voltage across the SQUID oscillates with a period equal to one flux quantum φ_0.

39.2.9 Signal Conditioning

Figure 39.13 is a block diagram of one implementation of a dc SQUID magnetometer that can be used for wide dynamic range field measurements. A large superconducting loop, which is exposed to the magnetic field being measured, is connected to a multiturn signal winding that is magnetically coupled directly to the SQUID. At cryogenic temperatures, the loop and signal winding effectively form a dc induction coil. External flux applied to the coil will generate a current in the loop that keeps the net flux within the loop constant, even for dc magnetic fields. The signal winding magnifies the flux that is applied to the SQUID.

The SQUID is magnetically biased at an optimal sensitivity point. A small ac magnetic field at 100–500 kHz is superimposed on the bias field. The output of the SQUID is a suppressed carrier amplitude-modulated signal where the amplitude indicates the change in magnetic field from the bias point, and the phase indicates the polarity of the change. The output signal is amplified and then synchronously demodulated down to the base band. The resulting dc signal is amplified and feed back through a resistor to a coil coupled to the SQUID. The current through the coil generates a magnetic field at the SQUID that opposes the applied field. This keeps the SQUID operating point very near the bias point. The scale factor of the magnetometer depends on the feedback resistor and the coil constant of the feedback winding in the same manner that it does for a field feedback fluxgate magnetometer.

The pickup loop, signal coil, SQUID, feedback coil, and feedback resistor are kept in a cryogenic temperature chamber and, except for the pickup coil, are magnetically shielded. The rest of the circuit is operated at room temperature.

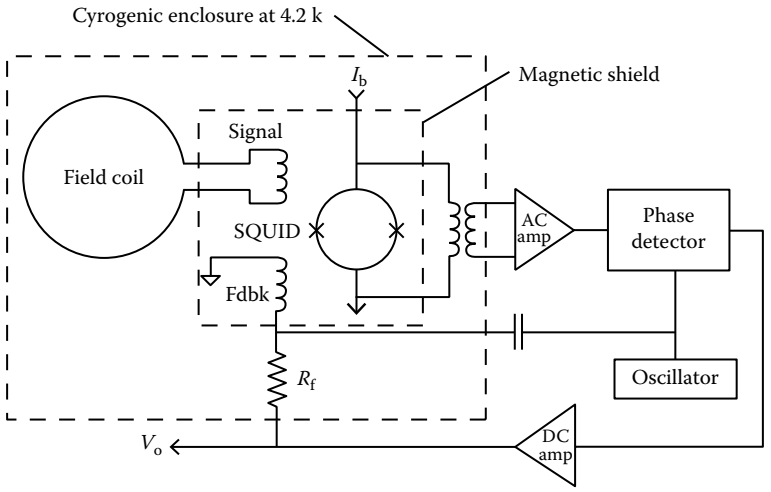

FIGURE 39.13 Wide dynamic range dc SQUID magnetometer. A magnetic field produced by connecting resistor R_f between the output and a feedback coil keeps the field in the SQUID within one flux quantum over its operating range. (Adapted from Wellstood, F. et al., *Rev. Sci. Instrum.*, 66, 952, 1984.)

39.3 High-Field Vector Gaussmeters

39.3.1 Hall Effect Gaussmeter

The Hall effect device, which is probably the most familiar and widely used sensor for measuring strong magnetic fields, is based on the discovery of the Hall effect by Edwin H. Hall in 1897. The Hall effect is a consequence of the Lorentz force law, which states that a moving charge q, when acted upon by a magnetic induction field $\vec{B}$, will experience a force $\vec{F}$ that is at right angles to the field vector and the velocity vector v of the charge as expressed by the following equation:

$$\vec{F} = -q(\vec{B} + \vec{v} \times \vec{B}) \tag{39.31}$$

The Hall effect device consists of a flat, thin rectangular conductor or semiconductor with two pairs of electrodes at right angles to one another as illustrated in Figure 39.14. An electric field E_x is applied along the x or control axis. When a magnetic field B_z is applied perpendicular to the surface of the device, the free charge, which is flowing along the x-axis as a result of E_x, will be deflected toward the y or Hall voltage axis.

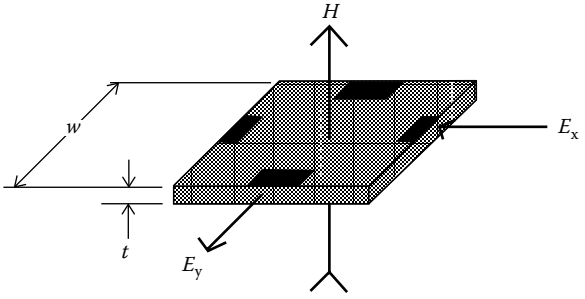

FIGURE 39.14 Hall effect sensor. A magnetic field H applied normal to the surface of the sensor, which is conducting current along the x-direction, will generate a voltage along the y-direction. E_x is the applied electric field along the x-direction, and E_y is the Hall effect electric field along the y-direction.

Since current cannot flow in the y-axis under open-loop conditions, this will cause a buildup of charge along the y-axis that will create an electric field that produces a force opposing the motion of the charge:

$$E_y = v_x B_z \tag{39.32}$$

where v_x is the average drift velocity of the electrons (or majority carriers). In a conductor that contains n free charges per unit volume having an average drift velocity of v_x, the current density is

$$J_x = qnv_x \tag{39.33}$$

and

$$E_y = \frac{J_x B_z}{qn} = R_H J_x B_z \tag{39.34}$$

where R_H is called the Hall coefficient.

A semiconductor is treated in terms of the mobility μ (drift velocity/field) of the majority carrier (electron or hole) and conductivity σ. In this case,

$$E_y = \mu E_x B_z \quad \text{and} \quad E_x = \frac{J_x}{\sigma} \tag{39.35}$$

Therefore,

$$E_y = \frac{\mu}{\sigma} J_x B_z \quad \text{and} \quad R_H = \frac{\mu}{\sigma} \tag{39.36}$$

The value of R_H varies substantially from one material to another and is both temperature and field magnitude dependent. Its characteristics can be controlled to a certain extent by doping the base material with some impurities. For example, doping germanium with arsenic can reduce the temperature dependence at the expense of magnitude.

The voltage measured across the y-axis terminals is the integral of the electric field along the y-axis. If a constant control current I is flowing along the x-axis, then

$$J_x = \frac{I}{wt} \tag{39.37}$$

and the measured output voltage is

$$e_y = \frac{R_H I B_z}{t} \tag{39.38}$$

where

t is thickness (m)

w is the distance between the y-axis terminals

Another characteristic specified by manufacturers of Hall effect devices is the magnetic sensitivity γ_b at the rated control current I_c:

$$\gamma_b = \frac{e_y}{B_z} = \frac{R_H I_c}{t} \tag{39.39}$$

Although conductors such as copper (Cu) can be used to make a Hall effect device, semiconductor materials, such as gallium arsenide (GaAs), indium antimonide (InSb), and indium arsenide (InAs), produce the highest and most stable Hall coefficients. InAs, because of its combined low temperature coefficient

of sensitivity (<0.1%/°C), low resistance, and relatively good sensitivity, is the material favored by commercial manufacturers of Hall effect devices.

The typical control current for Hall effect devices is 100 mA, but some do operate at currents as low as 1 mA. Sensitivities range from 10 mV/T to 1.4 V/T. Linearity ranges from 1/4% to 2% over their rated operating field range. The control input and the voltage output resistance are typically in the range of 1–3 Ω. The sensor element is usually tiny (on the order of 10 mm square by 0.5 mm thick), and a three-axis version can be housed in a very small package. These devices are most effective for measuring flux densities ranging from 50 μT to 30 T.

39.3.2 Signal Conditioning

A simple Hall effect gaussmeter can be constructed using the signal conditioning circuit shown in Figure 39.15. The voltage reference, operational amplifier, and sense resistor R_s form a precision constant-current source for the Hall effect device control current I_c. For best performance, the voltage reference and R_s, should be very stable with temperature and time. A general-purpose operational amplifier can be used for low control currents. A power amplifier is required for control currents above 20 mA.

The Hall voltage can be conditioned and amplified by any high input impedance (>1 kΩ) differential amplifier. A precision instrumentation amplifier is a good choice because it has adequate input impedance, its gain can be determined by a stable resistor, and the amplifier zero offset trim resistors can be used to cancel the zero offset of the Hall effect device. Some devices require a load resistor across the Hall voltage terminal to achieve optimum linearity.

The zero offset and 1/*f* noise of the Hall voltage amplifier limit the performance of a Hall effect gaussmeter for low-field strength measurements. Sometimes, these effects can be reduced by using an ac precision current source. The ac amplitude-modulated Hall voltage can then be amplified in a more favorable frequency band and synchronously detected to extract the Hall voltage signal. If the field to be measured requires this amount of signal conditioning, it probably is better to use a fluxgate magnetometer for the application.

39.3.3 Magnetoresistive Gaussmeter

The magnetoresistance effect was first reported by William Thomson (Lord Kelvin) in the middle of the nineteenth century. He found that a magnetic field applied to a ferromagnetic material caused its resistivity to change. The amount of change depends on the magnetization magnitude and the direction in which the current used to measure resistivity is flowing. Nickel–iron alloys show the greatest change

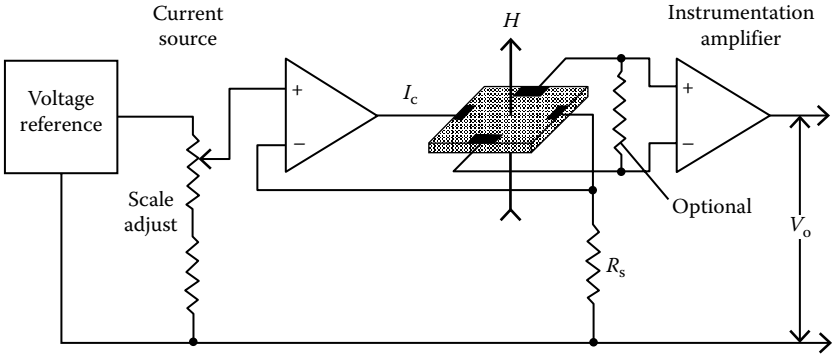

FIGURE 39.15 Example of how to construct a Hall effect gaussmeter. The operational amplifier and resistor R_s form a stable constant-current source for the Hall effect sensor. An instrumentation or differential amplifier amplifies and scales the Hall voltage. A load resistor is sometimes required across the Hall voltage output terminals.

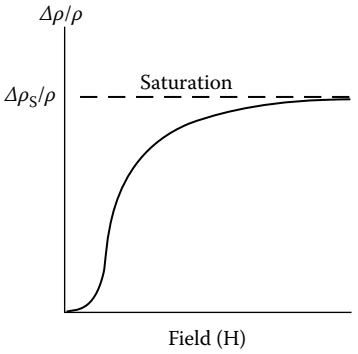

FIGURE 39.16 Change in resistivity in a ferromagnetic material. As field is applied, the resistivity changes rapidly at first. As the material approaches magnetic flux saturation, the resistivity change approaches its maximum value.

in resistivity (about 5% maximum). Figure 39.16 illustrates how the resistivity changes in permalloy (a nickel–iron alloy) for a field applied parallel to the current flow. As magnetic field is increased, the change in resistivity increases and asymptotically approaches its maximum value when the material approaches saturation. Bozorth [6] points out that the shape of the curve and the magnitude of the change depend on the composition of the alloy. Permalloy with 80% Ni and 20% Fe provides a high magnetoresistance effect with near-zero magnetostriction and is a favorite material for magnetoresistors.

The change in resistivity in permalloy film [18] is also a function of the angle θ between the magnetization direction and the current direction:

$$\rho(\theta) = \rho_0 + \Delta\rho_m \cos^2\theta \tag{39.40}$$

where

$\Delta\rho_m$ is the magnetoresistivity anisotropy change
ρ_0 is the resistivity for $\theta = \pi/2$

It was mentioned earlier that magnetic materials have anisotropic magnetic properties (their magnetic properties are direction dependent). The physical shape of an object (see the discussion on demagnetizing factor earlier) and the conditions that exist during fabrication strongly determine its anisotropic characteristics. A thin long film of permalloy can be made to have highly uniaxial anisotropic properties if it is exposed to a magnetizing field during deposition. This characteristic is exploited in the anisotropic magnetoresistance (AMR) sensor.

The basic resistor element in an AMR is a thin rectangular shaped film as shown in Figure 39.17. One axis, called the anisotropy or easy axis, has a much higher susceptibility to magnetization than

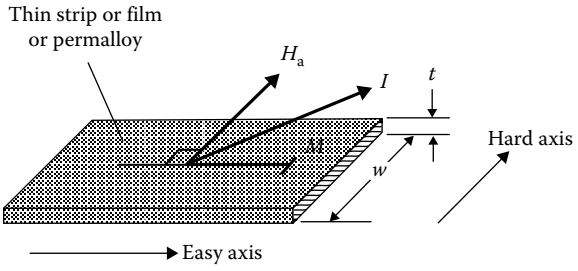

FIGURE 39.17 An AMR resistor element. During fabrication, a magnetic field is applied along the strip's length to magnetize it and establish its easy axis. Current I is passed through the film at 45° to the easy or anisotropic axis. A magnetic field H_a applied at right angles to the magnetization vector M causes the magnetization vector to rotate and the magnetoresistance to change.

the other two. The easy axis is normally along the length of the film. Because of its thinness, the axis normal to the film has virtually no magnetic susceptibility. The axis transverse to the easy axis (across the width) has very little susceptibility as well.

A bias field H_b is used to saturate the magnetization along the easy axis and establish the magnetization direction for zero external fields. For a simplified analysis, the film can be modeled as a single domain.

The effect of an external field in the plane of the film and normal to the anisotropy axis is to rotate the magnetization vector and, according to Equation 39.40, change the resistivity. Kwiatkowski and Tumanski [19] stated that the change in resistance of the film can be approximated by Equation 39.41:

$$\Delta R \approx R_s \frac{\Delta\rho_m}{\rho}\left(h_a^2\cos 2\theta + h_a\sqrt{1-h_a^2}\,\sin 2\theta - \frac{1}{2}\cos 2\theta\right) \tag{39.41}$$

where

h_a is the normalized externally applied field (i.e., $h_a = H_a/H_k$)
R_s is the nominal resistance
$\Delta\rho_m/\rho$ is the maximum resistivity change

H_k is the anisotropy field. Optimum linear performance is obtained when $\theta = \pi/4$ and Equation 39.41 reduces to

$$\Delta R \approx R_s \frac{\Delta\rho_m}{\rho}\frac{1}{H_k + H_b}H_a \tag{39.42}$$

The anisotropy field is given by

$$H_k = \sqrt{H_{k0}^2 + (NM_s)^2} \tag{39.43}$$

where

H_{k0} is the film anisotropy field
N is the demagnetizing factor (≈ thickness(t)/width(w))
M_s is the saturation magnetization

An AMR is constructed using long thin film segments of deposited permalloy. During deposition, a magnetic field is applied along the length of the film to establish its easy axis of magnetization. The shape of the film also favors the length as an easy axis. As shown in Figure 39.18, a series of these permalloy films is connected together to form the magnetoresistor. The current is forced to flow at a 45° angle to the easy axis by depositing thin strips of highly conductive material (e.g., gold) across the permalloy film. The level of magnetization of the film is controlled by a bias field that is created through the deposition of a thin layer of cobalt over the resistors, which is then magnetized parallel to the easy axis of the permalloy.

A typical AMR sensor suitable for a gaussmeter or magnetometer consists of four AMRs connected in a Wheatstone bridge as shown in Figure 39.19. The transfer function polarity of the *A* and *D* resistors is made to be opposite that of the *B* and *C* resistors by rotating the current shunt 90°. This complimentary arrangement enhances the output voltage signal for a given field by a factor of four over a single resistor. Kwiatkowski and Tumanski [19] showed that the transfer function for the bridge configuration is described by

$$v = IR_s\frac{\Delta\rho_m}{\rho}\cos 2\Delta\varepsilon h_a\sqrt{1-h_a^2} \tag{39.44}$$

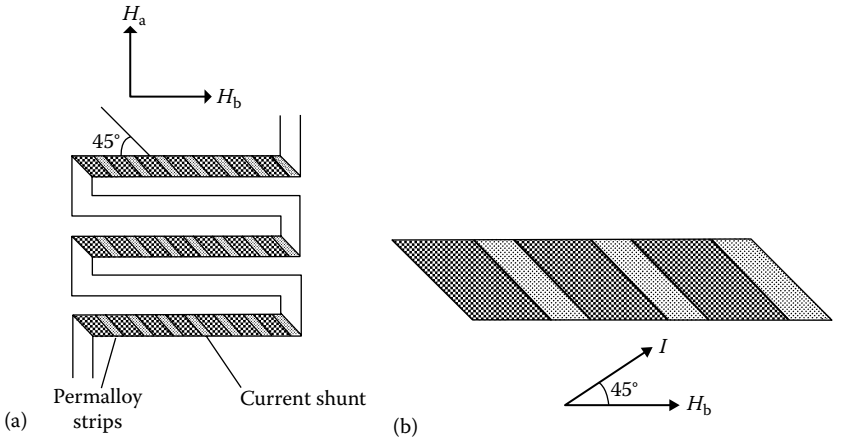

FIGURE 39.18 Magnetoresistor construction: (a) A typical AMR element consists of multiple strips of permalloy connected together in a serpentine pattern. Current shunts force the current to flow through the permalloy at 45° to the easy axis, and (b) a close-up view.

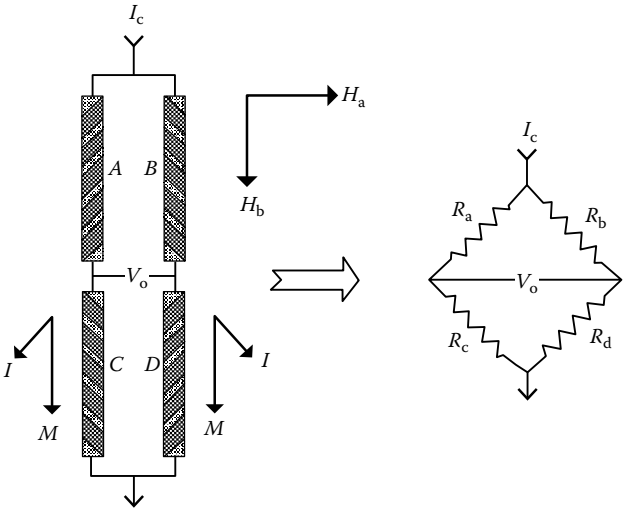

FIGURE 39.19 AMR bridge sensor. In an AMR bridge, the current shunts of resistors *A* and *D* are the same and reversed from *B* and *C*. Thus, the resistors on diagonal legs of the bridge have the same response to an applied field and opposite that of the other diagonal pair. Bridge leg resistance varies from 1 to 100 kΩ.

where

$$\cos 2\Delta\varepsilon = \frac{H_{k0}^2 + H_k^2 - (NM_s)^2}{2H_{k0}H_k} \tag{39.45}$$

$$h_a = \frac{H_a}{H_k + H_b} \tag{39.46}$$

For best linearity, $H_a < 0.1\ H_k$. The linearity of the bridge can be controlled during fabrication by adjusting the *l*/*w* ratio and H_{k0}. The bias field can also be used to optimize linearity and establish the measurement field range. Some transfer functions for a typical AMR bridge [20] are shown in Figure 39.20. A more comprehensive discussion of AMR theory can be found in [21–23].

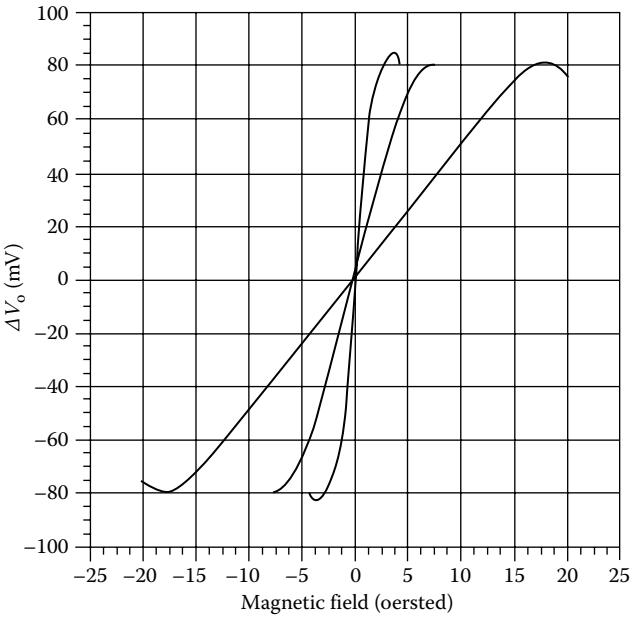

FIGURE 39.20 Typical AMR bridge sensor transfer functions. The sensitivity of an AMR bridge can be adjusted by changing its bias field. Increases in sensitivity are accompanied by corresponding decreases in range.

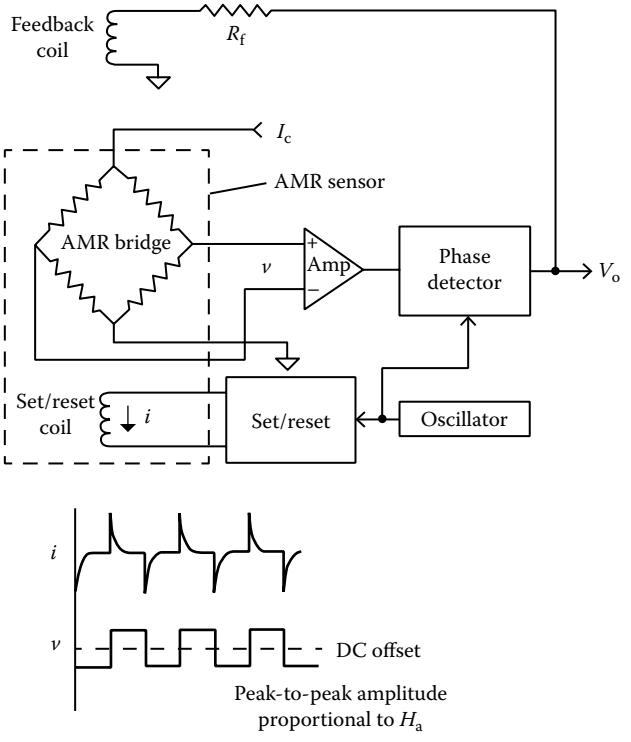

FIGURE 39.21 Example AMR gaussmeter. The magnetization direction can be alternately flipped to eliminate zero offset. The resulting ac signal can then be amplified and synchronously phase detected to recover the field-related signal. Optionally, the range and stability of the AMR gaussmeter can be increased by connecting the output voltage through a resistor to a feedback coil that produces a field that nulls the applied field.

39.3.4 Signal Conditioning

Conventional Wheatstone bridge signal conditioning circuits can be used to process the AMR bridge. The bridge sensitivity and zero offset are proportional to the bridge voltage, so it is important to use a well-regulated supply with low noise and good temperature stability.

As Equation 39.44 shows, the polarity of the transfer function is determined by the polarity of $(H_k + H_b)$. If the sensor is exposed to an external field that is strong enough to reverse this field, then the transfer function polarity will reverse. To overcome this ambiguity, the polarity should be established prior to making a measurement. This can be accomplished by momentarily applying a strong magnetic field along the easy axis of the AMR bridge. Some commercial AMR bridges come with a built-in method for performing this action.

Figure 39.21 is a block diagram for a signal conditioner that takes advantage of the bias field polarity flipping property to eliminate zero offset errors and low-frequency $1/f$ noise. A square wave oscillator is used to alternately change the direction of the bias field and thus the polarity of the transfer function. The duration of the current used to set the bias field direction should be short in order to minimize power consumption. The amplitude of the ac signal from the bridge is proportional to the field magnitude, and its phase relative to the oscillator gives the field direction. This signal can be amplified and then phase detected to extract the field-related voltage. Optionally, the output signal can be fed back through a coil that produces a magnetic field opposing the field being measured. This feedback arrangement makes the AMR bridge a null detector and minimizes the influence of changes in its transfer function on overall performance. Of course, the added circuitry increases the size, cost, and complexity of the instrument.

39.4 Scalar Magnetometers

Scalar magnetometers measure the magnitude of the magnetic field vector by exploiting the atomic and nuclear properties of matter. The two most widely used scalar magnetometers are the proton precession and the optically pumped magnetometer. When operated under the right conditions, these instruments have extremely high resolution and accuracy and are relatively insensitive to orientation. They both have several common operating limitations. The instruments require the magnetic field to be uniform throughout the sensing element volume. They have a limited magnetic field magnitude measurement range: typically 20–100 μT. And they have limitations with respect to the orientation of the magnetic field vector relative to the sensor element.

The proton precession magnetometer uses a strong magnetic field to polarize the protons in a hydrocarbon and then detects the precession frequency of the protons while they decay to the nonpolarized state after the polarizing field is turned off. The precession frequency is proportional to the magnitude of any ambient magnetic field that is present after the polarizing field is removed. This sampling of the magnetic field strength through the polarize-listen sequence makes the proton precession magnetometer response very slow. Maximum rates of only a few samples per second are typical. Because of its dependence on atomic constants, the proton precession magnetometer is the primary standard for calibrating systems used to generate magnetic fields and calibrate magnetometers.

The optically pumped magnetometer is based on the Zeeman effect. Zeeman discovered that applying a field to atoms, which are emitting or absorbing light, will cause the spectral lines of the atoms to split into a set of new spectral lines that are much closer together than the normal lines. The energy-related frequency interval between these hyperfine lines is proportional to the magnitude of the applied field. These energy levels represent the only possible energy states that an atom can possess. The optically pumped magnetometer exploits this characteristic by optically stimulating atoms to produce an overpopulated energy state in one of the hyperfine spectral lines and then causing the energy state to depopulate using a radio frequency (RF) magnetic field. The RF required to depopulate the energy state is equal to the spectral difference of the hyperfine lines produced by a magnetic field

and, therefore, is proportional to the magnetic field strength. The optically pumped magnetometer can be used to sample the magnetic field at a much higher rate than the proton precession magnetometer and generally can achieve a higher resolution. The sample rate and instrument resolution are interdependent.

39.4.1 Proton Precession Magnetometer

The proton precession magnetometer works on the principle that a spinning nucleus, which has both angular momentum $\vec{L}$ and a magnetic moment $\vec{\mu}_p$, will precess about a magnetic field like a gyroscope, as shown in Figure 39.22. The precession frequency ω_ρ is proportional to the applied field. When the magnetic field $\vec{H}_a$ is applied to the nucleus, it will produce a torque:

$$\vec{T} = \vec{\mu}_\rho \times \vec{H}_a \tag{39.47}$$

on the nucleus. Because the nucleus has angular momentum, this torque will cause the nucleus to precess about the direction of the field. At equilibrium, the relationship between the torque, precession rate, and angular momentum is

$$\mu_\rho \times \vec{H}_a = \vec{\omega}_\rho \times \vec{L} \tag{39.48}$$

Solving for the magnitude of the (Larmor) precession frequency, one finds that

$$\omega_\rho = \left(\frac{\mu_\rho}{L}\right) H_a = \gamma H_a \tag{39.49}$$

where γ is called the gyromagnetic ratio and equals $(2.6751526 \pm 0.0000008) \times 10^{-8}$ T^{-1} s^{-1}.

Figure 39.23 is a block diagram of a proton precession magnetometer. The sensor is a container of hydrocarbon rich in free hydrogen nuclei. A solenoid wrapped around the container is used to both polarize the nuclei and detect the precession caused by the ambient field. Before the polarizing field is applied, the magnetic moments of the nuclei are randomly oriented, and the net magnetization is zero. Application of the polarizing field (typically 3–10 mT) causes the nuclei to precess about the field. The precession axis can be parallel or antiparallel (nuclear magnetic moment pointing in the direction of the field) to the applied field. From a quantum mechanical standpoint, the antiparallel state is a lower energy level than the parallel state. In the absence of thermal agitation, which causes collisions between atoms, the fluid would remain unmagnetized. When a collision occurs, the parallel precession-axis nuclei lose energy and switch to the antiparallel state. After a short time, there are more nuclei with magnetic

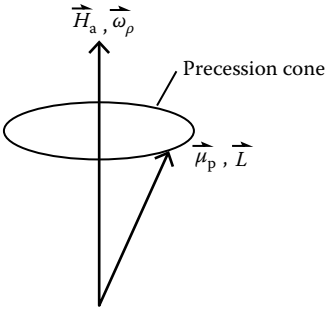

FIGURE 39.22 Nuclear precession. A spinning proton with angular momentum L and magnetic moment μ_ρ, when subjected to a magnetic field H_a, will precess about the field at an angular rate ω_ρ equal to $\mu_\rho H_a/L$.

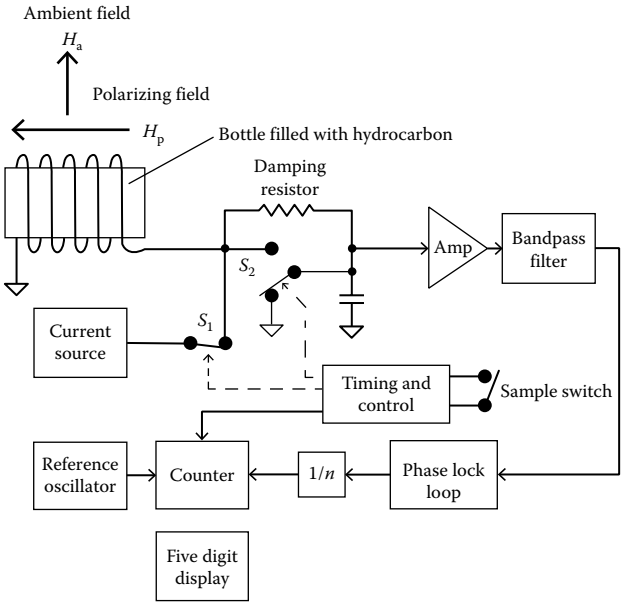

FIGURE 39.23 Typical proton precession magnetometer. A polarizing field is applied to the hydrocarbon when *S*1 is closed. The amplifier input is shorted to prevent switching transients from overdriving it. After a few seconds, *S*1 is opened and the coil is connected to the signal processor to measure the Larmor frequency.

moments pointing in the direction of the field than away from it, and the fluid reaches an equilibrium magnetization M_0. The equation that relates magnetization buildup to time is

$$M(t) = M_0(1 - e^{-t/\tau_e}) \tag{39.50}$$

where τ_e is the spin–lattice relaxation time.

The equilibrium magnetization is based on thermodynamic considerations. From Boltzmann statistics for a system with spins of 1/2,

$$\frac{n_p}{n_a} = e^{2\mu_\rho H_a/kT} \tag{39.51}$$

where

n_p is the number of precession spin axes parallel to H_a
n_a is the number of precession spin axes antiparallel to H_a
k is Boltzmann's constant
T is temperature (kelvin)

If n is the number of magnetic moments per unit volume, then

$$n = n_p + n_a = n_a(1 + e^{2\mu_\rho H_a/kT}) \tag{39.52}$$

and

$$M_0 = (n_p - n_a)\mu_\rho \approx \frac{n\mu_\rho^2 H_a}{kT} \tag{39.53}$$

Once the fluid has reached equilibrium magnetization, the field is removed and the nuclei are allowed to precess about the local ambient field until they become randomized again. This process of excitation–relaxation can take as long as several seconds.

The hydrocarbon spin–lattice relaxation time can be adjusted by mixing paramagnetic salts, such as ferrous nitrate, into the solution. The trade-off in reduced relaxation time is increased signal-to-noise and resolution. Benzene is a good general-purpose hydrocarbon that can be used in a proton precession magnetometer.

39.4.2 Signal Conditioning

The block diagram shown in Figure 39.23 is an example of the signal conditioning required for a proton precession magnetometer. The coil surrounding the bottle containing the hydrocarbon serves two purposes. At the beginning of a measurement, the current source is connected to the coil to generate the magnetic field that polarizes the fluid. This field is on the order of 10 mT. After a few seconds, the current source is disconnected and the coil, which now has a decaying nuclear precession signal at its output, is connected to the input of the amplifier. The signal is amplified and filtered and then the period of the Larmor frequency is measured, averaged, scaled, and presented to the user in magnetic field units on a digital display.

The scale factor of the proton precession magnetometer is based on the gyromagnetic ratio, which is 0.042579 Hz nT^{-1}. High resolution, up to 0.01 nT, is achieved by measuring the period of the signal rather than the frequency. The signal frequency can be divided down and used to gate a high-frequency oscillator that is driving a counter.

The sampling of the field is controlled manually in many commercially available proton precession magnetometers. Some magnetometers have an internally controlled sample rate. The sample rate and resolution are inversely related to one another. A higher sample rate produces a poorer resolution.

39.4.3 Optically Pumped Magnetometer

As explained earlier, the optically pumped magnetometer is based on the Zeeman effect. This effect is most pronounced in alkaline vapors (rubidium, lithium, cesium, sodium, and potassium). Figure 39.24 is the hyperfine spectral structure for the valence electrons of rubidium (Rb) 85, which is commonly used in these types of magnetometers. The energy-related frequency interval between these hyperfine lines is proportional to the applied field. The magnetic quantum number m is related to the angular momentum number and specifies the possible component magnitude of the magnetic moment along the applied field. The optically pumped magnetometer takes advantage of this characteristic.

Transitions occur between levels of different m values and obey the rule that the change in m can only have the values 0, 1, and –1. Table 39.5 lists the relationship between the polarization of the light stimulating the transition and the allowable change in m.

When not optically excited, the energy states of the valence electrons will be distributed according to Boltzmann statistics and will be in a state of equilibrium. If the electrons are excited with circularly polarized light at the $D1$ frequency (794.8 nm wavelength), they will absorb photons and transition from the $^2S_{1/2}$ state to the $^2P_{1/2}$ state according to the transition rules. The excited electrons will then fall back in a random fashion to the lower states, being distributed with an equal probability among all the m states.

But the rules state that the change in m can only be 1 or –1 for polarized light. If one uses right circularly polarized light, then the change in m can only be 1, and the electrons in the $m = 3$ level of the $^2S_{1/2}$ state cannot transition since there is no $m = 4$ level at the $^2P_{1/2}$ state. Therefore, these electrons remain in the $m = 3$ state. All other electrons transition to the higher state and then fall back to the lower state with equal probability of arriving at any of the m levels, including $m = 3$. Thus, the $m = 3$ level fills up,

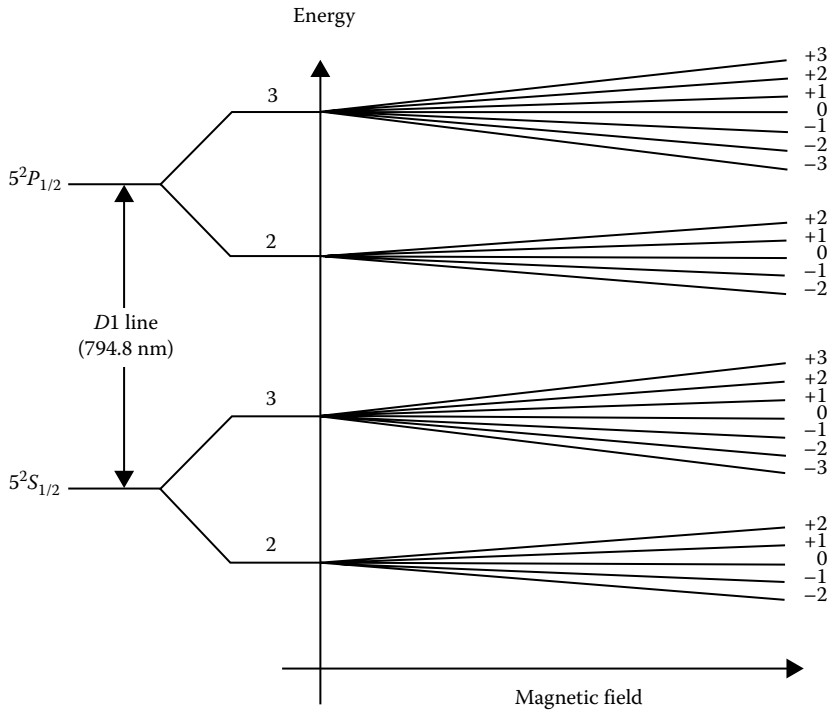

FIGURE 39.24 Rb-85 energy diagram. When a magnetic field is applied, the energy levels split into Zeeman sublevels that diverge as the field increases. Quantum mechanical factors determine the number of sublevels at each primary energy level.

TABLE 39.5 Allowable Change in *m* when Jumping from One Energy Level to Another Depends on the Polarization of the Light Causing the Transition

Polarization	*M*
Left circular	−1
Parallel	0
Right circular	1

and the other levels empty until all the electrons are in the $m = 3$ level, and no more transitions to the higher state can take place and pumping stops.

When pumping begins, the vapor is opaque. As time goes on, fewer electrons are available for absorbing photons, and the vapor becomes more transparent until, finally, pumping action stops and the vapor is completely transparent.

If a small RF magnetic field at the Larmor frequency is applied at right angles to the magnetic field being measured, the electrons in the $m = 3$ state will be depumped to the other *m* levels, making them available for further pumping. The optically pumped magnetometer exploits this situation in a positive feedback arrangement to produce an oscillator at the Larmor frequency.

The scale factors for optically pumped magnetometers are significantly higher than for the proton precession magnetometer. Table 39.6 lists these scale factors for a number of alkali vapors.

As a result, the sample rate and resolution can be much higher. A resolution of 0.005 nT is possible. Sampling rates can be as high as 15 samples per second.

TABLE 39.6 The Change in Frequency for a Change in Field Is Much Higher in Optically Pumped Magnetometers than in Proton Precession Magnetometers

Alkali	Scale Factor (Hz nT^{-1})
Rb-85	4.66737
Rb-87	~7
Cesium	3.4986

39.4.4 Signal Conditioning

Descriptions of several optically pumped magnetometers and their operating principles can be found in [24–26]. There are a number of different signal conditioning arrangements that can be used to derive a useful readout of the measured fields. Two of the more common methods are described in [26] and are shown in Figure 39.25.

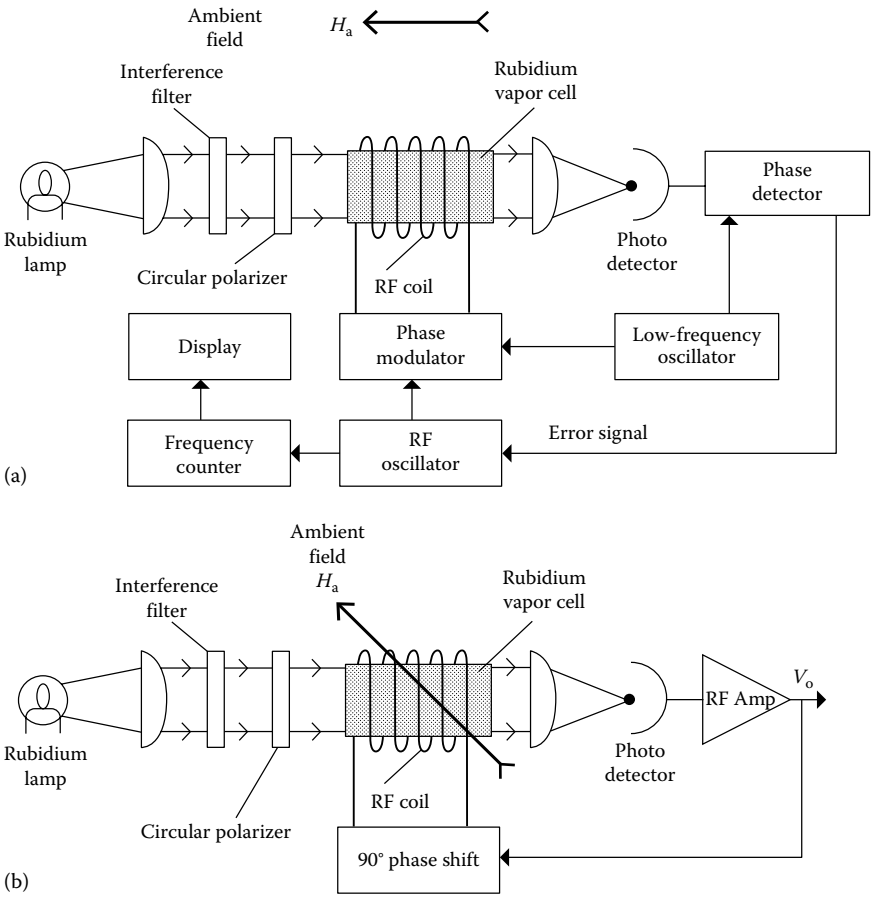

FIGURE 39.25 Two examples of optically pumped scalar magnetometers: (a) The servoed magnetometer slightly modulates the RF field at a low frequency, causing the vapor transmissivity to modulate. A phase detector provides an error signal that is used to lock the RF oscillator to the Larmor frequency; (b) A self-oscillating magnetometer: the transmissivity of the vapor, at right angles to the applied field, is made to oscillate at the Larmor frequency by phase shifting the detected light modulation and feeding it back to the RF field generator. (Adapted from Hartmann, F., *IEEE Trans. Magn.*, MAG-8, 66, 1972.)

In the servoed type shown in Figure 39.25a, the magnetic field being measured and the RF field are coaxial. The frequency of the RF oscillator is modulated with a fixed low-frequency oscillator. This causes the RF to sweep through the Larmor frequency. If the sweeped RF oscillator is not centered about the Larmor frequency, the photocell output signal will contain a fundamental component of the RF modulation frequency. The phase of the signal relative to the modulator oscillator determines whether the central RF is above or below the Larmor frequency. The photocell output is phase detected to produce an error voltage that is used to drive the RF toward the Larmor frequency. The RF can be measured to determine the magnetic field. If a linear voltage-controlled oscillator is used as the RF oscillator, its control voltage can also be used as an output since it is a measure of the Larmor frequency.

The auto-oscillating type shown in Figure 39.25b is based on the transmission of a polarized beam that is at right angles to the field being measured. The intensity of this crossbeam will be modulated at the Larmor frequency. The photocell signal will be shifted by 90° relative to the RF field. By amplifying the photocell signal, shifting it 90°, and feeding it back to drive the RF field coil, an oscillator is created at the Larmor frequency. In practice, only one light source is used, and the field being measured is set at an angle of 45°.

Defining Terms

Anisotropic: The material property depends on direction.

Gaussmeter: An instrument used to measure magnetic fields greater than 1 mT.

Induced magnetization: The object's magnetization is induced by an external magnetic field and disappears when the inducing field is removed.

Initial permeability: The slope at the origin of the magnetization curve.

Isotropic: The material property is the same in all directions.

Magnetic dipole moment: A vector quantity that describes the strength and direction of a magnetic field source, such as a small current loop or spinning atomic nucleus.

Magnetically "hard" material: The material has a significant residual (permanent) magnetization after an external magnetic field is removed.

Magnetically "soft" material: The material's magnetization is induced by an external magnetic field and the material has no significant residual (permanent) magnetization after the field is removed.

Magnetization curve: A plot of flux density B versus magnetic field H for an initially unmagnetized ferromagnetic material.

Magnetization: A vector quantity describing the average density and direction of magnetic dipole moments.

Magnetometer: An instrument used to measure magnetic fields with magnitudes up to 1 mT.

Magnetoresistance: The change in the electrical resistivity of a material in response to an applied magnetic field.

Maximum permeability: The maximum slope of the line drawn from the origin of the magnetization curve to a point on the magnetization curve.

Permanent magnetization: The source of an object's magnetization is internal and does not depend on the presence of an external field.

Permeability: A function that describes the relationship between an applied magnetic field and the resulting flux density.

Relative permeability: The permeability of a material normalized (divided) by the permeability of a vacuum.

Scalar magnetometer: A magnetometer that measures the magnitude of a magnetic field vector.

Vector magnetometer: A magnetometer that measures one or more of the individual components of a magnetic field vector.

40.1 Introduction

A *signal* is usually defined by a time-varying function carrying some sort of information. Such a function most often represents a time-changing electric or magnetic field, whose propagation can be in free space or in dielectric materials constrained by conductors (waveguides, coaxial cables, etc.). A signal is said to be periodic if it repeats itself exactly after a given time T called the period. The inverse of the period T, measured in seconds, is the frequency f measured in hertz (Hz).

A periodic signal can always be represented in terms of a sum of several (possibly infinite) sinusoidal signals, with suitable amplitude and phase and having frequencies that are integer multiples of the signal frequency. Assuming an electric signal, the square of the amplitudes of such sinusoidal signals represents the power in each sinusoid and is said to be the power spectrum of the signal. These concepts can be generalized to a nonperiodic signal; in this case, its representation (spectrum) will include a continuous interval of frequencies, instead of a discrete distribution of integer multiples of the fundamental frequency. The representation of a signal in terms of its sinusoidal components is called Fourier analysis. The (complex) function describing the distribution of amplitudes and phases of the sinusoids composing a signal is called its Fourier transform (FT). The Fourier analysis can be readily generalized to functions of two or more variables; for instance, the FT of a function of two (spatial) variables is the starting point of many techniques of image processing.

A typical way to analyze a time-dependent electric signal, then in the so-called *time domain*, is through an *oscilloscope*. The flat screen of this instrument is arranged in such a way to display the signal amplitude voltage on a vertical scale, while the horizontal scale is continuously updated to account for the evolution of the time.

The *spectrum analyzer*, instead, is said to operate in the *frequency domain* because it allows one to measure the harmonic content of an electric signal, that is, the power of each of its spectral components. In this case, the vertical scales read powers available in each prefixed bandwidth, centered at the frequency reported in the horizontal scale. The two domains are mathematically well defined, and

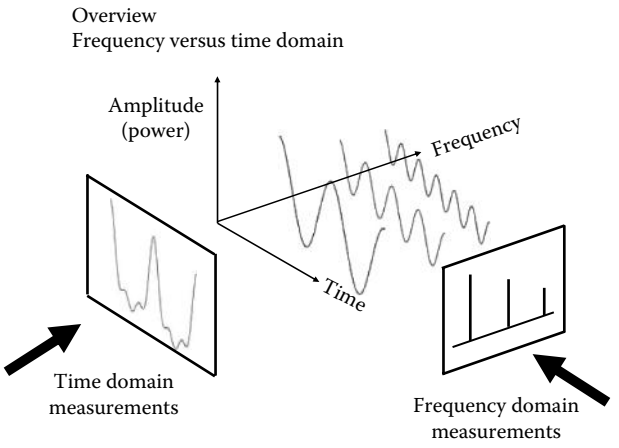

FIGURE 40.1 How the same signal can be displayed. (Courtesy of Agilent Technologies.)

through the FT algorithm, it is not too difficult to switch from one response to the other. Their graphical, easily perceivable representation is shown in Figure 40.1 where the two responses are shown lying on orthogonal planes. It is trivial to say that the easiest way to make a Fourier analysis of an electric signal is to have it displayed on a spectrum analyzer. Many physical processes, when detected by appropriate sensors, generate (electric) signals whose nature is not deterministic, but rather stochastic, or even of true random origin, like noise. Such signals can also be analyzed in terms of FT, although in a statistical sense only.

A time signal is said to be band limited if its FT is nonzero only in a finite interval of frequencies, say $(F_{max} - F_{min}) = B$, being the bandwidth. Usually, this is the case; then, an average frequency F_0 can be defined. Although the definition is somewhat arbitrary, a (band-limited) signal is referred to as radio frequency (RF) if F_0 is in the range 100 kHz–1 GHz and as a microwave signal in the range 1–1000 GHz. The distinction is not fundamental theoretically, but it has very strong practical implications in instrumentation and spectral measuring techniques. A band-limited signal can be described further as narrowband, if $B/F_0 << 1$, or wideband otherwise.

The first step in performing a spectral analysis of a narrowband signal is generally the so-called heterodyne downconversion: it consists in the mixing ("beating") of the signal with a pure sinusoidal signal of frequency F_L, called local oscillator (LO). In principle, mixing two signals of frequency F_0 and F_L in any nonlinear device will result in a signal output containing the original frequencies as well as difference $(F_0 - F_L)$ and the sum $(F_0 + F_L)$ frequencies and all their harmonic (multiple) frequencies. In the practical case, the best mixer devices are selected in order to exhibit an almost pure quadratic transfer function with the output including only the frequencies $(F_0 - F_L)$, $2F_L$, $2F_0$, and $(F_0 + F_L)$. The first term (called the intermediate frequency or IF) will be easily separated from the others, which have a much higher frequency, by a proper termination and filtering of the mixer output. The bandwidth of the IF signal will be the same as the original bandwidth B; however, to preserve the original information fully in the IF signal, stringent limits must be imposed on the LO signal, because any deviation from a pure sinusoidal law will show up in the IF signal as added phase and amplitude noise, corrupting the original spectral content. The process of downconverting a (band-limited) signal is generally necessary to perform spectral analysis in the very high-frequency (microwave) region, to convert the signal to a frequency range more easily handled by the following analyzing hardware and software.

When the heterodyne process is applied to a wideband signal (or whenever $F_L > F_{min}$), "negative" frequencies will appear in the IF signal. This process is called *double sideband* mixing, because a given IF bandwidth B (i.e., $(F_L + B/2)$ will include two separate bands of the original signal, centered at F_L + IF

("upper" sideband) and F_L – IF ("lower" sideband). This form of mixing is obviously undesirable in spectrum analysis, and input filters are generally necessary to split a wideband signal in several narrowband signals before downconversion. Alternatively, special mixers can be used that can deliver the upper and lower sidebands to separate IF output ports. A band-limited signal in the frequency interval $(F_{max} - F_{min}) = B$ is said to be converted to *baseband* when the LO is placed at $F_L = F_{min}$, so that the band is converted to the interval $(B - 0)$. Modern digital circuits are best matched to this case, being essentially limited on the maximum working frequency. Here, it is possible to employ analog-to-digital converters (ADCs) to get a discrete numerical representation of the analog signal, and the spectral analysis is then performed numerically, either by direct computation of the FT (generally via the fast Fourier transform, FFT, algorithm) or by computation of the signal autocorrelation function, which is directly related to the square modulus of the FT via the Wiener–Khinchin theorem. Considering that the ADC must sample the signal at least at the Nyquist rate (i.e., at twice the highest frequency present) and with adequate digital resolution, this process is feasible and practical only for frequencies (bandwidths) less than a few hundreds of megahertz. Also, the possibility of a real-time analysis with high spectral resolution may be limited by the availability of very fast digital electronics and special-purpose computers. The digital approach is the only one that can provide extremely high spectral resolution, up to several hundred thousand channels.

40.2 Practical Approach to Spectrum Analysis

Spectrum analysis is normally done in order to verify the harmonic content of oscillators, transmitters, frequency multipliers, etc., or the spurious components of amplifiers and mixer [1]. Other specialized applications are possible, such as the monitoring of radio-frequency interference (RFI), electromagnetic interference (EMI), and electromagnetic compatibility (EMC). These applications, as a rule, require an antenna connection and a low-noise, external amplifier. Which are then the specifications to look for in a good spectrum analyzer? First, we would suggest evaluating what are the critical parameters that are most relevant for your application. Then identify what is the instrument performance that has to drive the selection of the industrial product that best matches your needs.

Here follows a list of the typical characteristics of a spectrum analyzer:

1. It should display selectable, both wide and narrow, bands of the EM radio spectrum with amplitude power and frequency readable with good accuracy.
2. Its selectivity should range, in discrete steps, from few hertz to megahertz so that sidebands of a selected signal can be spotted in details as well as monitored in the spectral environment where that signal is immersed in.
3. It should possess a very wide dynamic range, so that signals differing in amplitude six to eight orders of magnitude can be observed at the same time on the same view of the display.
4. Its sensitivity must be compatible with the measurements to be taken. As already mentioned, specialized applications may require external wideband, low-noise amplifiers, and an antenna connection.
5. The type of power supply (mains or battery), weight, and dimensions should be compatible with the type of operation, fixed or portable, you want to have.
6. Phase noise stability of the LO shall be carefully verified before attempting to reach your ultimate target in spectral resolution measurements.
7. Consider your data logger requirements: the capability of direct driving a plotter or a printer, archive data on external memory devices, and finally the interface protocol that will allow controlling your spectrum analyzer, from a personal computer (PC).
8. Analog and/or digital averaging and other special functions can extend the measuring capabilities in dedicated measuring configurations.
9. Periodic calibration of the unit by an authorized center will guarantee that your results could be traced to international standards, along the operating life of the instrument.

A block diagram of a commercial spectrum analyzer is shown in Figure 40.2.

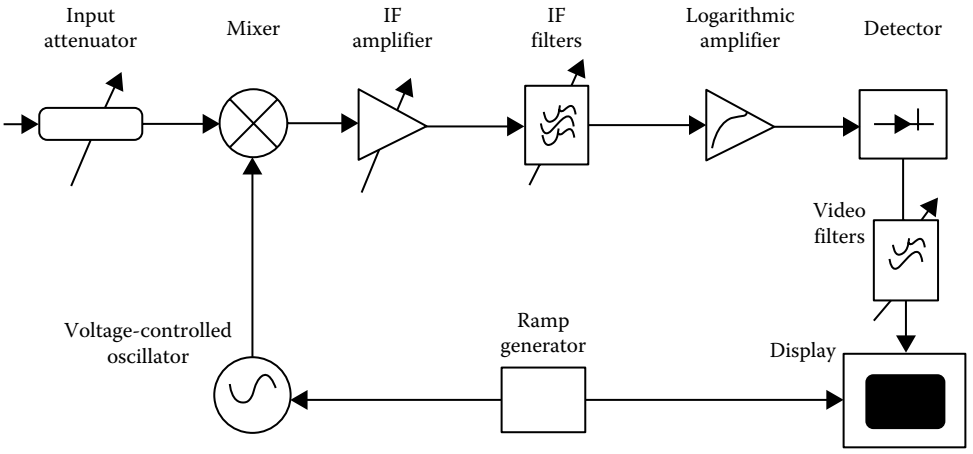

FIGURE 40.2 Block diagram of a commercial spectrum analyzer. (Courtesy of Hewlett-Packard, Rohde Schwarz, Hameg, Tektronix companies, and IEEE Microwave Measurements.)

Figure 40.2 shows that we are confronted with a radio-receiver-like superhet with a wideband input circuit. The horizontal scale of the instrument is driven by a ramp generator, which is also applied to the voltage-controlled LO [2].

A problem arises when dealing with a broadband mixing configuration like the one shown earlier, namely, avoiding receiving the image band.

The problem is successfully tackled here by upconverting the input band to a high-valued IF. An easily designed input low-pass filter, not shown in the block diagram for simplicity, will now provide the necessary rejection of the unwanted image band.

Nowadays, with the introduction of YIG band-pass filter preselectors, tunable over very wide input bands, upconversion is not always necessary. Traces of unwanted signals may, however, show up on the display although at very low level (less than −80 dBc) even on good analyzers.

A block diagram of a commercial spectrum analyzer exploiting both the mentioned principles is shown in Figure 40.3. This instrument includes a very important feature that greatly improves its performance: the LO frequency is no longer coming from a free-running source but rather from a synthesized unit referenced to a very stable quartz oscillator. The improved quality of the LO both in terms of its own noise and frequency stability optimizes several specifications of the instrument, such as frequency determining accuracy, finer resolution on display, and reduced noise in general.

Further, a stable LO generates stable harmonics that can then be used to widen the input-selected bands up to the millimeter region. As already stated, this option requires external devices, for example, a mixer-amplifier as shown in Figure 40.4a and b.

The power reference on the screen is the top horizontal line of the reticle. Due to the very wide dynamic range foreseen, the use of a log scale (e.g., 10 dB/square) seems appropriate. Conventionally, 1 mW is taken as the zero reference level: accordingly, dBm are used throughout.

The noise power level present on the display without an input signal connected (noise floor) is due to the input random noise multiplied by the IF amplifier gain. Such a noise is always present and varies with input frequency, IF selectivity, and analyzer sensitivity (in terms of noise figure).

The "on display dynamic range" of the analyzer is the difference between the maximum compression-free level of the input signal and the noise floor. As a guideline, the dynamic range of a good instrument could be of the order of 70–90 dB.

An input attenuator, always available on the front panel, allows one to apply more power to the analyzer while avoiding saturation and nonlinear readings. The only drawback is the obvious sensitivity loss.

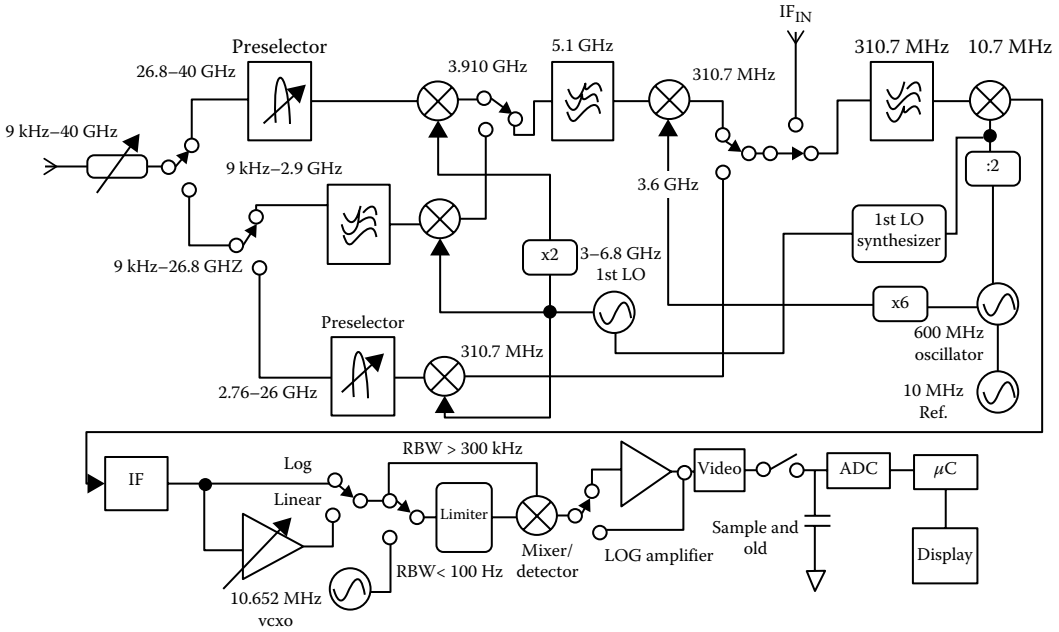

FIGURE 40.3 Standard block diagram of a modern spectrum analyzer. (Courtesy of Hewlett-Packard, Rohde Schwarz, Hameg, Tektronix companies, and IEEE Microwave Measurements.)

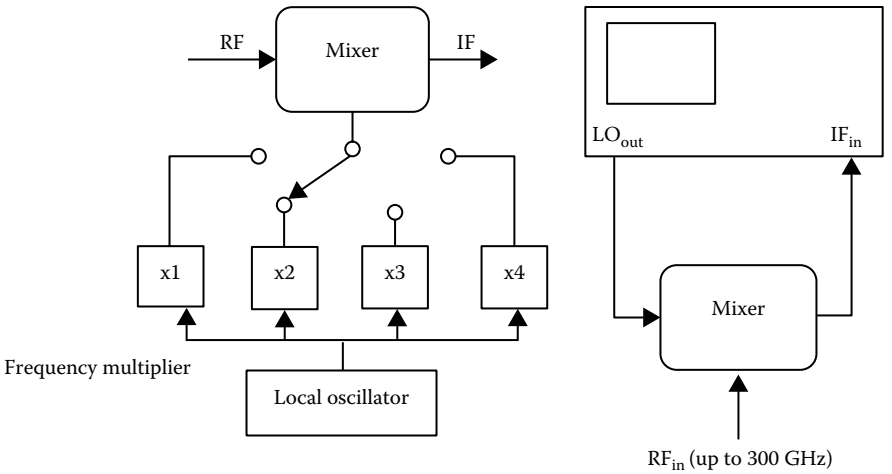

FIGURE 40.4 Increasing the input bandwidth characteristics. (Courtesy of Hewlett-Packard, Rohde Schwarz, Hameg, Tektronix companies, and IEEE Microwave Measurements.)

When kept calibrated over the specified warranty periods, modern spectrum analyzer can exhibit measurement uncertainties of a fraction of a dB and Hertz resolutions up to a few GHz.

When more accurate measurement of power sources, with slow time variations, is needed, the suggestion is to use a *bolometer* instead of a spectrum analyzer. An erratic signal pattern on display and a fancy level indication may be caused by the wrong setting of the "scan time" knob. It must be realized that high-resolution observation of a wide input band requires the proper scanning time. An incorrect parameter setting yields wrong readings, but usually an optical alarm is automatically switched on to

warn the operator. In any case, never forget that pulsed signal, in particular even when repeated with very low duty cycles, cannot be represented with fidelity by a frequency swept spectrum analyzer.

The knowledge of the noise floor level allows a good valuation of the noise temperature, T_n (and therefore of the sensitivity), of the analyzer, a useful parameter on many occasions. The relations involved are as follows.

The Nyquist relation states that

$$P = k \times T_n \times B \tag{40.1}$$

where

P is the noise floor power level read on the display (W)
k is the Boltzmann constant = 1.38×10^{-23} (J/K)
B is the passband of the selected IF (Hz)

Therefore,

$$T_n = \frac{P}{k \times B} \tag{40.2}$$

Usually, engineers prefer to quote the noise figure of receivers. By definition, we can write

$$N = \left(\frac{T_n}{T_0} \right) + 1 \tag{40.3}$$

where

N is the noise factor
$T_0 = 290$ K
F (noise figure) = 10 log N

A typical F for a good spectrum analyzer is of the order of 10–20 dB.

It must be said, however, that the "ultimate sensitivity" of the spectrum analyzer will depend not only on its noise figure but also on the setting of other parameters like the video filter, the IF bandwidth, the insertion of averaging functions, the scan speed, and the type of transfer function of the detector used.

As a rough estimate, a noise floor level of –130/–140 dBm is very frequently met by a good instrument.

Another criterion to select a spectrum analyzer is a good "IMD dynamic range," that is, the tendency to create spurious signals by intermodulation due to saturation.

This figure is generally quoted by the manufacturers, but it is also easily checked by the operator by injecting two equal amplitude sinusoidal signals at the input socket of the analyzer. The frequency separation between the two should be at least a couple of "resolution bandwidths," that is, the selected IF bandwidth. As the input levels increase, spurious lines appear at the sum and difference frequencies and spacing of the input signals.

The range in decibels between the nonoverloaded input signals on display and the barely noticeable spurious lines is known as the "spurious free dynamic range," shown graphically in Figure 40.5a, where the third-order "intercept point" is also graphically determined. If input power is increased, higher-order spurious signals appear, as shown in Figure 40.5b. The input connector of most spectrum analyzers is of the 50 Ω coaxial type. Past instruments invariably used *N*-type connectors because of their good mechanical and electric behavior up to quite a few gigahertz. Today, type SMA or type K connectors are preferred.

External millimeter wave amplifiers and converters use waveguide input terminations. As is discussed in the next section, multipurpose analyzers are available where power meter, frequency

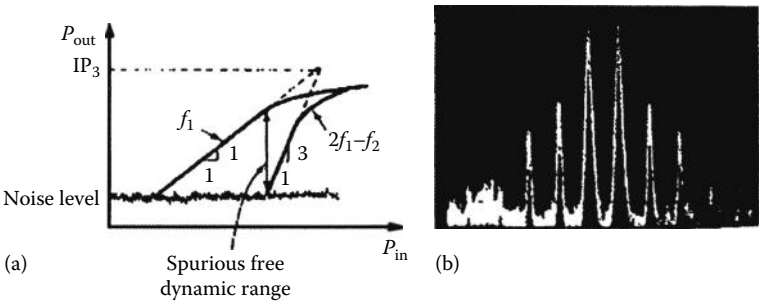

FIGURE 40.5 (a) Spurious free dynamic range and (b) higher-order spurious. (Courtesy of Hewlett-Packard, Rohde Schwarz, Hameg, Tektronix companies, and IEEE Microwave Measurements.)

counter, tracking generator, etc., can all be housed in the same cabinet. The economic and practical convenience of these units must be weighed on a case-by-case basis.

Finally, we mention that spectrum analyzers are available equipped with AM and FM detectors to facilitate their use in the RFI monitoring applications in order to identify the name of the interferer.

40.3 Selecting Correct Spectrum Analyzers for Specific Purposes

Several manufacturers offer a large number of spectrum analyzer models; the choice may be made on the basis of application field (i.e., CATV, mobile telephony, R-LAN, service, surveillance, and R&D), performance (resolution bandwidth, frequency range, accuracy, battery operation, etc.), or cost. Very often, the newest RF models exhibit also the signal analyzer function, intended as some kind of characterization in the time domain, by computing the FFT of the signal under test, that is, baseband modulation and phase noise.

In addition, it is important to know that most spectrum analyzers need some accessories generally not furnished as a standard: for example, a connectorized, coaxial, microwave cable is always required; a directional coupler, power divider, or handheld sampler antenna may be very useful to pick up the signals; and a PC is useful to collect, store, reduce, and analyze the data.

There are six main families of RF and microwave spectrum analyzers.

40.3.1 Family 1

The bench instruments are top performance but also large, heavy, and the most expensive class, intended for metrology, certification, factory reference, and radio surveillance done by government and military institutions.

Their operating frequencies span from a few tens of hertz to RF (i.e., 2.9 GHz), or up to the microwave region (i.e., 26.5 GHz), or even reach millimeter wavelengths (i.e., 40–67 GHz). This class of instruments includes lower-noise figures, approximately 20–25 dB at medium frequencies that can be decreased down to 10–15 dB with an integrated preamplifier. The synthesized LO has a good phase noise (typically 10 dB better than general-purpose spectrum analyzers) for precise, accurate, and stable measurement. Also, this class of instruments can be integrated with plug-in instruments like a power meter (for more accurate power measurements), a frequency counter (for accurate frequency measures), or a tracking generator (for network analysis and mixer testing).

An interface to a computer (and printer) such IEEE-488, USB, and in particular LAN is now standard in all units. Now, even the front panel acts as the remote control terminal for the instrument inside. Optical encoders, up and down push buttons, and the digital keyboard have substituted for all old analog or mechanical input switches. The output display is now typically a colorful flat LED monitor, with greater advantages for a clearer and much more detailed view. Having inside powerful, state-of-the-art

microprocessor controllers, RAM memories, and plug-in cards for storing data, all sort of statistical and mathematical analysis can be implemented in many different measuring configurations, each stored for later usage with a single press of recovery functions. Among the most appreciated and qualified trademarks, we mention Agilent [3] and Rohde & Schwarz [4]. Indicative prices are between $50,000 and $100,000.

40.3.2 Family 2

Less-expensive bench instruments, the workhorse class of spectrum analyzers, portable and lightweight, are associated with a synthesized LO that includes a frequency range from a few kilohertz up to the RF region (i.e., 2.9 GHz), microwave region (i.e., 26.5 GHz), or near millimeter wavelengths (i.e., 40–50 GHz). A typical noise figure of 30 dB is good enough to ensure most measurements. A large number of filters down to a few hertz of resolution are offered; digital filters are preferable to analog ones, because they give a faster refresh rate of the trace on the display. This kind of spectrum analyzer nearly always has the capability to extend the frequency range up to millimeter and submillimeter wavelengths with an external mixer. One of the most important features for a spectrum analyzer in this class is the quality of the LO; it should be synthesized phase-locked loop (PLL) to achieve stability, precision, accuracy, and low phase noise. Demodulation is also an important feature to listen to AM and FM on the loudspeaker and to display complex modulations onto the screen, which is often required by people working on surveillance, TV, and mobile telephone. The interface to a computer such as IEEE-488/USB/LAN is standard in a large number to display TV pictures or complex modulations onto the screen, which is often required by people working on surveillance, TV, and mobile telephone. The interface to a computer such as IEEE-488 or RS232 is standard in a large number of spectrum analyzers and allows the remote control and data reading, storing, and manipulation.

This kind of instrument may integrate a tracking generator, a frequency counter, and other instruments that can transform the spectrum analyzer into a compact, full-featured RF and microwave laboratory. Agilent [3], Anritsu [5], IFR [6], Rohde & Schwarz [4], and Tektronix [7] are the leader companies in the market. Prices typically span from $30,000 to $75,000.

40.3.3 Family 3

The entry level, a more economical class of spectrum analyzer, is intended for field use or for one specific application. If your need is mainly EMI/EMC, CATV, mobile telephone, or surveillance, perhaps you do not need the extreme stability of a synthesized LO, and a frequency range up to 2 GHz may be enough; however, if you need some special functions such as "quasi-peak detector" or "occupied bandwidth measurement," two functions that originate from a combination of a mathematical treatment with some legislative requirements, you can find off the shelf what you need in a dedicated instrument.

Manufacturers are the same, while costs typically run from around $10, 000 to $35,000.

40.3.4 Family 4

Handheld spectrum analyzers are very popular nowadays, being low cost, with a high level of performance for their deep usage of the newest digital processing techniques. Frequency coverage up to 43 GHz, and just a few kilograms of weight, can satisfy a large number of users in general fields and in particular when it is required to make a measurement in outdoor open spaces. Agilent [3], Anritsu [5], Rohde & Schwarz [4], Tektronix [7], and some minor companies offer such units from $5,000 to $45,000, according to their specific performance.

40.3.5 Family 5

The most economical class of spectrum analyzer, with prices around $2000–$6000, includes instruments that perform only the basic functions with a limited frequency range and filter availability.

They are intended for service, for general-purpose measurements (i.e., IP_3, harmonic distortion), or for precertification in EMI/EMC measurements. One of the most popular is HAMEG [8] and RIGOL [9].

In this class are some special spectrum analyzers that come on a PC board. Such spectrum analyzers are generally cheap (typically $2000–$4000), with a frequency range up to 2 GHz, and may include PLL LOs, tracking generators, and other advanced characteristics. The input is through a coaxial connector on the board, the output and the control are done by a virtual instrument running on the PC.

Other unusual RF spectrum analyzers working in conjunction with a PC and worth noting are the instruments for EMI/EMC measurements and reduction in power lines and power cords. For this type of instrument, the core is not the hardware but the software that performs the measurement according to international standards and may guide the engineer to meet the required compatibility.

40.3.6 Family 6

Many modern applications require "modal analysis," for example, at acoustic frequencies in mechanical systems. All devices have moving parts, like wheels, axels, and ropes so they can be applied to cars as well as civil elevators, just as the most common examples. These applications require industrial qualifications based on a deeper knowledge of their dynamical properties to avoid dangerous resonances and dissipative losses and finally improve their efficiencies.

Extremely low-frequency spectrum analyzers, with resolutions down at the millihertz level, are quite common. They are very cheap (with respect to the RF spectrum analyzers), being made of only digital hardware, acquiring the input signal in the time domain, and then computing the frequency spectrum by dedicated FFT processors. In this case, the dynamic range can be raised a few decades, ranging up to 90–110 dB. The tracking generator is generally built in, as well as many anti-aliasing input filtering choices.

40.4 Advanced Applications

Completely new families of integrated circuits now offer unprecedented functionalities. For example, off-the-shelf components now make analog-to-digital conversions up to a few giga samples per second with a large dynamic range (of 48 dB, meaning 8 bits of resolution or even more). Such a huge amount of data can only be handled by an extremely fast processing system equipped with field programmable arrays (FPGAs) or graphics processing units (GPUs).

Fundamental research like radio astronomy has found a great benefit from these technological developments opening new possibilities in advanced spectrum analysis applications. Autocorrelators, with a typical frequency resolution of ~5/25 kHz, have been extensively used in radio astronomy. Their performance is well documented; the autocorrelation function is computed online and recorded. Later, the FFT of the function is computed off-line in order to get the power spectrum.

As a matter of fact, the FPGA represents a medium-/high-cost approach to the state of the art of very high-performance silicon engines. FPGA advantages are low power consumption at high clock rates and easy reconfiguration for different very high computing demanding projects. They are limited to only linear and pipelined elaboration, under PC control for final data storage.

Fully dedicated applications allow quickly implementing even very complex algorithms on the FPGA chips. The final huge processing power is a result that comes out from combining the unreached velocity of the hardware together with the extremely high flexibility of the software, with the benefit of low power consumption per clock rate.

Current FPGA applications demonstrate the capability of processing more than 500 MHz bandwidth with up to 1,000,000 channels using polyphase filter banks (PFBs) in real time.

Here follows a simple block diagram of a high-resolution spectrum analyzer powered by FPGA using the PFB and the FFT engine blocks: our configuration is capable to synthetize in real time several hundred million frequency channels over an input band of 500 MHz [10].

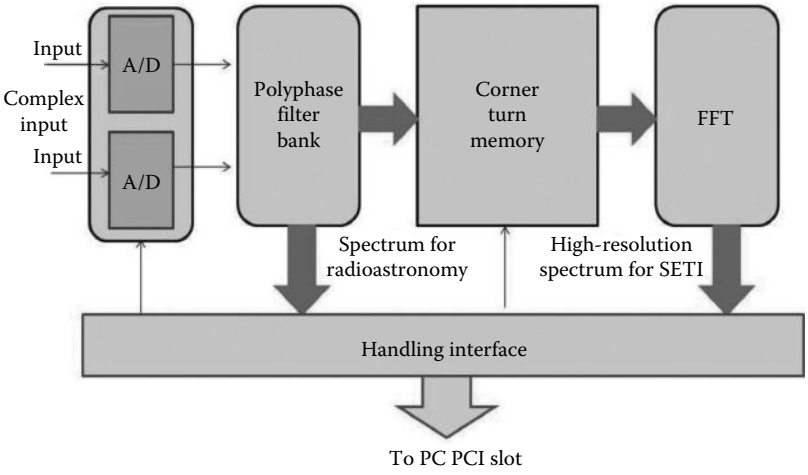

FIGURE 40.6 Block diagram of a high-resolution spectrum analyzer.

Another state-of-the-art low-cost approach for spectrum analysis is based on GPU; this is a dedicated microprocessor conceived to off-load and accelerate 3D or 2D graphics rendering, made available from its associated CPU. This kind of powerful engine is primarily used in workstations, game consoles, etc. Due to their highly parallel structure, modern GPUs are more effective than standard CPUs for implementing a wide range of complex algorithms.

Their main advantages are high computing power, suitable to drive directly data parallel computing, and easy programmability with little overhead in standard C language and with runtime configurations, scalable on different GPU clusters. In conclusion, a GPU offers an extremely powerful tool as the "number crunching" machine that is requested for the huge FFT computations needed for reaching top performance in spectrum analysis with high frequency resolution and over large bandwidths. The block diagram of a high-resolution spectrum analyzer is illustrated in Figure 40.6.

IV

Time and Frequency

41

Time Measurement

Michael A. Lombardi
National Institute of Standards and Technology

Although we have no control over its passage, we can measure time with more resolution and less uncertainty than any other physical quantity. The base unit of time, the second (s), is one of the seven base units of the International System of Units (SI) and can be measured so accurately that numerous other units, including the meter and ampere, depend upon its definition.

Time measurements can be divided into two general categories: *time interval* measurements and *time synchronization* measurements. Time interval measurements determine the duration or elapsed time between two events. Time standards typically produce 1 pulse per second (pps) signals. The period of these signals is a standard second that serves as a time interval reference. Many engineering and scientific applications require the measurement of time intervals much shorter than 1 s, such as *milliseconds* (ms, 10^{-3} s), *microseconds* (μs, 10^{-6} s), *nanoseconds* (ns, 10^{-9} s), *picoseconds* (ps, 10^{-12} s), and *femtoseconds* (fs, 10^{-15} s). Thus, the instrumentation used to measure time intervals always requires subsecond resolution.

Time synchronization measurements determine the time offset between the test signal and the Coordinated Universal Time (UTC) second. The reference for these measurements is typically a 1 pps signal synchronized to UTC. If the 1 pps signal is labeled or time tagged, it can be used to synchronize time-of-day clocks and can also be used to record when an event happened. *Time tags* typically include the year, month, day, hour, minute, second, and often the fractional part of a second. When we ask the everyday question, "What time is it?" we are asking for a current time tag. By comparing and aligning time tags, we can ensure that events are *synchronized* or scheduled to occur at the same time.

Both types of time measurements are referenced to the frequency of a *periodic event* that repeats at a constant rate. For example, this periodic event could be the swings of a pendulum. We could agree to establish a base unit of time interval by defining the second as one complete swing, or cycle,

of the pendulum. Now that we have defined the second, we can measure longer time intervals, such as minutes, hours, and days, by simply counting the swings of the pendulum. This process is how a *time scale* is formed. A time scale is simply an agreed upon way to order events and keep time. It is formed by measuring and establishing a base time unit (the second) and then counting elapsed seconds to establish longer time intervals. A device that measures and counts time intervals to mark the passage of time is called a *clock*. Let's continue our discussion by looking at the evolution of clocks and timekeeping.

41.1 Evolution of Clocks and Timekeeping

All clocks share several common features, including a device that continuously produces the periodic event mentioned previously. This device is called the *resonator*. In the case of a pendulum clock, the pendulum is the resonator. Of course, the resonator needs an energy source, such as a mainspring or motor, so it can run continuously. Taken together, the energy source and the resonator form an *oscillator* that runs at a rate called the *resonance frequency*. Another part of the clock counts the oscillations and converts them to time units. And finally, the clock must display or record the results [1].

The frequency uncertainty of a clock's resonator is directly related to the timing uncertainty of the clock, as shown in Table 41.1.

Throughout history, clockmakers have searched for better oscillators that would allow them to build more accurate clocks. As early as 3500 BC, time was kept by observing the movement of an object's shadow between sunrise and sunset. This simple clock is called a *sundial*, and the resonance frequency is the apparent motion of the sun. Later, water clocks, hourglasses, and calibrated candles allowed dividing the day into smaller units of time or hours. Mechanical clocks first appeared in the early fourteenth century. Early models used a verge and foliot mechanism for an oscillator and had an uncertainty of about 15 min/day ($\cong 1 \times 10^{-2}$). However, mechanical clocks did not display minutes until near the end of the sixteenth century.

A timekeeping breakthrough occurred with the invention of the *pendulum clock*, a technology that dominated timekeeping for several hundred years and established the second as a usable unit of time interval. In the early 1580s, Galileo Galilei observed that a given pendulum took the same amount of time to swing completely through a wide arc as it did a small arc. Galileo wanted to apply this natural periodicity to time measurement and had begun work on a mechanism to keep the pendulum in motion in 1641, a year prior to his death. In 1656, the Dutch scientist Christiaan Huygens invented an escapement that kept the pendulum swinging. The uncertainty of Huygens's clock was less than 1 min/day ($\cong 7 \times 10^{-4}$) and later reduced to about 10 s/day ($\cong 1 \times 10^{-4}$). The first pendulum clocks were weight driven, but later versions were powered by springs. Huygens is often credited with inventing the spring and balance wheel assembly still found in some of today's mechanical wristwatches.

TABLE 41.1 Relationship of Frequency Uncertainty to Timing Uncertainty

Frequency Uncertainty	Measurement Period	Timing Uncertainty
$\pm 1.00 \times 10^{-3}$	1 s	±1 ms
$\pm 1.00 \times 10^{-6}$	1 s	±1 μs
$\pm 1.00 \times 10^{-9}$	1 s	±1 ns
$\pm 2.78 \times 10^{-7}$	1 h	±1 ms
$\pm 2.78 \times 10^{-10}$	1 h	±1 μs
$\pm 2.78 \times 10^{-13}$	1 h	±1 ns
$\pm 1.16 \times 10^{-8}$	1 day	±1 ms
$\pm 1.16 \times 10^{-11}$	1 day	±1 μs
$\pm 1.16 \times 10^{-14}$	1 day	±1 ns

Major advances in timekeeping accuracy resulted from the work of John Harrison, who built and designed a series of clocks in the 1720s that kept time to within fractions of a second per day (parts in 10^6). This performance was not improved upon until the twentieth century. Harrison dedicated most of his life to solving the British navy's problem of determining longitude, by attempting to duplicate the accuracy of his land clocks at sea. He built a series of clocks (now known as H1 through H5) in the period from 1730 to about 1770. He achieved his goal with the construction of H4, a clock much smaller than its predecessors, about the size of a large pocket watch. H4 used a spring and balance wheel escapement and kept time within fractions of a second per day during several sea voyages in the 1760s.

The practical performance limit of pendulum clocks was reached in 1921, when W. H. Shortt demonstrated a clock with two pendulums, one a slave and the other a master. The slave pendulum moved the clock's hands and freed the master pendulum of tasks that would disturb its regularity. The pendulums used a battery as their power supply. The Shortt clock kept time within a few seconds per year ($\cong 1 \times 10^{-7}$) and was once used as a primary standard for time interval in the United States [1–3].

Quartz crystal oscillators, based on the phenomenon of piezoelectricity discovered by P. Curie in 1880, worked better than pendulums, resonating at a nearly constant frequency when an electric current was applied. Credit for developing the first quartz oscillator is generally given to Walter Cady, who built prototypes shortly after World War I and patented a piezoelectric resonator designed as a frequency standard in 1923. Joseph W. Horton and Warren A. Marrison of Bell Laboratories built the first clock based on a quartz crystal oscillator in 1927. By the late 1930s, quartz oscillators began to replace pendulums as the standard for time interval measurements.

Billions of quartz oscillators are now manufactured annually. They are found in nearly every type of electronic circuit, including many devices that display time such as clocks, watches, cell phones, radios, and computers. Even so, quartz oscillators are not an ideal timekeeping source. Their resonance frequency depends on the size and shape of the crystal, and no two crystals are exactly alike or produce exactly the same frequency. Their frequency is also sensitive to changes in the environment, including temperature, pressure, and vibration. These limitations make them unsuitable for high-accuracy timekeeping and led to the development of atomic oscillators [1,4–6].

41.2 Atomic Oscillators

The practice of using resonant transitions in atoms or molecules is attractive for several reasons. For example, an unperturbed atomic transition is identical from atom to atom, so that, unlike a group of quartz oscillators, a group of atomic oscillators should all generate the same frequency. Also, unlike all electrical or mechanical resonators, atoms do not wear out or change their properties over time. These features were appreciated by Lord Kelvin, who suggested using transitions in sodium and hydrogen atoms as timekeeping oscillators in 1879. However, it wasn't until the late 1930s that technology made his idea possible, when I. I. Rabi and his colleagues at Columbia University introduced the idea of using an atomic resonance as a frequency standard.

Atomic oscillators use the quantized energy levels in atoms and molecules as the source of their resonance frequency. The laws of quantum mechanics dictate that the energies of a bound system, such as an atom, have certain discrete values. An electromagnetic field can boost an atom from one energy level to a higher one. Or an atom at a high energy level can drop to a lower level by emitting electromagnetic energy. The resonance frequency (f) of an atomic oscillator is the difference between the two energy levels divided by Planck's constant (h):

$$f = \frac{E_2 - E_1}{h} \tag{41.1}$$

The basic principle of the atomic oscillator is simple: Because all atoms of a specific element are identical, they should produce exactly the same frequency when they absorb energy or release energy.

Thus, atomic oscillators easily surpassed the performance of all previous standards. In theory, the atom is a perfect pendulum whose oscillations can be used as a standard of frequency or counted to measure time interval.

The three major types of commercial atomic oscillators are based on rubidium, cesium, and hydrogen atoms, respectively. The least expensive and most common type is the *rubidium oscillator*, based on the 6.8347 GHz resonance of ^{87}Rb. Rubidium oscillators are well suited for applications that require a small, high-performance oscillator. The frequency uncertainty of a rubidium oscillator over a 1 day interval typically ranges from about $\pm 5 \times 10^{-9}$ to $\pm 5 \times 10^{-12}$.

The second type of atomic oscillator, the *cesium oscillator*, serves as a primary standard in many laboratories, because the resonance frequency of cesium (9.1926 GHz) is used to define the second (Section 41.3). Because the base unit of time is defined with respect to cesium resonance, the 1 pps output from a cesium oscillator serves as an internationally recognized time interval standard. Commercially available cesium beam oscillators typically have a frequency uncertainty over a 1 day interval near $\pm 1 \times 10^{-13}$, with the best units about one order of magnitude better. Even so, a cesium cannot recover time by itself and cannot be used as a synchronization reference unless it has been synchronized with another source.

Currently (2010), the world's best time interval standards are cesium fountains. These devices are large, sometimes several meters tall. They are not sold commercially but have been built by several national metrology laboratories. Cesium fountains work by laser cooling atoms to a temperature near absolute zero (less than 1 μK) and then lofting them vertically. The atoms make two passes (one on the way up, the second on the way down) through a microwave cavity where the atomic resonance frequency is measured. The atoms can be observed for about 1 s. This allows a cesium fountain to outperform cesium beam standards, which have a much shorter observation period, typically about 1 ms. The primary frequency and time interval standard in the United States is a cesium fountain called NIST-F1 (Figure 41.1) that can realize the second with an uncertainty of about 3×10^{-16}.

A third type of atomic oscillator, the *hydrogen maser*, is based on the 1.42 GHz resonance frequency of the hydrogen atom. Hydrogen masers typically are more stable than cesium oscillators for periods

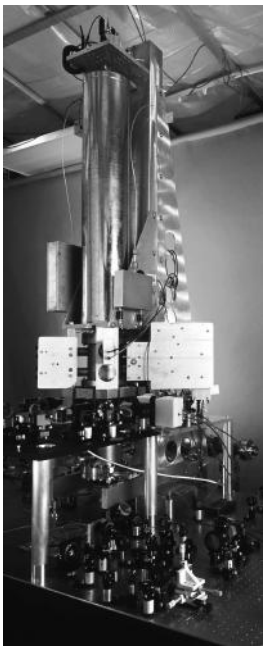

FIGURE 41.1 NIST-F1 cesium fountain.

TABLE 41.2 Evolution of Clock Design and Performance

Type of Clock	Resonator	First Appearance	Typical Time Uncertainty (1 Day)	Typical Frequency Uncertainty (1 Day)
Sundial	Apparent motion of sun	3500 BC	NA	NA
Mechanical	Verge and foliot mechanism	Fourteenth century	±15 min	$\pm 1 \times 10^{-2}$
Pendulum	Pendulum	1656	±10 s	$\pm 7 \times 10^{-4}$
Harrison chronometer	Pendulum	1761	±400 ms	$\pm 4 \times 10^{-6}$
Shortt pendulum	Two pendulums, slave and master	1921	±10 ms	$\pm 1 \times 10^{-7}$
Quartz	Quartz crystal	1927	±100 μs	$\pm 1 \times 10^{-9}$
Rubidium	Rubidium atomic resonance (6.834682610904 GHz)	1958	±1 μs	$\pm 1 \times 10^{-11}$
Cesium beam	Cesium atomic resonance (9.19263177 GHz)	1952	±10 ns	$\pm 1 \times 10^{-13}$
Cesium fountain	Cesium atomic resonance (9.19263177 GHz)	1995	±0.1 ns	$\pm 1 \times 10^{-15}$
Hydrogen maser	Hydrogen atomic resonance (1.420405751768 GHz)	1960	±10 ns	$\pm 1 \times 10^{-13}$
CSACs	Cesium or rubidium atomic resonance	2001	±10 μs	$\pm 1 \times 10^{-10}$

shorter than about 1 month. However, they lack the accuracy of cesium standards. Few are manufactured and sold due to their high cost, which often exceeds $200,000 [4–9].

Miniature atomic clocks, known as chip scale atomic clocks (CSACs), based on either rubidium or cesium resonance, were first reported on at NIST in 2001. At this writing (2010), these devices have been reduced to a volume of about 10 cm^3, have low power consumption requirements that can be satisfied by an AA battery, and are stable enough to keep time to within about 10 μs/day [10]. It seems likely that they will eventually be embedded in many types of commercial products.

Future atomic clocks will undoubtedly be based on the optical frequency of atoms, instead of the microwave frequencies. The resonance frequency of an optical atomic clock will be approximately 10^{15} Hz or about 10^5 times higher than the cesium resonance frequency. Thus, optical clocks will operate with a much smaller unit of time, a change comparable to using the second instead of the day as the base unit of time interval and making huge reductions in uncertainty possible. Many experimental optical atomic clocks have already been successfully designed and tested, but it is difficult to predict when they will replace the existing microwave standards [6,11,12].

Table 41.2 summarizes the evolution of clock design and performance. The uncertainties listed are for modern (2010) devices and not the original prototypes. Note that the performance of time and frequency standards has improved by about 14 orders of magnitude in the past 700 years and by about 10 orders of magnitude during the past 100 years.

41.3 Definition of the Second

As noted, the uncertainty of a clock depends upon the irregularity of some type of periodic motion. This periodic motion can be measured and used to define the second, which is the base unit of time interval in the SI. Because atomic time standards were clearly superior to their predecessors, they quickly became the world reference for time interval measurements. The atomic timekeeping era formally began in 1967, when the SI second was redefined based on the resonance frequency of the cesium atom:

> The duration of 9,192,631,770 periods of the radiation corresponding to the transition between two hyperfine levels of the ground state of the cesium 133 atom.

Before the invention of atomic clocks and the acceptance of atomic time, the second was defined by using astronomical time scales. The astronomical definitions of the second were very different from the atomic definition. Instead of *multiplying* the period of a short atomic event to form a longer time interval, the early definitions of the second were based on *dividing* the period of a long astronomical event to form a shorter time interval. There was no official metrological definition of the second until the SI was formed in 1960. However, prior to that date, the second was obtained by dividing the *mean solar day* or the average period of one revolution of the Earth on its axis. The *mean solar second* was 1/86,400 of the mean solar day and served as the base unit of time interval for the Universal Time (UT) family of time scales. Several variations of UT were defined:

UT0: The original mean solar time scale, based on the rotation of the Earth on its axis. UT0 was first kept by pendulum clocks. When quartz clocks became available, astronomers noticed errors in UT0 due to polar motion, which led to the UT1 time scale.

UT1: UT1 improved upon UT0 by correcting for the shift in longitude of the observing station due to polar motion. Because the Earth's rate of rotation is not uniform, the uncertainty of UT1 can be as large as a few milliseconds per day.

UT2: Mostly of historical interest, UT2 is a smoothed version of UT1 that corrects for known deviations in the Earth's rotation caused by angular momenta of the Earth's core, mantle, oceans, and atmosphere.

The *ephemeris second* was defined in 1956 and designated as the original SI second in 1960. It was defined by dividing the tropical year or the interval between the annual vernal equinoxes that occur on or about March 21. The tropical year was defined as 31,556,925.9747 ephemeris seconds. Determining the precise instant of the equinox is difficult, and this limited the uncertainty of ephemeris time (ET) to ±50 ms over a 9 year interval. It also made the ephemeris second nearly impossible to realize in a laboratory and of little or no use to metrologists or engineers. Thus, its tenure was understandably short. It remained part of the SI for just 7 years before being replaced by the much more accessible atomic definition [5,6,13].

41.4 Coordinated Universal Time

Coordinated Universal Time (UTC) is an atomic time scale that is based on the SI definition of the second and that serves as the official time reference for most of the world. UTC is maintained by the Bureau International des Poids et Mesures (BIPM) in Sevres, France. As of 2010, it is computed from a weighted average of nearly 400 atomic standards located at some 70 laboratories, including the National Institute of Standards and Technology (NIST) and the US Naval Observatory (USNO). Most of these devices are cesium beam standards, but some are hydrogen masers. In addition, about ten cesium fountain standards contribute to the accuracy of UTC.

UTC is a virtual time scale, generated from computations made on past measurements, and is distributed only through a monthly BIPM publication called the *Circular T*. No physical clock generates the official UTC. To support physical measurements of time and time interval, many laboratories maintain local UTC time scales that generate real-time signals that approximate UTC as closely as possible, often within a few nanoseconds. The *Circular T* reports the time differences between UTC and these local time scales, which are generically referred to as UTC(k), where k represents the acronym for the timing laboratory. For example, NIST maintains UTC(NIST) and the USNO maintains UTC(USNO).

The BIPM derives UTC from an internal time scale called International Atomic Time (TAI). Both UTC and TAI run at the same frequency. However, UTC differs from TAI by an integer number of seconds. This difference increases when *leap seconds* occur. When necessary, leap seconds are added to the UTC time scale on either June 30 or December 31. Their purpose is to ensure that the difference between atomic time (UTC) and astronomical time (UT1) does not exceed 0.9 s. Time codes (Section 41.5) contain a *DUT1 correction* or the current value of UT1 minus UTC. By applying this correction to UTC, users who need astronomical time can obtain UT1.

Leap seconds have been added to UTC when necessary since 1972. From 1972 to 2008, UT1 has lost (on average) more than 600 ms/year with respect to UTC; thus, 24 leap seconds were added during the 36 year interval. This means that atomic seconds are shorter than astronomical seconds and that UTC runs faster than UT1. There are two reasons for this. The first and most important reason is the definition of the atomic second. The atomic second was originally defined with respect to the ephemeris second and was shorter than the mean solar second from the beginning. The second reason is that the Earth's rotational rate is gradually slowing down and the astronomical second is gradually getting longer. When a positive leap second is added to UTC, the sequence of events is

23 h 59 m 59 s

23 h 59 m 60 s

0 h 0 m 0 s

The insertion of the leap second creates a minute that is 61 s long. This "stops" UTC for 1 s, so that UT1 can catch up [5,6,13]. Some timekeeping laboratories and other organizations have found the leap second to be cumbersome to implement and support, and there is currently an International Telecommunications Union (ITU) proposal to eliminate the leap second and instead make a larger time correction, such as a leap hour, when one is eventually needed. However, leap seconds are still in effect at this writing (2010), and the issue remains unresolved.

41.5 Time Interval Measurements

A common, but not particularly accurate, way to measure time interval is to use an oscilloscope. Oscilloscopes allow us to view the pulse waveforms, making it possible to select the start and end points that define a time interval, a major advantage when dealing with odd-shaped or noisy waveforms. Sometimes one pulse is displayed, while a different pulse is used to trigger the oscilloscope. Another method is to display both time pulses on a dual-trace oscilloscope. Triggering can be achieved from either of the two displayed pulses or from a third external pulse. The divisions along the horizontal axis of an oscilloscope are in units of time, and many oscilloscopes have a delta-time function (Δt) that will measure and displays the time interval between two cursors that can be moved along the horizontal axis. The oscilloscope display in Figure 41.2 shows a 358 ns time interval between two cursors that are aligned with the rising edge of two 1 pps signals.

Time interval measurements made with oscilloscopes are limited by a lack of resolution and range. Oscilloscope range varies, and some models can scale from 50 ps to 10 s per time division. However, the resolution of the time interval measurement is proportional to the length of the interval. If the time pulses are 10 ms apart, for instance, the best oscilloscopes can resolve the interval to only about 1 μs. However, if the pulses are only 100 μs apart, the resolution is 10 ns. In both cases, the relative uncertainty is 1×10^{-4}.

A time interval counter (TIC) is usually the best instrument for measuring all but the shortest time intervals. Universal counters can measure time interval (along with other quantities such as frequency and period), and dedicated TICs are also available. A TIC measures the time interval between a start pulse and a stop pulse. The start pulse gates the TIC (starts it counting), and a stop pulse stops the counting. While the gate is open (Figure 41.3), the counter counts zero crossings from time base oscillator cycles, and the resolution of the simplest TICs is equal to the period of these cycles (e.g., 100 ns for a 10 MHz time base). However, many TICs use interpolation or digital processing schemes to divide the period into smaller parts. For example, dividing 100 ns by 5000 allows 20 ps resolution, a feat achieved

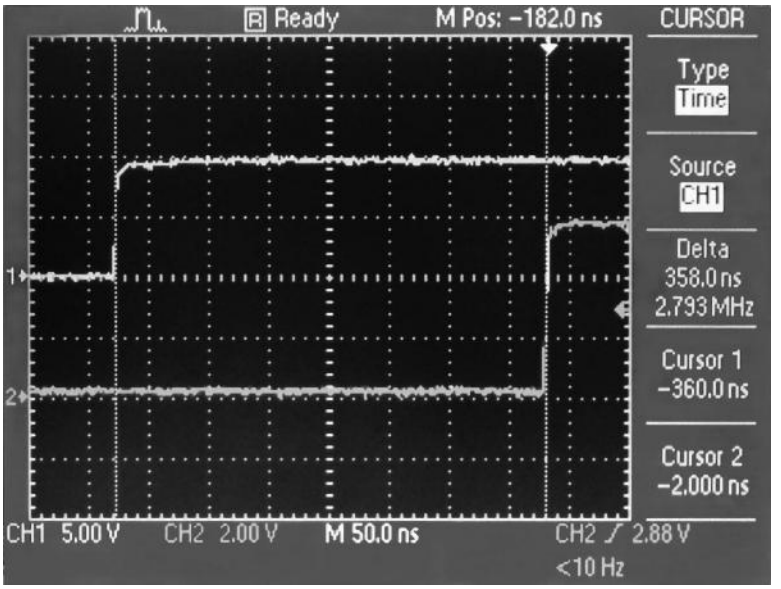

FIGURE 41.2 Measuring time interval with an oscilloscope.

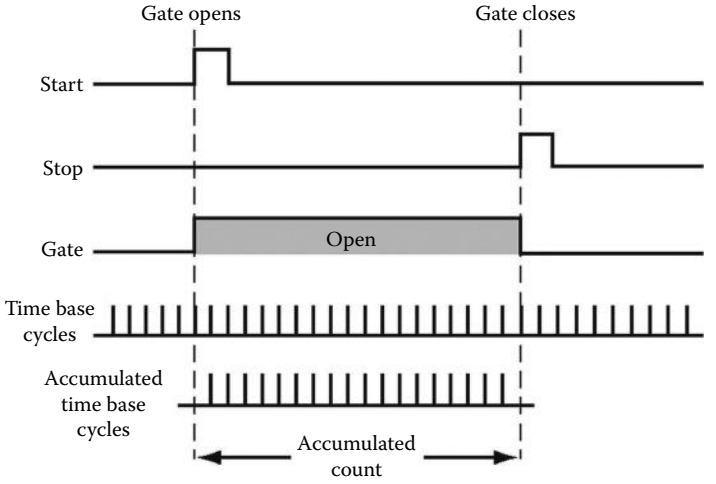

FIGURE 41.3 Gate and counting function of TIC.

by some universal counters, and some dedicated TICs achieve 1 ps resolution. These fine resolutions allow TICs to reach measurement uncertainties of 2×10^{-11} or less over a 1 s interval, often averaging down to parts in 10^{15} or 10^{16} after a few hours.

The uncertainty of TIC measurements can be limited, however, by resolution, trigger errors, or time base errors. A TIC generally has some ambiguity in its least significant digit of resolution. However, this count ambiguity often averages out when multiple readings are taken and is usually a problem only with single measurements. Trigger errors are a more significant problem. They occur when the counter does not trigger at the expected voltage level on the input signal and can be caused by incorrect trigger settings or by input signals that are noisy, too large, or too small. It is imperative to make sure that the TIC is triggering at the proper point on both the start and stop waveforms (if necessary, view the waveforms on an oscilloscope). Time base errors are generally not a problem when measuring short time intervals.

For example, consider a typical counter with 1 ns resolution and a time base stability of 1×10^{-8}. When a 1 ms interval is measured, the time base uncertainty is 10^{-3} s/$10^{8} = 10^{-11}$ s or 10 ps. This is much smaller than the uncertainty contributed by the counter's resolution. Even so, the best oscillator available should be used as the counter's external time base, because time base errors can be significant when long time intervals are measured.

A TIC can also measure medium and long time intervals if it has the necessary range. For example, a TIC that counts 100 ns periods with a 32 bit counter will overflow after $2^{32} \times 100$ ns or about 429 s. However, many TICs keep track of counter overflows, and some have the ability to measure intervals of about 1 day in time interval mode. If the TIC range is insufficient, most universal counters have a totalize mode that simply counts cycles from an external frequency source. Some commercial counters can count up to 10^{15} cycles. The period of the external gate frequency determines the resolution of this type of measurement. For example, if 1 μs resolution is desired, use a 1 MHz gate frequency. In this case, the time interval range would be $10^{15}/10^{6} = 10^{9}$ s or nearly 32 years.

The most common time interval measurements are probably made with stopwatches and similar low-cost timing devices. These devices are used to measure time intervals ranging from several seconds to many hours, and although the measurement uncertainties are high, stopwatches still must be periodically calibrated. These calibrations are typically performed by manually triggering the stopwatch while listening to an audio time signal or viewing a synchronized time display. The legally required uncertainty for stopwatch calibrations is often 1 or 2 parts in 10^{4}, a requirement limited mostly by human reaction time, which is often 10–100 times worse than the uncertainty of the oscillator inside the stopwatch.

Other stopwatch calibration methods reduce or eliminate the problem of human reaction time. One method utilizes a universal counter in the totalize mode described earlier. The counter is gated with a signal from a calibrated signal generator. The gate frequency should have a period at least one order of magnitude smaller than the resolution of the stopwatch. For example, if the stopwatch has 10 ms resolution, use a 1 kHz frequency (1 ms period). The operator then starts and stops the totalize counter by rapidly pressing the start–stop button of the stopwatch against the start–stop button on the counter. The readings from both instruments are recorded, and the equation $\Delta t/T$ is used to get the result, where Δt is the difference between the counter and stopwatch displays and T is the length of the measurement run. For example, if $\Delta t = 100$ ms and $T = 1$ h, the uncertainty is roughly 2.8×10^{-5}, which exceeds the legal requirement.

A second method involves measuring the frequency offset of the oscillator inside the stopwatch, which is usually a 32,768 Hz quartz oscillator. For example, if the stopwatch time base oscillator has a 1 Hz frequency offset, the dimensionless frequency offset ($1/32{,}768 = 3 \times 10^{-5}$) translates to a time offset of about 110 ms in 1 h or near the value for Δt in the previous example. Commercially available instruments with acoustic or inductive sensors can detect the oscillator frequency and automate this measurement [14].

41.6 Time Synchronization Measurements

Many applications require multiple clocks to be *synchronized* or set to the same time. Using the time interval measurement methods described in Section 41.5, a clock can be synchronized by comparing it to a UTC reference and adjusting the time offset until it is as near zero as possible. *Time transfer* is the practice of transferring the time from a reference clock at one location and using it to measure or synchronize a clock at another location.

The reference signals used for time transfer generally need to provide two things: an on-time marker (OTM) and a time code. The OTM is typically a 1 pps signal that is synchronized to the start of the UTC second. The time code provides time-of-day information including the UTC hour, minute, and second, as well as the month, day, and year. These reference signals usually originate from a UTC time scale maintained by a national timekeeping laboratory.

Time can be transferred through many different mediums, including coaxial cables, optical fibers, radio signals, telephone lines, and computer networks. Before discussing the available radio and Internet time transfer signals, the methods used to transfer time [15] are examined.

41.6.1 Time Transfer Methods

As noted, time transfer methods are used to synchronize or compare a local clock to a reference clock. The single largest contributor to time transfer uncertainty is *path delay* or the delay introduced as the signal travels from its source to its destination. To illustrate the path delay problem, consider a reference time signal broadcast by radio. To synchronize a remote clock at a receiving site to the reference time, we need to calculate how long it took for the signal to travel from the transmitter to our receiver. Radio signals travel at the speed of light at about 3.3 μs/km. Therefore, if the receiver is 1000 km from the transmitter, the time will be 3.3 ms late when we receive it. We can compensate for this path delay by making a 3.3 ms adjustment to the remote clock. This practice is called *calibrating the path*.

In the example earlier, we are assuming that the signal travelled the shortest path between the transmitter and receiver, which are not always true. Many factors limit how well the path can be calibrated, and our knowledge of the received time will always be limited by our knowledge of the path delay. However, many innovative ways have been developed to compensate for path delay. The various time transfer methods can be divided into five general categories:

1. *One-way method* (*user calibrates path*): This is the simplest type of time transfer, a one-way system where the user is responsible for calibrating the path (if required). The signal from the transmitter to the receiver is delayed τ_{ab} by the medium (Figure 41.4). To obtain the best results, the user must estimate τ_{ab} and calibrate the path by compensating for the delay. In many cases, however, the time is already accurate enough to meet the user's requirements, so the delay through the medium is simply ignored.
2. *One-way method* (*self-calibrating path*): This method is a variation of the simple one-way method shown in Figure 41.4. However, the time transfer system (and not the user) is responsible for estimating and removing the τ_{ab} delay.

   One of two techniques is commonly used to reduce τ_{ab}. The first technique is to simply estimate τ_{ab} and to send the time out early. For example, if we estimate that τ_{ab} will be at least 20 ms for all users, we can transmit the OTM 20 ms before the arrival of the UTC second and reduce the uncertainty for all users.

   A more sophisticated technique is to compute τ_{ab} and apply a correction. This can be done if the coordinates of both the transmitter and receiver are known. If the transmitter is stationary, a constant can be used for the transmitter position. If the transmitter is moving (e.g., a satellite), it must broadcast its coordinates in addition to broadcasting a time signal. The receiver's coordinates must either be computed by the receiver (in the case of satellite navigation systems) or input by the user. Then, the receiver firmware can compute the distance between the transmitter and receiver and compensate for the path delay by correcting for τ_{ab}. The uncertainty of this method is still limited by position errors for either the transmitter or receiver and by variations in the transmission speed of the signal along the path.

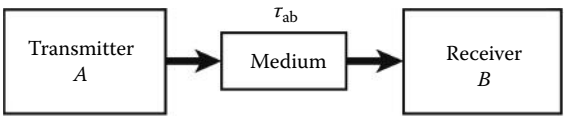

FIGURE 41.4 One-way time transfer.

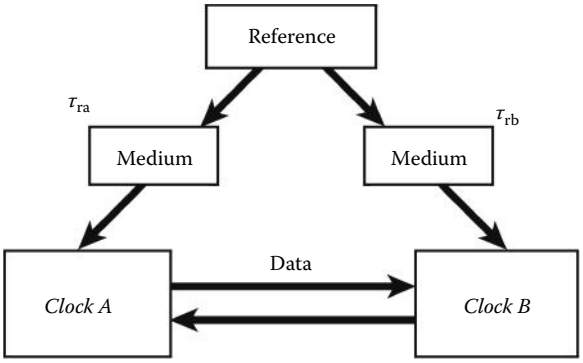

FIGURE 41.5 Common-view time transfer.

3. *Common-view method*: The common-view method involves a reference transmitter (*R*) and two receivers (*A* and *B*). The transmitter is in "common view" to both receivers. Both receivers compare the simultaneously received signal to their local clock and record the data (Figure 41.5). Receiver *A* receives the signal over the path τ_{ra} and compares the reference to its local clock (*R* – *Clock A*). Receiver *B* receives the signal over the path τ_{rb} and records (*R* – *Clock B*). The difference between the two measurements is an estimate of the difference between the two clocks. Errors from the two paths (τ_{ra} and τ_{rb}) that are common to the reference cancel out, eliminating much of the uncertainty caused by path delay. The result of the measurement is (*Clock A* – *Clock B*) – ($\tau_{ra} - \tau_{rb}$).

   Unlike the one-way methods, the common-view method cannot synchronize clocks in *real time*, because data from both receiving sites must be transferred and processed before the final measurement results are known. However, the Internet makes it possible to transfer and process the data very quickly. Therefore, common-view data can synchronize clocks in *near real time*, a method now commonly employed by NIST and other laboratories.
4. *Two-way method*: The two-way method requires two users to both transmit and receive timing signals through the same medium at the same time (Figure 41.6). This differs from the passive common-view method where timing signals are only received and not transmitted. Sites *A* and *B* simultaneously exchange time signals through the same medium and compare the received signals with their own clocks. Site *A* records $A - (B + \tau_{ba})$ and site *B* records $B - (A + \tau_{ab})$, where τ_{ba} is the path delay from *B* to *A* and τ_{ab} is the path delay from *A* to *B*. The difference between the two clocks is $(A - B)/2 + (\tau_{ba} - \tau_{ab})/2$. If the path is reciprocal ($\tau_{ab} = \tau_{ba}$), then the difference is simply $(A - B)/2$.

   When properly implemented, the two-way method outperforms all other time transfer methods and has many potential applications. It can, however, be complex to implement. When wireless mediums are used, it can require a substantial amount of equipment, as well as government licensing so that users are allowed to transmit. Like the common-view method, the two-way method requires measurement data to be transferred. However, because users have the ability to transmit, it is possible to send data through the same medium as the time signals.
5. *Loop-back method*: A variation of the two-way method, the loop-back method also requires the receiver to send information back to the timing source. For example, an OTM is sent from the transmitter (*A*) to the receiver (*B*) over the path τ_{ab}. The receiver (*B*) then sends the OTM back to

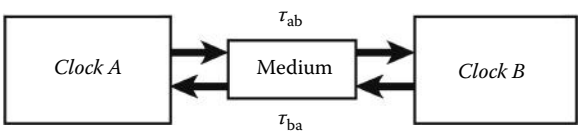

FIGURE 41.6 Two-way time transfer.

the transmitter (*A*) over the path $\tau_{ba.}$ The one-way path delay is assumed to be half of the measured round trip delay or $(\tau_{ab} + \tau_{ba})/2$. The transmitter calibrates the path by sending another OTM that has now been advanced by the estimated one-way delay. The method usually works well but is less accurate than the two-way method because the OTM transmissions are not simultaneous, and it is not known whether the path delay is the same in both directions. The loop-back method is not practical to use through a wireless medium and is typically applied to telephone or network connections where it can be implemented entirely in software.

41.6.2 Time Codes

A *time code* is a message containing time-of-day information that allows the user to synchronize a clock. ITU guidelines state that all time codes should distribute the UTC hour, minute, and second, as well as a DUT1 correction.

Time codes are broadcast in a number of different formats (including binary, binary coded decimal [BCD], and ASCII). There is very little standardization of broadcast time codes, but standards for redistributing time codes within a facility were first developed by the Inter-Range Instrumentation Group (IRIG) in 1956 and are still used by today's equipment manufacturers. IRIG defined numerous time code formats, but the most common is probably IRIG-B. These standardized time codes make it possible for manufacturers to build compatible equipment. For example, a satellite receiver with an IRIG-B output can drive a time-of-day display that accepts an IRIG-B input. Or it can provide a timing reference to a computer that can read IRIG-B.

The IRIG time code formats are serial, width-modulated codes that can be used in either dc level shift or amplitude-modulated (AM) form. For example, IRIG-B has a 1 s frame period and can be transmitted as either a dc level shift modulation envelope or a modulated 1000 Hz carrier. Time-of-day data (days, hours, minutes, and seconds) in BCD or straight binary format is included within the frame. Simple IRIG-B decoders retrieve just the encoded data and provide 1 s resolution. Other decoders count carrier cycles and provide resolution equal to the period of the 1000 Hz cycle (1 ms). More advanced decoders phase lock an oscillator to the time code and provide resolution limited only by the signal-to-noise ratio of the time code (typically ±2 μs).

41.7 Radio Time Transfer

Several types of receivers and signals are used to transfer time by radio. The cost of a time transfer receiver can vary widely, from less than $10 for a simple radio-controlled clock that synchronizes once per day and keeps time within 1 s of UTC to $20,000 or more for a receiver that adjusts a rubidium oscillator with satellite signals and keeps time within nanoseconds of UTC. When selecting a time transfer receiver, make sure that the signal can be received at your location, that the uncertainty is low enough to meet your requirements, and that the appropriate type of antenna can be mounted. The following sections summarize the various signals used for radio time transfer.

41.7.1 HF Time Signal Stations

High-frequency (HF) or *shortwave* radio signals are used for time transfer at moderate performance levels. These stations are useful because they provide worldwide coverage under optimal receiving conditions, they can be heard with any shortwave receiver, and they provide audio time announcements that can serve as a "talking clock." The audio signals are also widely used by metrologists as a time interval reference for stopwatch and timer calibrations. The practical limit of time transfer uncertainty with HF stations is about 1 ms. This is because the signals often travel by *sky wave* and the path length varies, making it difficult to accurately determine the path delay.

TABLE 41.3 HF Time Signal Station List

Call Sign	Location	Frequencies (MHz)	Controlling Agency
WWV	Fort Collins, Colorado, United States	2.5, 5, 10, 15, 20	NIST
WWVH	Kauai, Hawaii, United States	2.5, 5, 10, 15	NIST
BPM	Lintong, China	2.5, 5, 10, 15	National Time Service Center (NTSC)
CHU	Ottawa, Canada	3.33, 7.85, 14.67	National Research Council (NRC)
HLA	Taejon, Korea	5	Korea Research Institute of Standards and Science (KRISS)

Table 41.3 provides a list of HF time signal stations that are referenced to UTC as of 2010. Only a few stations remain, as many have been turned off in recent years. This is probably because far more accurate time signals can now be easily obtained from satellites and because low accuracy time (within 1 s) can now be easily obtained from the Internet or from inexpensive low-frequency (LF) radio-controlled clocks.

The best known HF time signal stations are WWV and WWVH, both operated by NIST. WWV is located near Fort Collins, CO, and WWVH is on the island of Kauai, HI. Both stations broadcast continuously on 2.5, 5, 10, and 15 MHz, with WWV also available on 20 MHz. All frequencies carry the same audio broadcast, which includes short pulses transmitted every second that sound similar to the ticking of a clock. At the start of each minute, a voice announces the current UTC hour and minute. WWV uses a male voice to announce the time, and WWVH uses a female voice. The voice announcement is followed by a long audio pulse of 800 ms in duration. In addition to the audio, a time code is sent on a 100 Hz subcarrier at a 1 bit per second (bps) rate.

41.7.2 LF Time Signal Stations

LF signals are seldom used for high-accuracy time transfer, but they have a major advantage over HF and satellite signals—they can be easily received indoors without an external antenna. This makes LF time signal stations the ideal synchronization source for radio-controlled clocks and wristwatches. Signals from NIST radio station WWVB synchronize an estimated total of more than 50 million radio-controlled clocks in the United States daily as of 2010, with many millions of new clocks being sold each year.

Several countries operate LF time signal stations at frequencies ranging from 40 to 77.5 kHz (Table 41.4). These stations do not provide voice announcements but do provide an OTM and a time code.

NIST radio station WWVB, which covers most of North America, has a format similar, but not identical, to that of the other stations listed in Table 41.4. WWVB requires a full minute to send its

TABLE 41.4 LF Time Signal Station List

Call Sign	Location	Frequencies (kHz)	Controlling Agency
WWVB	Fort Collins, Colorado, United States	60	NIST
BPC	Lintong, China	68.5	NTSC
DCF77	Mainflingen, Germany	77.5	Physikalisch-Technische Bundesanstalt (PTB)
JJY	Japan	40, 60	National Institute of Information and Communications Technology (NICT)
MSF	Rugby, United Kingdom	60	National Physical Laboratory (NPL)
RBU	Moscow, Russia	66.67	Institute of Metrology for Time and Space (IMVP)

time code in BCD format. Bits are sent a rate of 1 bps by shifting the power of the carrier. The carrier power is reduced 17 dB at the start of each second, and the first carrier cycle after the power drop serves as the OTM. If full power is restored after 200 ms, it represents a binary 0. If full power is restored after 500 ms, it represents a binary 1. Reference markers and position identifiers are sent by restoring full power after 800 ms. The WWVB time code provides year, day, hour, minute, and second information, a DUT1 correction, and information about daylight saving time, leap years, and leap seconds.

Calibrating the path is easier with LF signals than HF signals, because part of the LF signal is *ground wave* and follows the curvature of the Earth. However, due to uncertainties in the estimate of path delay and because it is difficult to determine the correct OTM to within better than a few cycles of the carrier, the practical limit for timing uncertainty with WWVB and similar stations is about 0.1 ms or roughly 1000 times larger than the timing uncertainty of GPS, as explained in the next section.

41.7.3 Global Positioning System

The Global Positioning System (GPS) is a global navigation satellite system (GNSS) developed and operated by the US Department of Defense (US DoD). GPS was designed as a positioning and navigation system but has become the main system used to distribute high-accuracy time signals worldwide. The GPS constellation includes as many as 32 satellites in semi-synchronous orbit at a height of 20,200 km. The orbital period is 11 h and 58 min, which means that each satellite passes over a given location on Earth 4 min earlier than it did on the previous day. By processing GPS signals, even a low-cost handheld receiver can determine its position on Earth with an uncertainty of a few meters.

The GPS satellites carry atomic clocks that are steered from US DoD ground stations to agree with UTC(USNO), which is normally well within 20 ns of UTC. GPS time must be accurate in order for the system to meet its specifications for positioning and navigation. To illustrate this, consider that the satellites receive clock corrections from Earth-based control stations once during each orbit or about once every 12 h. The maximum acceptable contribution from the satellite clocks to the positioning uncertainty is considered to be about 1 m. Since light travels at about 3×10^8 m/s, the 1 m requirement means that the time error between clock corrections must be less than about 3.3 ns.

All GPS satellites broadcast on the *L*1 (1.57542 GHz) and *L*2 (1.2276 GHz) carrier frequencies, with satellites launched after May 2010 also utilizing the *L*5 carrier at 1.17645 GHz. The satellites are identified by a unique spread-spectrum waveform, called a pseudorandom noise (PRN) code, which it transmits on each carrier. There are two types of PRN codes. The first type is a coarse acquisition (*C*/*A*) code with a chip rate of 1.023 megabits/s. The second type is a precision (*P*) code with a chip rate of 10.230 megabits/s. The *C*/*A* code is broadcast on *L*1, and the P code is broadcast on both *L*1 and *L*2. A 50 bit/s data message is also broadcast on both carriers [16–18]. Dual-frequency timing receivers have become more common as of 2010, but most timing devices receive only *L*1. Nearly all GPS timing receivers can simultaneously track at least eight satellites.

41.7.4 One-Way Time Transfer Using GPS

GPS receivers transfer time from the satellites to the receiver clock through a series of range measurements. The range measurements used to calculate position are derived by measuring the time required for the signals to travel from each satellite to the receiver. After the receiver position (*x, y, z*) is solved for, the solution is stored. Then, by using the travel time of the signal and the exact time when the signal left the satellite, time from the satellite clocks can be transferred to the receiver clock.

This time difference between the satellite and receiver clocks, when multiplied by the speed of light, produces not the true geometric range but rather the pseudorange. The equation for the pseudorange observable is

$$p = \rho + c \times (dt - dT) + d_{\text{ion}} + d_{\text{trop}} + r_{\text{n}} \tag{41.2}$$

where

p is the pseudorange
c is the speed of light
ρ is the geometric range to the satellite
dt and dT are the time offsets of the satellite and receiver clocks with respect to GPS time
d_{ion} is the delay through the ionosphere
d_{trop} is the delay through the troposphere
r_{n} is the effects of receiver and antenna noise, including multipath

Estimates of d_{ion} and d_{trop} are obtained from the GPS broadcast.

The receiver produces a local time estimate for each satellite by using the pseudorange data to compensate for propagation delay and by applying satellite clock corrections received from the broadcast. The receiver then combines the satellite time estimates, by simple averaging or another statistical technique, and uses this information to synchronize a 1 pps timing signal. Two additional corrections, one large and one small, are also necessary to convert GPS time to UTC(USNO). GPS time differs from UTC(USNO) by the number of leap seconds that have occurred since the origination of the GPS time scale (January 6, 1980). It also differs from UTC(USNO) by a small number of nanoseconds that continuously change. Both corrections are included in data messages broadcast by the satellites and are automatically applied by the receiver firmware. Thus, both the time-of-day and the OTM obtained from a GPS timing receiver are referenced to UTC(USNO).

Several factors limit the uncertainty of GPS time synchronization, including receiver and antenna cable delays, antenna coordinate errors, ionospheric and tropospheric delay effects noted earlier, multipath reflections, and environmental effects. Even when all of these factors are ignored, the uncertainty of the time produced by a GPS receiver will likely be less than 1 μs with respect to UTC. By calibrating the receiver and accounting for the factors listed earlier, it is usually easy to reduce this uncertainty to within ±100 ns, with ±20 ns being the practical limit.

41.7.5 Common-View Time Transfer Using GPS

Unlike the one-way method, the common-view GPS (CVGPS) method does not use GPS time as the reference source. Instead, GPS is simply a vehicle used to transfer time from one site to another. The CVGPS method compares two clocks at different locations to each other by simultaneously comparing them both to GPS signals that are in "common view." The comparison results are recorded and exchanged, and the difference between the two comparisons is the time difference between the two clocks. Because GPS is available worldwide, the CVGPS method can potentially be used to compare any two clocks on Earth to each other or to synchronize a given clock on Earth to any other clock.

The CVGPS method involves one or more GPS satellites (S) and two receiving sites (A and B), each containing a GPS receiver and a local clock (Figure 41.7). The satellites transmit signals that are received at both A and B, and both sites compare the received signals to their local clock. Thus, the measurement at site A compares GPS signals, S, received over the path d_{SA} to the local clock, *Clock A – S*. Site B receives GPS signals over the path d_{SB} and measures *Clock B – S*.

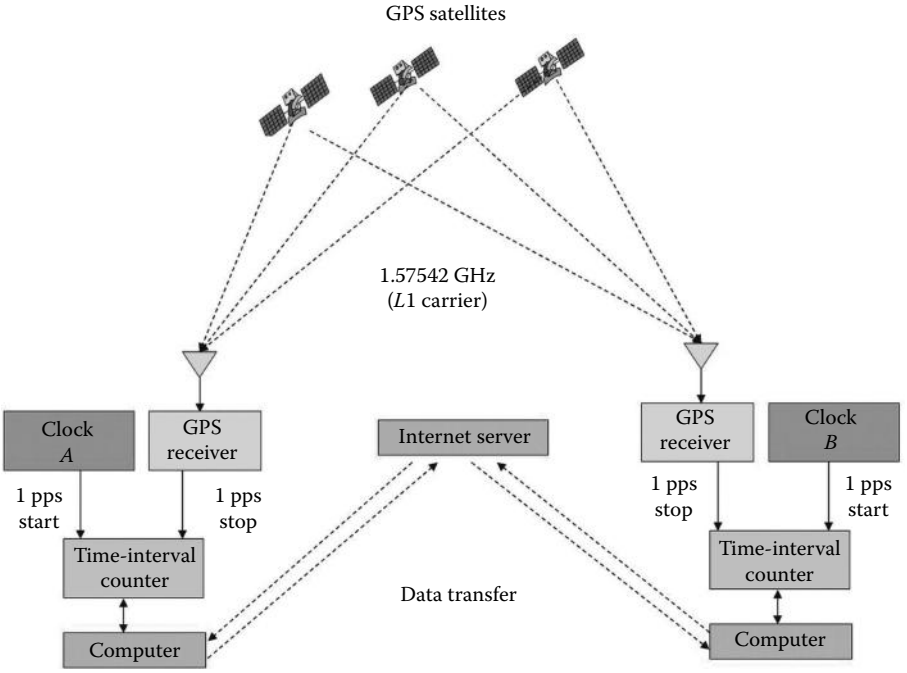

FIGURE 41.7 *C/A* code CVGPS using the *L*1 carrier.

The difference between the two measurements is an estimate of *Clock A – Clock B*. Delays that are common to both paths d_{SA} and d_{SB} cancel even if they are unknown, but uncorrected delay differences between the two paths add uncertainty to the measurement result. Thus, the basic equation for a CVGPS measurement is

$$(Clock\ A - S) - (Clock\ B - S) = (Clock\ A - Clock\ B) + (e_{SA} - e_{SB}) \tag{41.3}$$

The components that make up the $(e_{SA} - e_{SB})$ error term include delay differences between the two sites caused by ionospheric and tropospheric delays, multipath signal reflections, environmental conditions, and errors in the GPS antenna coordinates. These factors can be measured or estimated and applied as a correction to the measurement, or they can be accounted for in the uncertainty analysis. It is also necessary to calibrate the GPS receivers used at both sites and account for the local delays in the receiver, antenna, and antenna cable.

Figure 41.7 is a simplified diagram that illustrates *C/A* code common view using the *L*1 carrier, but there are several other variations of the CVGPS measurement technique that can provide lower measurement uncertainties. The uncertainty depends upon the type and quality of the GPS equipment in use and the technique used. For example, the differential ionospheric delay can be nearly eliminated by receiving both the *L*1 and *L*2 carrier frequencies. The quality of equipment also makes a difference; some GPS receivers are less sensitive to environmental changes than others, and some antennas are more effective than others at mitigating multipath. The most sophisticated techniques and equipment compare the local clock to the GPS carrier, rather than to the *C/A* code, and can reduce the time uncertainty to a few nanoseconds or less, but the incremental performance gains obtained from the additional cost and effort are relatively small. Even when inexpensive GPS hardware (*L*1 band only) and simple processing techniques are used, the measurement uncertainty of the CVGPS technique is often within ±15 ns, with ±5 ns being the practical limit for the most advanced techniques.

TABLE 41.5 Satellite Systems Used for Time Transfer

System	Controlling Region	Type of System	Completion Date	Number of Satellites
Compass	China	GNSS	2015	30
EGNOS	European Union	Augmentation, geostationary orbit	Completed	3
GPS	United States	GNSS	Completed	32
Galileo	European Union	GNSS	2015	30
GLONASS	Soviet Union	GNSS	Completed	24
QZSS	Japan	Augmentation, highly elliptical orbit	2013	3
WAAS	United States	Augmentation, geostationary orbit	Completed	2

41.7.6 Other Satellite Systems Used for Time Measurements

Several other GNSS and augmentation systems can be used a reference for time measurements. Receivers for these systems are not yet available in some cases as of 2010, but performance should eventually be comparable to GPS in both one-way and common-view modes. In many cases, the systems were designed to interoperate with each other and thus share the same or similar frequency bands as GPS, with carrier frequencies ranging from about 1.1 to 1.6 GHz. Table 41.5 summarizes the various systems, including GPS.

41.7.7 Two-Way Satellite Time Transfer via Geostationary Satellites

The two-way satellite time transfer (TWSTT) method (Figure 41.8) requires more equipment and effort than the passive GPS methods, because users are required to both transmit and receive time signals. Signals are transmitted and received from two Earth stations through the transponder on a geostationary satellite. Each Earth station contains a local clock, a spread-spectrum satellite modem, a dish antenna, a TIC, and transmitting and receiving equipment. The carrier frequency used for the radio link is typically in the K_u band.

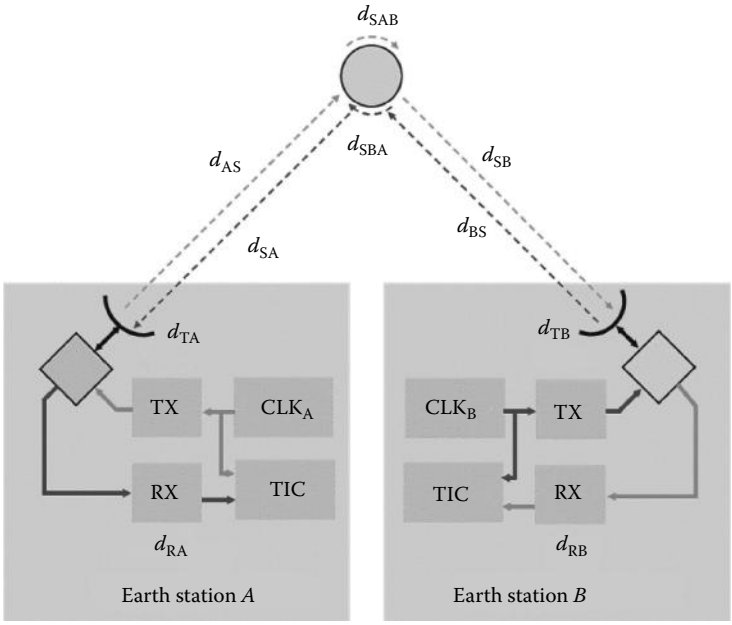

FIGURE 41.8 Two-way satellite time transfer.

TABLE 41.6 Performance of Radio Time Transfer Signals

Method	Time Uncertainty with Little or No Effort Made to Calibrate Path or Equipment	Practical Uncertainty Limit	Items Needed to Reach Uncertainty Limit
HF (WWV)	<30 ms	±1 ms	Good path delay estimate, radio propagation model
LF radio (WWVB)	<15 ms	±0.1 ms	Good path delay estimate, ability to determine the correct OTM to within a few cycles of the carrier
GPS (one way)	<1 μs	±20 ns	Calibrated receiver with antenna surveyed to within 1 m
GPS (common-view code)	±50 ns	±15 ns	Calibrated receivers at both sites with antennas surveyed to within 1 m and antennas designed to mitigate multipath
GPS (common-view carrier)	±10 ns	±5 ns	Calibrated receivers at both sites that accept the local clock input and that produce files with carrier phase observables
TWSTT	±10 ns	±1 ns	Calibrated satellite terminals at both Earth stations, good environmental control

Earth stations *A* and *B* simultaneously exchange time signals by transmitting a unique PRN code and receiving the PRN code sent by the other station. Each station compares the received time signal to its local clock. Station A records $TIC_A = CLK_A - (CLK_B + \tau_{ba})$, where CLK_A is the time from the local clock, CLK_B is the time from the remote clock, and τ_{ba} includes all of the terms that make up the path delay from *B* to *A*, including delays in the transmitting modem, the satellite uplink, the satellite transponder, the satellite downlink, and the receiving modem. Station *B* records $TIC_B = CLK_B - (CLK_A + \tau_{ab})$, where τ_{ba} includes all of the terms that make up the path link from *B* to *A*.

The two stations then exchange their results and compute their time difference:

$$A - B = \frac{TIC_A - TIC_B}{2} - \frac{\tau_{ba} - \tau_{ab}}{2}. \tag{41.4}$$

If the paths were reciprocal ($\tau_{ab} = \tau_{ba}$), then the difference would simply be $(TIC_A - TIC_B)/2$. The paths will never be completely reciprocal in practice, but most of the significant differences in the path delay do cancel. When properly implemented, the two-way satellite method outperforms all other satellite time transfer methods. The uncertainty can often be reduced to ±1 ns [12].

Table 41.6 summarizes the various radio time transfer methods. Table 41.7 provides a list of companies that manufacture and sell atomic oscillators, GPS timing receivers, and TICs.

41.8 Internet and Network Time Transfer

The synchronization of computer clocks is a very common time transfer application. Computers connected to the Internet can synchronize their clocks quickly and easily because Network Time Protocol (NTP) [19] client software is often included with the operating system. NTP is a hierarchical clock system, where each level of the hierarchy is termed a stratum. Synchronization flows from primary servers at the lowest stratum to secondary servers at progressively higher strata. Servers referenced to national time standards are designated as Stratum-1. As of 2010, NIST maintains about half of the approximately 50 Stratum-1 NTP servers located in the United States that are accessible to the general public (see ntp.org for a current list). The demand for these servers is high, and the NIST servers handle several billion NTP requests per day.

Client computers (which can also be servers to computers at higher stratums) issue time requests to an NTP server via TCP/IP port 123. They receive a data packet that contains a UTC time code and other time stamps that indicate when the request was made, when it arrived, and when the packet was sent. This information is used to calibrate the path, to synchronize the client's clock, and to steer the client's clock between synchronizations. The performance of NTP depends upon the client hardware and software and network conditions and varies widely, but uncertainties of less than a millisecond have been demonstrated under optimal conditions. A typical computer, running the Microsoft Windows operating system on the public Internet, can usually keep time within 1 or 2 s of UTC with one NTP synchronization request per week.

The Precision Time Protocol (PTP) can obtain much lower uncertainties than NTP, often less than 1 μs, but is generally not suited for the public Internet. Defined by the IEEE-1588 standard, PTP is primarily intended for local area networks where path delays can be better measured and estimated. The grandmaster clock is the time reference for all other clocks in a PTP system. The other clocks are designated as ordinary clocks, which have a single PTP port, and boundary clocks, which have multiple network connections and can bridge synchronization from one network segment to another.

Time transfer methods normally associated with satellites, such as the two-way and loop-back methods, are also applicable to private or dedicated networks. In fact, experiments using optical fibers as the time transfer medium over short distances have demonstrated much lower uncertainties than any of the satellite-based methods [20]. However, there are technical and financial obstacles that make it difficult to implement these techniques over long distances. For example, it is not easy to maintain the symmetry

of the path delay in very long fibers, and it is hard to justify the cost of an optical fiber network that is dedicated to time transfer. Even so, it seems likely that optical fiber networks will play a large role in future state-of-the-art time transfer experiments.

41.9 Future Developments

Optical atomic clocks will eventually replace cesium fountain clocks as the world's most accurate time standards, and the SI second will eventually be redefined, with the new definition based on an optical atomic transition, rather than a microwave transition. When this occurs, the uncertainty of the physical realization of the SI second is likely to improve by at least two orders of magnitude.

As clocks continue to improve, time transfer systems will in turn have to lower their measurement uncertainties in order to improve the performance of UTC. The future of time transfer should involve continued enhancements to satellite systems and measurement techniques, an increased reliance on signals sent over optical fibers, and perhaps the use of technologies yet to be developed.

Time-of-day clocks that are synchronized to within 1 s of UTC will become more common and should eventually become the norm rather than the exception. Many technologies could contribute to this trend, including LF radio signals, satellite signals, mobile phone signals, Internet time codes, and CSACs.

42

Frequency Measurement

Michael A. Lombardi
National Institute of Standards and Technology

Frequency is the rate of occurrence of a repetitive event. If T is the period of a repetitive event, then the frequency is its reciprocal, $f = 1/T$. The International System of Units (SI) states that the period should be expressed in seconds (s), and the frequency should be expressed in hertz (Hz). The frequency of electrical signals is often stated in units of kilohertz (kHz), megahertz (MHz), or gigahertz (GHz), where 1 kHz equals one thousand (10^3) events per second, 1 MHz equals one million (10^6) events per second, and 1 GHz equals one billion (10^9) events per second.

Frequency metrology first became a topic of interest around 1920, when the burgeoning radio industry began erecting radio transmitters all over the world. These transmitters had to stay near their assigned frequencies to avoid interference with signals from other stations. In addition, the many millions of radio receivers that were soon manufactured had to be able to tune to a desired frequency so that the selected station could be heard. The original requirements for transmitter accuracy were low, about one part per thousand (1×10^{-3}), but at the time, they posed a challenging metrology problem. Within a few years, however, the development of the quartz oscillator soon made that type of accuracy trivial. By the 1930s, commercial quartz oscillators accurate to about one part per million (1×10^{-6}) were widely available, and by the late 1960s, quartz technology with about the same accuracy found its way into low-cost wristwatches and clocks. The production of commercial atomic oscillators also began in earnest in the 1960s, resulting in huge improvements in accuracy and resulting in many new technologies. For example, the infrastructure that we now take for granted, including telecommunication networks and the electric power grid, requires frequency accurate to about 1×10^{-11} to be simultaneously generated around the world during every hour of every day. In calibration and metrology laboratories, frequency measurements accurate to one part per ten trillion (1×10^{-13}) have now become routine, and the Global Positioning System (GPS) depends upon oscillators that are stable to parts in 10^{14} for multiple hours. This level of performance separates frequency metrology from most of the other fields of metrology, where one part per billion (1×10^{-9}) is often either unattainable or considered a major accomplishment.

This chapter provides an overview of frequency measurements. It focuses on the measurement of the electrical signals produced by oscillators. For our purposes, an *oscillator* is a device that

produces electrical signals at a specific frequency, typically in the form of either a sine or a square wave. Section 42.1 begins by discussing the concepts of accuracy and stability, which are essential to understanding oscillator specifications. Section 42.2 then describes the various types of oscillators used as frequency standards, including quartz and atomic oscillators, and oscillators disciplined to agree with an external reference signal. Section 42.3 describes the methods and techniques used to measure frequency and calibrate oscillators. Section 42.4 provides a brief look at the likely future of frequency metrology.

42.1 Frequency Accuracy and Stability

This section looks at the two main specifications used to characterize an oscillator: accuracy and stability. A good understanding of the basic concepts introduced in this section is necessary when evaluating equipment or performing measurements.

42.1.1 Frequency Accuracy

The accuracy of an oscillator is the difference between its actual frequency, as determined by measurement, and its *nominal frequency*. The nominal frequency is labeled on the oscillator output and refers to an ideal frequency with zero uncertainty. For example, an oscillator with an output labeled "10 MHz" would ideally produce perfect 10 MHz signals, but its actual signals will differ from its nominal frequency by some amount. The difference between the actual frequency and the nominal frequency is called the *frequency offset* and determines the accuracy of an oscillator at a given point in time or over a specified interval.

Frequency offset is measured by comparing a test oscillator to a more accurate reference oscillator. There are several established measurement methods (described later in Section 42.3) that can provide this comparison in either the *frequency domain* or the *time domain*. The standard equation for estimating frequency offset in the frequency domain is

$$f_{\text{off}} = \frac{f_{\text{meas}} - f_{\text{nom}}}{f_{\text{nom}}}, \tag{42.1}$$

where

f_{off} is the frequency offset
f_{meas} is the actual frequency in hertz reported by the measurement
f_{nom} is the nominal frequency in hertz that the oscillator would ideally produce

Note that in practice, f_{meas} has an associated measurement uncertainty, but f_{nom} is always an ideal value with no uncertainty. Note also that the nominal frequency is included in both the numerator and the denominator. Thus, the resulting value for f_{off} is dimensionless, and not in units of hertz.

This equation is often simplified in the literature as

$$f_{\text{off}} = \frac{\Delta f}{f}, \tag{42.2}$$

where

f_{off} is the dimensionless frequency offset
Δf is the difference between the measured and nominal frequency in hertz
f is the nominal frequency in hertz

For example, if an oscillator labeled as 10 MHz (10^7 Hz) produces a frequency that is higher than nominal by 1 Hz, the equation becomes

$$f_{\text{off}} = \frac{1}{10^7} = 1 \times 10^{-7} \tag{42.3}$$

In many cases, the frequency offset of an oscillator is obtained in the *time domain* by measuring *time interval*. This works because frequency is the reciprocal of period, which is expressed as a time interval. A mathematical definition of frequency is

$$f = \frac{1}{T} \tag{42.4}$$

where

T is the period of the signal in seconds
f is the frequency in hertz

This can also be expressed as

$$f = T^{-1} \tag{42.5}$$

If we perform mathematical differentiation on the frequency expression with respect to time and substitute in the result, we can show that the average dimensionless difference in frequency is equivalent to the average dimensionless difference in time or that $\Delta f/f$ is equivalent to $\Delta t/T$. For example,

$$\Delta f = -T^{-2}\Delta t = -\frac{\Delta t}{T^2} = -\frac{\Delta t}{T} f \tag{42.6}$$

Therefore,

$$f_{\text{off}} = \frac{\Delta f}{f} = -\frac{\Delta t}{T} \tag{42.7}$$

where

Δt is the difference between two time interval measurements
T is the elapsed time between the two measurements

To keep the sign correct, note that the first reading must be subtracted from the second, therefore,

$$f_{\text{off}} = \frac{TI_2 - TI_1}{T} = -\frac{\Delta t}{T} \tag{42.8}$$

To illustrate this, consider a simple example where a time interval (TI_1) is measured, followed by another time interval measurement (TI_2) one second (10^9 ns) later. If $TI_2 - TI_1 = 100$ ns, this produces the same value for f_{off} that was previously shown in Equation 42.3:

$$f_{\text{off}} = \frac{100}{10^9} = 1 \times 10^{-7} \tag{42.9}$$

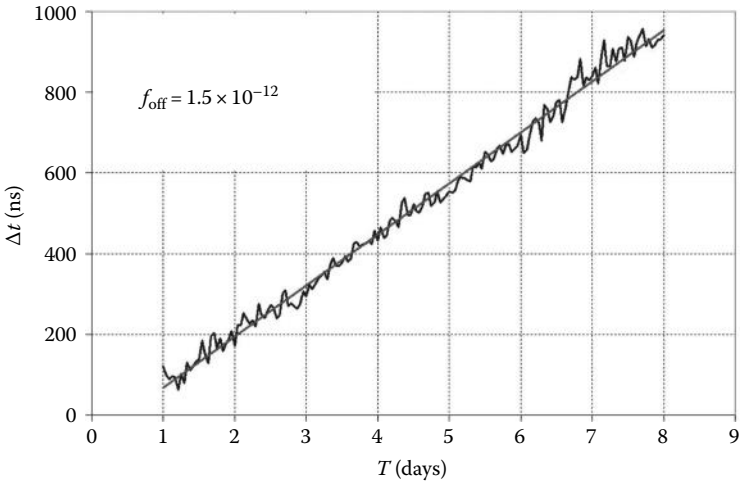

FIGURE 42.1 A sample phase graph used to estimate frequency accuracy.

In practice, more than two interval measurements are recorded, and it is common to graph the results of continuous time interval measurements recorded over multiple hours or days. These graphs are known as *phase* or time difference graphs. Phase graphs (Figure 42.1) use the standard Cartesian *x*/*y* format. The *x*-coordinate indicates elapsed time. This is the quantity T shown earlier in Equation 42.8. The values plotted as the *y*-coordinate represent the change in phase between the two electrical signals that are being compared to each other. However, since the phase changes are usually measured with instruments that express their results in units of time and not in radians or degrees, the *y*-coordinate is labeled to show the change in time or the Δt quantity in Equation 42.8.

Average frequency accuracy over a given interval can be estimated from the slope of a phase graph. In practice, a linear least squares line is often fitted to the phase data, and the slope of the least squares line is used to estimate Δt. In many cases, the slope of the least squares line is nearly identical to the slope of the actual data, because of the nearly constant frequency offset between the two oscillators being compared. In fact, to get a good estimate of frequency accuracy, the measurement period must be long enough to show this linear slope and detect a trend. A "clean" phase lot ensures that Δt is really a measure of the test oscillator's performance and indicates that neither the measurement system nor the reference oscillator has degraded the results by introducing excessive noise.

To illustrate this, Figure 42.1 shows a sample phase graph of an oscillator that was compared to a reference for a period of 7 days. During this period, the total accumulated time difference, Δt, was nearly 1000 ns, as indicated by both the actual data and the least squares line that was fitted to the data. From the slope of the least squares line, we can estimate that $f_{off} = 1.5 \times 10^{-12}$. The actual data are nosier than the least squares line, because some noise is contributed by the measurement system and the oscillators involved in the comparison. Even so, a strong linear trend is easily detected, and we can be comfortable that this is a good estimate of frequency accuracy.

If necessary, it is easy to convert a dimensionless frequency offset estimate to units of frequency (Hz) if the nominal frequency is known. To illustrate this, consider an oscillator with a nominal frequency of 10 MHz that is high in frequency by 1×10^{-11}. To find the frequency offset in hertz, multiply the nominal frequency by the dimensionless offset:

$$f_{nom} \times f_{off} = (1 \times 10^{7})\ (+1 \times 10^{-11}) = 1 \times 10^{-4} = +0.0001 \text{ Hz} = +0.1 \text{ mHz} \tag{42.10}$$

The actual frequency in this case is 10,000,000.0001 Hz, which is obtained by simply adding the offset frequency to the nominal frequency.

To summarize, frequency accuracy and frequency offset are equivalent terms that indicate how closely an oscillator produces its nominal frequency at a given point in time or over a given interval. Frequency accuracy can be estimated in either the frequency domain or the time domain. The accuracy of an oscillator can usually be at least temporarily improved by adjusting it to agree with a more accurate reference [1,2].

42.1.2 Frequency Stability

Frequency stability indicates how well an oscillator can produce the same frequency offset over a given time interval. Any frequency that "stays the same" is a stable frequency, regardless of whether the frequency is "right" or "wrong" with respect to its nominal value. To understand the difference between stability and accuracy, consider that an oscillator in need of adjustment might produce a stable frequency with a large offset. Or, an unstable oscillator that was recently adjusted might temporarily produce an accurate frequency near its nominal value. The stability of an oscillator cannot be changed by adjustment, so unlike accuracy, it tells us something about the inherent quality of an oscillator. In fact, the accuracy of an oscillator over a given interval can never be better than its stability. Figure 42.2 shows the relationship between stability and accuracy.

Frequency stability is normally estimated with statistics that quantify the frequency fluctuations of an oscillator's output over a given time interval. The fluctuations are measured with respect to a mean frequency offset, and the larger the dispersion of the fluctuations, the greater the instability of the oscillator. *Short-term stability* usually refers to fluctuations over intervals less than 100 s but is commonly used to discuss an oscillator's stability at an interval of 1 s. *Long-term stability* can refer to any measurement interval greater than 100 s, but commonly is used to discuss stability over intervals of 1 day or longer.

Normally, metrologists rely on classical statistics such as *standard deviation* (or *variance*, the square of the standard deviation) to estimate dispersion. Variance is an estimate of the numerical spread of a dataset with respect to its average or mean value. However, variance works only with stationary data, where the results must be time independent. This assumes the noise is *white*, meaning that its power is evenly distributed across the frequency band of the measurement. Oscillator data are usually nonstationary. For stationary data, the mean and variance will converge to particular values as the number of measurements increases. With nonstationary data, the mean and variance never converge to any particular values. Instead, there is a moving mean that might change each time a new measurement is added [3].

For these reasons, frequency metrologists generally rely on nonclassical statistics to estimate and specify the frequency stability of oscillators [4]. The most common statistic employed for stability estimates is often called the *Allan variance*, but because it is actually the square root of the variance, its proper name is the *Allan deviation* (ADEV). Similar to the standard deviation, ADEV is better suited for

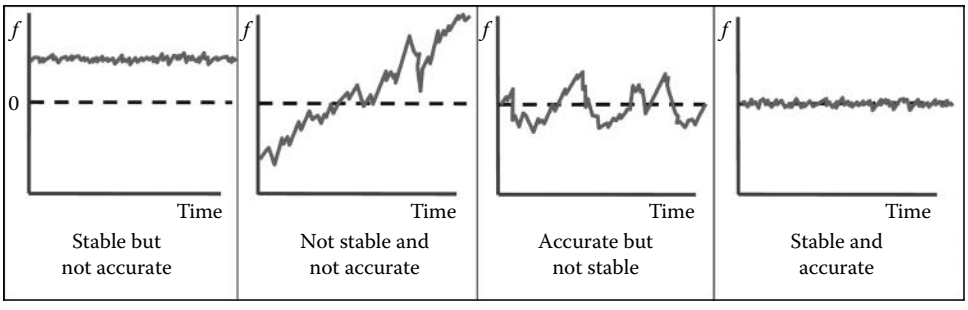

FIGURE 42.2 The relationship between frequency accuracy and stability.

frequency metrology because it has the advantage of being convergent for most types of oscillator noise. The equation for ADEV using frequency measurements and nonoverlapping samples is

$$\sigma_y(\tau) = \sqrt{\frac{1}{2(M-1)} \sum_{i=1}^{M-1} \left(\bar{y}_{i+1} - \bar{y}_i\right)^2} \tag{42.11}$$

where $\bar{y}_i$ is the ith in a series of M dimensionless frequency measurements averaged over a measurement or sampling interval designated as τ. Note that while classical deviation subtracts the mean from each measurement before squaring their summation, ADEV subtracts the previous data point. Since stability is a measure of frequency fluctuations and not of frequency offset, the differencing of successive data points is done to remove the time-dependent noise contributed by the frequency offset. Also, note that the $\bar{y}$ values in the equation do not refer to the average or mean of the entire dataset, but instead imply that the individual measurements in the dataset can be obtained by averaging.

The equation for ADEV using phase measurements and nonoverlapping samples is

$$\sigma_y(\tau) = \sqrt{\frac{1}{2(N-2)\tau^2} \sum_{i=1}^{N-2} [x_{i+2} - 2x_{i+1} + x_i]^2}, \tag{42.12}$$

where x_i is the ith in a set of N phase measurements spaced by the measurement interval τ.

To improve the confidence of a stability estimate, ADEV is normally used with overlapping samples that allow estimating stability with all possible combinations of the dataset. The equation for ADEV using phase measurements and overlapping samples is

$$\sigma_y(\tau) = \sqrt{\frac{1}{2(N-2m)\tau^2} \sum_{i=1}^{N-2m} [x_{i+2m} - 2x_{i+m} + x_i]^2}, \tag{42.13}$$

where the averaging factor, m, has been added to Equation 42.12. To understand the averaging factor, consider that τ_0 is the basic measurement interval or the shortest interval at which data are taken. To obtain stability estimates for longer intervals, τ_0 is simply multiplied by m; thus, $\tau = m\tau_0$. Even though the overlapping samples are not statistically independent, the number of degrees of freedom still increases, thus improving the confidence in the stability estimate [5].

One important advantage of ADEV over classical statistics is its ability to estimate stability over different intervals from the same dataset. Most ADEV graphs found in the literature use the *octave* method, where each successive value of τ is twice as long as the previous value. This method saved computational time, but as computers have become faster, it has become more common to estimate ADEV for all possible values of τ. A typical ADEV graph plots log τ on the x-coordinate to indicate the averaging period and log $\sigma_y(\tau)$ on the y-coordinate to indicate dimensionless frequency stability. These graphs are often referred to colloquially as "sigma–tau" graphs. ADEV graphs generally show the stability improving as the averaging period increases, until the point where the oscillator reaches its noise floor, or *flicker floor*, when no further gains will be made by averaging additional measurements. Figure 42.3 shows a sample ADEV graph that shows stability estimates using the octave method for intervals of τ ranging from 1 s to more than 2 h. This device was stable to about 3×10^{-12} at $\tau = 1$ s and reached a noise floor near 5×10^{-13} at $\tau = 512$ s. When τ exceeded 1000 s, the oscillator had begun to change frequency. Thus, further averaging degraded, rather than improved, the results.

In addition to estimating stability, ADEV can help identify the types of oscillator noise. Five noise types are commonly discussed in the time and frequency literature: *white phase*, *flicker phase*, *white frequency*, *flicker frequency*, and *random walk frequency*. A brief description of each noise type is provided

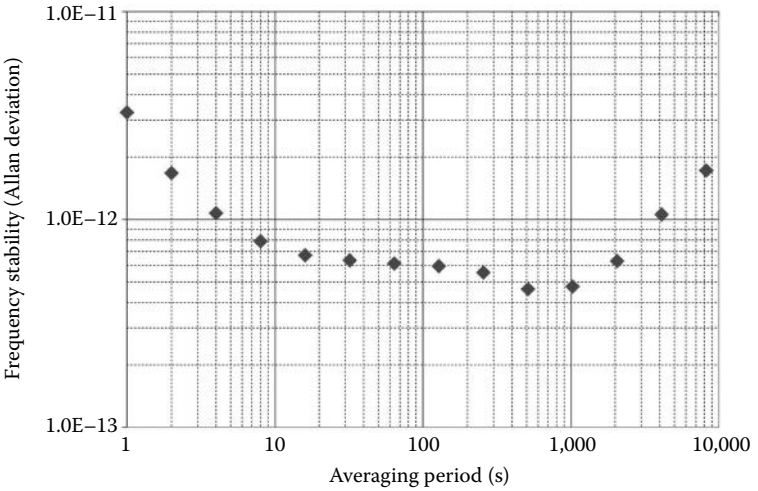

FIGURE 42.3 A sample ADEV graph used to estimate frequency stability.

in Table 42.1. The noise type can be identified from the slope of the line on an ADEV graph (Figure 42.4). Note that ADEV cannot distinguish between white phase and flicker phase noise. However, the modified ADEV, Mod $\sigma_y(\tau)$, can make this distinction, and numerous other variations of ADEV exist for specific applications, such as the improved identification of oscillator noise or improved estimates of long-term stability [4,5].

ADEV and similar statistics have proven to be very useful. However, they appear so often in the literature that confusing stability with accuracy has become a common mistake. It is important to know

TABLE 42.1 Oscillator Noise Types

Noise Type	Description	ADEV Slope
White phase	Fluctuations in the phase of a signal that have the same power at all frequencies across a given bandwidth. The stability is improving at a rate proportional to the averaging period. Mod ADEV can distinguish between white and flicker phase noise (ADEV cannot) and identifies white phase noise as having a slope of $\tau^{-3/2}$.	T^{-1}
Flicker phase	Also known as $1/f$ phase noise. As the frequency goes up, the intensity of the noise goes down. For example, if the frequency doubles, the power of the noise is cut in half. Unlike white phase noise, flicker phase noise is not evenly distributed across the frequency band.	T^{-1}
White frequency	Fluctuations in the frequency of a signal that have the same power at all frequencies across a given bandwidth. The stability is still improving, but at a rate proportional to the square root of the averaging period.	$T^{-1/2}$
Flicker frequency	Also known as $1/f$ frequency noise. The oscillator has reached a noise floor that shows its best possible stability (often called the "flicker" floor). There is nothing to be gained by more averaging.	τ^0
Random walk	Successive random steps in frequency. The difference between two steps is nearly constant, but the direction of the steps is random. Even so, it is clear that the oscillator frequency is now changing. A slope of τ^1 is sometimes used to distinguish frequency drift from random walk.	$\tau^{1/2}$

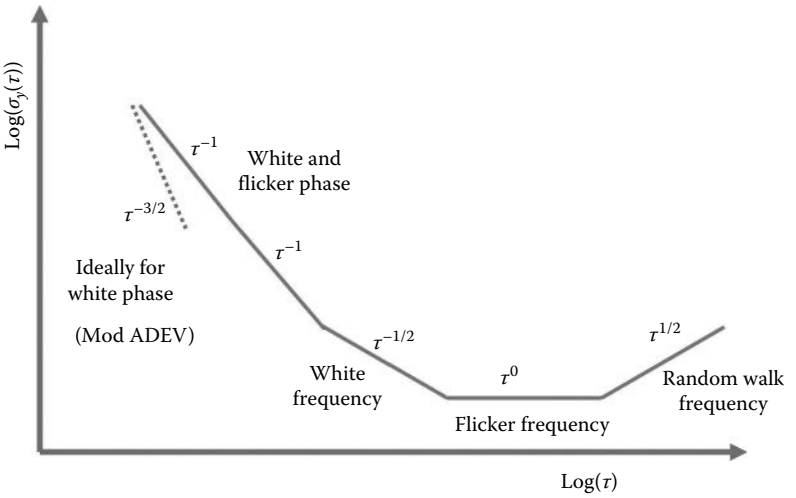

FIGURE 42.4 Identification of oscillator noise types.

that the two specifications mean different things and can have very different values for the same oscillator. For example, an oscillator accurate to only 1×10^{-8} might still be stable to 1×10^{-13} at $\tau = 1$ s. This means that even though the frequency of the oscillator is changing by only a small amount during short intervals, it is not particularly close to its nominal value.

42.2 Frequency Standards

As noted previously, stability measurements can tell us something about the inherent quality of an oscillator, and the stability of an oscillator is closely related to its *quality factor*, or *Q*. The *Q* of an oscillator is its resonance frequency divided by its resonance width. The resonance frequency is the natural frequency of the oscillator. The resonance width is the range of possible values where the oscillator will run. Obviously, a high resonance frequency and a narrow resonance width are both advantages when seeking a high *Q*. Stability and *Q* are generally correlated, because a high *Q* means that an oscillator has to stay close to its natural resonance frequency.

This section discusses the various types of oscillators used as frequency standards. It begins by discussing quartz oscillators, which achieve the highest *Q* of any mechanical-type device. It then discusses oscillators with higher *Q* factors, based on the atomic resonance of rubidium, hydrogen, and cesium. This is followed by a discussion of disciplined oscillators. These devices can be either quartz oscillators or atomic oscillators, but their frequency is automatically adjusted to agree with an external reference. The section concludes with a discussion of which type of frequency standard is best suited for use in a metrology laboratory. Table 42.2 provides a summary [2,6–8].

42.2.1 Quartz Oscillators

Billions (10^9) of quartz crystal oscillators are manufactured annually. Most are miniature, inexpensive devices that are embedded inside wristwatches, clocks, computers, cellular phones, and nearly every type of electronic circuit. However, only the larger, more expensive varieties of quartz oscillators are used as frequency standards. These devices are sometimes sold as stand-alone instruments but are more typically found inside test and measurement equipment, such as counters, signal generators, and oscilloscopes.

A quartz crystal inside the oscillator serves as resonator. The crystal strains (expands or contracts) when a voltage is applied. Reversing the polarity of the applied voltage will reverse the strain and force

TABLE 42.2 Summary of Oscillator Types

Oscillator Type	Quartz (OCXO)	Rubidium	Cesium	Active Hydrogen Maser	GPSDO
Primary standard	No	No	Yes	No	No
Resonance frequency	Mechanical (varies)	6.834682610904 GHz	9.19263177 GHz	1.420405751768 GHz	NA
Quality factor, Q	$\sim 10^6$	$\sim 10^7$	$\sim 10^8$	$\sim 10^9$	NA
Frequency accuracy (1 day average)	1×10^{-6} to 1×10^{-10}	5×10^{-9} to 5×10^{-12}	1×10^{-12} to 1×10^{-14}	$\sim 1 \times 10^{-13}$	1×10^{-12} to 5×10^{-14}
Stability, $\sigma_y(\tau)$, $\tau = 1$ s	1×10^{-11} to 1×10^{-13}	5×10^{-11} to 5×10^{-12}	1×10^{-11} to 5×10^{-12}	$\sim 2 \times 10^{-13}$	1×10^{-10} to 1×10^{-12}
Stability, $\sigma_y(\tau)$, $\tau =$ 1 day	1×10^{-10}	5×10^{-12}	8×10^{-14} to 2×10^{-14}	$\sim 2 \times 10^{-16}$	1×10^{-12} to 5×10^{-14}
Aging/year	5×10^{-9}	2×10^{-10}	None	$\sim 1 \times 10^{-13}$	None
Phase noise (dbc/Hz, 10 Hz from carrier)	−125 to −140	−90 to −130	−130 to −136	−130 to −142	−90 to −140
Life expectancy	Indefinite	>15 years	5–20 years	>15 years	>15 years
Cost (USD)	$500–$5,000	$2,000–$10,000	$30,000–$80,000	~$200,000	$1,000 to $20,000

the crystal to mechanically oscillate. This is known as the *piezoelectric effect*. The energy needed to sustain oscillation is obtained by taking a voltage signal from the resonator, amplifying it, and feeding it back to the resonator. Figure 42.5 is a simplified circuit diagram that shows the basic elements of a quartz crystal oscillator.

The rate of expansion and contraction is the resonance frequency and is determined by the cut and size of the crystal. No two crystals can be exactly alike or produce exactly the same frequency. The output frequency of a quartz oscillator is either the fundamental resonance or a multiple of the resonance, called an *overtone frequency*. Most high-stability units use either the third or fifth overtone to achieve a high Q. Overtones higher than the fifth are rarely used because they make it harder to tune the device to the desired frequency. A typical Q for a quartz oscillator ranges from 10^3 for a wristwatch-type oscillator to higher than 10^6 for the most stable devices. The maximum Q for a high-stability quartz oscillator can be roughly estimated as $Q = 16$ million/f, where f is the resonance frequency in megahertz.

Environmental changes can change the resonance frequency of a quartz crystal. Temperature changes are the largest problem, but other parameters such as humidity, pressure, and vibration can also change the frequency. There are several types of design packages that reduce these environmental problems. The most stable type of quartz oscillator is the *oven-controlled crystal oscillator* (OCXO), which encloses

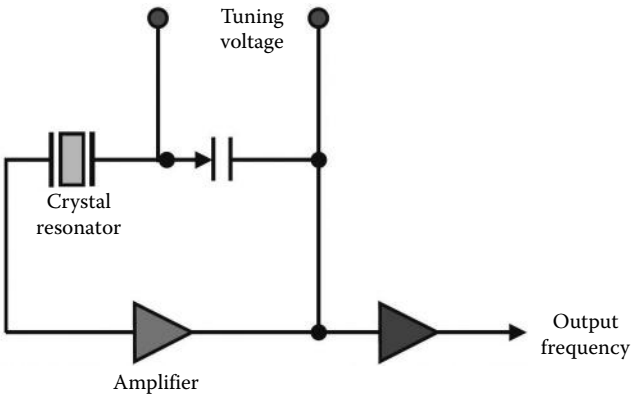

FIGURE 42.5 Block diagram of quartz oscillator.

the crystal in a temperature-controlled chamber called an oven. When an OCXO is turned on, it goes through a warm-up period while the temperatures of the crystal resonator and its oven stabilize. During this period, the performance of the oscillator continuously changes until it reaches its normal operating temperature. The temperature within the oven then remains constant, even when the outside temperature varies. An alternative solution to the temperature problem is the *temperature-compensated crystal oscillator* (TCXO). These devices include a temperature sensor that generates a correction voltage that is applied to a voltage-variable reactance, or varactor. The varactor then produces a frequency change equal and opposite to the frequency change produced by temperature. This technique does not work as well as oven control, but it generally costs less. Therefore, TCXOs are used when high stability over a wide temperature range is not required.

The best quartz oscillators have excellent short-term stability. A high-quality OCXO might be stable to 1×10^{-13} at $\tau = 1$ s. However, quartz oscillators are not stable over long intervals. Their long-term stability is limited by *aging*, which causes their frequency to change over time due to internal changes in the oscillator. Aging usually results in a nearly linear change in the resonance frequency that can be either positive or negative. A reversal in the direction of the aging occasionally occurs, and ironically, the aging rate of a quartz oscillator sometimes decreases as the device gets older. Aging has many possible causes, including a buildup of foreign material on the crystal, changes in the oscillator circuitry, or changes in the quartz material or crystal structure. A high-quality OCXO might age at a rate of less than 5×10^{-9} per year, while a TCXO might age 100 times faster.

The simple design of quartz oscillators makes them very reliable, and many devices have run continuously for decades without failing. However, their accuracy can change rapidly due to aging and environmental factors, and even a high-quality OCXO will need regular adjustments to maintain frequency accurate to within 1×10^{-9}. They are also subject to large frequency shifts when they are turned on after a power outage. For these reasons, quartz oscillators are usually a poor choice as a frequency standard, unless the measurement requirements of a laboratory are very low [8,9].

42.2.2 Atomic Oscillators

Atomic oscillators derive their resonance frequency from the quantized energy levels in atoms. The laws of quantum mechanics dictate that the energies of a bound system, such as an atom, have certain discrete values. An electromagnetic field can boost an atom from one energy level to a higher one. Or, an atom at a high energy level can drop to a lower level by emitting electromagnetic energy. The resonance frequency (f) of an atomic oscillator is the difference between the two energy levels divided by Planck's constant (h):

$$f = \frac{E_2 - E_1}{h} \tag{42.14}$$

All atomic oscillators are *intrinsic standards*, because their frequency is inherently derived from a fundamental natural phenomenon. There are currently (2011) three types of atomic oscillators sold commercially: rubidium standards, cesium standards, and hydrogen masers (discussed individually in the following sections). All three types contain an internal quartz oscillator that is locked to a resonance frequency generated by the atom of interest. This method causes the factors that degrade the long-term stability of a quartz oscillator to disappear. As a result, the long-term stability of an atomic oscillator is at least several orders of magnitude better than that of a quartz oscillator, but the short-term stability is unchanged [2,8,10].

42.2.3 Rubidium Oscillators

Rubidium oscillators are outperformed by the other types of atomic oscillators, but they have the advantage of being much smaller and less expensive. Because of their low cost and small size, rubidium

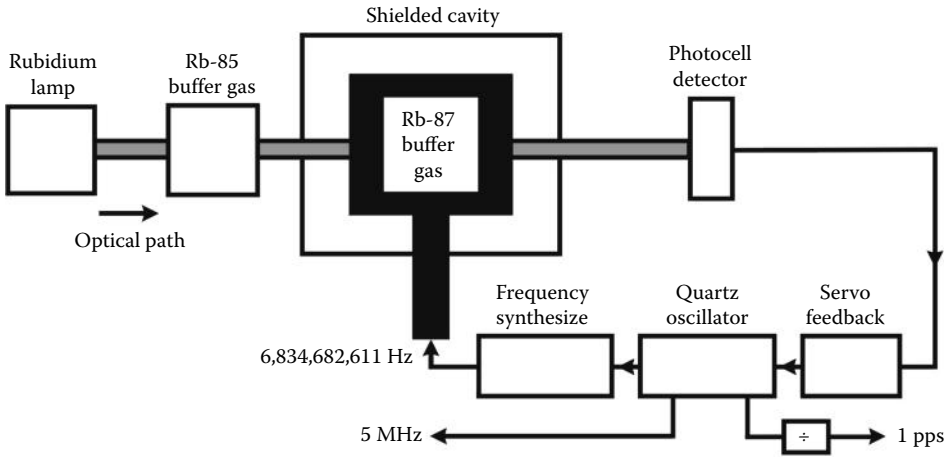

FIGURE 42.6 Block diagram of rubidium oscillator.

oscillators are often found in telecommunication networks and as time base oscillators in test and measurement equipment. They operate at 6,834,682,610.904 Hz, the resonance frequency of the rubidium atom (^{87}Rb), and use the rubidium frequency to control the frequency of a quartz oscillator. A microwave signal derived from the crystal oscillator is applied to the ^{87}Rb vapor within a cell, forcing the atoms into a particular energy state. An optical beam is then pumped into the cell and is absorbed by the atoms as it forces them into a separate energy state. A photocell detector measures how much of the beam is absorbed and tunes a quartz oscillator to a frequency that maximizes the amount of light absorption. The quartz oscillator is then locked to the resonance frequency of rubidium, and standard frequencies are derived and provided as outputs (Figure 42.6).

The Q of a rubidium oscillator is about 10^7. The shifts in the resonance frequency are mainly caused by collisions between the rubidium atoms and other gas molecules. These frequency shifts limit the long-term stability. Stability at $\tau = 1$ s is typically less than 1×10^{-11} and near 1×10^{-12} at $\tau = 1$ day. There is generally no guaranteed specification for accuracy, but after a warm-up period of a few minutes, a rubidium oscillator will typically be accurate to within parts in 10^{10} or less, and some devices might be as accurate as 5×10^{-12}. However, if an application has an accuracy requirement of parts in 10^9 or smaller, a rubidium oscillator will need to be regularly measured and adjusted, because accuracy better than about 5×10^{-9} cannot be assumed. With regular frequency adjustments, a rubidium can maintain average frequency to within a few parts in 10^{11} or 10^{12} over periods of months or years. The adjustments are made to compensate for the aging and frequency drift that changes the rubidium frequency slowly over time. Manufacturers typically specify the aging rate as less than 5×10^{-11} per month, but this is sometimes conservative, as the frequency of a well-behaved rubidium standard might change by less than 1×10^{-11} over the course of a month. Even so, the frequency change can exceed 1×10^{-10} if left unadjusted for a year, which is unacceptable for some applications [2,6–8].

42.2.4 Cesium Oscillators

Cesium oscillators are *primary frequency standards* because the SI second is defined using the resonance frequency of the cesium atom (^{133}Cs), which is 9,192,631,770 Hz. A properly working cesium oscillator should have inherent accuracy and stability and be close to its nominal frequency without adjustment.

Cesium is a complicated atom with $F = 3$ and $F = 4$ ground states (Figure 42.7). Each atomic state is characterized not only by the quantum number F but also by a second quantum number, m_F, which can have integer values between $-F$ and $+F$. There are 16 possible magnetic states of cesium, but the

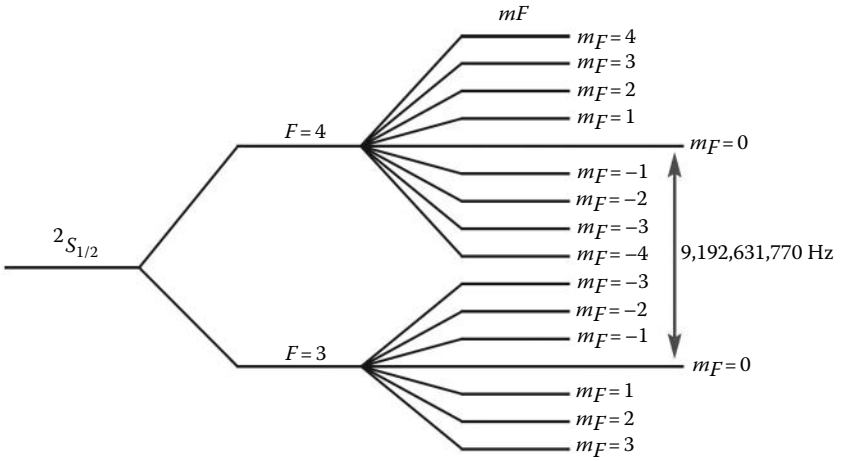

FIGURE 42.7 Cesium atomic structure.

transition between the |4,0⟩ and |3,0⟩ states is insensitive to magnetic fields. Thus, the frequency of this transition was chosen to define the SI second.

Figure 42.8 provides a simplified schematic of a cesium beam frequency standard. The design details of a cesium beam standard can vary significantly from model to model, but their basic design principles are similar. As shown on the left side of the figure, ^{133}Cs atoms are heated to a gaseous state in an oven. A beam of atoms emerges from the oven at a temperature near 100 °C and travels through a magnetic field, where the beam is split into two beams of atoms with different magnetic states. One beam is absorbed by the getter and is of no further interest. The other beam is deflected into the microwave interrogation cavity (commonly known as the Ramsey cavity).

While inside the Ramsey cavity, the cesium beam is exposed to a microwave frequency from a frequency synthesizer driven by a quartz oscillator. If this frequency is tuned to precisely match cesium resonance, some of the atoms will change their magnetic state. After leaving the Ramsey cavity, the atoms pass through a second magnetic field. These magnets direct only the atoms that changed state to the detector; the other atoms are directed to a getter and absorbed. In essence, the magnets located on

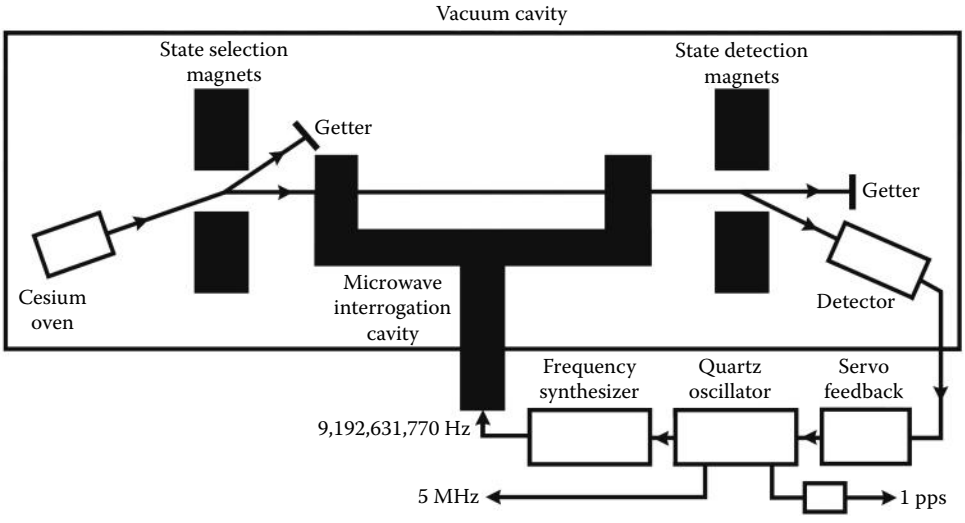

FIGURE 42.8 Block diagram of cesium oscillator.

both sides of the Ramsey cavity serve as a "gate" that allows only those atoms that undergo the desired $|4,0\rangle \leftrightarrow |3,0\rangle$ energy transition to pass through and reach the detector. The detector sends a feedback signal to a servo circuit that continually tunes the quartz oscillator so that the maximum number of atoms reaches the detector, thereby increasing the signal strength. This process is analogous to carefully tuning a radio dial until the loudest and clearest signal is heard and keeps the quartz oscillator frequency locked as tightly as possible to cesium resonance. Output frequencies, such as 1 Hz, 5 and 10 MHz, are then derived from the locked quartz oscillator.

The Q of a commercial cesium standard is about 10^8. The beam tube is typically less than 0.5 m in length, and the atoms travel at velocities of greater than 100 m/s inside the tube. This limits the observation time to a few milliseconds and the resonance width to a few hundred hertz. Stability ($\sigma_y\tau$, at $\tau = 1$ s) is typically 5×10^{-12}, normally reaching parts in 10^{14} at $\tau = 1$ day. The frequency offset is typically near 1×10^{-13} after a warm-up period of 30 min. Because the second is defined based on cesium resonance, there should be no change in frequency due to aging. However, in practice a cesium oscillator will slowly change its frequency by a very small amount, typically by parts in 10^{17} per day.

Cesium standards have a limited life expectancy and a high cost. The major component of a cesium oscillator, called the *beam tube*, typically lasts for about 5–10 years, and replacing the beam tube can cost nearly as much as replacing the entire device. When the beam tube fails, a cesium standard will no longer be locked to cesium resonance and will become a free-running quartz oscillator. For this reason, cesium frequency standards should be regularly monitored or checked to ensure that they are working properly [8,10–12].

42.2.5 Hydrogen Masers

The *hydrogen maser* is the most expensive commercially available frequency standard and is therefore found in only a small number of metrology laboratories. The word *maser* is an acronym that stands for microwave amplification by stimulated emission of radiation. The resonance frequency of the hydrogen atom is 1,420,405,751.768 Hz.

There are two types of hydrogen masers. The first type, called an *active maser*, has a microwave cavity that oscillates spontaneously, and a quartz oscillator is phase locked to this active oscillation. The second type, called a *passive maser*, frequency locks a quartz oscillator to the atomic reference in much the same fashion as a rubidium or cesium oscillator. Because active masers derive their output frequency more directly from the atomic resonance, they are more stable than passive masers in both the short and long term. Both types of maser are more stable in the short term than cesium oscillators and are well suited for applications where optimal frequency stability is required. Over long intervals, however, hydrogen masers are less accurate than cesium oscillators. This is due to several factors: their accuracy depends upon a more complex set of conditions, the resonance frequency of their microwave cavity can change over time, and also because the definition of the SI second is based on cesium resonance [2,8,10].

An active hydrogen maser works by sending hydrogen gas through a magnetic gate that only allows atoms in certain energy states to pass through. The atoms that make it through the gate enter a storage bulb surrounded by a tuned, resonant cavity. Once inside the bulb, some atoms drop to a lower energy level, releasing photons of microwave frequency. These photons stimulate other atoms to drop their energy level, and they in turn release additional photons. In this manner, a self-sustaining microwave field builds up in the bulb. The tuned cavity around the bulb helps to redirect photons back into the system to keep the oscillation going. The result is a microwave signal that is locked to the resonance frequency of the hydrogen atom and that is continually emitted as long as new atoms are fed into the system. This signal keeps a quartz crystal oscillator in step with the resonance frequency of hydrogen (Figure 42.9).

The resonance frequency of hydrogen is much lower than that of cesium, but the resonance width of a hydrogen maser is usually just a few hertz. Therefore, the Q is about 10^9 or about one order of magnitude better than that of a commercial cesium standard. As noted, a hydrogen maser is more stable than

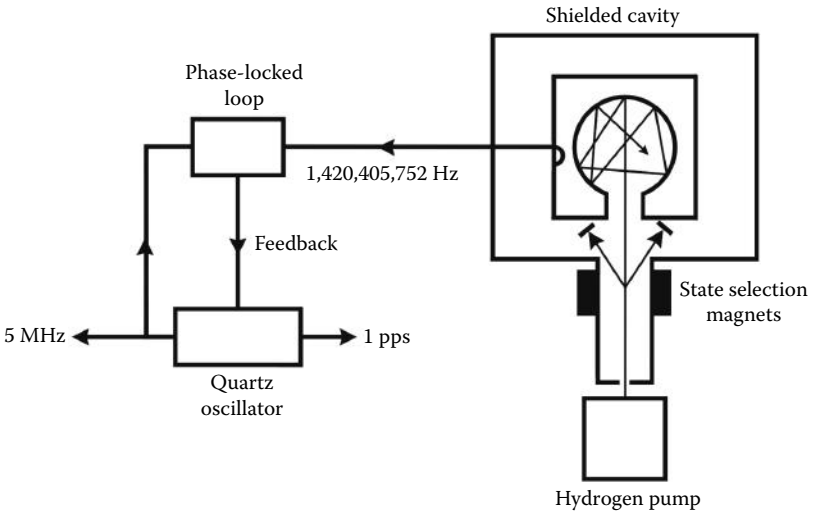

FIGURE 42.9 Block diagram of an active hydrogen maser.

a cesium oscillator for periods ranging from 1 s to perhaps weeks or months. The stability of an active maser will typically reach a few parts in 10^{13} at $\tau = 1$ s and a few parts in 10^{16} at $\tau = 1$ day.

42.2.6 Disciplined Oscillators

Oscillators whose frequency is controlled by an external reference signal are known as *disciplined oscillators*. Unlike free-running oscillators that need to be periodically adjusted to stay within specification, disciplined oscillators are locked to a reference signal and never require manual adjustment. The best disciplined oscillators can generate local signals with nearly the same accuracy and stability as the remote reference. Various types of radio signals have been used to discipline oscillators, but the vast majority of disciplined oscillators in use today (2011) employ signals from the GPS satellites as their reference source. For this reason, this section will focus entirely on GPS-disciplined oscillators (GPSDOs).

Unlike the other types of frequency standards described earlier, a GPSDO requires a small antenna to be mounted on a rooftop location with a clear view of the sky. A GPSDO will normally begin surveying its antenna position as soon as it is turned on. The survey is a one-time process that typically lasts for several hours. When the antenna survey is complete, the GPSDO is ready to use as a frequency standard and will typically produce sine wave signals of 5 and/or 10 MHz.

The basic function of a GPSDO is to receive signals from the GPS satellites and to use the information contained in these signals to control the frequency of a local quartz or rubidium oscillator. GPS signals are kept in agreement with the Coordinated Universal Time scale maintained by the United States Naval Observatory (UTC[USNO]). Nearly all GPSDOs use the coarse acquisition (C/A) code on the L1 carrier frequency (1575.42 MHz) as their incoming reference signal. The satellite signals can be trusted as a reference for two reasons: (1) they originate from atomic oscillators and (2) *they must be accurate and stable* to within parts in 10^{14} over a 12 h averaging period in order for GPS to meet its specifications as a positioning and navigation system. The best GPSDOs transfer as much of the inherent accuracy and stability of the satellite signals as possible to the signals generated by the local quartz or rubidium oscillator.

Many of the methods used to discipline oscillators are proprietary, and GPSDO manufacturers seldom disclose exactly how their products work. However, there are a few basic concepts that apply to most designs. Generally, the local oscillator is controlled with one or more servo loops, with each loop having a fixed or variable time constant. For example, one type of servo loop is a *phase-locked loop*, or PLL. In a GPSDO, the reference input signal to the PLL comes from a GPS receiver that tracks

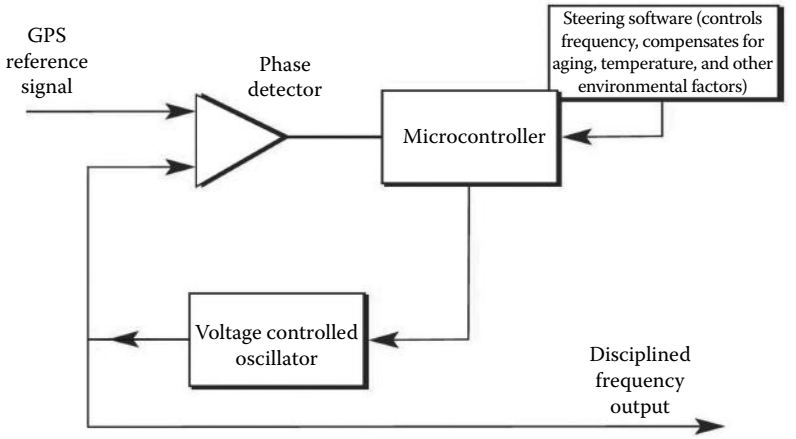

FIGURE 42.10 Block diagram of a GPSDO that steers its local oscillator.

multiple satellites and outputs a 1 pulse per second (pps) signal. A phase detector measures the difference between the 1 pps signal from the GPS receiver and a signal from a voltage-controlled oscillator (VCO). The VCO typically has a nominal frequency of 10 MHz, so its signal is divided to a lower frequency (often all the way down to 1 pps) prior to this phase comparison. A microcontroller reads the output of the phase detector and monitors the phase difference. When the phase difference changes, the software changes the control voltage sent to the VCO, so that the phase difference is held within a given range (Figure 42.10). The GPSDO is locked when the phase of the VCO has a constant offset relative to the phase of the GPS signals. Ideally, the servo loop must be loose enough to ignore the short-term fluctuations of the GPS signals, reducing the amount of phase noise and allowing the VCO to provide reasonably good short-term stability. However, the loop must be tight enough to track GPS closely and to allow the GPS signals to control the VCO frequency in the longer term. The microcontroller software often compensates not only for the phase and frequency changes of the local oscillator but also for the effects of aging, temperature, and other environmental parameters.

Another type of GPSDO design does not correct the frequency of the local oscillator. Instead, the output of a free-running local oscillator is sent to a frequency synthesizer. Steering corrections are then applied to the output of the synthesizer (Figure 42.11). Modern direct digital synthesizers (DDSs) have

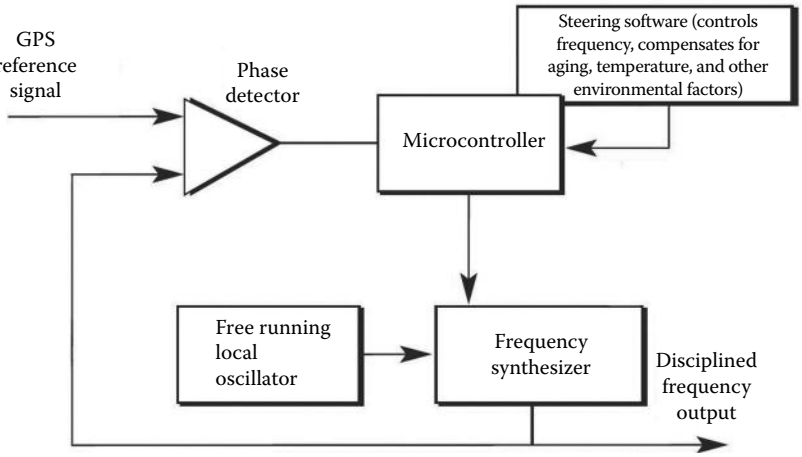

FIGURE 42.11 Block diagram of a GPSDO that adjusts a frequency synthesizer.

excellent resolution and allow very small frequency corrections to be made. For example, 1 μHz resolution at 10 MHz allows instantaneous frequency corrections of 1×10^{-13}. In addition, allowing the local oscillator to free run often results in better performance than the VCO method, where unexpected shifts in the control voltage can produce unwanted adjustments in the output frequency.

A reasonably good metric to use when evaluating GPSDO performance is its frequency stability at $\tau = 1$ day, as estimated with ADEV. Stability of 1×10^{-13} or less at $\tau = 1$ day normally indicates a device of high quality, and many (but certainly not all) GPSDOs can reach this specification. To demonstrate how the performance of GPSDOs can vary significantly, a test was conducted between two rubidium-based GPSDOs at National Institute of Standards and Technology (NIST). Both devices had the same type of rubidium local oscillator and cost approximately the same amount. During the test, both GPSDO devices were connected to the same GPS antenna with an antenna splitter. The antenna's position had previously been surveyed with an uncertainty of less than 1 m, and these precise coordinates were keyed into both units. The 10 MHz outputs of both devices were then simultaneously compared to the US national frequency standard at NIST, UTC(NIST), for a period of 80 days. The results are shown in the phase graph in Figure 42.12.

The results show that the frequency of Device A was tightly controlled. The peak-to-peak phase variation over the entire 80 day period was just 38 ns, with most of this variation due to the difference between UTC(USNO), the reference for GPS, and UTC(NIST) during the measurement interval. The frequency accuracy, as estimated from the slope of the phase, was about 1×10^{-15}. In sharp contrast, the frequency of Device B was very loosely controlled, and the phase plot shows a very large peak-to-peak phase variation of 588 ns, much larger than the dispersion of the GPS timing signals. Figure 42.13 shows the long-term frequency stability of both devices as estimated with ADEV, for values of τ ranging from 1 h to about 3 weeks. Device A is more stable than Device B at all averaging periods by roughly a factor of 10. Stability at $\tau = 1$ day, the metric discussed earlier, is about 6×10^{-14} for Device A, comparable to the performance of a cesium standard. However, the stability of Device B is worse by more than a factor of 10, about 70×10^{-14}.

In spite of the wide performance disparity between Device A and Device B, these examples still illustrate that a GPSDO that is even loosely locked to the satellite signals should be inherently accurate (parts in 10^{13} or better) and inherently stable in the long term. This is because the signals broadcast by the GPS satellites are continuously steered to agree with UTC and GPSDOs that simply "follow" the satellites will produce frequency that closely agrees with UTC over long intervals.

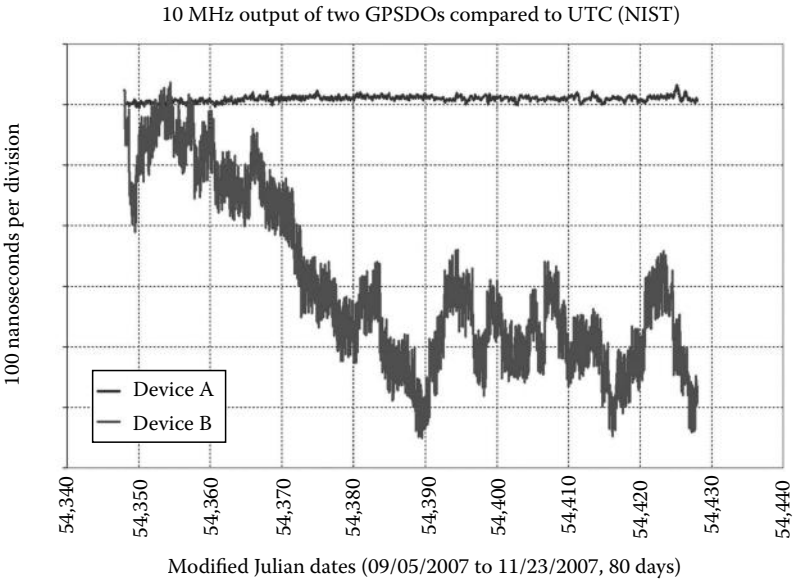

FIGURE 42.12 Phase comparison of two GPSDOs.

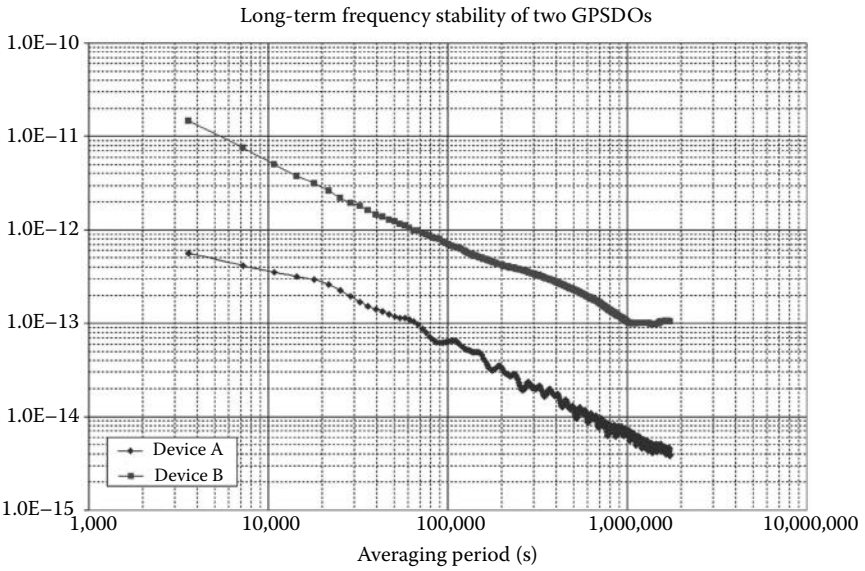

FIGURE 42.13 Stability comparison of two GPSDOs.

GPSDOs are generally reliable, but users should be aware that they will eventually fail if the GPS signal is unavailable. The most likely cause of failure is probably RF interference, because GPS signals are highly susceptible to intentional or unintentional interference due to their low power levels. A GPSDO can stop tracking satellites if there are interfering signal only a few orders of magnitude more powerful than the minimum received GPS signal strength, which is –160 dBW on Earth for the L1 carrier, equivalent to 10^{-16} W. When the GPS signal is unavailable, a GPSDO continues to produce frequency but begins relying on its *holdover* capability. In many cases, a GPSDO will simply become a free-running local oscillator while in holdover mode, in which case, its frequency accuracy will probably be several orders of magnitude worse than normal, perhaps parts in 10^9 or 10^{10} for a device with a rubidium local oscillator after a few hours without GPS and parts in 10^7 or 10^8 for a quartz based device under the same conditions. Some devices implement holdover algorithms that continue to steer the local oscillator without GPS, but the performance of these algorithms will degrade over time. As is the case with a cesium standard, it is important to verify that a GPSDO is working properly [13].

42.2.7 Choosing a Frequency Standard for a Metrology Laboratory

As noted earlier, a quartz oscillator is generally a poor choice as a frequency standard, and only those laboratories with the most demanding frequency stability requirements will be able to justify the expense of a hydrogen maser. Thus, when a metrology laboratory decides which frequency standard to buy, it will likely be choosing between a rubidium oscillator, a cesium oscillator, and a GPSDO. The specifications of the various oscillator types are summarized in Table 42.2. The specifications listed in the table were obtained from manufacturer's specification sheets and from the results of measurements performed by NIST.

As Table 42.2 indicates, a GPSDO will have better long-term frequency accuracy and stability than a stand-alone rubidium oscillator, and the GPSDO will never require adjustment. A GPSDO will normally cost more than a stand-alone rubidium standard, but in most cases, the performance and convenience of the GPSDO will easily justify the higher cost. Therefore, for most metrology laboratories, a GPSDO is probably a better choice.

Choosing between a cesium standard and a GPSDO is more difficult. As noted earlier, the SI second is defined based on energy transitions of the cesium atom; thus, cesium oscillators are often the preferred choice of frequency standard for laboratories with the best measurement capabilities and the most

demanding performance requirements. However, as also noted earlier, cesium oscillators are expensive and have a limited life expectancy, and not all laboratories can afford them. Assuming that a calibration laboratory can afford a cesium standard, should they still economize by choosing a GPSDO as their frequency standard? There are several pros and cons related to GPSDOs that should be considered before answering this question. First the pros:

- A GPSDO costs much less than a cesium standard to initially purchase, sometimes as much as 90% less. It also costs less to own, because there is no cesium beam tube to replace. This means that a calibration laboratory could buy multiple GPSDOs for less than the cost of a cesium standard and use the additional standards for crosschecks and redundancy.
- Unlike a cesium standard, a GPSDO can recover time by itself (time-of-day and an on-time pulse synchronized to UTC). This is important if a laboratory needs time synchronization capability.
- Cesium standards seldom require adjustment, but a GPSDO will never require adjustment, because its frequency is controlled by the signals from the GPS satellites.

Now, the cons:

- GPSDOs generally have poorer short-term stability and higher phase noise than cesium standards.
- GPSDOs require an outdoor antenna that must be located in an area with access to the roof. A cesium standard can be operated anywhere where electric power is available.
- Cesium standards are autonomous and independent sources of frequency, which means they can operate without input from another source. GPSDO can operate properly only where signals from the GPS satellites are available and are not suitable for applications that need an autonomous frequency source.

Based on these criteria, it seems likely that many laboratories that can afford a cesium standard will undoubtedly choose a GPSDO as a lower-cost alternative that meets all of their requirements. However, a certain percentage of laboratories do require a cesium standard, and some laboratories will operate both types of standards. Even if a laboratory already owns a cesium standard, it might be wise to acquire a GPSDO as a secondary standard so that the two devices can be compared to each other to ensure that both are working properly. Table 42.3 lists suppliers of the various types of frequency standards.

42.3 Calibration and Measurement Methods

The objective of a frequency calibration is to measure the accuracy and/or stability of the *device under test* (DUT), which will be one of the oscillator types described in Section 42.2. During the calibration, the DUT is compared to a *standard* or *reference*. In most cases, both the DUT and the reference produce oscillating sine wave signals, as illustrated in Figure 42.14. The sine wave signals produce one cycle (2π radians of phase) in one period. The period is measured in units of time, and the amplitude is measured in units of voltage. The nominal frequency of the DUT is normally 1 MHz or higher, with 5 or 10 MHz being common.

In order for the calibration to be valid, the reference must outperform the DUT. The ratio by which the reference outperforms the DUT is called the *test uncertainty ratio* (TUR). A TUR of 10:1 is preferred, but not always possible. If a smaller TUR is used (4:1, for example), then the calibration will take longer to perform, because more measurements and more averaging will be required.

To further validate a measurement result, it is necessary to establish the *traceability* of a frequency measurement to the International System (SI) of units. Because frequency is the reciprocal of time interval, establishing traceability in frequency metrology means establishing traceability to the SI second through an unbroken and documented chain of calibrations. The SI second is a virtual and not a physical standard, so the chain of calibrations typically extends back to a national standard maintained by a laboratory that contributes to the UTC, such as NIST in the United States. The traceability chain will have only one link if a DUT is calibrated by NIST or an equivalent laboratory. However, there are often several links (calibrations) involved when establishing a traceability chain back to the SI.

Once a suitable reference and a plan for traceability have been chosen, the next step is to select a calibration or measurement method. The remainder of this section discusses several established techniques that are commonly used to measure frequency. With the appropriate hardware and software, measurement systems designed around these techniques can produce data that can be used to estimate either frequency accuracy or stability.

The comparison of the sine wave signal produced by the DUT to the sine wave signal produced by the reference can be made in either the time domain or in the frequency domain, but time domain

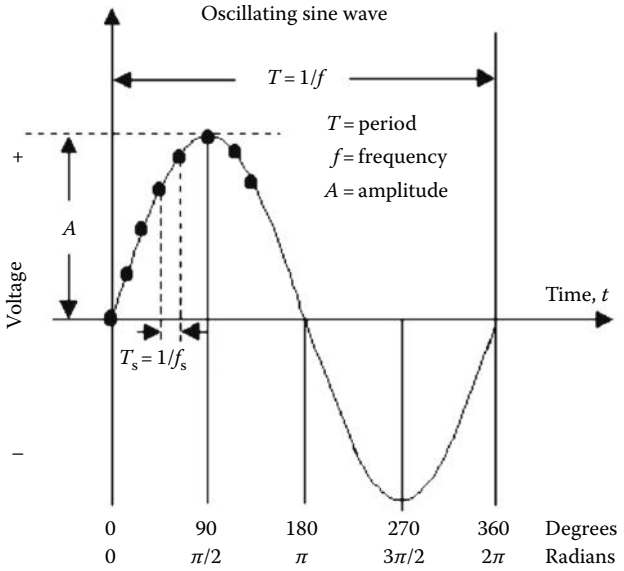

FIGURE 42.14 An oscillating sine wave.

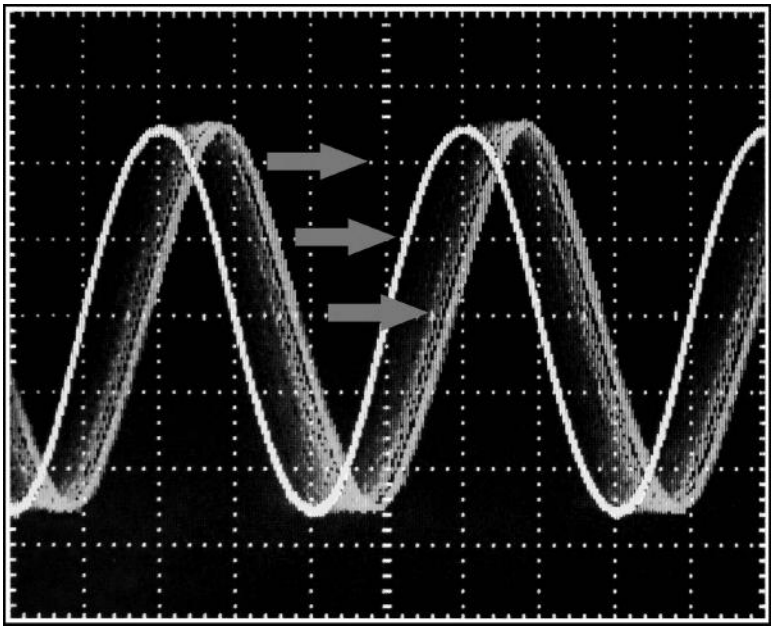

FIGURE 42.15 Phase comparison with an oscilloscope.

comparisons are more common. A simple time domain comparison that nicely illustrates the concept is the *oscilloscope pattern drift method*. This method requires a two-channel oscilloscope. In this example, both the DUT and reference signals are 10 MHz sine waves. The reference signal is produced by a cesium oscillator and the DUT signal is produced by a quartz oscillator. The scope is triggered with the reference signal on channel 2, and the DUT signal is connected to channel 1. The amplitude and position of both waveforms are adjusted on the oscilloscope display so that they overlap (Figure 42.15).

If the two frequencies were exactly the same, both sine waves would appear to be stationary on the oscilloscope display. However, because the two frequencies are not the same, their phase relationship will be continuously changing. The reference sine wave will appear to be stationary and the DUT sine wave will move. The direction of the sine wave motion will determine whether the DUT frequency is low or high with respect to the reference. A stopwatch can be started when the two signals are exactly in phase and stopped after one complete *cycle slip* has occurred and they are exactly in phase again. Frequency accuracy can be estimated as $\Delta t/T$ (see Equation 42.8), where Δt = 100 ns (the period of 10 MHz) and T is the elapsed time indicated on the stopwatch. If one cycle slip occurs per second, the frequency accuracy of the DUT is 1×10^{-7} [1].

As noted, this method is very useful for demonstrating the concept of a phase comparison, and oscilloscopes are indispensible for simple measurements and for viewing waveforms. However, the shortcomings of the pattern drift method quickly become obvious: If DUT were accurate to 1×10^{-12}, a single cycle slip would take more than a day to occur. For this reason and others, you will probably seldom use an oscilloscope to measure frequency, especially if you have a universal counter available.

Universal counters can be configured as either a *frequency counter* (FC) or a *time interval counter* (TIC). FCs are the most common instrument used for frequency measurements, and they are especially handy, because they can quickly measure a DUT's frequency and instantly display the results. The reference for this type of measurement is the FC's time base oscillator, which is usually a quartz oscillator of unknown accuracy (typically no better than 1×10^{-8}). For this reason, the laboratory's best oscillator

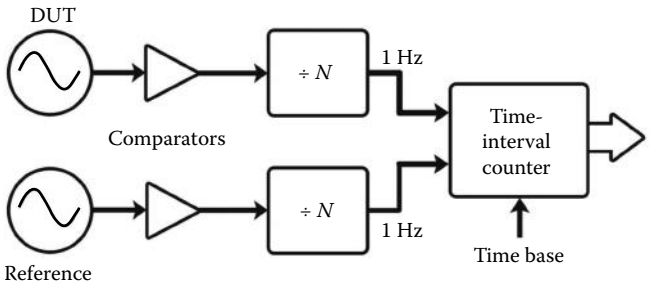

FIGURE 42.16 TIC measurement system.

should be connected to the FC's external time base input. Frequency accuracy can be estimated by using Equation 42.1, where f_{meas} is the reading taken from the FC display. The smallest frequency offset that an FC can detect with a single reading will be determined by its *resolution*, which is limited by the number of digits on the counter's display. For example, a 10-digit FC will be unable to detect a frequency change smaller than 1×10^{-9} without averaging when measuring a 10 MHz signal, but a 12-digit counter can reduce this value by two orders of magnitude to 1×10^{-11}.

TICs are commonly used to measure frequency in the time domain (Figure 42.16). When the *time interval method* is used to measure frequency, it is no longer practical to work directly with 10 MHz signals, because low-frequency input signals must be used to start and stop the counter. The solution is to use *a frequency divider* to convert standard frequency signals to a much lower frequency, typically to 1 Hz. Frequency dividers can be stand-alone instruments, integrated into the oscillator design or, in some cases, integrated into the TIC. Dividing to 1 Hz can be accomplished by blocking $f_{nom} - 1$ cycles of the frequency from passing through to the counter. The use of low-frequency signals reduces the problem of counter overflows and underflows (cycle ambiguity) and helps prevent errors that can occur when the start and stop signals are too close together. It is also important to make sure that the TIC is triggering at the correct voltage level on the input signal. This involves either carefully adjusting the trigger levels or using a TIC with fixed trigger levels and converting both signals to an identical shape and amplitude prior to the comparison.

A TIC has inputs for two signals. Typically, a signal from the DUT starts the counter and a signal from the reference stops the counter. The time interval reading will change, typically very slowly, to indicate the difference in frequency between the two signals. A single reading from an FC can immediately produce useful information, because it can be differenced from the nominal frequency. However, in the case of a TIC, at least two readings are required to produce useful frequency information. As indicated in Equation 42.8, a quick estimation of the DUT's frequency offset can be made by recording a single TIC reading, waiting for a specified period, and then recording a second TIC reading. The difference between the two readings divided by the measurement period ($\Delta t/T$) provides an estimate of the frequency offset. In practice, data are usually collected continuously, typically every second, and then averaged over longer intervals of time to get a better estimate.

Modern universal counters typically have a single-shot time interval resolution of less than 1 ns. The best devices have a resolution near 10 ps, which enables them to detect frequency changes of 1×10^{-11} in 1 s, which is equivalent to the capability of a 12-digit FC. Dedicated TICs can have a resolution near 1 ps, making it possible in theory to detect a frequency change of 1×10^{-12} in 1 s. However, the ability of a time interval system to detect small frequency changes is limited by factors other than TIC resolution, including trigger errors, time base errors, and noise from frequency dividers, and 1×10^{-11} at 1 s usually represents best case performance [1,14,15].

The time interval method is widely implemented and is an excellent way to measure long-term accuracy and stability. However, systems with higher resolution are needed to measure short-term stability.

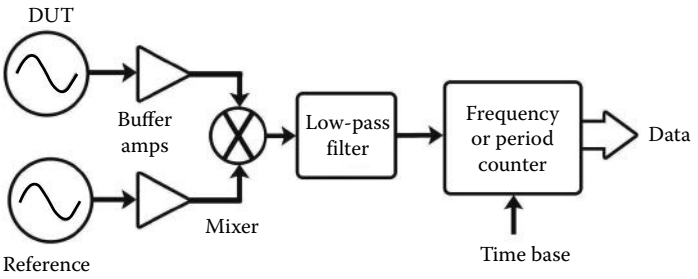

FIGURE 42.17 Simple heterodyne measurement system.

These systems continue to use counters but employ heterodyne techniques, rather than frequency dividers, to obtain the necessary low-frequency signals. The reason for this is straightforward: When dividers are used, both the frequency of the DUT and its phase fluctuations (noise) are divided by the same amount, and thus, no resolution is gained. The resolution of the system remains the same as the resolution of the counter. In contrast, heterodyne techniques convert the DUT frequency to a lower frequency, known as the intermediate frequency (IF) or *beat frequency*, without dividing the device's phase fluctuations (noise). Thus, phase information is preserved in the heterodyne process, and when the DUT changes frequency relative to the reference, the beat frequency changes by the same amount. The resolution of the counter is potentially improved by the downconversion or *heterodyne factor*, which equals f_{nom}/f_{beat}. Unlike divider systems, which typically produce 1 Hz signals, the beat frequency is usually not lower than 10 Hz, because it must be large enough to account for a wide range of possible frequency differences between the DUT and reference, including situations where a quartz oscillator is involved in the comparison.

Figure 42.17 shows a simple heterodyne system where a low-pass filter (LPF) and double-balanced mixer are used in conjunction with a universal counter in frequency or period mode. Although not shown in the figure, in most designs, the reference oscillator is intentionally offset in frequency, normally by 100 Hz or 1 kHz, by use of a frequency synthesizer. The double-balanced mixer mixes the reference frequency with the DUT signal, producing a beat frequency that is nominally the same as the intentional frequency offset of the reference. If a 10 MHz frequency is downconverted to 1 kHz, the resolution of the counter can be potentially enhanced by a heterodyne factor of 10^4 ($10^7/10^3$). The beat frequency is sent through a LPF to remove carrier frequency harmonics and then measured with either an FC or a period counter. If an FC is used, the frequency offset $f_{off} = (f_{fc} - f_{beat})/f_{nom}$, where f_{fc} is the reading on the FC, f_{beat} is the nominal beat frequency, and f_{nom} is the nominal frequency of the DUT.

The *dual-mixer time difference* (DMTD) method (Figure 42.18) combines the best features of the time interval and heterodyne methods. The DMTD method uses a transfer oscillator and two double-balanced mixers in parallel. The transfer oscillator is offset from the nominal frequencies by a small amount, typically by 10 Hz. The transfer oscillator does not have to be particularly stable or accurate because the noise it produces is common to both measurement channels and cancels when the phase difference is computed. Even so, the transfer oscillator signal is usually obtained by locking a frequency synthesizer to the reference oscillator. Typically, both the DUT and the reference must have the same nominal frequency, usually 5 or 10 MHz, and DMTD systems are often designed to measure only one nominal frequency. However, the use of frequency synthesizers allows some DMTD systems to measure a number of DUT frequencies within a specified range (e.g., 1–30 MHz) and can even allow the DUT and the reference to have different nominal frequencies.

The transfer oscillator signal is heterodyned with both the reference oscillator and the DUT to produce two beat frequencies. The two beat frequencies are out of phase by an amount proportional to the time difference between the DUT and reference, and this phase difference is measured with a TIC. Before being sent to the TIC, the beat frequencies pass through a LPF that removes harmonics

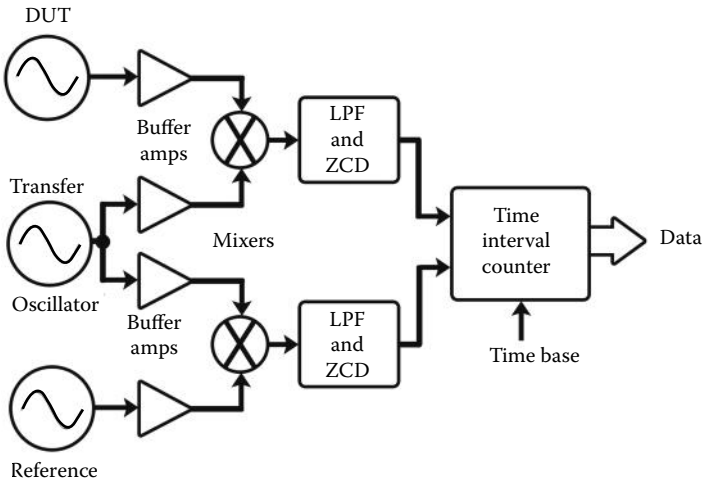

FIGURE 42.18 DMTD measurement system.

and a *zero-crossing detector* (ZCD) that determines the zero crossing of each beat frequency cycle. A DMTD system works best if the zero crossings are coincident or can be interpolated to a common epoch. Thus, a variable phase shifter is sometimes used to put the DUT signal nominally in phase with the reference before the DUT signal is mixed with the transfer oscillator. After the mixing process, some systems use an event counter to count the whole beat note cycles to eliminate the ambiguity of the zero crossings; other systems time-tag the zero crossings. The resolution of a DMTD system is determined by the resolution of the TIC or the time-tagging hardware, divided by the heterodyne factor. For example, if the TIC resolution is 100 ns and the heterodyne factor is 10^6 (based on a 10 MHz nominal frequency and a 10 Hz beat frequency), then the DMTD resolution can be estimated at 10^{-7} s/10^6 or 0.1 ps. This high resolution allows some DMTD systems to detect frequency changes of 1×10^{-13} in 1 s or two or three orders of magnitude better than a typical universal counter. It should be noted that all components of heterodyne or DMTD systems must be carefully chosen for optimum stability and not all frequency measurement systems are stable enough to support their theoretical resolution [1,5,14,16,17].

Recently developed frequency measurement systems employ digital signal processing (DSP) techniques to achieve even higher resolutions. These systems rapidly sample the DUT and reference signals with analog-to-digital converters and then fit the digitized signals with a sinusoidal waveform at an IF that is much lower than the carrier frequency. Figure 42.19 shows the relationship between the oscillator signal, the sampling clock, and the resulting IF sine wave. Again, the idea is simply to compare two

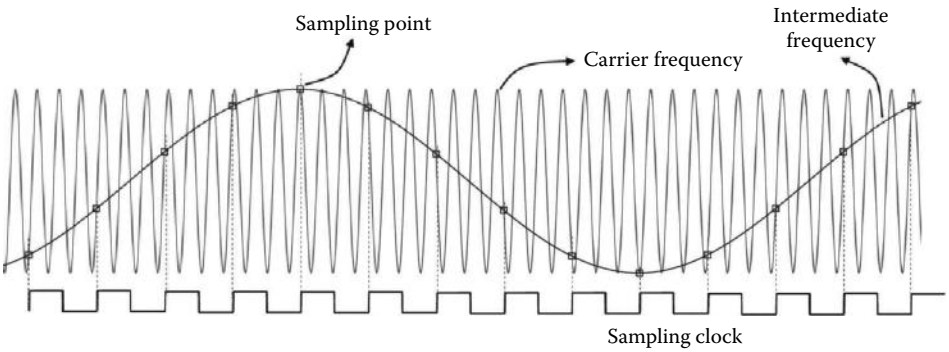

FIGURE 42.19 Digital sampling of the carrier frequency.

low-frequency signals, but note that the DSP hardware and software replaces the analog mixers shown in Figures 42.17 and 42.18 or the dividers shown in Figure 42.16. After two low-frequency signals are obtained for comparison, the subsequent filtering and phase detection is also accomplished with DSP techniques.

At this writing (2011), the available digital sampling frequency measurement systems are relatively expensive but can outperform DMTD systems by a wide margin. The best systems have a resolution of a few femtoseconds (10^{-15} s) and can detect frequency changes of less than 5×10^{-15} at 1 s. These systems can also measure phase noise, can simultaneously estimate time and frequency domain statistics with the same hardware, and can measure oscillators with a wide range of nominal frequencies [18].

To provide a practical, "real-world" comparison of the most commonly used frequency measurement systems, Figure 42.20 compares the FC, time interval, single-mixer, and DMTD methods by showing an ADEV graph of the same OCXO measured with all four systems. The same universal counter, with an external time base connection to an atomic oscillator, was used for the first three methods. The counter chosen was typical of those found in many metrology laboratories, with a 12-digit display and a time interval resolution of 150 ps. For the FC method, the counter was configured as an FC and used by itself. For the time interval method, the counter was configured as a TIC and used with a low-cost divider circuit. For the mixer method, the counter was used in conjunction with a low-cost double-balanced mixer and a frequency synthesizer that generated a signal offset by 1 kHz from the reference. A commercially available system was used for the DMTD measurement.

Only the DMTD system was able to correctly show that the OCXO reaches its noise floor at an averaging period of 10–20 s, when its stability briefly drops below 3×10^{-12}. Due to a lack of resolution and due to measurement system noise that exceeds the oscillator noise at short intervals, the other three systems incorrectly indicate that the OCXO noise floor is not reached until after several hundred seconds of averaging, when a random walk noise process had already begun. The FC and TIC methods provide similar results at all intervals, but the TIC estimates are smoother and have fewer variations. The single-mixer system was not optimized for best performance, but was somewhat quieter than the FC and TIC systems at short averaging periods. It is interesting to note that when the averaging interval exceeds several hundred seconds, all four methods produce similar results. This demonstrates that the choice of a measurement system is not critical when measuring long-term stability or accuracy, but is critical when measuring short-term stability.

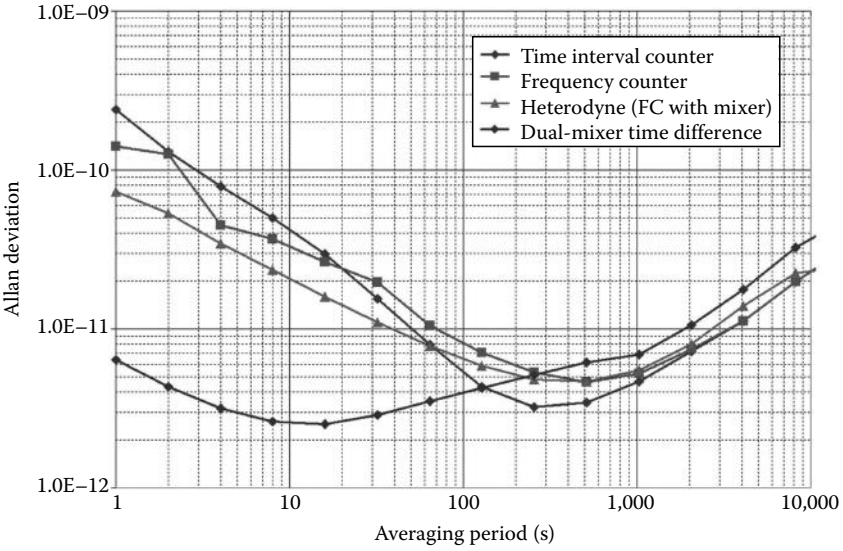

FIGURE 42.20 ADEV graph comparing different measurement methods.

42.4 Future Developments

Cesium fountain standards currently (2011) serve as the national standards of frequency at NIST and a number of other laboratories. These devices implement techniques such as a vertical microwave cavity and laser cooling to increase the interrogation period of the cesium atoms. By doing so, they reduce the resonance width and increase the oscillator Q to about 10^{10}. As a result, their accuracy and stability is about a factor of 100 times better than commercial cesium standards [19]. Perhaps cesium fountains or another type of laser-cooled microwave frequency standard will eventually be sold commercially.

It seems almost certain that optical atomic standards will have a huge impact on the future of frequency metrology. Optical standards operate at much higher resonance frequencies than microwave standards; the stabilized lasers that serve as their resonators typically operate at a frequency near 10^{15} Hz, as opposed to less than 10^{10} Hz for cesium. As a result, these standards promise accuracies and stabilities that are several orders of magnitude better than the best microwave standards. Optical frequency standards have been constructed at NIST utilizing single-ion techniques based on mercury (^{199}Hg+) and aluminum (^{27}Al+), as well as neutral atom techniques based on calcium (^{40}Ca), ytterbium (^{174}Yb), and strontium (^{87}Sr). It appears likely that the SI second will eventually be redefined, with the new definition based on one of these optical atomic transitions [20].

The accurate measurement of optical frequencies had historically been difficult, involving large and complex chains of frequency-doubled and frequency-mixed lasers. This changed in the early part of the twenty-first century, with the advent of the self-referenced femtosecond laser frequency combs. These devices, which are now sold commercially, have made the linkage of optical to microwave frequencies, or optical to optical frequencies, relatively simple. A self-referenced femtosecond laser frequency comb generates a series of discrete, equally frequency-spaced modes. The mode spacing, f_{rep}, is given by the repetition rate of a mode-locked laser, which is typically around 1 GHz. The frequency of an individual mode can be expressed as $f(m) = f_o + m \times f_{rep}$, where m is an integer. The frequency offset f_o is measured by a method called self-referencing. An optical standard can be compared to a conventional frequency standard by referencing the comb to a cesium standard or a GPSDO and then measuring the heterodyne beat frequency f_{beat} between the optical standard and the nearest tooth of the comb. This will lead to determination of the frequency of the optical standard in terms of f_o, f_{rep}, and f_{beat}, if the integer m is known. Frequency combs also allow the ratio of two optical frequencies to be compared without being limited by the accuracy of conventional standards [21]. Frequency comb comparisons of optical standards have successfully measured relative frequency differences of parts in 10^{19}, an astounding 16 orders of magnitude smaller than the requirements that existed less than a century ago for the measurements of radio frequencies.

43.1 Introduction

Photoconduction has been observed, studied, and applied for more than 100 years. In the year 1873, W. Smith [1] noticed that the resistance of a selenium resistor depended on illumination by light. Since that time, photoconduction has been an important tool used to evaluate material properties, to study semiconductor device characteristics, and to convert optical into electric signals. The Radio Corporation of America (RCA) was a leader in the study and development of photoconductivity and of photoconductive devices. Richard H. Bube of RCA Laboratories wrote the classic book *Photoconductivity in Solids* [2] in 1960. Today, photoconducting devices are used to generate very fast electric pulses using laser pulses with subpicosecond rise and fall times [3]. For optoelectronic communications, photoconducting devices allow operation in the gigabit per second range.

Photoconductive devices normally have two terminals. Illumination of a photoconductive device changes its resistance. Conventional techniques are used to measure the resistance of the photoconductor. Frequently, small changes in conductivity need to be observed in the study of material or device characteristics. Also, in the measurement of light intensities of faint objects, one encounters small photoconductive signals.

Only solid photoconductors, such as Si, PbS, PbSe, and mercury–cadmium–telluride (HgCdTe), will be treated here. Photoconduction has been observed in amorphous, polycrystalline, and single-crystalline materials. During the last decade, major improvements in material growth have occurred that directly translate in better device performance such as sensitivity and stability. Growth techniques such as molecular beam epitaxy (MBE) and metal organic chemical vapor deposition (MOCVD) allow the growth of single-crystal layers with an accuracy of the lattice constant. Artificially structured materials can be fabricated with these growth techniques for use in novel photoconducting devices.

Absorption of light in semiconductors can free charge carriers that contribute to the conduction process. Figure 43.1 presents the band diagram for a direct bandgap semiconductor where the excitation

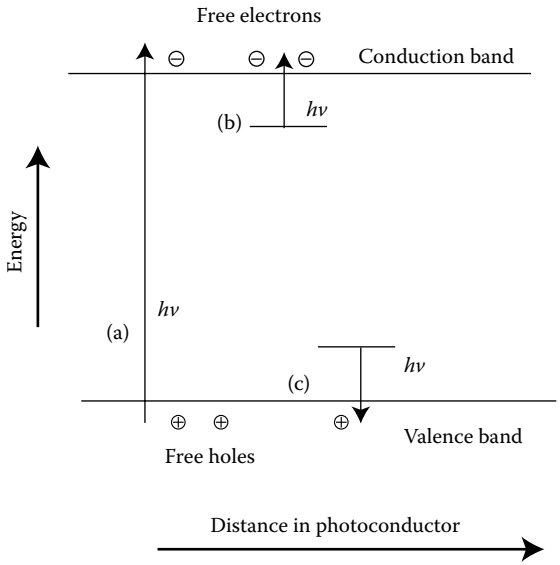

FIGURE 43.1 Example of electronic transitions in a photoconductor: (a) band-to-band excitation, (b) excitation from a trap or a donor, and (c) transition from a trap or an acceptor to the valance band; $h\nu$ is the energy of the absorbed photon.

processes are indicated. Excitation process (a) is a band-to-band transition. The photon energy for this excitation has to exceed the bandgap of the semiconductor. The absorption constant is larger for this process than for any of the other processes shown in this figure. Typical semiconductors used for electronic applications have bandgaps in excess of 1 eV, corresponding to light in the near-infrared (IR) region. Special semiconductors have been developed with narrower bandgaps to provide absorption in the mid- and long-wavelength IR regions. Indium antimonide (InSb) and HgCdTe semiconductors provide photosensitivity in the 4 and 10 μm wavelength range, respectively. The photogenerated carriers increase the electron and hole densities in the conduction and valence bands, respectively, which leads to an increase in conductivity [4]. For the simplified case with one type of carrier dominating, the conductivity σ is given by

$$\sigma = ne\mu \tag{43.1}$$

where
- n is the density of free carriers
- e is the charge
- μ is the mobility

Absorption of light results in a change in free-carrier density and a corresponding change in conductivity $\Delta\sigma$:

$$\Delta\sigma = \Delta ne\mu + \Delta\mu en \tag{43.2}$$

$\Delta\sigma$ is the definition for photoconductivity. In Equation 43.2, one assumes that due to the photon absorption, the density of carriers changes. Also, the mobility of the carriers changes due to the modified free-carrier density. The latter effect is very small except for special band transitions, as with InSb at very low temperatures.

Figure 43.1 indicates that other excitation processes exist. For example, bound electrons can be excited into the conduction band. This process can lead to persistent photoconductivity. In this example, the trapped holes have a long lifetime while the electrons move freely due to the applied electric field. Charge neutrality requires that the electrons collected at the anode be replenished by electrons supplied by the cathode. This effect leads to an amplification of the photogenerated charge (i.e., more than one electron is collected at the anode of the photoconducting device per absorbed photon). Often, the storage times are long, in the millisecond range. Hence, photoconductive devices with large amplification have a slow signal response.

Small bandgap semiconductors, such as HgCdTe and InSb, are difficult to manufacture. Thus, artificially structured layers of commonly used materials are being developed to replace these. Spatial modulation of doping has been proposed by Esaki and Tsu [5] to achieve a lattice containing a superlattice of *n*-doped and undoped, and *p*-doped and undoped layers *(n-I-p-I)*. Due to the energy configuration of this structure, the effective bandgap is less than that of the undoped material. The effective bandgap depends on the thickness of the layers and their doping concentrations. The quantum-well IR photodetector (QWIP) [6] is another approach to obtain photoconduction in the far-IR wavelength range. In this structure, energy wells exist in the conduction band of the material heterostructure due to the energy band discontinuities. Subbands form in the superlattice and electrons in these wells are confined due to the heterobarriers. IR photons can excite electrons from their confined states to the continuum, which leads to an increase in conductivity.

While it is possible to use noncontact methods to measure the conductivity in a material, electric contacts are commonly placed onto the structure during the device fabrication process. Typically, ohmic contacts are formed to fabricate metal–semiconductor–metal (MSM) structures (Figure 43.2). These contacts control the Fermi level in the material structure and provide carriers to retain charge neutrality.

43.2 Detector Performance Parameters

43.2.1 Responsivity

Variations in photon flux density incident on a photoconductor interact with the material to change the conductivity. These changes produce a signal voltage that is proportional to the input photon flux density. The detector area A collects flux contributing to the signal. J_s is the integrated power density over a spectral interval. Responsivity (R_v) is the ratio of the rms signal voltage (or current) to the rms signal power and is expressed in units of volts per watt. It is expressed as amps per watt for current responsivity:

$$R_v = \frac{V_s}{AJ_s} \tag{43.3}$$

V_s is normally linear with photon flux for low levels but can saturate under high flux conditions. One should ensure operation in the linear range for radiometric and photometric instrumentation.

43.2.2 Noise

The performance of a visible or IR instrument is ultimately limited when the signal-to-noise ratio equals one (SNR = 1). The noise from the instrument's signal processing should be less than the noise from the detector in the ideal case. This means reducing this noise within the restrictions of signal processing design limitations. These may include cost, size, and input power. The detector noise should be minimized.

Johnson noise is the limiting noise in all conductors [7]. It is frequency independent and independent of the current going through the device. Johnson noise is defined in Equation 43.4, where k is the

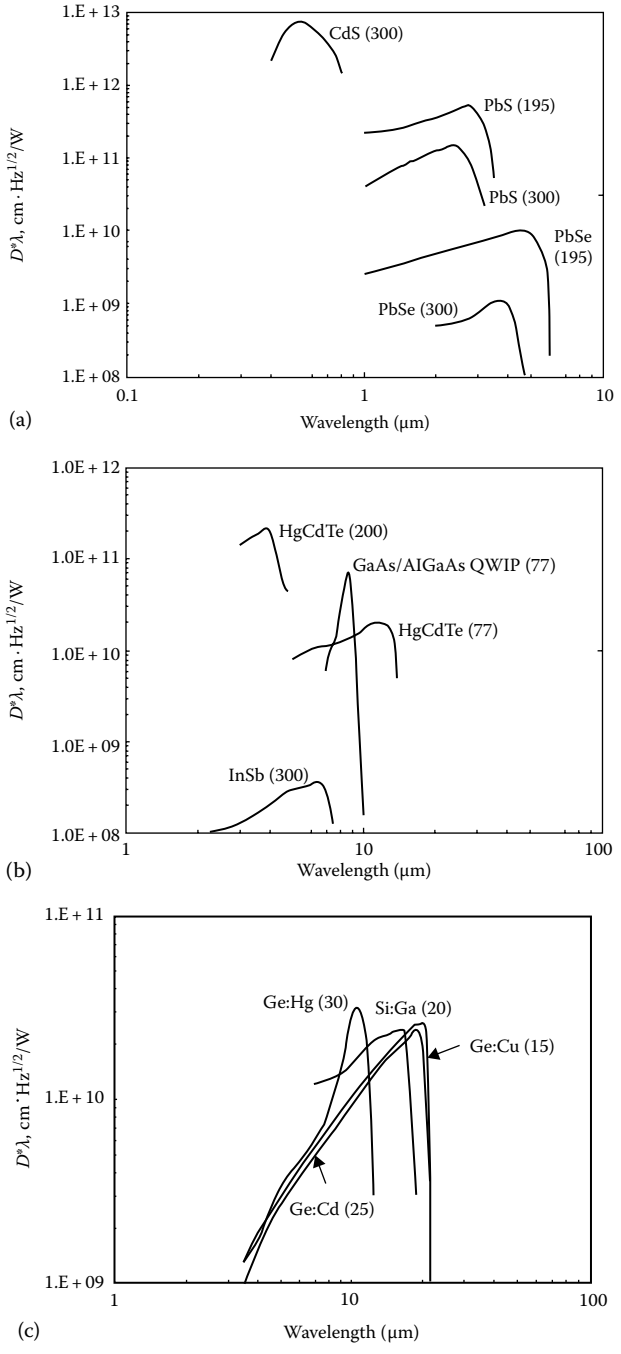

FIGURE 43.2 (a) Absolute spectral response of photoconductive detectors with the operating temperatures in K in parentheses: CdS visible and Pb salt IR detectors; (b) Absolute spectral response of photoconductive detectors with the operating temperatures in K in parentheses: III–V and II–VI intrinsic photoconductors plus a III–V QWIP detector; (c) Absolute spectral response of photoconductive detectors with the operating temperatures in K in parentheses: long-wavelength extrinsic Ge and Si photoconductors.

Boltzmann constant (1.38×10^{-23} J/K), T is the detector temperature (K), R is the resistance (Ω), and Δf is the amplifier bandwidth (Hz):

$$V_J = \sqrt{4kTR\Delta f} \tag{43.4}$$

Another type of noise known as $1/f$ noise (V_f) is present in all semiconductor detectors that carry current. The spectrum of this noise varies as $1/f^n$, with n approximately 0.5 [8].

Noise due to fluctuation in generation and recombination of charge carriers [9] varies linearly with current. This noise may be caused by the random arrival of photons from the background (photon noise), fluctuation in the density of charge carriers caused by lattice vibration (g–r noise), by interaction with traps, or between bands.

Excess noise from the amplifier or signal processing (V_{amp}) can also limit photoconductive detector performance.

These uncorrelated noises add in quadrature, giving the total noise (V_N):

$$V_N^2 = V_J^2 + V_{g-r}^2 + V_{amp}^2 \tag{43.5}$$

The total noise may be given in units of $V\sqrt{Hz}$. It may also be integrated over some frequency range to provide volts rms. Photoconductive detectors often have a g–r noise independent of frequency from dc to 100 kHz.

43.2.3 Detector Sensitivity

Minimum detectable signal power, that is, noise-equivalent power (NEP) is a convenient means to express detector sensitivity. NEP is expressed in units of watts or $W\sqrt{Hz}$:

$$\text{NEP} = \frac{V_N}{R_V} \tag{43.6}$$

The reciprocal of NEP, the detectivity D, is frequently used. In attempting to make possible comparison among detectors, detectivity can be normalized to an electronic bandwidth of 1 Hz and a detector area of 1 cm^2. This yields the highly used parameter specific detectivity or D^* (pronounced "dee-star") [10]:

$$D^* = \frac{R_V}{V_N}\sqrt{(A\Delta f)} \tag{43.7}$$

The units of D^* are $cm \cdot Hz^{1/2}/W$, sometime simplified to "Jones."

This normalization is based on evidence that noise varies as the square root of the electronic bandwidth and D varies inversely as the square root of the detector area. This relationship may not hold closely over a wide range of device sizes and bandwidths. Comparison of device performance is most meaningful among devices having similar sizes and measured under similar conditions, including operating temperature, chopping frequency/scanning rate, and detector field of view.

43.3 Preparation and Performance of Photoconductive Detectors

43.3.1 Cadmium Sulfide

CdS is normally prepared by vapor deposition or sintering a layer of high-purity CdS powder on a ceramic substrate [11]. It has the largest change in resistance with illumination of any photoconductor. The peak response of this intrinsic detector is at 0.5 μm. Its spectral response is similar to that of the human eye and operates without cooling.

43.3.2 Lead Sulfide

PbS was among the earliest IR detector material investigated. Cashman was one of the earliest researchers in the United States. [12]. This intrinsic detector material is prepared by deposition of polycrystalline thin films by vacuum sublimation or chemical deposition from a solution. The spectral response extends to approximately 3 μm. PbS operates over the temperature range from 77 K to room temperature. The frequency response slows considerably at the lowest temperatures. The spectral response extends to somewhat longer wavelengths with cooling.

43.3.3 Lead Selenide

PbSe is an intrinsic detector that operates over the temperature range from 77 K to room temperature. Its spectral response extends to longer wavelengths with cooling. Preparation of PbSe is by sublimation or chemical deposition. Noise in PbSe detectors follows a $1/f$ spectrum.

43.3.4 Indium Antimonide

InSb is prepared by melting together stoichiometric quantities of indium and antimony. It operates over the range from 77 K to room temperature. The higher performance and ease of operation with signal processing electronics lead photovoltaic InSb detectors to be much more widely used than photoconductive.

43.3.5 Mercury Cadmium Telluride

HgCdTe is a versatile intrinsic material for IR detectors. CdTe and HgTe are combined to form the alloy semiconductor $Hg_{1-x}Cd_xTe$. For the alloy with $x \approx 0.2$, the bandgap is approximately 0.1 eV, providing a long-wavelength cutoff of 12.4 μm. HgCdTe was initially grown into bulk crystals by solid-state crystallization (also called quench and anneal). Currently, thin-film growth techniques of liquid-phase epitaxy (LPE), MOCVD, and MBE are preferred to obtain larger, more uniform wafers. By appropriately choosing the alloy composition, photoconductive HgCdTe detectors are possible over the 2–20 μm range. CdZnTe wafers permit lattice-matched surfaces for HgCdTe thin-film growth. Operating temperatures can range from 77 K to room temperature, with the lower temperatures necessary for the longer wavelength devices.

43.3.6 Extrinsic Germanium and Silicon

The photoresponse of an extrinsic detector occurs when a photon interacts with an impurity added to a host semiconductor material. With an intrinsic material, the photoresponse is from the interaction with the basic material.

For the extrinsic detector, incident photons may produce free electron-bound hole pairs or bound electron-free hole pairs. The extrinsic detector's spectral response is achieved using an impurity (or doping element). Intrinsic detection occurs with a detector having the necessary bandgap width for the desired spectral response.

Extrinsic detectors require lower temperatures than do intrinsic and QWIPs, but have the advantage of longer wavelength response.

Ge and Si are zone refined to achieve high purity by making multiple passes of a narrow molten zone from one end to the other of an ingot of the material. Unwanted impurities can be reduced to levels of 10^{12}–$10^{13}/m^3$ [13]. Growth of single crystals is by the Czochralski approach of bringing an oriented seed crystal in contact with the melt and withdrawing it slowly while it is rotated or by applying the horizontal zone refining approach, whereby an oriented seed crystal is melted onto the end of a polycrystalline ingot. A molten zone is started at the meeting of the ingot and seed and moved slowly down the ingot, growing it into a single crystal. An inert atmosphere is required to prevent oxidation.

TABLE 43.1 Photoconductive Detectors

Material	Cutoff Wavelength (μm)	Temperature (K)	Responsivity (V/W)	D (cm Hz$^{1/2}$/W)
CdS	0.7	300	1×10^6	1×10^{13}
PbS	3	300	5×10^4–1×10^3	1.5×10^{11}–3.3×10^{11}
PbSe	5.8	77–300	1×10^6–1×10^3	2×10^{10}–7×10^8
InSb	7	300	5	4×10^8
HgCdTe	5	150–220	1×10^5–2×10^4	
HgCdTe	12	65–100	1×10^5	3×10^{10}
Ge/Hg	13	4–25	8×10^5	2×10^{10}
Ge/Cd	24	20–30	5×10^5	2×10^{10}
Ge/Cu	33	5	5×10^5	3×10^{10}
GaAs/AlGaAs (QWIP)	9	77	780 mA/W	7×10^{10}

Hg, Cd, Cu, and Zn are impurities for doping Ge detectors; Ga and As are dopants for Si detectors. See Table 43.1 and Figure 43.3.

43.3.7 Gallium Arsenide/Aluminum Gallium Arsenide QWIP

QWIP technology uses a quantum-well structure to provide intraband (intersubband) transitions to achieve an effective long-wavelength response in a wide bandgap material. Quantum wells are used to provide states within the conduction or valence bands. Since $h\nu$ of the desired spectral region is less than the bandgap of the host material, the quantum wells must be doped. Quantum-well structures are designed to permit photoexcited carriers to depart the structure and be accumulated as signal (photocurrent). The QWIP detector is generally comparable to extrinsic photoconductive detectors [16,17], in that both have lower than desirable quantum efficiency. GaAs/AlGaAs QWIPs have the advantage of higher operating temperatures than extrinsic detectors.

43.4 Instrumentation

The Stanford Research Systems SR570 low-noise current preamplifier can be used to amplify the current flowing through a photoconductive device. This preamplifier can be programmed to apply a voltage to the terminals of the photoconducting device. Its output voltage is proportional to the device current. Frequently, the IR radiation or visible light is chopped and the ac component of the device current is detected using lock-in-amplifier techniques. This approach allows the study of very small changes in device conduction. The Stanford Research Systems SR570 and the EG&G Instruments Model 651 are examples of a lock-in amplifier and a mechanical radiation/light chopper, respectively.

Photojunction Sensors

Michael R. Squillante
Radiation Monitoring Devices, Inc.

Kanai S. Shah
Radiation Monitoring Devices, Inc.

James F. Christian
Radiation Monitoring Devices, Inc.

44.1 Introduction

Photojunction sensors (photodiodes and phototransistors) are semiconductor devices that convert the electrons generated by the photoelectric effect into a detectable electronic signal. The *photoelectric effect* is a phenomenon in which photons lose energy to electrons in a material. In the case of a semiconductor, when the energy of an interacting photon ($h\nu$) exceeds the energy of the semiconductor bandgap (E_g), the energy absorbed can promote an electron from the valence band to the conduction band of the material. This causes the formation of an electron–hole pair. In the presence of an electric field, these charges drift toward electrodes on the surface and produce the signal.

The junction in the photojunction device creates a diode that provides a small built-in electric field to propel the charges to the electrodes (photovoltaic mode of operation). In the photovoltaic mode, either the photocurrent or the photovoltage can be measured.

Photojunction sensors are an alternative to other light sensing technologies, such as vacuum tube detectors, for example, photomultiplier tubes. There are a variety of advantages to be gained by using photojunction sensors, including higher quantum efficiency (QE), tailored spectral response, increased ruggedness, reduced power requirements, reduced weight, compact size, elimination of a warm-up period, reduced sensitivity to temperature and voltage fluctuations, and insensitivity to magnetic fields.

In general, semiconductor photojunction sensors produce more dark current than photomultiplier tubes, especially at room temperature. Upon cooling, the noise in semiconductors can be reduced significantly due to a reduction in dark current.

44.2 Photodiodes

Photodiode devices are most often operated with a bias voltage applied opposing the junction (*reversed bias*) to provide the electric field. The presence of the junction in a diode allows for the application of a relatively large bias to be applied while maintaining a relatively low reverse leakage current and thus relatively low noise. The result of an applied bias on a junction is the increase of the "depletion region," which is the sensitive volume of the detector. Any charges generated within this volume are swept toward the electrodes by the field, adding to the reverse leakage current. The *total reverse* current is the sum of the *dark current*, which is often dominated by the thermal generation of charges in the depletion region, and the *photocurrent*, which is produced due to optical illumination. The dark, or leakage, current contains contributions from the thermal generation of charge carriers in the bulk and surface, as well as ohmic terms associated with the conduction of current through the high-field regions at the surfaces of the device. The sensitivity of the detector to optical illumination decreases as the dark current increases.

There are several fundamental types of junction photodiodes [1,2], as shown in Figure 44.1. A *Schottky barrier* diode is a device in which the junction is formed at the surface of the semiconductor by the application of a metal electrode that has a work function that is different from the work function of the semiconductor; a *heterojunction diode* is a device in which two different

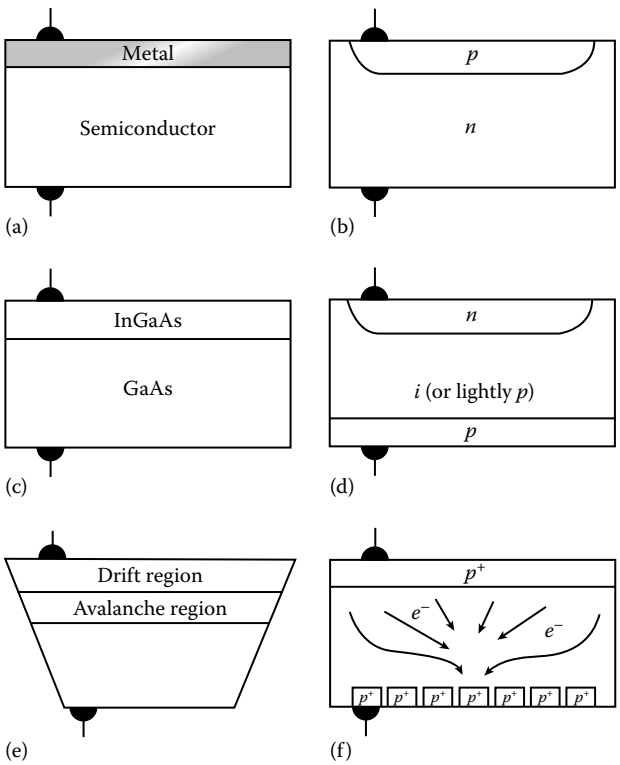

FIGURE 44.1 Schematic of photodiode device structures: (a) Schottky junction, (b) homojunction, (c) heterojunction, (d) *p-i-n*, (e) APD, and (f) drift diode.

semiconductor materials with differing work functions are joined; a *homojunction diode* is a device in which the junction is created at an interface in a single material and the difference in work function is created by doping the material *n*-type and *p*-type. Most photodiodes are homojunction devices made using silicon. Other, more complex types of photojunction devices, which are discussed later, include *p-i-n photodiodes, avalanche photodiodes (APDs), drift photodiodes, Geiger photodiodes (GPDs), and phototransistors*.

Photodiodes are typically characterized by several properties, including spectral response, operating bias, operating temperature, dark current, junction capacitance, noise equivalent power (NEP), and peak wavelength. Other specifications usually provided by manufacturers include size, packaging details, operating temperature range, capacitance, and price. The bandwidth is generally not an independent intrinsic property of the photodetector but is often related to the readout electronics and the selected integration time.

Photodiodes are used in numerous applications, including CD-ROM systems, television remote control systems, fax machines, copiers, optical scanners, fiber optic telecommunication repeaters, surveillance systems such as motion detectors, certain smoke detectors, and light meters. They are also used in a wide variety of scientific instrumentation including spectrophotometers, scintillation detectors, optical trackers, laser range finders, Laser Interferometry Detection and Ranging (LIDAR), LAser Detection And Ranging (LADAR), analytical instrumentation, optical thermometers, nephelometers, densitometers, radiometers, laser detectors, shaft encoders, and proximity sensors. Photodiode arrays are available for use as position-sensitive detectors that can either be used for imaging (such as in laser scanners, night vision equipment, spectrophotometers, and edge detection) or alignment systems. Medical imaging applications such as x-ray computed tomography (CT) scanners also use large arrays of photodiodes.

Varieties of materials are used in the fabrication of photodiodes, but most are fabricated using silicon. Other materials used include Ge; Se; II–VI compounds such as CdS, PbS, CdSe, and $Hg_xCd_{(1-x)}Te$; and III–V compounds such as GaAs, GaP, InP, InGaAs, and GaAlAs. In addition, materials with unique properties can be used to fabricate photojunction sensors that solve very specific and unusual problems, including HgMnTe, HgI_2, and InI.

Table 44.1 lists a few examples of available photodiodes. These are only a small fraction of the commercially available photodiodes and photodiode manufacturers. Lists of photodiode manufacturers are available [3,4].

TABLE 44.1 Examples of the Variety of Commercially Available Photodiodes

Commercial Source	Type	Region	Example Device	Comments
RMD	Si APD	Visible	SH8S	169 mm², $2850

44.2.1 Equivalent Circuit

The following parameters describe the current–voltage relationship for a diode: I_d = dark current (current present with no incident photons), I_j = reverse saturation current, I_o = output current, I_p = photocurrent current, and V_j = junction voltage. The dark current contains two contributions, one from an ideal rectifier, I_{ir}, which includes generation and recombination in only the charge neutral regions, that is, excluding contributions from the depletion region, and a second contribution from generation and recombination in the depletion region, I_{dw} [5]. The current from the diode, I_{ir}, assuming the diode is an ideal rectifier, is given by [6]

$$I_{ir} = I_j \cdot \left(\exp\left(\frac{qV_j}{kT} \right) - 1 \right) \tag{44.1}$$

where
- k is the Boltzmann's constant
- q is the electronic charge
- T is the absolute temperature

This expression neglects recombination and generation in the depletion region, which underestimates the dark current. The reverse saturation current depends on the intrinsic carrier density, n_i, acceptor and donor concentrations, diffusion constants, and the electron and hole lifetimes in the charge neutral regions, which excludes the depletion region. Neglecting the contribution from the charge neutral regions, which is often reasonable for many photodiodes, the following expression describes the current–voltage relationship for the diode, I_{dw} [7,8]:

$$I_{dw} = I_{jd} \cdot \left(\exp\left(\frac{qV_j}{2kT} \right) - 1 \right), \quad \text{where} \quad I_{jd} = \frac{qAn_i w}{2\tau} \tag{44.2}$$

where
- I_{jd} is the saturation current from the depletion region, which is dominated by midband, trap-assisted transitions
- A is the area
- w is the depletion width
- τ is the minority carrier lifetime

When operating photodiodes under reverse bias, the sum of the "ideal diode" saturation current and the saturation current from the depletion region describes the dark current. The depletion width contains a dependence on bias, V_j. In many photodiodes, the contribution from the current in the depletion region is dominant. Presumably, the sum of Equations 44.1 and 44.2 describes the current–voltage relationship of photodiodes. The following expression describes the total current under illumination:

$$I_o = I_{ir} + I_{dw} + I_p \tag{44.3}$$

For a more rigorous treatment, refer to [1, pp. 752–754] and [2,9].

44.2.2 *I–V* Characteristics of Photodiodes

With no illumination, photodiodes have *I–V* curves to equivalent standard diodes connected to an external power supply given by the sum of Equations 44.1 and 44.2. Illumination by light causes the

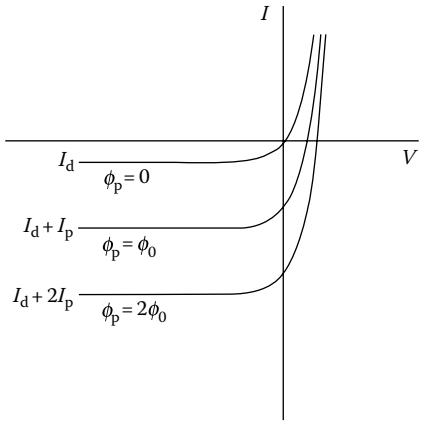

FIGURE 44.2 *I–V* characteristics of photodiode under illumination. The variable ϕ_p represents the photon flux.

current to increase. Figure 44.2 shows a family of *I–V* curves for a photodiode under illumination with equally increasing increments of incident light intensity, quantified by the photon flux φ_p. As the illumination on the device increases, the curve shifts downward by the amount of current generated by the incident light. The lower right-hand quadrant represents the photovoltaic mode of operation. When a photovoltaic device is operated in "current mode" with low or no load resistance (as with an operational amplifier, as in Figure 44.4a), the output is linear with incident light intensity. When operated in "voltage mode" with a high load resistance, there is an exponential relationship between the output and the incident illumination. The lower left-hand quadrant shows the reversed bias mode of operation. Again, in this mode, the output is nearly linear with the incident intensity.

44.2.3 Output Current under Reverse Bias

In a reverse-bias *p-n* junction under bias, the depletion width (W) increases as a function of applied bias (V_b) until the device is fully depleted. The dark leakage current (I_d) under reverse-bias conditions can arise from the generation–recombination effects (I_{jd}) and from diffusion (I_D) as well as surface effects. In most cases, the diffusion current is significantly smaller than the generation–recombination component. Thus, it is possible to assume that $I_d \cong I_{dw}$, as illustrated in Equation 44.2. This dark current is often referred to as the bulk dark current, which arises from trap-assisted generation in the depletion region.

The total diode current under illumination (I_o) is the sum of the dark leakage current (I_d) and the photocurrent (I_p):

$$I_o = I_d + I_p \tag{44.4}$$

44.2.4 Quantum Efficiency

In an ideal diode, the entire light incident on the photodiode surface is converted to electron–hole pairs, and all of the charges drift to the electrodes and are collected. In a real device, there are reflection losses at the surface, attenuation by the electrode and/or front dead layers of the device, and charge trapping so that only a fraction of the charges are collected at the electrodes. The behavior of real sensors deviates

from the ideal, and the QE characterizes the ideality of the sensor. The QE of a photodiode is the ratio of the charge pairs generated to the incident photons:

$$\eta = \frac{I_p/q}{P_i/h\upsilon} \tag{44.5}$$

where

P_i is the optical power incident on the photodiode
$h\upsilon$ is the energy of the photons

In the days of yore, before LEDs and calibrated photodiodes, light intensity was measured with power meters and bolometers. With these devices, the measured response is proportional to the energy of the photons, as well as the number of photons. Therefore, the responsivity, R, is the ratio of the photocurrent to the incident optical power (A/W):

$$R = \frac{I_p}{P_i} = \frac{\eta q}{h\upsilon} \tag{44.6}$$

Rearranging Equation 44.3 gives the following expression for the photocurrent:

$$I_p = \frac{q\eta P_i}{h\upsilon} \tag{44.7}$$

44.2.5 Simplified Equivalent Circuit

A simplified version of the equivalent circuit for a photodiode operated in photovoltaic mode is shown in Figure 44.3, where C_j = junction capacitance, I_j = reverse saturation current, I_o = output current, I_p = photocurrent current, R_j = junction shunt resistance (or parallel resistance), R_s = series resistance, V_j = junction voltage, V_o = output voltage, and R_L is the load resistance. In this mode, the diode is forward biased, and the reverse-bias saturation current, I_j, which is injected into the junction, subtracts from the photocurrent.

In the equivalent circuit for the photodiode, the junction shunt resistance is a measure of the ohmic leakage along the diode surfaces, the junction capacitance is inversely proportional to the depletion width and proportional to the device area, and the series resistance includes resistance associated with the diode material and contacts.

44.3 Photodiode Circuits

Figure 44.4a shows a simple circuit for operating a photodiode in the photovoltaic mode. In this mode, photocurrent is usually measured because the photocurrent is nearly proportional to the input signal. The output of the photodiodes is typically connected to the input of an op-amp current-to-voltage converter. Figure 44.4b shows a simple circuit for operating a photodiode under reverse bias.

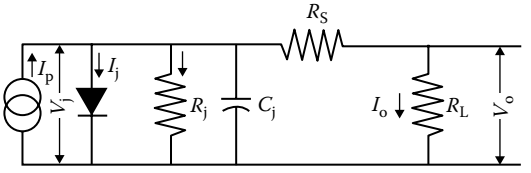

FIGURE 44.3 Equivalent circuit for a photodiode.

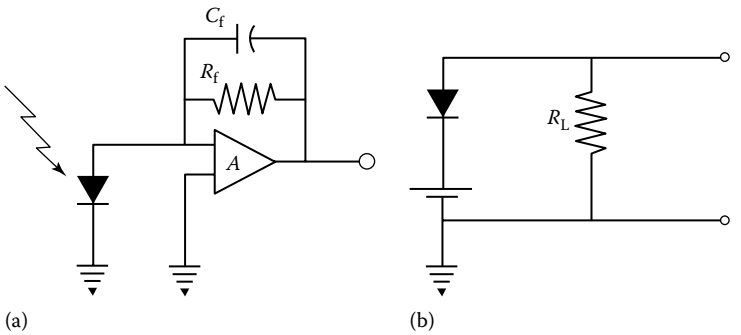

FIGURE 44.4 Typical circuits for operation of a photodiode: (a) circuit for photodiode operation in photovoltaic mode and (b) circuit for photodiode operating under reverse bias.

44.3.1 Noise

There are two main sources of noise when using a photodiode: *shot noise* in the diode and *thermal noise*. The shot noise current is related to the bulk dark current by the formula:

$$I_s = (2qI_dB)^{1/2} \tag{44.8}$$

where B is the bandwidth of the readout circuit or measurement. It should be noted that the noise currents described in this section are actually the fluctuations in the dark, or noise, current. In other words, the shot noise current is the root-mean-square (rms) variance in the average dark current.

Assuming that the diode shunt resistance and the input resistance of the measuring circuit to be used to measure the output of the photodiode are high relative to the load resistance, the thermal noise current, I_t, is given by

$$I_t = \left(\frac{4kTB}{R_L}\right)^{1/2} \tag{44.9}$$

where R_L is the load resistance. The total noise current is the sum of these currents in quadrature.

44.3.2 Quadrant Detector Arrays

Many manufacturers offer photodiodes fabricated in a *quadrant* configuration, where four photodiodes are fabricated in a square, 2 × 2 geometry. When coupled to a lens or a pinhole, they can be operated as position-sensitive detectors. In operation, the outputs of the four photodiodes are monitored, and the position of the light source can be determined by the projection of the light spot on the detector surface. Applications of quadrant detectors include position sensing, target tracking, laser ranging, fluorescence spectroscopy, laser alignment, and atomic force microscopy [10]. More recently, manufacturers are offering linear and area arrays of photodiodes that can be used as imaging devices.

44.4 Phototransistors

Phototransistors are photojunction devices similar to transistors except that the signal amplified is the charge pairs generated by the optical input. Like transistors, phototransistors can have high gain. This high gain, however, is often restricted to large signals in detectors with a macroscopic size. As the size of the phototransistor increases, the amount of charge needed to change the field in the transistor

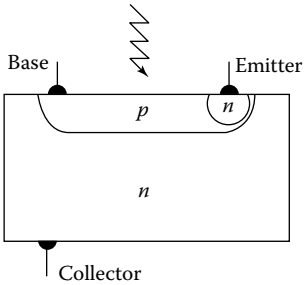

FIGURE 44.5 Schematic representations of a simple bipolar phototransistor. Note that the phototransistor has a large *p*-*n* junction region that is the photosensitive portion of the device.

to provide gain increases. In other words, phototransistors generally do not provide efficient gain for small signals. Phototransistors can be made on silicon using *p*- and *n*-type junctions or can be heterostructures. Figure 44.5 shows a sketch of the structure of a simple bipolar phototransistor, which is essentially the same as that of a simple bipolar transistor. The main difference is the larger base–collector junction, which is the light-sensitive region. This results in a larger junction capacitance, and, although the devices have gain, the capacitance gives phototransistors lower-frequency response than photodiodes.

Using thin-film transistor (TFT) technology developed for flat panel displays, large arrays of phototransistors can be fabricated on amorphous silicon to form imaging devices that can be used in place of other imaging technologies such as vidicon tubes or even film. Examples of this are the very large-area detectors (hundreds of square centimeters) being investigated for use in medical radiography by combining the TFT arrays with radiographic phosphor screens [11] or coupled to semiconductor films [12–15].

44.5 Silicon Photojunction Detector Structures

44.5.1 Silicon *p-i-n* Detectors

Silicon *p*-*i*-*n* diodes are an extension of the standard *p*-*n* junction diodes but are more attractive for low-noise applications due to reduced capacitance in these devices [1]. The reduction in capacitance is achieved by incorporating an intrinsic region between the *p* and *n* regions. This increases the depletion width of the detector and thereby lowers its capacitance. Silicon *p*-*i*-*n* detectors can be designed to have a lower junction capacitance, and therefore a higher frequency response, than *p*-*n* junctions.

In operation, *p*-*i*-*n* detectors are similar to *p*-*n* junction detectors, but the surface region (either *p* or *n*) is made thin so that the optical photons penetrate this entrance layer and are stopped in the intrinsic (*i*-region) where electron–hole pairs are produced, as shown in Figure 44.1. These electron–hole pairs are swept toward the appropriate electrodes by the applied electric field. For fabrication, *p*-*i*-*n* detectors require high-resistivity material, and typical photodiodes have a thickness ranging from 100 to 500 μm. Important applications of *p*-*i*-*n* detectors include optical sensing of scintillated light in CT scanners, general scintillation spectroscopy, charged particle spectroscopy, and high-speed sensing applications.

44.5.2 Silicon Drift Detectors

Silicon drift photodiodes are an extension of the *p*-*i*-*n* geometry. In recent extensive studies, they have been found to provide very low capacitance (<1 pF for 1 cm^2 detector with 300 μm thickness) [16,17]. This is achieved by reducing the area of ohmic electrode (anode in most cases) significantly as compared to the entrance electrode as shown in Figure 44.1f. Since the charge sensing electronics are connected to the smaller electrode, the device capacitance is proportional to its size and not to the actual

detector area. Thus, by exploiting this concept, significantly lower capacitance has been achieved than in a comparable *p-i-n* detector.

In drift detectors, it is important to ensure that charges created over the entire active volume will be collected at the anode. In order to achieve this, drift rings are provided around the anode. The outermost ring is biased at highest potential, with the inner rings biased to lower potentials in a successive manner. This arrangement creates a potential minimum at the anode and thereby enables efficient charge collection over the entire detector volume. A variety of device geometries have been explored based on this concept, and in some instances, these detectors are capable of providing position-sensitive and imaging detection as well [18,19]. While many of these detectors are in the research stage, excellent performance has been demonstrated by prototypes.

44.5.3 Silicon Avalanche Photodiodes

While the conventional silicon diodes, such as *p-n* junction diodes, *p-i-n* diodes, and drift diodes, have no gain, silicon APDs have internal gain that enables them to operate with high signal-to-noise ratios (SNRs) placing less stringent requirements on supporting electronics. Figure 44.6 shows a photograph of commercially available silicon APDs.

In its simplest form, an APD is a *p-n* junction formed in a silicon wafer structured in such a way that it may be operated near breakdown voltage under reverse bias. The absorption of either photons or charged particles in the silicon generates electron–hole pairs that are accelerated by the high electric field. These electrons gain sufficient velocity to generate free carriers by impact ionization, resulting in internal gain [20]. Small-area APDs have been in routine use in the telecommunications industry for some years [21–23] and in a variety of other applications such as optical decay measurement, time domain reflectometry, and laser ranging [24]. The standard large-area avalanche diode is a single element sensor made on a thin silicon wafer.

Initial research on large-area silicon APDs was carried out in the late 1960s [25], but large-area APDs attracted little attention until the 1980s when improved fabrication techniques led to higher gains and better reproducibility [26]. These devices have been used for a wide variety of nuclear spectroscopy applications [27–29]. In comparison to photomultiplier tubes, these sensors are smaller, more rugged, and more stable and use less power. They are also far more sensitive and have inherently better SNRs than the other semiconductor photosensors. In addition, they may be operated without cooling and are insensitive to magnetic fields and vibration.

The APD generally consists of several regions including the "drift" region and the active junction that contains the multiplication region. The drift region is typically 20 μm thick, while the active region of the device is approximately 120 μm thick, and the multiplication region is less than 10 μm thick. Ionizing radiation or light with energy greater than the bandgap that strikes the drift region will cause the generation of free charge carriers, which are then transported to the active region. No external field is present here, but a gentle gradation in dopant concentration causes a small electric field to impart

FIGURE 44.6 Photographs of commercially available silicon APD devices.

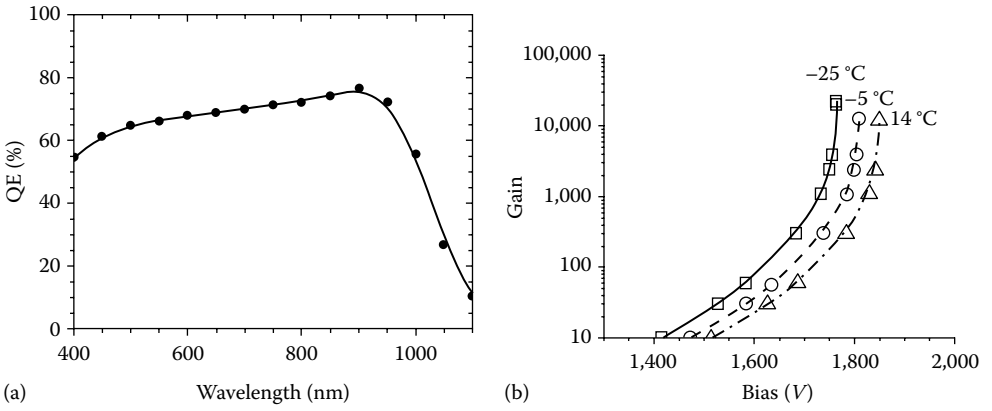

FIGURE 44.7 The diagram (a) shows a typical QE versus wavelength plot for high-gain silicon APD. The plot (b) shows the gain versus bias relationship for a high-gain APD. Higher gains are achievable at lower voltages as the temperature is decreased.

a net movement of electrons toward the multiplication region. Since the dopant concentration in this region is relatively light, the carrier lifetimes are quite large, and efficient transport is easily attained with the high-quality silicon now available. Within the multiplication region, the charge carriers are amplified in accordance with the gain of the device. Electrons entering this region quickly attain velocities large enough to cause knock-on collisions with bound electrons in the lattice. This process then frees additional electrons that can also undergo new collisions. The multiplication process occurs many times, with the result that a single electron will commonly generate hundreds of free electrons, which produces a significant net gain in the electric signal. This built-in signal multiplication allows very low-energy particles, such as beta emissions from tritium beta decay, to be amplified and detected with high efficiency.

APDs with small areas (a few mm in diameter) can be manufactured with standard planar processing and have a gain of a few hundred. These detectors are widely used in the telecommunications industry. It is difficult to fabricate high-gain detectors with large areas using the planar process; however, special detector designs with beveled edges (see Figure 44.1) have been fabricated to provide high gain (>10,000) in large areas (>1 cm^2) [30]. The APD gain versus bias behavior for such a device is shown in Figure 44.7. Recent advances in surface preparation and dead layer reduction have extended the application of these detectors to the UV region. While they are relatively expensive, these detectors are well suited to a number of commercial applications such as medical imaging, astronomy, charged particle and x-ray detection, scintillation spectroscopy, and optical communications.

44.5.3.1 Equivalent Circuit

The diagram for the equivalent circuit of an APD is similar to that of a photodiode, shown in Figure 44.3; however, there is no component that would introduce an injection current because the diode must be reverse biased to provide gain. The contributions from the shunt resistance can increase because the reverse operating bias can be large. When considering diodes with avalanche gain, it is often useful to delineate bulk dark current, I_{db}, which undergoes impact ionization, from surface leakage, I_{ds}, which is often approximated using a linear, or ohmic, dependence on the applied bias. Equation 44.10 relates the previously defined terms for dark current from the depletion region and the ideal rectifier to the bulk and surface terms:

$$I_d = (I_{dw} + I_{ir}) + I_{ds} = I_{db} + I_{ds} \tag{44.10}$$

The expression for the total current under illumination of an APD contains an additional term for the gain, *M*, as described in the following equation:

$$I_o = M \cdot I_{db} + I_{ds} + M \cdot I_p \tag{44.11}$$

where
I_{db} is the bulk dark current
I_{ds} is the surface dark current, which can include ohmic components

For simplicity, all of the dark bulk current is assumed to experience multiplication in Equation 44.11. Although there could be gain associated with the surface components, the gain should be small, or negligible, in an ideal device.

44.5.3.2 Quantum Efficiency

The fundamental expression for the QE of a photodiode [2] applies to the APD, as follows:

$$\eta = (1 - \Re) \cdot \beta \cdot (1 - Exp(-\mu \cdot \ell)) \tag{44.12}$$

where
$\Re$ is the reflectivity
η is the charge collection efficiency
β is the absorption coefficient
ℓ is the width of the active region

The QE of an APD can be different than that of the equivalent photodiode due to the collection of charge at the higher biases needed to produce gain through impact ionization.

The QE and gain are separate properties; however, most measured quantities include the product of the QE and gain. Therefore, analysis is needed [31] to determine the gain dependence of the QE and the wavelength dependence of the gain.

44.5.3.3 Noise

In addition to the sources of noise present in photodiodes, multiplied by the gain, APDs introduce an additional term due to the noise generated by the multiplication process, defined as the excess noise, *F*. For an ideal APD, the excess noise ranges from two to higher, depending on the amount of hole multiplication, which generally increases with the gain. The shot noise current in the APD from the dark current can be written as

$$I_s = (2 \cdot q \cdot (M \cdot F \cdot I_{db} + I_{ds}) \cdot B)^{1/2} \tag{44.13}$$

Assuming the APD shunt resistance and the input resistance of the measuring circuit to be used to measure the output of the photodiode are high relative to the load resistance, the thermal noise current, I_t, is given by

$$I_t = \left(\frac{4kTBM}{R_L} \right)^{1/2} \tag{44.14}$$

where R_L is the load resistance. The total noise current is the sum of these currents in quadrature. It should be noted that these expressions include terms, such as *B* and R_L, which are specific to the measurement.

44.5.4 Geiger Photodiodes

The gain of an APD increases with increasing bias voltage, and as the bias voltage approaches the breakdown voltage, the gain goes to infinity. At the breakdown voltage, both electrons and holes have sufficient velocity to cause knock-on multiplication, which leads to a self-propagating avalanche or Geiger avalanche. At this voltage, the device effectively becomes a short circuit with the current limited by the resistance of the circuit. By adding ballast, or quenching, resistor, the GPD devices function like a Geiger–Mueller tube that discharges the junction capacitance, which determines the gain that can be 10^6–10^8. A single charge generated in the device causes breakdown, whether from a photon or thermally generated.

When properly constructed, as described by Mcntyre [32,33], it is possible to raise the bias above breakdown for macroscopic periods of time between thermally generated charges. In this overbiased state, the device becomes sensitive to single visible light photons. Such devices are APDs operated in Geiger mode, called GPDs by Cova [34,35] and [36]. Figure 44.8 shows a photograph of GPD devices designed by Vasile and Christian et al. at RMD.

44.5.4.1 Equivalent Circuit

Figure 44.9 shows a SPICE-equivalent model for a GPD element with a quenching resistor, R_q. The current source is a current pulse with an integrated charge of ~200 fC, which represents the gain, G, of the GPD.

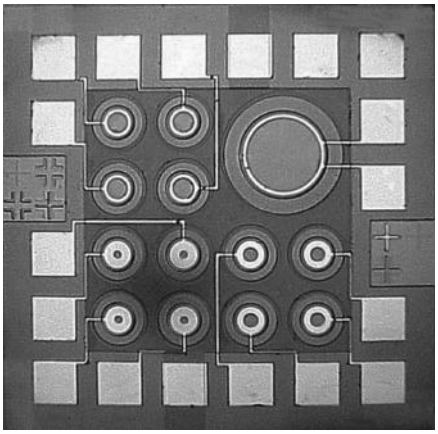
The expression for the total current under illumination of a GPD contains a term for the gain, G, as described by:

$$I_o = G \cdot I_{db} + I_{ds} + G \cdot I_p \tag{44.15}$$

where

I_{db} is the bulk dark current

I_{ds} is the surface dark current, which can include ohmic components



(a)

(b)

FIGURE 44.8 Photograph of two chips containing round GPD elements in sizes ranging from 5 μm diameter to as large as 180 μm in diameter. The chip (a) was fabricated with a custom process, *circa* 1997; the chip (b) uses a commercial CMOS process and was fabricated around 2005. The photographs are roughly to scale: the square contact pads at the perimeter of each chip are 100 μm × 100 μm.

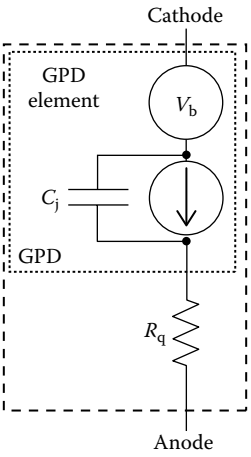


FIGURE 44.9 SPICE equivalent of a GPD element with an integrated quenching resistor, R_q. The internal voltage source subtracts the breakdown voltage from the pulse generated by the current source, which is in parallel with the junction capacitance, C_j.

Notice that like the APD, the gain minimizes the contribution of nonbulk leakage current; however, the gain associated with the GPD is appreciably larger, ~10^6, than that of an APD. The excess bias, V_x, is the bias above the breakdown voltage, V_b, as described in the following equation:

$$V_x = V_{bias} - V_b \tag{44.16}$$

where V_{bias} is the reverse bias applied to the diode. The gain, G, is the product of the junction capacitance, C_j, and the excess bias:

$$G = C_j \cdot V_x \tag{44.17}$$

The individual GPD element is effectively a binary device that detects individual optical photons. The signal associated with each Geiger pulse is only proportional to the gain of the GPD element and is not related to the number of photons that may have triggered the GPD. The current expressions assume that the photocurrent is continuously distributed in time, that is, the illumination is not pulsed.

44.5.4.2 Quantum Efficiency

The QE of a GPD is similar to that of an APD; however, the single-photon detection efficiency (DE) contains an additional term for the probability to generate a Geiger avalanche or Geiger probability, P_g:

$$\mathrm{DE} = \eta \cdot P_g \sim \eta(\lambda) \cdot P_g(V_x) \tag{44.18}$$

In Equation 44.18, the approximation refers to the dependence of the QE on the wavelength and the Geiger probability on the excess bias. GPD elements are often very thin, unlike many APDs that have a separate drift and multiplication region, and the QE and Geiger probability depend on both the wavelength and the bias. The dependence of the QE on bias arises from the bias dependence of the charge

collection and the wavelength dependence of the absorption depth. The dependence of P_g on wavelength arises from the wavelength dependence of the absorption depth and differing Geiger probabilities for electron-initiated Geiger events compared to hole-initiated Geiger events.

44.5.4.3 Noise

The GPD is essentially a digital device, and thus there is no corresponding multiplication, that is, excess, noise in an ideal GPD. Of course, there is the shot noise associated with the input referenced dark or photocurrent. The shot noise in the GPD from the dark current can be written as

$$I_s = (2 \cdot q \cdot (G \cdot I_{db} + I_{ds}) \cdot B)^{1/2} \tag{44.19}$$

Due to the very high gain provided by the GPD element, the surface leakage term, I_{ds}, can often be neglected. The expression for the thermal noise current variance, I_t, is essentially the same as that for an APD, where G replaced M for the gain variable.

44.5.5 Solid-State Photomultiplier

A solid-state photomultiplier (SSPM) is an array of APD elements operated in Geiger mode, that is, above the reverse-bias avalanche breakdown voltage, with integrated quenching components [37–39]. The elements contain a quenching component, such as a resistor, that serves the same purpose as the ballast resistor in a Geiger tube. Each element, referred to as a GPD, is a Geiger detector for optical photons, and proportional information, that is, the number of photons detected, is proportional to the number of triggered GPD elements when the array is uniformly illuminated. Important characteristics of the SSPM detectors are that they provide single photoelectron resolution, they exhibit low excess noise factors, and they can withstand illumination by room lights when biased without damage, that is, they are robust.

Single GPD elements were introduced by McIntyre [32,33] and advanced by Cova et al. [34,35] and Vasile et al. [36,40]. Buzhan et al. [37,41], who refer to SSPM as SiPMs, introduced a process where arrays of GPD elements with an integrated quenching resistor could be fabricated. Phelan et al. [42] also developed analogous sensors, which is the foundation for devices manufactured by SensL, Inc. RMD [43] and Rochas et al. [44] developed SSPMs using commercial CMOS foundry processes. We prefer to call these devices SSPMs because we are interested in generalizing the concept of an array of GPD elements to materials other than silicon. Hamamatsu has introduced the multi-pixel photon counter (MPPC), which is an equivalent device as an SSPM. Companies offering SSPM devices, or their equivalent, include Hamamatsu (Japan), Philips (Netherlands), RMD (Watertown, MA), SensL (Ireland), FBK (Italy), Photonique SA (Switzerland), and Excelitas (New York).

Figure 44.10a shows a photograph of 1 cm × 1 cm CMOS SSPM devices from RMD, next to a table of characteristics for the devices (Figure 44.10b), along with an illustration of the pulse-height spectra (Figure 44.10c), showing the proportionality to the number of triggered GPD elements.

SSPM detectors are particularly well suited for specialized scintillation detection applications, such as medical imaging. An example is as dual-mode imaging, where nuclear imaging is coupled to magnetic resonance imaging (MRI). In these applications, the compact size and insensitivity to magnetic field are critical performance characteristics. Images can be generated from events detected and localized in segmented scintillation detectors coupled to segmented SSPM detectors. Other specialized SSPM detector configurations, for example, position-sensitive configurations, are being developed to minimize the number of readout channels.

44.5.5.1 Equivalent Circuit

Like the GPD description, the expression for the equivalent circuit of an SSPM contains a term for the gain, G, as described in the following equation:

$$I_o = G \cdot I_{db} + I_{ds} + G \cdot I_p \tag{44.20}$$

where

I_{db} is the bulk dark current

I_{ds} is the surface dark current, which can include ohmic components

Notice that like the APD, the gain minimizes the contribution of nonbulk leakage current. Unlike the GPD, however, the SSPM can accommodate the detection of multiple photon events when the photons are distributed over the array into distinct GPD elements.

44.5.5.2 Quantum Efficiency

The QE and DE of an SSPM is similar to that of the constituent GPD elements; however, the DE, DE_{SSPM}, contains an additional term for geometric fill factor, *ff*:

$$DE_{SSPM} = DE_{GPD} \cdot ff \tag{44.21}$$

44.5.5.3 Noise

Although the constituent GPD elements nominally do not produce gain, that is, multiplication noise, the SSPM performance can be characterized by an excess noise factor. The primary processes responsible for producing excess noise are cross talk between GPD elements and after pulsing in the GPD element. The after pulsing contribution contains a dependence on the integration time, which is specific to event detection applications. Generally, the excess noise factors of SSPM devices are equivalent to that of PMTs but depend on the excess bias. The characterization of the excess noise for SSPM devices is described in the literature [45–48]. After pulsing and cross talk trigger GPD elements in addition to an incident stimulus and can thus be described as gain or multiplication terms. The fluctuations in the amplification terms associated with cross talk and after pulsing produce gain noise, that is, excess noise.

The shot noise in the SSPM from the dark current can be written as shown in the following equation:

$$I_s = (2 \cdot q \cdot (G \cdot F \cdot I_{db} + I_{ds}) \cdot B)^{1/2} \tag{44.22}$$

In applications detecting pulses of photons, such as the detection of gamma-ray events by a scintillation detector, the noise not only broadens the peaks in the histogram of pulse heights, that is, the gamma-ray spectrum, but also introduces a noise floor that produces a lower limit to the detected energy of the gamma ray or amplitude of the scintillation pulse. In these applications, the dark current represents an uncorrelated source of single-photon events, unlike the detection of the scintillation pulse associated with the detection of a gamma-ray event.

For the detection of scintillation pulses, the dark counts will produce an amplitude spectrum, which defines the noise floor of the SSPM. In the absence of cross talk and after pulsing, a Poisson distribution (see Equation 44.23) characterizes this idealized noise floor when operating a GPD array as an SSPM [45]:

$$P(n) = \frac{(I_d \tau)^{n-1}}{(n-1)!} e^{-I_d \tau} \tag{44.23}$$

$P(n)$ describes the probability for generating an n-photon event from the thermally generated dark counts in the SSPM. The term I_d denotes the dark count rate of the SSPM, which is the sum of the dark count rate for each of the individual pixels, and τ represents the integration time of the amplifier. In this expression, the dark count rate refers to the input referenced bulk dark current, that is, the dark current divided by the gain.

In pulse detection applications, the width of the zero-amplitude peak defines the noise floor, which should be convolved with the features associated with the detected events. The relative amplitude of the noise floor peak, however, is related to the maximum detection rate, or bandwidth, of the readout electronics and multichannel analyzer that histograms the pulse amplitudes.

44.6 Photodiode Arrays

Photodiode arrays consist of multiple photodiode elements, which can be in the form of a linear, square, or rectangular array. CMOS imaging sensors and SSPMs are essentially arrays of photodiodes. Photodiode arrays are used in applications where CCDs are not suitable because of sensitivity or speed requirements and where very high spatial resolution is not as critical. They are frequently the detector of choice in medical x-ray and gamma-ray imaging applications, such as CT, single-photon emission tomography (SPECT), and positron-emission tomography (PET). Arrays made from silicon photodiodes, APDs, and GPDs are available for response to specific wavelengths. Photodiodes made in other materials are also available for response to specific wavelengths based on the bandgap of the material. Nominally, CMOS active pixel sensor cameras [49,50] can be considered as an array of individually addressable photodiodes.

44.6.1 APD Arrays

A number of researchers have investigated the use of arrays of APD for use in medical imaging. Figure 44.11 shows a monolithic, 8 × 8-element APD array. APDs have the advantage of being insensitive to magnetic fields and are being investigated for use in dual-modality PET/MRI and SPECT MRI medical imaging cameras [51–57]. The ability to operate in magnetic fields also makes these photosensors attractive for nuclear physics and high-energy physics applications.

The internal gain of the APD reduces the effect of the readout noise on the SNR. The gain provided by the monolithic array shown in Figure 44.11 exhibits a low excess noise factor compared to small, shallow CMOS APD structures. The excess noise factor, F, degrades the signal-to-noise performance as described in the following:

$$\text{SNR} \propto \frac{\text{QE}}{F} \tag{44.24}$$

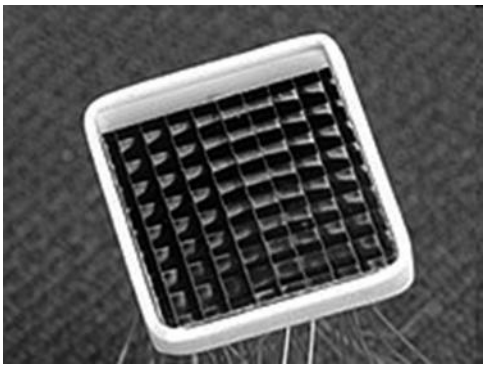

FIGURE 44.11 Monolithic 8 × 8 element APD array. The size of each individual element in the array is approximately 1 mm × 1 mm.

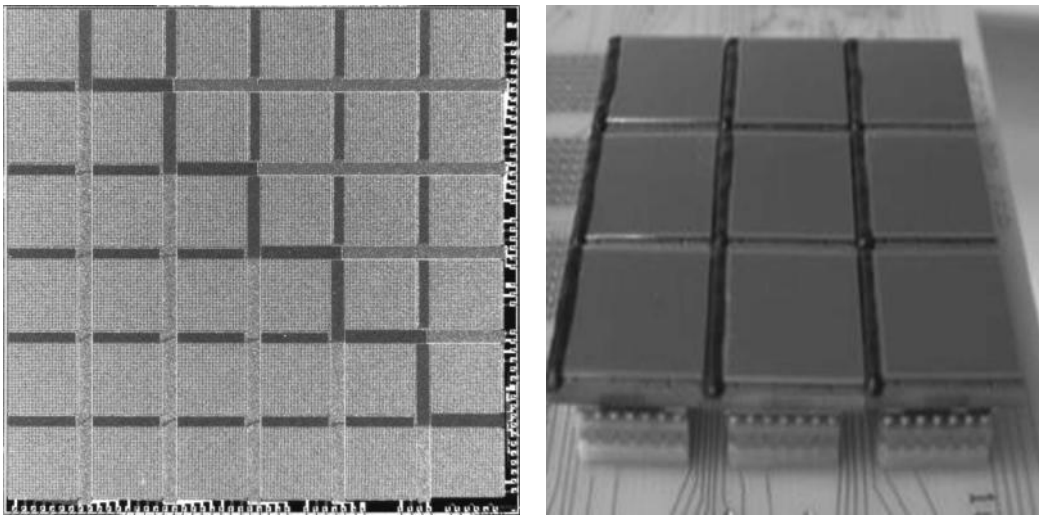

(a) (b)

FIGURE 44.12 (a) Monolithic 6 × 6 array of SSPM detectors. The size of each SSPM in the array is 1.5 × 1.5 mm, and the size of the detector is 11 mm × 11 mm. (b) Segmented SSPM array formed from a 3 × 3 array of 2 × 2 SSPM elements. Each chip in the 3 × 3 array is 11 mm × 11 mm and comprised of a 2 × 2 array.

44.6.2 SSPM Arrays

SSPM devices are inherently an array of GPD elements. Monolithic and discrete arrays of SSPM devices have been developed for nuclear imaging applications using segmented scintillation detectors. Figure 44.12a shows a 6 × 6 monolithic SSPM array chip, which is 11 mm × 11 mm; Figure 44.12b shows a 6 × 6 SSPM of discrete 3 × 3 chips, where each chip is a 2 × 2 SSPM array.

44.6.3 Position-Sensitive APDs

Traditional gamma cameras used in nuclear imaging applications generate images with the signals from multiple detectors connected by a resistive network using Anger logic. Position-sensitive photomultiplier tubes (PMTs) distribute the detected charge pulse into a resistor network that divides the signal into four or more readout contacts. The spatial location of the scintillation event on the photocathode is determined by the analysis of the relative signal amplitudes at the four contacts. Analogous to a position-sensitive PMT, the charge from an APD can be distributed by the sheet resistance of the silicon to divide the charge into four contacts, producing a position-sensitive APD device. These devices are well suited for nuclear imaging applications that involve strong magnetic fields, such as PET and SPECT imaging coupled with MRI. Figure 44.13a, shows two position-sensitive APD detectors; Figure 44.13b shows the detector module constructed with the devices, along with an image generated with the detector module.

44.6.4 Position-Sensitive SSPM

The fabrication of SSPM in standard CMOS processes facilitates the integration of components for specialized configurations. For example, a charge-dividing resistive network produces a position-sensitive SSPM (PS-SSPM) for nuclear imaging applications [38,45,58] analogous to the charge-division network used in position-sensitive PMTs [59,60]. In nuclear imaging applications, the location of the event, as well as the energy of the event, must be resolved. In an Anger camera, the scintillation light is distributed over a number of PMT detectors. In some incarnations, the signal from the PMT detectors is connected to a charge-dividing resistive network. The ratio of the signal at the four contacts of the resistive network yields the location of the scintillation event, while the sum yields the energy.

(b)

FIGURE 44.13 (a) Monolithic position-sensitive APD device. (b) PET nuclear imaging module based on PS-APD detectors.

In a PS-SSPM, the ratio of the signal at four readout contacts determines the location of the event [61], and the sum of the signals determines the energy of the event. Figure 44.14a shows a photograph of a segmented LYSO scintillation array, next to a photograph of a 5 mm × 5 mm PS-SSPM (Figure 44.14b). When coupled to the PS-SSPM, the segmented scintillation detector produced the image shown in Figure 44.14c when irradiated with a flood field of gamma rays from a 22-Na source.

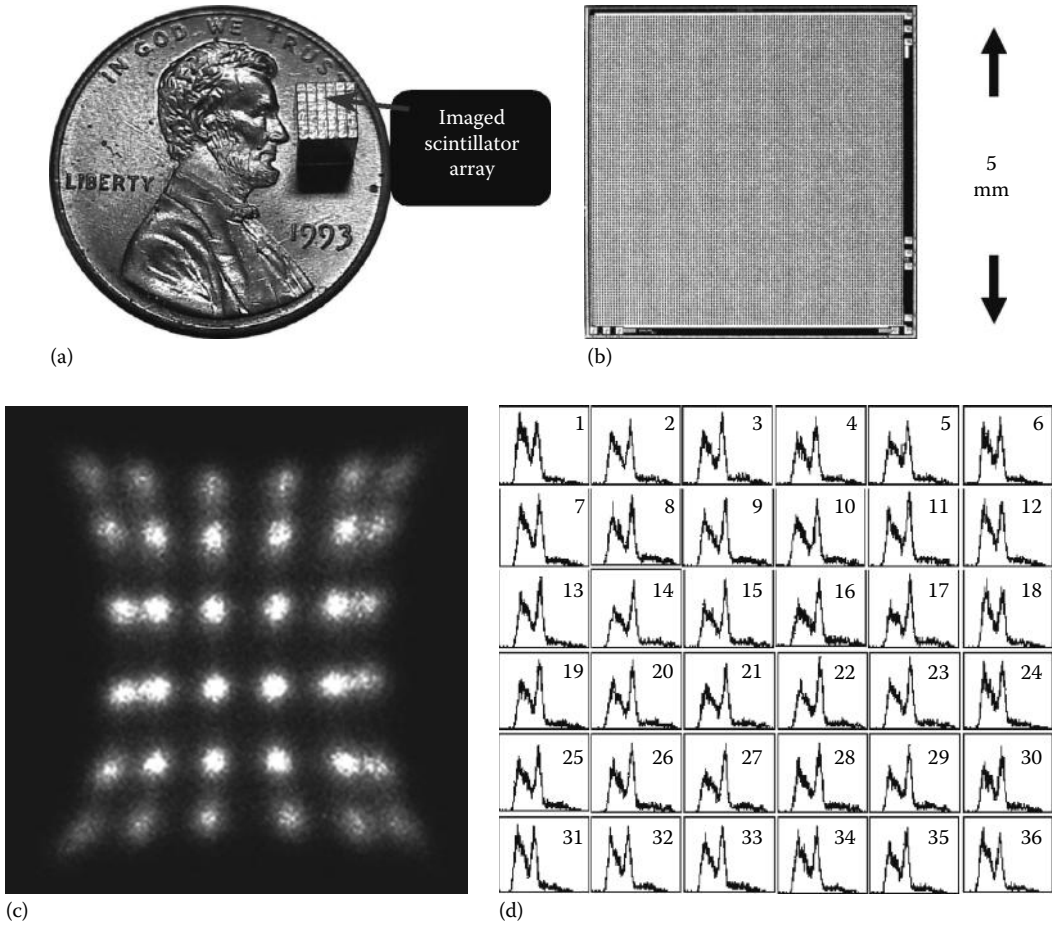

FIGURE 44.14 (a) Segmented LYSO scintillation array, (b) 5 mm × 5 mm PS-SSPM, (c) image when irradiated with a flood field of gamma rays from a 22-Na source, (d) energy spectrum for each of the scintillation segments.

As seen in the image, the location of each of the scintillation segment is cleanly resolved. Figure 44.14d shows the energy spectrum obtained for each of the scintillation segments resolved in the image.

44.6.5 Amorphous Silicon Detectors

While impressive results have been obtained with various device structures on crystalline silicon such as drift detectors, APDs, and CCDs, they are limited to active areas of only a few square centimeters. As a result, considerable attention has been devoted to the development of hydrogenated amorphous silicon (a-Si:H) [11]. This material is produced by an RF plasma technique in large areas (30 cm × 30 cm) on glass substrates. The films are typically a few micrometers in thickness, although films as thick as 200 μm have been reported. Device structures such as *p-n* junctions were developed initially for use in solar cells with lower cost than crystalline silicon devices.

Recently, more complicated devices such as *p-i-n* sensors and TFTs have been fabricated from a-Si:H and have been configured in an array format as shown in Figure 44.15. In these arrays (as large as 20 cm × 20 cm), each pixel consists (200–500 μm) of a *p-i-n* sensor connected to a TFT, and the entire array is read out in matrix fashion. These arrays are well suited for high-resolution document imaging and also for medical x-ray imaging applications with phosphors.

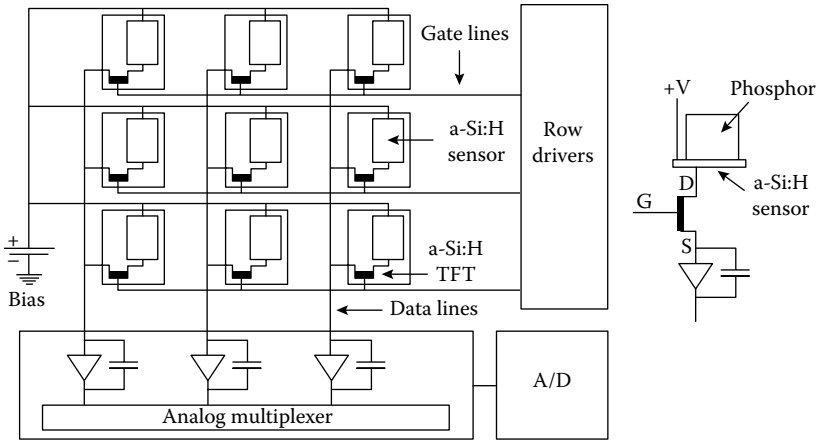

FIGURE 44.15 Schematic representation of a 2D x-ray imager consisting of a-Si:H *p-i-n* diodes connected to a-Si:H TFTs for readout. The *p-i-n* diodes are coupled to a phosphor layer to increase sensitivity.

44.7 Other Materials for Photojunction Detectors

44.7.1 Novel Materials for Photodiodes

Applications involving the detection of infrared (IR) light require the use of detector materials with small bandgaps, <1 eV, compared to silicon. Although silicon is by far the most common material used for semiconductor photodetectors, silicon cannot be used for making IR sensors because the long wavelength light is not absorbed by the silicon. To address near-IR sensing, III–V semiconductors are used for making photosensors and photosensor arrays. Table 44.2 lists materials, and their properties, used for the construction of photodiodes designed to operate at room temperature.

Applications such as scintillation detection with certain emerging UV-emitting scintillation material require the detection of UV light in addition to visible light. For these applications, a material with a wide bandgap, >1 eV, may provide lower dark current enabling an increase in the area of the device. Although the bandgap energy certainly affects the dark current, the quality of the material may be a limiting factor in the dark current performance, especially for nonsilicon devices. This is important because the sensitivity of many scintillation-based nuclear detectors scales with the size of the detector, and the ability of optics to concentrate the spatially distributed emission is limited. Table 44.3 lists materials that are ideal for detecting 380 nm scintillation light.

As stated in Table 44.3, GaP is an indirect bandgap material with bandgap energy of approximately 2.26 eV. The maximum photo absorption wavelength is around 550 nm based on the calculation from the bandgap energy. $GaAs_{1-x}P_x$ is an indirect bandgap material when the phosphorus mole fraction of the compound reaches beyond 50% ($x > 0.5$). At this condition, the bandgap is around 2.12–2.33 eV. Similar to GaP, the high impact ionization ratio and dark noise of GaAsP make it less ideal for GPD development in the project.

Important requirements for photodiodes include high QE, good charge collection efficiency, and low noise. The low-noise requirement is satisfied by reducing detector capacitance and its dark current. In order to satisfy the QE requirements over a wide range of wavelengths, new semiconductor materials are being extensively investigated [78]. Since most semiconductors show high optical response near their bandgap, special materials are developed for various applications. Furthermore, since the bandgap represents a cut-off point in the optical response of the material, by selecting an appropriate material, it is possible to obtain response in a desired band [79]. For example, materials such as GaN and SiC are being explored to obtain UV detection with no sensitivity in the visible region. Other materials are being studied to exploit their unique properties such as high QE, high-temperature operation, and high-speed response.

TABLE 44.2 Properties of Semiconductor Materials Used for Construction of Photodiodes at 25°C

Material	Bandgap	Dielectric Constant	Resistivity (Ω-cm)	Electron Mobility (cm^2/V s)	Electron Lifetime (s)	Hole Mobility (cm^2/V s)	Hole Lifetime (s)	μ_τ (e) (cm^2/V)	μ_τ (h) (cm^2/V)
HgTe	0.14	6.4		22,000		100			
InAs	0.36	12.5	30,000	240					
Ge	0.67	16	50	3,900	$>10^{-3}$	1900	1×10^{-3}	>1	>1
Si	1.12	11.7	$\leq 10^4$	1,400	$>10^{-3}$	480	2×10^{-3}	>1	=1
InP	1.35	12.5	10^7	4,600	1.5×10^{-9}	150	$<10^{-7}$	4.8×10^{-6}	$<1.5 \times 10^{-5}$
GaAs	1.43	12.8	10^7	8,000	10^{-8}	400	10^{-7}	8×10^{-5}	4×10^{-6}
CdSe	1.73	10.6	10^8	720	10^{-6}	75	10^{-6}	7.2×10^{-4}	7.5×10^{-5}
a-Si	1.8	11.7	10^{12}	1	6.8×10^{-9}	.005	4×10^{-6}	6.8×10^{-8}	2×10^{-8}
InI	2.01	26	10^{11}					7×10^{-5}	
HgI_2	2.13	8.8	10^{13}	100	10^{-6}	4	10^{-5}	10^{-4}	4×10^{-5}
SiC	2.2								
T1BrI	2.2–2.8		10^{10}					9×10^{-5}	
GaP	2.24								
a-Se	2.3	6.6	10^{12}	.005	10^{-6}	0.14	10^{-6}	5×10^{-9}	1.4×10^{-7}
Pbl_2	2.32		10^{12}	8	10^{-6}	2		8×10^{-6}	
CdS	2.5	11.6		300		50			
TIBr	2.68	29.8	10^{12}	6	2.5×10^{-6}		1.6×10^{-5}	1.5×10^{-6}	
GaN	3.4	12	$>10^{10}$	300–1,000					
Diamond	5.4	5.5		2,000	10^{-8}	1600	$<10^{-8}$	2×10^{-5}	$<1.6 \times 10^{-5}$

TABLE 44.3 List of Candidate Wide-Bandgap Materials for SSPM Development

Wide-Bandgap Material	Bandgap Type	Bandgap Energy (eV)	Max Absorption (Based on BGE) (nm)	Dark Noise	Impact Ionization Ratio (k)
GaP [62,63]	Indirect	~2.26	~550	Similar to Si	Close to 1
$GaAs_{1-x}P_x$ [64,65]	Indirect	~2.12–2.33	~532	Similar to Si	Close to 1
SiC-3C [66,67]	Indirect	~2.3	~540	Lower than Si	n/a
SiC-4H [68–70]	Indirect	~3.23	~384	Lower than Si	<0.1
GaN [71,72]	Direct	3.4	~365	Very high	<0.1
$Al_xGa_{1-x}N$ [73,74]	Direct	$3.43 + 1.44x + 1.33x^2$	<250	Very high	<0.1
$Al_xGa_{1-x}As$ [75–77]	Indirect for $x > 0.4$	~1.42–2.16	~574	Lower than Si	<0.1

44.7.2 GaN

GaN is an attractive material for *UV photodiode* fabrication due to its wide bandgap ($E = 3.4$ eV). Due to the difficulty in growing bulk crystals of GaN, much of the work is done with films of GaN prepared by chemical vapor deposition or molecular beam epitaxy [80]. A variety of optical devices (e.g., blue LEDs and lasers, field effect transistors, photoconductive detectors, and photodiodes) have been fabricated using GaN films. GaN photodiodes have the capability of solar blind UV detection and are capable of fast response time due to high electron mobility (as high as 1000 cm^2/V s), which is comparable to silicon. Even though GaN has a low impact ionization ratio, it has extremely high dark noise and suffers from microplasma-related quality issues. Direct bandgap materials, like GaN, also pose

challenges associated with the generation of light when used as detector materials. AlGaN alloy suffers similar performance and quality issues.

44.7.3 SiC

SiC is another material that has shown promise for UV detection due to its wide bandgap (E_g = 3.0 and 3.2 eV for 6H and 4H phases, respectively) [81]. Silicon carbide has long been hailed as the future replacement of silicon in the microelectronics and optoelectronics industries. Its distinct characteristics—wide bandgap, low dark noise, and low impact ionization ratio—make it a suitable candidate for the development of next-generation photodetectors. Two polytypes of SiC are of high interest. 3C-SiC has a bandgap of 2.3 eV, which is ideal for detecting photons in the 200–500 nm range. However, the present quality of starting substrate material for 3C-SiC is lacking compared to its 4H sibling, and the most recent studies in literature [66] have shown comparably lower optical performance (shown in Figure 44.16). The recent improvements in 4H-SiC material quality and processing maturity have accelerated the development of electronic and optoelectronic devices based on this polytype. 4H-SiC has an indirect bandgap around 3.23 eV. This makes the material sensitive to photons in the UV and near-UV range (220–380 nm); however, the sensitivity drops significantly beyond 380 nm, which would raise concerns for scintillation lights in the shallow UV/blue region.

44.7.4 InI

Indium iodide (InI) is a wide-bandgap semiconductor (E_g = 2.0 eV) being developed for detection in visible and near-UV regions [82]. The resistivity of the material is quite high (>10^{10} Ω-cm), and Schottky diodes are fabricated using evaporated palladium electrodes. Because of the high resistivity, it is possible to deplete relatively large thicknesses (0.5–1 mm) at low bias (<200 V). One of the unique properties of InI photodiodes is their high QE (>70%) in the 300–600 nm wavelength region, as shown in Figure 44.17, which in combination with its low dark current makes it attractive for low light level detection applications such as scintillation spectroscopy.

44.7.5 Alloys and Bandgap Engineering

In many instances, required properties are attained by bandgap engineering where two or more semiconductors are alloyed together to create a *ternary semiconductor.* The use of a ternary semiconductor
