The Landsat series of satellites is the oldest land monitoring satellite system. Initiated in 1967, the Earth Resource Technology Satellites (ERTS) program was planning a series of six satellites to perform a broad-scale, repetitive survey of the Earth's land areas. After the launch in 1972 of the first ERTS-1, the ERTS program was renamed "Landsat." As of 1997, five Landsat satellites have been launched, each one carrying two instruments. The payload of Landsat-1 and -2 included a Return Beam Vidicon (RBV) camera and a Multispectral Scanner (MSS), while Landsat-4 and -5 still use the MSS and the TM. The first RBV system consisted of three television-like cameras with a ground resolution of 80 m, each looking respectively, at the green, red, and near-IR portions of the spectrum. On Landsat-3, the RBV was 30 m panchromatic. MSS quickly became of primary interest due mainly to its capability of producing multispectral data in a digital format. The four MSS spectral bands are shown in Figure 79.3, and the spatial resolution of MSS data is about 80 m. Very early on, the utility of MSS data was recognized for such applications as agriculture, mapping, forest monitoring, geology, as well as water resource analysis. The same MSS system was kept on Landsat-4 and -5, but the RBV system was replaced by the TM system. Like MSS, TM is a MSS, but includes spatial, spectral, and radiometric improvements over MSS. With seven bands instead of four (see Figure 79.3), TM covers a larger portion of the visible wavelengths, and includes two mid-IR and one thermal-IR bands. Data are quantized over 256 levels (8 bits) instead of the 64 levels for MSS, and the spatial resolution of a TM pixel is about 30 m. TM data are usually chosen to perform classification of land-cover features, manmade or natural. In vegetation and change detection applications, leaf segmentation is studied with TM visible channel data, while cell structure can be seen in near-IR, and leaf water content is found in the mid-IR channel data. The two mid-IR bands (5 and 7) are also useful for geologic applications. All the Landsat satellites are placed in low Earth orbit (at an altitude of about 900 km for Landsat-1 to -3 and 705 km for Landsat-4 and -5) and in a near-polar, sun-synchronous orbit. Landsat-4 and -5 cross the equator at 9:45 a.m. to hopefully take advantage of cloud-free imagery. Landsat-4 and -5 have a 16 day repeat cycle and their orbits are 8 days out of phase. Landsat-6 failed to achieve orbit in 1993; Landsat-7 is planned to be launched in 1998 and includes an improved TM instrument, the Enhanced Thematic Mapper (ETM), which will also include a panchromatic band at a spatial resolution of 15 m. For a more in-depth description of Landsat systems, see Refs. [1,29,30]; for more applications and analysis of Landsat data, see Ref. [30].

As previously mentioned, NOAA's AVHRR is primarily used for atmospheric applications but is also utilized for land surface applications. Having a near-polar, sun-synchronous orbit (at 833 km above the Earth's surface), the AVHRR instrument provides global data with a 1.1 km spatial resolution at nadir, and includes five bands, with daily or twice-daily (for thermal-IR) coverage. Since 1978, AVHRR data are available at full resolution (called Local Area Coverage [LAC]) or subsampled to 4 km (known as Global Area Coverage [GAC]). Because of its high temporal resolution, the AVHRR instrument is very useful in applications such as flood, storm, or fire monitoring, as well as volcanic eruption. Because of its GAC, AVHRR is also often utilized for studying geologic or physiographic features, vegetation conditions, and trends at a global, continental, or regional level, snow cover mapping, soil moisture analysis, and sand storms and volcanic eruptions worldwide. A popular parameter extracted from AVHRR data is the Normalized Difference Vegetation Index (NDVI), computed from GAC data as NDVI = (Channel 2 – Channel l)/(Channel 1 + Channel 2). GAC data are processed daily and composited on a weekly basis to produce a global map showing vegetation vigor. An example of NDVI applications is the monitoring of the Sahara desert extent. AVHRR data are also used for sea surface temperature.

The first Système Pour l'Observation de la Terre (SPOT), designed by CNES, was launched in 1986. SPOT-2 and SPOT-3 were launched, respectively, in 1990 and 1993. The SPOT satellites fly in a near-polar, sun-synchronous low Earth orbit at an altitude of 832 km and cross the equator at 10:30 a.m. SPOT's repeat cycle is 26 days, but due to its off-nadir viewing capability (viewing angle up to 27°), SPOT has a "revisiting" capability with which the same area can be seen up to five times every 26 days. This off-nadir viewing capability also enables some stereo imaging possibilities. The SPOT payload includes two identical high-resolution visible (HRV) imaging instruments that can be employed in panchromatic or multispectral modes, with pointing capabilities. Spectral coverage of these two modes is given in Figure 79.3. The panchromatic mode is 10 m spatial resolution, while multispectral data have a 20 m spatial resolution. Whereas Landsat is a scanning mirror-type instrument, SPOT employs a push-broom system with a linear array of detectors simultaneously acquiring all data pixels in one image line, which minimizes geometric errors. SPOT data are very useful for applications involving small features. Due to its increased spatial resolution, revisit and pointing capabilities, simultaneous panchromatic and multispectral data, and stereo data capabilities, SPOT opens a new range of applications, such as topographic mapping, studies of earthflows (e.g., land, rock, and mudslides), urban management, and military applications. SPOT-4 is planned for launch in 1998, and SPOT-5 in 2002. Among the planned improvements, a mid-IR channel will be added to SPOT-4, which will also carry a new AVHRR-type instrument, the European Vegetation instrument.

Since 1988, India has launched a series of five satellites, the IRS series. These satellites were designed in support of India's agriculture and exploration businesses, and they seem to be successful in this challenge of bringing remote sensing to the users (see Ref. [10]). For land applications, IRS-1A, -IB, and -1C all carry the LISS instrument, which is a MSS very similar to Landsat-TM. LISS-2 acquires imagery in four bands similar to bands 1–4 of Landsat-TM (from visible to near-IR) at the spatial resolution of 36.5 m (see Figure 79.3 for wavelengths description). LISS-3, carried on IRS-1C, also acquires imagery in four bands, but the visible blue band has been suppressed and replaced by a mid-IR band similar to TM/band 5. Due to their similarity to Landsat data, IRS/LISS-2 data could be used as complements or replacements to Landsat data if needed until Landsat-7 is launched. IRS-1C also carries a 5 m panchromatic instrument whose data are coregistered with LISS-2 data. For more details on IRS data, see Refs. [10,27].

Other instruments are also available. JERS-1, designed by Japan, was launched in 1992, and its payload includes both an SAR instrument and an optical imaging system; see Figure 79.3 for its spectral channels from visible to mid-IR wavelengths, with spatial resolutions of 18 and 24 m. MOMS, the German Modular Optoelectronic Multispectral Scanner, has been flying as a research instrument on U.S. Space Shuttle missions, and has a spatial resolution ranging from 4.5 to 13.5 m; see Ref. [27] for more details on these different instruments.

Among the first EOS instruments to be launched is the Moderate Resolution Imaging Spectrometer (MODIS). MODIS is being developed to provide global monitoring of the atmosphere, terrestrial

ecosystem, and oceans, and to detect climate change. MODIS will cover the visible to IR portions of the spectrum with 36 channels at spatial resolutions of 250 m to 1 km. Many interesting land studies will be performed by fusing together AVHRR, Landsat, and MODIS data.

The fusion of several of these types of data is becoming a very important issue [26]. Already, sensors such as SPOT or LISS-3 present the advantage of acquiring coregistered panchromatic and multispectral data. It would be of great interest to combine data from sensors with different spectral and spatial resolutions, as well as different viewpoints. The combination of coarse resolution viewing satellites for large-area surveys and finer resolution sensors for more detailed studies would offer the multilevel information necessary to assess accurately the areal extent of features of interest (e.g., tropical forests). The fusion of multispectral data with SAR data would provide information on ground cover reflectance with the shape, roughness, and moisture content information from SAR. Of course, multidata fusion requires very accurate registration of the data, as will be described in the next section.

79.3.2 Geologic Studies

Other examples of terrestrial studies are the mapping of geologic features, such as geologic faults and earthquake sites, or volcanic eruptions. Although many geologic features lie beneath the surface of the Earth, remote sensing (aerial or satellite) provides a valuable tool to perform geologic mapping, landforms and structures analysis, as well as mineral exploration. This is due to the fact that topography and soil properties provide clues to underlying rocks and structural deformations. Landsat and SPOT gather data about the effects of subsurface geologic phenomena on the surface. These data are especially useful to recognize some specific landforms (such as volcanoes), to depict topographic features, to discriminate some geologic facies and rock unit distribution patterns, and more generally to provide regional overviews of surface geology. In mineral exploration, rock or soil alteration can be detected by spaceborne sensors and may indicate the presence of mineral deposits or oil reservoirs. Other types of sensors that are very useful for geologic applications are radar sensors, such as the two radar systems, SIR-C and X-SAR, carried on the Space Shuttle Endeavour in 1994. These sensors captured in real time the eruption of a volcano in Russia and an earthquake in Japan [31]. For more information on geologic applications, see Refs. [2,32].

79.3.3 Geophysics Studies

Other satellites, such as the LAGEOS-1 and -2, have proved very useful in geophysics for the study of the Earth's gravity field, tectonic plate motion, polar motion, and tides. LAGEOS sensors are reflector orbs covered with laser beams. For more information on these studies, see Refs. [33,34].

79.3.4 Ocean Studies

Oceans cover 75% of the Earth's surface and contain most of the energy of the planet. Although their role in climate evolution is very important, it is still poorly understood. By understanding chemical, physical, and biological processes in oceans, scientists will be able to model the interactions between oceans and the atmosphere and determine how these interactions affect Earth temperature, weather, and climate.

An example of interaction between oceans and the atmosphere is illustrated by the phenomenon known as El Niño/Southern Oscillation, which occurs in the tropical Pacific Ocean, usually around Christmas time. El Niño is due to a mass of warm water, usually located off Australia which moves eastward toward equatorial South America. El Niño develops every few years (observed on average every 4 years to a maximum of 7 years), and alters the weather in Australia, Africa, South Asia, and the tropical parts of the Americas. By understanding how winds and waves move in the tropical Pacific, scientists have been able to predict the El Niño phenomenon up to 1 year in advance. Similar phenomena are being studied in the Atlantic Ocean, where patterns seem to move much more slowly.

Besides being used to create global models, and in storm and weather forecasting, ocean data are also very important for day-to-day applications such as ship routing, oil production, and ocean fishing.

79.3.4.1 Ocean Colors

Ocean color data are critical for the study of global biogeochemistry and to determine the ocean's role in the global carbon cycle and the exchange of other critical elements and gases between the atmosphere and the ocean [35,36]. It is thought that marine plants remove carbon from the atmosphere at a rate equivalent to terrestrial plants, but knowledge of interannual variability is very poor. For most oceans, the color observed by satellite in the visible part of the spectrum varies with the concentration of chlorophyll and other plant pigments present in the water. Subtle changes in ocean color usually indicate various types and quantities of microscopic marine plants (i.e., phytoplankton are present in the water); the more phytoplankton present, the greater the concentration of plant pigments and the greener the water.

The launched (October 1997) Sea-viewing Wide Field-of-view Sensor (SeaWiFS), which is a part of MTPE, provides quantitative data on global ocean biooptical properties to the earth science community. SeaWiFS is a follow-on sensor to the Coastal Zone Color Scanner (CZCS), which ceased operations in 1986. See Figure 79.3 for a channel description of these two sensors; notice that all channels are concentrated in the (0.4, 0.7 μm) interval of the electromagnetic spectrum.

Other sensors for ocean color are the imaging spectrometer for ocean color applications MOS-IRS, launched on the Indian Remote Sensing Satellite IRS-P3 in March 1996, and the imaging spectrometer MOS-PRIRODA, launched aboard the Russian multisensor remote sensing module PRIRODA and docked to space station MIR in April 1996.

79.3.4.2 Ocean Dynamics

By studying ocean circulation and sea-level trends, scientists will be able to create global maps of ocean currents and of sea surface topography. Since sea surface height and sea-level variations are related to sea surface temperatures, the monitoring of mean sea levels enables the gathering of evidence that can measure global warming or El Niño-type events. For example, conditions related to El Niño may result in a change in sea surface height of 18 cm or greater [37].

TOPEX/Poseidon (T/P) is an important collaboration between USA/NASA and France/CNES. T/P uses radar altimetry to provide 10 day maps of the height of most of the ice-free oceans' surface. Circling the world every 112 min, the satellite gathers data for 3–5 years, and could be operational for 10 years. The T/P satellite was launched in August 1992 on an Ariane rocket. TOPEX measures the height of the ocean surface, as well as changes in global mean sea level. From these altimetry data, global maps of ocean topography are created, from which speed and direction of ocean currents are computed worldwide. Changes in mean sea level are monitored and currently are viewed mostly as related to natural ocean variability and not climate change. Climate change must be studied over a much longer time series of altimeter data. T/P also enables study of tides, wave geophysics, and ocean surface winds.

Sea winds are also being studied with scatterometers such as the NASA Scatterometer (NSCAT) and the soon to be launched EOS Scatterometer, SearWinds. These high-frequency radar instruments measure the reflected signals from the ocean surface to detect wind speed and direction.

ERS-1 is another satellite utilized to measure ocean dynamics. ERS-1 was launched in 1991 on a sun-synchronous, near-polar low-Earth orbit at an altitude of 780 km. ERS-1 orbits the Earth in 100 min and covers the entire planet in 3 days. Its payload consists of two specialized radars and one IR sensor. The Active Microwave instrument, consisting of a synthetic aperture radar and wind scatterometer, produces extremely detailed images of 100 km swath of the Earth's surface, with a spatial resolution of 20 m. The radar altimeter provides accurate range to sea surface and wave heights, and the along-track scanning radiometer constructs detailed pictures of the thermal structure of the seas and oceans from

surface temperature measurements at accuracy of <0.5 °C. ERS-1 images are also utilized for land applications where the instruments need to "look through" the cloud cover.

The study of sea ice with passive and active microwave sensors is also very important and additional reading in this topic can be found in Refs. [14,38].

79.3.5 Space Science Applications

Astronomical satellites have been developed to observe far distant objects that are usually beyond the range of ground-based instruments. They explore phenomena in the solar system, and beyond. Satellite observation of astronomical objects is also less sensitive to atmospheric interactions and can achieve higher accuracy than ground-based measurements. This section will give a brief description of the most important space science satellites.

The first astronomical satellite to be put into synchronous orbit was the International Ultraviolet Explorer (IUE) laboratory. IUE was launched in 1978 under a joint program involving NASA, ESA, and the United Kingdom. In more than 15 years of service, IUE gathered observations on >10,000 celestial objects. A program for coordinating its observations with those of the ROSAT satellite has been carried out under the title RIASS (Rosat-IUE All-Sky Survey). ROSAT, the Roentgen Satellite, is a joint collaboration between Germany, the United States, and the United Kingdom, and was launched in 1990. It is an x-ray observatory that carries two instruments, the x-ray telescope and the wide field camera.

The Infrared Astronomical Satellite (IRAS) is a joint project of the United States, the United Kingdom, and the Netherlands. The IRAS mission was intended to provide a survey of IR point sources (from 12 to 100 μm), but has also produced very high-quality image data. The Mid-Course Space Experiment (MSX), the Infrared Space Observatory (ISO), and the Space InfraRed Telescope Facility (SIRTF) are other examples of recently or soon-to-be launched sensors that provide an even finer resolution.

Hipparcos (High Precision Parallax Collecting Satellite) is an astronomy satellite launched in August 1989, with the purpose of determining the astrometric parameters of stars with unprecedented precision. After a life of 4 years, Hipparcos has produced two catalogs. The Hipparcos Catalogue provides position, parallax, and proper motion measurements with accuracy of 2 milliarcsec at 9 mag for over 120,000 stars. The Tycho Catalogue is the result of somewhat less precise astrometric measurements for some 1 million stars.

COBE, the Cosmic Origin Background Explorer developed by NASA, was launched in 1989. Designed to measure the diffuse IR and microwave radiation from the early universe, it carried three instruments: a Far Infrared Absolute Spectrophotometer (FIRAS), a Differential Microwave Radiometer (DMR), and a Diffuse Infrared Background Experiment (DIRBE). The first full-sky coverage was completed in 1990.

The Hubble Space Telescope (HST) is one of the most well-known astronomical satellites. It was built as a joint NASA/ESA project, and was launched in 1990 as a long-term space-based observatory. The heart of the system is a large reflector telescope 2.4 m in diameter. All the instruments on-board the HST use the light gathered by the reflector telescope. Current HST instruments are the Wide/Field Planetary Camera 2 (WFPC2), the Space Telescope Imaging Spectrograph (STIS), the Near-Infrared and Imaging Spectrograph (NICMOS), and the Faint Object Camera, FOC, provided by ESA. These different instruments can observe astronomical objects from UV to IR wavelengths. In 1993, the HST was serviced to correct a preliminary fault affecting the mirror with a corrective optical apparatus named COSTAR. Despite the preliminary mirror fault, and even more after correction, the HST has achieved much better results than those from observatories on Earth. Since it is located above the Earth's atmosphere (at 600 km), the HST produces highly detailed images of the stars and can detect objects beyond the range of ground-based instruments. Observations with the HST are scheduled as a space-based observatory according to worldwide astronomers' proposals.

The Advanced Satellite for Cosmology and Astrophysics (ASCA) is the product of a Japan/U.S. collaboration. Launched in 1993, this x-ray astronomy mission was still operational in 1997, and carries four large-area x-ray telescopes with arc minute resolution. ASCA data are being archived and can

be searched and retrieved online at the High Energy Astrophysics Science Archive Research Center, HEASARC. Gamma Ray Observatory (GRO) and the Advanced X-ray Astrophysics Facility (AXAF) are other examples of space sensors which operate in this spectrum range.

79.4 Management and Interpretation of Satellite Data

Satellite sensors gather the electromagnetic energy reflected or emitted from Earth (or any other planetary) surface features. This energy is then converted into a digital representation that is visualized by a user and interpreted either visually or with a computer. This section summarizes some preliminary ideas on how the digital representation is formed and the basic types of data processing necessary before any further interpretation of the data. For more details on the processing of remote sensing data, see Refs. [39–42].

79.4.1 Fundamental Data Levels

After transmission from the satellites, raw data are usually processed, calibrated, archived, and distributed by a ground-based data system. Most of NASA satellite data products are classified in the following data levels [7]:

- *Level* 0 *data* are the reconstructed raw instrument data at full resolution.
- *Level* 1*A data* are reconstructed, time-reference raw data, with ancillary information including radiometric and geometric coefficients.
- *Level* 1*B data* are corrected Level 1A data (in sensor units).
- *Level* 2 *data* are derived geophysical products from Level 1 data, at the same resolution and location, for example, atmospheric temperature profiles, gas concentrations, or winds variables.
- *Level* 3 *data* correspond to the same geophysical information as Level 2, but mapped onto a uniform space–time grid.
- *Level* 4 *data* are model output or results from analysis of lower-level data.

79.4.2 Image Restoration

Ideally, the scene as viewed and recorded by a sensor would be an exact rendering of the features within the sensor's viewing extent, represented as a spectral curve indicating the amount of energy reflecting/radiating for each point in a scene for a range of given wavelengths. From an engineering standpoint, this is impossible, however, because each image is discretized into a finite number of pixels. Variability defines nature, so each pixel will map into a region of the scene that contains a number of features, each producing its own unique spectral curve. The spectral signature recorded for a pixel is a function of these features and their relative sizes within the region covered by the pixel. The spectral response itself is also discretized into a finite number of bandwidths, where each bandwidth covers a small continuous band of the spectrum. The sensor records for each pixel the amount of energy observed for each band. This number itself, referred to as a Digital Number (DN), must be represented in a finite amount of computer memory, such as 8 bits, meaning that each band records activity as a whole number ranging from 0 to 255.

In practice, a number of events outside human control affect the quality of the observation, such as atmospheric scattering, variations in sun angle, high albedo, and instrument errors. Depending on the application, it may be desirable to correct for the presence of thin clouds within an image. The process of image restoration attempts to control and correct for these conditions [42].

Electromechanical effects due to the instrument itself can be discovered due to their periodic nature (such as caused by the repeated motion of a push broom, or the revolving of a mirror, or the physical process of gathering calibration points). A Fourier transform applied to an image from a sensor undergoing periodic interference exhibits strong noise spikes. A filter can then be used to remove the offending data.

Unfortunately, this also removes any good data that happens to fall at the same frequency, although normally this is but a small portion of the data. Data outages and instrument recorder failures appear as streaks in the image parallel with the scanline, and can be discovered by comparing the respective readings of the pixels in the surrounding scanlines of the image.

To account for the atmospheric effects of Rayleigh and aerosol scattering, an estimate of the portion of the signal that is due to the atmosphere is computed and subtracted from the recorded value. The reflectance of water in the near-IR region of the spectrum should be effectively zero, so the value to subtract for the near-IR band corresponds to the reading of the sensor observed over clear open water. To compute values to be subtracted for each of the other spectral components, a histogram should be formed for each band of a number of sample readings over clear open water. The lowest reading in each band is then used as an estimate of the value to subtract from each pixel to account for the atmospheric effect. In addition, information derived from TOVS, balloon readings, or the atmospheric correction software 5S can be useful in dealing with atmospheric effects.

79.4.3 Data Compression

Data compression is one of the most important tools to overcome the problems of data transmission, storage, and dissemination [43]. Data compression methods are usually classified as either lossless or lossy. With a lossless data compression scheme, the original data can be reconstructed exactly without any loss; in a lossy compression scheme, original data are reconstructed with a degree of error. For transmission from the satellite to the ground station, a lossless data compression must be utilized. For browsing purposes, lossy compression enables quick searches through large amounts of data. A compression scheme is also characterized by its compression ratio, that is, the factor by which the amount of information which represents the data is reduced through compression. For earth science data, lossless compression schemes provide compression ratios up to 2 or 3, while lossy techniques can reduce the amount of information by a factor of 20 or more without degrading the visual quality of the data.

Among the lossless compression methods, the Joint Photographic Experts Group (JPEG) developed a lossless compression method that is based on a predictor, an entropy encoder for prediction error, and an entropy code specifier. Another lossless compression scheme is the Rice algorithm, which can adapt to data of any entropy range. It is based on a preprocessor that spatially decorrelates the data, followed by a variable length encoder. This algorithm gives some of the best compression ratios among all lossless methods, and has been implemented on VLSI chips at NASA.

JPEG has also developed a lossy method based on the Discrete Cosine Transform (DCT). Other methods such as vector quantization or wavelet compression provide either lossless or lossy compressions. In a vector quantization technique, a dictionary of representative vectors is also called a codebook, and all data are encoded relative to the codebook. In this method, the one-time encoding step is computationally expensive but the decoding step at the user end is fast and efficient. Vector quantization is also utilized in a progressive scheme for "quick look"/browsing purposes. In a subband/wavelet compression method, signals are decomposed using quadrature mirror or wavelet filters [44]. Most energy is contained in the low-frequency subbands and high compression ratios can be obtained by compressing the high-frequency information.

For more information or references on data compression techniques, see Ref. [43].

79.4.4 Image Registration

In studying how the global environment is changing, programs such as Mission to Planet Earth [7] or the New Millennium program [45] involve the comparison, fusion, and integration of multiple types of remotely sensed data at various temporal, radiometric, and spatial resolutions. Results of this integration can be utilized for global change analysis, as well as for the validation of new instruments or of new data analysis. The first step in this integration of multiple data is registration, either relative image-to-image registration or absolute georegistration, to a map or a fixed coordinate system. Another case of

image registration is coregistration of multiple bands of one sensor. When the detectors of each spectral band have different spatial locations on the satellite's focal plane, there could be misregistration between each band's raw image [46,47].

Currently, the most common approach to image registration is to extract a few outstanding characteristics of the data, which are called *control points* (CPs), *tie points*, or *reference points*. The CPs in both images (or image and map) are matched by pair and used to compute the parameters of a geometric transformation. Most available systems follow this registration approach; and because automated procedures do not always offer the needed reliability and accuracy, current systems assume some interactive choice of the CPs. But such a point selection represents a repetitive, labor-, and time-intensive task that becomes prohibitive for large amounts of data. Also, since the interactive choice of control points in satellite images is sometimes difficult, too few points, inaccurate points, or ill-distributed points might be chosen, thus leading to large registration errors. A previous study [48] showed that even a small error in registration can have a large impact on the accuracy of global change measurements. For example, when looking at simulated 250 m spatial resolution MODIS data, a 1 pixel misregistration can produce 50% error in the computation of the NDVI. So, for reasons of speed and accuracy, automatic registration is an important requirement to ease the workload, speed up the processing, and improve the accuracy in locating a sufficient number of well-distributed accurate tie points.

Automatic image registration methods can be classified into two types: those that follow a human approach, by first extracting control points, and those that take a more global approach. Among the first methods, the most common features utilized as control points are the centers of gravity of regions—with or without region attributes such as areas, perimeters, ellipticity criteria, affine-invariant moments, and interregions distances. More recently, features extracted from wavelet decomposition have also been utilized, such as maxima and minima of wavelet coefficients, high-interest points, or local curvature discontinuities. A few methods utilize Delaunay triangulation methods to progressively increase the number of accurate control points. For the methods that do not match individual pairs of control points, the transformation is either found by correlation or by optimization, in the spatial or in the frequency domain. When in the spatial domain, correlation or optimization is performed either in the original data or on edge gradient data. Other methods propose a global image matching of edge segments or vectors linking feature points. Some recent research has also focused on the use of wavelets for global image registration. More complete surveys of image registration methods can be found in Refs. [47,49,50].

79.4.5 Dimension Reduction

The first step in analyzing multichannel data is to reduce the dimension of the data space. It is particularly important when the analysis method requires a training step, for example, supervised classification (see next section). The main issue in this case has often been referred as "the Curse of Dimensionality" [51]. If the original data have a large number of bands (e.g., for hyperspectral data), theoretical studies have shown that a very large training set should be utilized; but using a large training set deteriorates the estimation of the kernel density. To solve this problem, various dimension reduction schemes enable to perform classification in a smaller-dimensional subspace. Since the information contained in multiple channels is often redundant, it is possible to decorrelate spectrally the channels and reduce the number of channels to be analyzed without losing any information. Principal Component Analysis (PCA) and Projection Pursuit are the most common techniques for dimensionality reduction. For more information on these methods, refer to Refs. [39–42].

79.4.6 Data Mining

One objective of the NASA-initiated Mission to Planet Earth is to gather sufficient data to enable scientists to study the Earth as a dynamic system, resulting in a better understanding of the interactions between humans, the atmosphere, and the biosphere [8]. The episodic nature of most interesting events

would cause them to be missed if the data were not being gathered continuously. Comprehensive data sets allow scientists to construct and evaluate complex models of many Earth-related processes. But currently, due to computation and time constraints, only a small percentage of the data gathered by remote sensing are actually viewed by an individual user. Data-gathering missions tend to be multidisciplinary, so different aspects of the data sets are pertinent to different researchers.

Data mining can be defined as the process by which data content is automatically extracted from satellite data, enabling a scientist to query the data holdings based on high-level features present within an image [52]. Given the projected large volumes of data, it is not feasible to rely solely on conventional data management paradigms. Standard methods of segmenting images are inadequate as standalone techniques for image recognition, regardless of the speeds of processing, because there are no general methods for automatically assigning meaningful semantics to any homogeneous regions that are isolated. Metadata derived directly from the image header are not rich enough to enable robust querying of a database in most instances, but limit a user to retrieving all images at a given latitude/longitude during some time period, for example, regardless of the image quality or the unique features existing due to some unexpected set of circumstances. New approaches based on techniques such as image classification (described in the next section) are now feasible, due to the phenomenal increases in computing speed, the availability of massively parallel architectures, and the breakthroughs in signal processing.

An example of data mining is the browsing of 15 years of TOVS data with two complete coverages per day, which would require looking through 10,958 scenes per attribute. Of the several products generated, the scientists are primarily interested in browsing those with some given resolution. After locating a browse product that seems to indicate an interesting structure or phenomenon, a scientist might then retrieve this data temporally, or any supporting data set for further analysis. Scientists using the TOVS data sets desire a more intelligent form of querying so they can quickly and easily find relevant data sets that are pertinent to their research. Certain TOVS observations are more "interesting" than others, and the definition of "interesting" is a combination of objective fact and subjective opinion. Data mining is applicable here to aid in evolving a retrieval heuristic based on an individual scientist's definition of "interestingness." In one approach, the scientist could prepare a representative set of images that are labeled as positive or negative instances of "interesting," and a machine learning system (e.g., neural network, genetic algorithm) could perhaps be trained to classify the remaining images in the TOVS data set according to this definition. In a second approach, the scientists could be asked to identify explicitly structural features within the images that make them interesting, and image processing routines could then be applied to detect images with these features. Over time, a scientist could provide feedback to the heuristic classifier to improve its performance. Both approaches require that the underlying representation language (structures, bin size, spatial and temporal relationships) be robust and flexible enough to permit an appropriate level of expression.

79.4.7 Classification

Image classification is the task of developing a statistical model that labels every potential point in some multidimensional space. A *parametric classifier* assumes that data are described by some underlying parameterized probability density function (PDF). A training set of representative data from the domain is then used to supply appropriate values. For example, if a Gaussian or normal distribution is assumed, then the means, standard deviations, and joint-covariance matrix can be computed from the training data. A *nonparametric* or *unsupervised classifier* is typically used when there is insufficient knowledge about the type of underlying PDF for the domain. Self-organizing classifier models, such as certain kinds of neural networks, are also considered nonparametric classifiers when they make no *a priori* assumptions about any PDF.

In a *statistical* or *supervised classifier*, knowledge about the distribution of the data is utilized to assign a label to an unclassified pixel. Using "ground-reference data," a training set of known points is created. A prototype vector can then be calculated as the mean of all samples for each of the classes.

Assuming a Gaussian distribution in each of the channel readings for a given class, the standard deviation for each class is computed based on the sample. Then, the lowest distance from the given feature prototypes to an unclassified point determines the class of this incoming point. As simple and elegant as this approach might appear, in actuality its utility is limited. Features are not so discernible from a random labeling of an image. Thus, although this algorithm is inaccurate, it is consistent in its mislabelings. The algorithm's deterministic nature and underlying use of a continuous function combine to produce predictable behavior. In general, this algorithm labels all points similarly if they fall within the same neighborhood in the feature space.

Other parametric classifiers follow the *Maximum Likelihood Decision Rule*, which allows the construction of discriminant functions for the purposes of pattern classification. For more details on this technique, refer to Ref. [53].

The classifiers discussed earlier are, by definition, required to assign an unclassified pixel to the one nearest class. No measurement of the distance to that class or proximity to other classes is recorded, and no information on the confidence of the labeling is provided. *Fuzzy classifiers*, on the other hand, are not obligated to pigeonhole a pixel into a single class. Instead, the pixel is assigned a degree of membership for each possible class. Intuitively, and indeed for mathematical tractability, the pixel's memberships must sum to one, and the degree of membership for a given class must be between 0 and 1, inclusively. Two examples of fuzzy classifiers are given as follows. The *Fuzzy Nearest Neighbor* nonparametric classifier places an unclassified vector in the dominant class of its k-closest training vectors. If no class has an outright majority, then distances to the nearby vectors for each class which tied are summed and the unclassified vector is placed in the class with the minimum sum. The *Fuzzy Decision Tree Classifier* utilizes a decision tree as the data structure that encapsulates knowledge of what to do given a set of conditions. See Ref. [52] for more information on this method. Although this algorithm is conceptually simple, it is only recently that it has become computationally feasible due to the need to search the tree for each unclassified pixel to locate the nearest path. The search algorithm can also be sped up by running the algorithm on a parallel architecture such as a Single Instruction Multiple Data (SIMD) machine.

Many researchers have investigated the use of *neural networks* for automatically extracting metadata from images [54]. Many different neural network models have been considered, but with respect to performance accuracy, the backpropagation training technique has shown to be the best classifier [55]. The *backpropagation algorithm* is the most common method for training a neural network, and is the backbone of much of the current resurgence of research into neural nets [56]. With respect to pattern recognition, backpropagation can be considered to be a nonparametric technique for estimation of *a posteriori* probabilities.

79.4.8 Accuracy Assessment

A measurement derived solely from satellite imagery is of questionable use unless the technique employed for computing that measurement on those data has been validated. A technique that appears to work accurately on satellite imagery over some given location at some given time may perform abysmally on data from the same sensor at another location, or for the same location at another time. The reasons for this are many: through the course of a year, the sun angle changes causing different lighting conditions; from pass to pass, the viewing angle of the instrument can be different; with seasonal changes, surface reflectance varies due to weather conditions and the alteration of land cover as crops appear in different stages; atmospheric conditions fluctuate; and the sensor and spacecraft themselves age and possibly perform differently.

The key factor in any accuracy assessment of remote sensing data is the method and source used for determining what the satellite sensor is actually viewing. This ground reference data is gathered independent of the remote sensing data itself. There are several sources that can be construed as ground reference data, and each source has its own degree of accuracy. The most obvious is an actual site visit to the

area of interest. What is observed, also known as "ground truth," is recorded and compared to the digital rendition of the same spatial extent. This approach usually has a high degree of accuracy, but it is often prohibitively expensive. Depending on the time between the on-site ground reference gathering and the imaging of the area, the validity of the ground reference data may be lessened due to anthropomorphic or natural influences. The shorter the life of the feature being measured, the more difficult it is to find or gather meaningful time-critical ground reference data. If ground reference data are not available, it may be possible to perform photointerpretation with some degree of success. This itself depends on the knowledge of the photointerpreter, and the availability and suitability of a display device for viewing the image data and recording the photointerpreter's assessment. Another approach is to compare the digital image with other sources of ground reference data such as air photos or appropriate reference maps, provided the feature of interest is detectable using those sources. The degree of correspondence between the ground reference data and the measurement derived from the sensor data can then be compared for accuracy. In the worst case, the lack of adequate/accurate ground reference data requires using an unsupervised clustering approach that is usually less accurate but much cheaper to produce.

79.5 Future in Satellite Imaging and Sensing

Success of future earth and space science missions depends on increasing the availability of data to the scientific community who will be interpreting space-based observations, and on favoring interdisciplinary research for the analysis and the use of this data. One of the main challenges in the future of satellite imaging and sensing will be to handle, archive, and store all of these data in a way that can be easily accessible and retrieved by anyone who needs to use them. Systems such as the EOS Data and Information System (EOSDIS) [57,58] will require that over 1 terabyte per day be collected and processed into several levels of science data products within several hours after observation. After 15 years, the estimated amount of collected, processed, analyzed, and stored data will equal about 11,000 terabytes. Also at NASA, efforts are underway to design an advanced information system, based on an object-oriented database, with the express purpose of developing, incorporating, and evaluating state-of-the-art techniques for handling EOS-era scientific data challenges [59].

Another challenge will be to analyze this tremendous amount of data, and to find out new ways to fuse, integrate, and visualize this data. In particular, research in fast computational capabilities, such as field programmable gate arrays (FPGAs), will be of great importance.

On the other hand, the wide distribution of satellite data to the general public will be facilitated by regional distribution systems such as the Regional Application Centers (RACs) [60,61], whose goal is to provide local users, such as industry, agriculturalists, urban planners, regional communities, with local and "on-time" information about regional applications.

Satellite imaging and sensing is a field with a history of more than two decades, but is still in full expansion. The future in satellite imaging and sensing will see developments in several areas. The next millennium will see an explosion of commercial satellite systems and the profusion of satellite data, which will have economic and sociopolitical implications. As of this writing, over 30 commercial Earth sensing satellites are either being planned or being built. MTPE and EOS will generate unprecedented amounts of diverse resolution data. The future will also see the development of locally directed satellite systems, in answer to specific applications for specific areas of the planet. Telecommunications will also be a large part of the space market. In space, after the large success of the Mars Pathfinder mission, exploration of distant planets will see a flourishing of distant satellite systems providing unprecedented amounts of data to analyze regarding other planets' surface features, atmospheric, and magnetic properties. The understanding of other planets will also enable scientists to learn more about the Earth comparatively to other planets such as Mars, and to build a comprehensive data set to aid in planning future missions. The Mars Global Surveyor is an example of such as a mission; it will map the entire planet Mars by taking high-resolution pictures of the surface. The future might see a 10 year NASA program that will send pairs of Surveyor-like orbiters and Pathfinder-like landers to Mars every 26 months.

In order to gather novel and interesting data, this type of mission will need an increasing amount of on-board processing that will perform mission planning, image processing and understanding, as well as data compression and fusion. The design of systems including on-board processing will require new computational capabilities, such as reconfigurable hardware and parallel processors, as well as new developments in intelligent systems. In the near future, satellite imaging and sensing is a field that will produce unprecedented information about the Earth, its environment, and our solar system.

Acknowledgments

The authors would like to thank William J. Campbell for his support and for his useful comments upon reviewing our paper, Bob Mahoney for providing the spectral libraries used to generate Figure 79.2, and all the anonymous or nonanonymous authors of Web pages that we consulted during the research part of this endeavor. In particular, the online remote sensing tutorial by N.M. Short, edited by J. Robinson at the URL http://code935.gsfc.nasa.gov/Tutorial/TofC/Coverpage.html, and the list of selected links on remote sensing compiled by U. Malmberg and found at the URL http://www.ssc.se/rst/rss/index.html were very useful.

Humidity and Moisture Measurement

Gert J.W. Visscher
Institute of Agricultural and Environmental Engineering

Water and water vapor can be found everywhere. Because of the asymmetrical distribution of their electric charge, water molecules are easily adsorbed on almost any surface, where they are present as a mono- or multimolecular layer of molecules. Water vapor in the air or any other gas is generally called *humidity*; in liquids and solids, it is usually designated as *moisture*. The determination of humidity and moisture, as in prediction of floods, fog, conditions for the appearance of plant diseases, etc., is of great economic importance. Stored foodstuffs or raw materials may dry up at low humidity or get moldy at high humidity. In many industrial processes, the measurement of moisture and humidity is important for the maintenance of the optimum conditions in manufacturing. Humidity and moisture content can be expressed in a number of ways, and the number of methods for measuring them is even greater. An engineer whose main concern is to avoid condensation no matter where in his system will be interested in the *dew point* of the gas flow. A chemist may be interested in the mere *quantity* of water vapor, whereas in a printing office or a storage room, the *relative humidity* is of more importance.

Water vapor is one of the constituent gases of the Earth's atmosphere, the total pressure P of which is, according to Dalton's law, the sum of the partial pressures. This means that

$$P = P_{N_2} + P_{O_2} + P_{H_2O} + P_{\text{other gases}} \tag{80.1}$$

Like other gases, water vapor can be considered to behave as an ideal gas, except near saturation. In average environmental conditions, water can also be present in the liquid and solid phase, the reason to

speak of water vapor rather than of water gas. An empty space in equilibrium with a flat water (or ice) surface can, at a given temperature, hold a well-defined maximum quantity of water vapor [1–3]. When this *saturation vapor pressure* is reached, any further addition of water vapor results in condensation. In the presence of air molecules at atmospheric pressure, the saturation vapor pressure is about 0.4% higher (expressed by the so-called enhancement factor [4]). The saturation vapor pressure for water is about 611 Pa at 0 °C, 2339 Pa at 20 °C, and 7383 Pa at 40 °C. So, one can say that the average water vapor pressure in the Earth's atmosphere around us ranges from about a half to a few percent of the barometric pressure.

There are several ways to express humidity:

1. The *vapor pressure* is that part of the total pressure contributed by the water vapor.
2. The *absolute humidity* (or vapor concentration or vapor density) is the mass of water vapor per unit of volume. Effects of temperature and pressure are, except near saturation, according to gas laws.
3. The *relative humidity* is the ratio of the actual vapor pressure and the saturation vapor pressure at the prevailing temperature. It is usually expressed as a percentage. Since the maximum water vapor pressure depends on temperature, the relative humidity (r.h.) also depends, at given water content, on temperature. At constant temperature and given water content, the r.h. is, according to the equation for P mentioned earlier, dependent on total pressure.
4. The *dew-point temperature* is the temperature to which a gas must be cooled, at constant pressure, to achieve saturation. When the condensate is ice, it is called *frost point*. It is, with unchanging composition of the gas, independent of temperature. It changes with pressure since P_{H_2O} is proportional to P. Of course, condensation will occur if saturation vapor pressure is reached.
5. The *mixing ratio* is the mass of water vapor per unit mass of dry gas, usually expressed in grams per kilogram. If the ratio is related to a unit mass of humid air, it is called the *specific humidity*.
6. The *mole fraction* is the ratio of the number of moles of a component to the total number of moles present.

Conversions between the different parameters used to be cumbersome. They are now becoming standard since the introduction of the microprocessor.

Concentrations of water in a *liquid* or a *solid* are normally given in kg/kg. Except in soil physics, volumetric units are rarely used. The expression *equilibrium relative humidity* (e.r.h.) refers to a condition where there is no net exchange of water vapor between a moisture-containing material (paper, medicines, foodstuffs, tobacco, seeds, etc.) and its environment. It is the equivalent for *water activity*, a_w, used in the fields of biology or food technology, generally expressed as a ratio rather than a percentage (i.e., 0.6 instead of 60%).

It is probably difficult to find a material that is inert to water molecules and with which it would be impossible, with some physical method, to measure the presence of water. Water molecules change the length of organic materials, the conductivity and weight of hygroscopic materials and chemical absorbents, and in general the impedance of almost any material. Water absorbs infrared as well as ultraviolet radiation. It changes the color of chemicals, the refractive index of air and liquids, the velocity of sound in air or electromagnetic radiation in solids, and the thermal conductivity of gases as well as that of liquids and solids. More fundamentally, the water content can be measured by removing the water (vapor) from the sample and measuring the change of weight (or the change of pressure in a gas). Other fundamental principles are the evaporation from a water surface into the stream of sample gas (*psychrometer*) and the cooling of the gas sample until condensation is detected. Microwave absorbance, the measurement of capacitance, and nuclear magnetic resonance (NMR) have found application in the measurement of moisture in liquids and solids.

After an engineer has decided which parameter has to be measured, he has to realize a few things [5]:

1. What is the minimum range of operation required? Overspecification can be expensive. Besides, instruments suitable for drying processes at high temperatures and, at the same time, trace detection of water vapor in dry gases do not exist.

2. Unlike a temperature sensor, a humidity sensor can, at least in air, essentially not be shielded from its direct environment. The question of how to measure humidity cannot be separated from the measuring problem in question (contamination, condensation, etc.). A question might be Is there a danger of condensation before or after the period of real measurement?
3. The accuracy that may be expected in the field of hygrometry is considerably lower than that in other fields of measurement. One should be careful not to ask or to expect accuracies better than 2% or 3% r.h. or 0.5 °C in dew point. Before deciding to use a certain method or to buy a particular instrument, it is very useful to go once more through things like humidity as well as temperature and pressure range, possible contaminants in the process, and accuracy and response time really needed. After this, a consideration of frequency of service and calibration, cost of sensor replacement, etc. has to be made. At the end, it is sensible to find a supplier or manufacturer that is willing to think along with the customer. Table 80.1 provides a selective listing of the methods, ranges, and manufacturers for measuring humidity and moisture. The methods are discussed later.

TABLE 80.1 Methods for Measuring Humidity and Moisture

Method	g, l, s[a]	Range	Manufacturer[b]
Mechanical (hair)	g	0%–100% r.h.	Lambrecht, Thies, Haenni, Jumo, Sato, Casella, Pékly et Richard
Condensation dew point	g	−80°C/+100°C dp	General Eastern, Michell Instr., EG&G, E+H[3] MBW, Protimeter, Panametrics
Dry and wet bulb	g	10%–100% r.h.	Lambrecht, Thies, Haenni, ASL, Jenway, Casella, Ultrakust, IMAG-DLO
Lithium chloride	g	−45°C/+95°C dp	Honeywell, Jumo, Lee Engineering, Siemens, Philips, Weiss
Polymer (capacitance)	g, s	0%–100% r.h.	Vaisala, Rotronic, Testo, Hycal, Panametrics, Novasina, EE Elektronik, Chino, Lee Integer
Electrical (others)	g, s	0%–100% r.h.	PCRC, General Eastern, Rotronic, Chino, Elmwood, Shinyei Kaisha
Thermal conductivity	g	0–130 g/m^3	Shibaura Electronics Co. Ltd
Al_2O_3/silicon	g.1	−80°C/+20°C dp	E+H, Gen. Eastern, Panametrics, Michell Instr., MCM, Shaw
Phosphorous pentoxide	g	0.5–10,000 ppm	Anacon, Beckman, DuPont
Crystal oscillator	g	0.02–1000 ppm	DuPont
Infrared absorbance	g, l	0–50 ppm up to 65°C dp	Siemens, H&B, ADC, Anacon, Kent, Horiba, Sieger, Beckman, Li-Cor
Infrared reflectance	s	0.02%–100%	Anacon, Infrared Engin., Moisture Systems Corp., Pier Electronic, Zeltex, Bran & Luebbe, Bühler
NMR	l, s	0.05%–100%	Oxford Anal. Instr., Bruker
Neutron moderation	s	>0.5%	Kay Ray, Berthold, Nuclear Ent.
Microwave attenuation	s	0%–85%	Mütec, Scanpro, Kay Ray Inc., BFMRA
TDR	s	0%–100%	IMKO GmbH, Campbell Sci. Inc., Soil Moisture, Tektronix
FD	s	0%–100%	ΔT Devices, IMAG-DLO, VITEL, Troxler

[a] g, 1, s, gas/liquid/solid.

[b] This table is inevitably incomplete; a manufacturer not mentioned may deliver a high-quality instrument (see also Ref. [9]).

80.1 Gases

There are several methods of measuring humidity, the most important of which are described here. The scope of the present survey is limited. More can be found in the literature [6–10]. Reference [9] covers measurement in liquids and solids as well.

80.1.1 Gravimetric Method

The gravimetric method is the most fundamental way of accessing the amount of water vapor in a moist gas. In a gravimetric hygrometer, the water vapor is frozen out by a cold trap or absorbed by a chemical desiccant and weighed, while the volume or the mass of dry gas is measured directly. Since the result of a measurement gives the average value over an extended time, the instrument is used in combination with a humidity generator, capable of producing a gas of constant humidity. The method is used for primary standards of, among others, NIST in the United States, NPL in the United Kingdom, and NRLM in Japan. Achievable accuracies are approximately 0.1%–0.2% in mixing ratio, or 0.04 °C in the range of –35 °C to +50 °C dew point, increasing to 0.08 °C at +80 °C and 0.15 °C at –75 °C. The operation of such a standard requires high skill and sophisticated hardware.

80.1.2 Precision Humidity Generators

For less elaborate calibration work, a precision humidity generator is preferred. The best ones are reported to have accuracy comparable to that of a gravimetric standard [11]. Therefore, such a generator may be considered as a primary standard as well. Three practical methods to produce an atmosphere of known humidity are described by Hasegawa [12]: the two-flow, the two-temperature, and the two-pressure method. Briefly, in the first method, a test chamber is fed by two streams of air; one being dry, and the second one saturated with water at a known temperature. The resulting humidity can be calculated from the two flow rates. The two-temperature method uses air that has been saturated with water vapor at a well-known temperature, after which the air is heated to a higher temperature. In the two-pressure method, air is saturated with water vapor at an elevated pressure, and expanded isothermally to a lower, normally atmospheric pressure. Both temperature and pressure of the saturator and the test chamber are measured accurately. In general, precision generators are not transportable, so intercomparisons have to be made with a transfer standard of high accuracy. A good, if not the only, choice is a standard mirror dew-point meter.

80.1.3 Condensation Dew-Point Hygrometer

The saturation vapor pressure in air increases with temperature (Figure 80.1). This means that the air under test can be cooled to a temperature where it is just saturated with water vapor. If this is done at constant pressure and specific humidity, the true dew-point temperature is obtained. In practice, a sample of the gas is usually drawn over a thermoelectrically cooled metal mirror. The mirror is cooled until dew or frost is detected, by optical means. In some cases, where the mirror is replaced by an inert substrate, the formation of dew is detected by electrical means or the use of surface acoustic waves. The temperature is maintained such that the thickness of the deposit is neither increasing nor decreasing. The highest accuracy of a transfer standard can be expected to be 0.03 °C to 0.05 °C in the range of –20 °C to +40 °C dew point. Industrial optical condensation dew-point hygrometers claim accuracies up to 0.2 °C, which may be true in case of a clean mirror; in practice, 0.5 °C is often more realistic. Advantages of this principle are its fundamental nature and the wide range dew points to 90 °C under ambient temperature can be measured. One of the disadvantages is the susceptibility of the mirror to contaminants, especially soluble salts. The sensor may measure the dew point of another condensable vapor if its dew point is above that of the water. A good control of the mirror temperature requires a temperature difference between dew point and ambient temperature of the sensing head. This means that at high relative humidities, the gas must be heated and measured outside the process stream. At temperatures

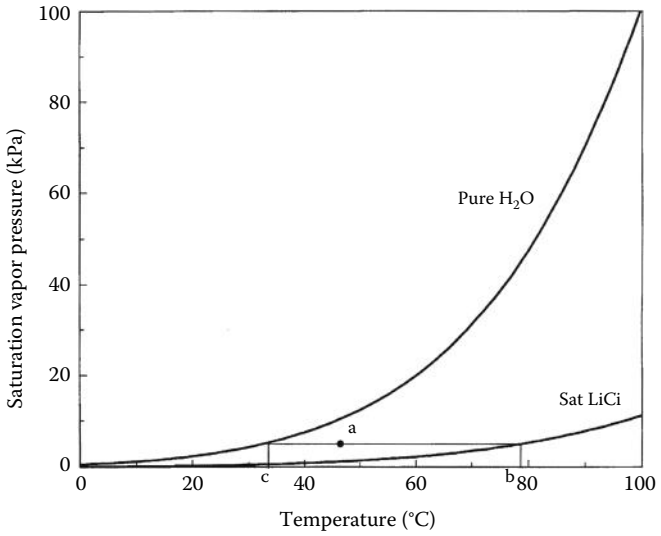

FIGURE 80.1 Saturation water vapor pressure above pure water and above a saturated solution of lithium chloride. In order to be in equilibrium with a gas sample at condition a, a saturated solution of LiCl has to be heated to temperature b. A free water surface must be cooled to a temperature b, as is the case in a mirror dew-point hygrometer.

below 0 °C, there may be supercooled water instead of ice on the mirror. Observations have shown that below –25 °C, the deposit will usually be ice. As the saturation vapor pressures over water and ice differ, one has to know the nature of the condensed layer; thus, for accurate measurements, a microscope is required. A rule of thumb is that the difference between water and ice on the mirror means a difference in dew point of one tenth of the temperature in degrees Celsius below zero, the dew point above water being the lower. Where low water content has to be measured, special attention should be given to the material and cleanliness of the pipes used. Stainless steel, polished at the internal surface, is to be preferred. The lower the moisture content, the more significant the effects are (Figure 80.2).

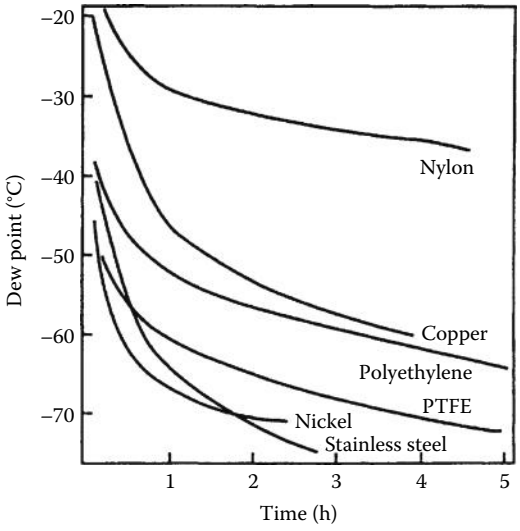

FIGURE 80.2 Illustration of the moisture given off by different tubing materials when flushed with very dry gas after being at ambient humidity. (From *A Guide to the Measurement of Humidity*, The Institute of Measurement and Control, London, U.K., 1996.)

80.1.4 Psychrometer

Two thermometers are ventilated with the gas of unknown humidity. One sensor, the dry bulb, measures the gas temperature t. The other sensor, the wet bulb, is surrounded by a wick saturated with pure water. The energy required to evaporate water into the air stream cools the wet bulb to a temperature t_w. The vapor pressure e in the sampled gas is calculated with the psychrometer equation:

$$e = e_w - A \cdot P\,(t - t_w) \tag{80.2}$$

where

e_w is the saturated vapor pressure at temperature t_w
P is the total atmospheric pressure
A is the psychrometer coefficient

A depends on ventilation speed, dimensions of the wet bulb, and radiative heat exchange between both dry and wet bulbs and their surroundings. The attractiveness of the psychrometric method lies in the fact that it is a direct and relatively simple method, with a theoretically strong basis. The accuracy of the method is determined by the accuracy of both dry and wet bulb sensors, the maintenance of a minimum ventilation speed, and a clean wick. With a ventilation speed of more than 3 m/s and a bulb diameter of 3–5 mm, A can, according to recent investigations, be assumed to be $(6.35 \pm 0.15) \times 10^{-4}\,°C^{-1}$, for Assmann-type psychrometers with a polished internal screen as well as sensors in a transverse air stream in a "black" radiation environment [13,14]. The radiation environment for axially ventilated psychrometers is of crucial importance. Especially when $t - t_w$ is measured directly the psychrometer is the preeminent instrument to measure near or at 100% r.h. The principle can be used up to a wet bulb temperature of 100 °C at atmospheric pressure; dry bulb temperature may exceed 100 °C (up to 165 °C, Ultrakust, Germany). Depending on the dry bulb temperature, the wick may have problems with water supply at strong evaporation. Frozen wet bulbs, already possible at ambient temperatures below 9 °C, can also lead to problems. Generally, this method adds water vapor to the atmosphere, which might be undesirable in specific applications.

80.1.5 Mechanical Hygrometers

Although mechanical hygrometers are losing ground, they are still widely used, mainly in room conditions. The principle relies on the elongation with r.h. of mainly human hair, textiles, or plastic fibers, the effect of which can be amplified mechanically to move a pen on a recorder. The best accuracy is 2%–3% r.h. (for hair, in the range between 35% and 95% r.h., if regenerated at regular intervals); in general, it is wise not to expect better than 5% r.h. In the case of hair, one must be aware of the fact that the hair may be in a state different from that during calibration. Hair exhibits a dry and a wet curve; the transition takes place below 35% r.h. Once at the dry curve, the instrument may read to 20% r.h. too high if it was calibrated at the wet curve as is usually done. If the instrument is kept overnight under a wet cloth, the wet curve calibration will be reestablished. The response time strongly depends on temperature: it ranges from a few minutes at 20 °C to 20 or 30 min at –10 °C. Temperature limits are –60 °C to +90 °C.

Although the initial costs of a mechanical hygrometer are low, the long-range costs of calibration and maintenance are considerable.

80.1.6 Lithium Chloride Dew-Point Meter

Addition of a hygroscopic soluble salt to pure water decreases the equilibrium saturation vapor pressure above the solution (*Raoult's law*). In Figure 80.1, this change is illustrated for a saturated lithium chloride solution, which has an equilibrium relative humidity of about 11% (see Table 80.2). A gas sample at condition *a* is in equilibrium with a saturated LiCl solution of a (higher) temperature *b*. (It is also in

TABLE 80.2 Equilibrium Relative Humidities (%) Over Some Saturated Salt Solutions

	Temperature (°C)			
	10	20	30	40
Salt	Relative Humidity (%)			
LiCl	11.3	11.3	11.3	11.2
$MgCl_2$	33.5	33.1	32.4	31.6
$Mg(NO_3)_2$	57.4	54.4	51.4	48.4
NaCl	75.7	75.5	75.1	74.7
KCl	86.8	85.1	83.6	82.3
K_2SO_4	98.2	97.6	97.0	96.4

equilibrium with pure water at a lower temperature *c*, note the similarity with a mirror dew-point meter.) The application of this principle led to a simple and effective sensor. A fabric sleeve over a bobbin with a bifilar winding of inert electrodes is coated with a dilute solution of lithium chloride. As the bobbin is heated by an alternating current, its resistance increases sharply at the point where the surface begins to dry out, the heating stops, the sensor begins to cool, attracts water vapor, etc., until an equilibrium temperature has been reached. This is measured by, for example, a resistance thermometer sensor in the bobbin. The sensor is simple, rugged, and relatively cheap and, after some calamity, it can be reactivated by recoating it. The dew-point range goes from −40 °C to +90 °C, with a claimed accuracy of about 0.5 °C. This estimate is often too optimistic because the influence of ambient temperature cannot be neglected. Moreover, LiCl has hydrates with one, two, three, and five molecules of water per molecule of salt. In the dew-point regions between 34 °C and 41 °C, the ambiguity leads to a possible error in that area of up to 1.5 °C in dew point. Below −12 °C, the error can rise to 3.5 °C. Low flow rates can cause stratification around the sensing surface, high rates can cool it too much, resulting in too high and too low readings, respectively. Flow rates somewhere between 0.05 and 1 m/s are generally recommended. Response times of commercially available sensors are on the order of minutes. Disadvantages include the lower limit lies at 11% relative humidity, the sensor is washed out by accidental immersion, and the power supply should not be turned off accidentally. From an ionic standpoint, the sensor can be considered precontaminated and therefore, according to the manufacturer [5], relatively insensitive to contamination. Another source [9] reports a number of gases, like sulfur vapors, ammonia, high concentrations of carbon dioxide, chlorine, hydrogen sulfide, and condensable hydrocarbons that could attack the lithium chloride sensor.

80.1.7 Electric Relative Humidity Sensors

Talking about numbers, the category of electric r.h. sensors is certainly by far the greatest part. The sensors are generally small, fast responding, do not dissipate heat, and can be used in confined spaces. Until 1975, the rights in this field were almost exclusively claimed by two resistance types: the Dunmore and the Pope sensor. The Dunmore sensor uses a dilute lithium chloride solution in a polyvinylacetate binder on an insulating substrate, with the danger of washout at saturation. The resistance of the sensor, measured between a bifilar grid, is a function of the r.h. of the surrounding air. This also applies to the Pope sensor, where a polystyrene substrate itself is the sensitive part of the sensor, after treatment with sulfuric acid. This sensor is less sensitive to washout, and has a wider range (15%–99% r.h.) than the Dunmore type. Modern bulk sensors, based on the measurement of the change in resistance, are manufactured by, for example, Shinyei Kaisha and Elmwood Sensors. Since 1970 a lot of work has been done in the development of capacitive sensors, where the stability, the influence of temperature, the temperature range, and the susceptibility for condensation conditions could be greatly improved. Since the 1980s, this sensor type has surpassed the mentioned resistance types. Basically, this type of sensor

consists of a thin polymer layer between two electrodes of various materials. The types differ mainly in polymer type and electrode material, resulting in sensors with different characteristics to withstand pollution and temperatures up to 190 °C. A drawback that still seems not completely under control is the fact that a polymer swells at high humidities, causing an undesirable shift in capacitance of the sensor.

80.1.8 Aluminum Oxide Hygrometers

Briefly, a sheet or wire of aluminum is anodized, producing a thin layer of water-sensitive pores. Subsequently, a conductive, water-permeable gold film is deposited over it. The radius of the pores is such that the sensor is specific for water molecules, and the amount absorbed is directly related to the dew point of the gas. The dew-point range goes from −110 °C to 20 °C, measured as a change in capacitance between the aluminum base and the gold electrode. The sensor works up to high pressures (30 MPa). The response time depends on the dew point, ranging from seconds at 10 °C to minutes below −40 °C. Stated accuracies are ±1 °C at higher dew points to ±3 °C at −100 °C. The sensors show slow drift, and recalibration at least twice a year is generally recommended. Where chemical attack of the aluminum can be expected, silicon capacitive type sensors may be an alternative. A commercially available type of MCM (Moisture Controls & Measurement Ltd., UK) is temperature-controlled, and has a very short response time: less than 15 s to a level of 1 ppm. Both aluminum and silicon sensors can withstand immersion in water.

80.1.9 Coulometric Method

In an electrolytic hygrometer, water in a sample stream is quantitatively absorbed by a phosphorous pentoxide layer. At the moment water molecules are present, the probe becomes electrically conducting. With a dc voltage over the sensor, water is electrolyzed and, according to Faraday's law, a current with a well-defined magnitude occurs (1 mA = 0.0935 μg H_2O/s). For the measurement of the mixing ratio, the flow through the cell must be measured accurately. Further calibration is, in principle, not necessary. At higher flow rates and moisture content (3000–10,000 ppm by volume), the water vapor may not be absorbed quantitatively, so this method is especially suited for low water contents, beginning at 1 ppm. The response time is about 1 min. Typical measurement uncertainties are 10% at 1 ppm, decreasing to 5% at higher values.

80.1.10 Crystal Oscillator

Even lower concentrations (down to 0.02 ppm by volume) can be detected with a hygroscopic coating on the surface of a quartz crystal. The resonant frequency of the crystal is a function of the mass of the coating—in other words, the moisture content of the gas. The crystal is alternately exposed to dry and humid gas, and the shift in frequency is measured. The response time is 1 min. Typical measurement uncertainty is 1 ppm or 5%. The instrument is relatively expensive (DuPont).

80.1.11 Infrared Methods

Like any heteroatomic gas, water vapor absorbs radiation in the infrared region. So, if the gas is led through the optical path between an infrared source and a detector, there is a reduction of the transmitted radiation. The source can be dispersive, that is, generated by a monochromator, or nondispersive, wideband radiation, generated by a heated tungsten or nichrome wire. In the monochromatic mode, the transmittance ratio at two different wavelengths is measured. In the nondispersive (NDIR) method, usually another path through a reference gas is taken. The detector can be gas-filled, solid-state, or pyroelectric, with adequate optical or gas filters in the right wave bands. A popular detector was and still is the Luft type. A Luft detector has two radiation-absorbing chambers containing the specific gas of interest, separated by a thin membrane. Since the detector is a dynamic device, the radiation paths are chopped, allowing the measurement of the change in capacitance. This method allows

measurement over a wide range, from ppm level up to saturation. It can be used in corrosive gases, the concentration of which can be measured simultaneously by the use of another detector. The instrument must be calibrated at regular intervals; typical measurement uncertainty is 1%. Response times to <1 s are possible, depending on the attainable refreshment time in the measuring chamber. Since the absorption depends on the number of atoms, transmittance depends on pressure. The method used to be relatively expensive, even compared with a mirror dew-point meter, but developments in the field of inexpensive semiconductor detectors and better optical filters have reduced prices. Further developments are going on in the direction of fiber-optic probes.

80.1.12 Miscellaneous Methods in Air

- The zirconia cell, acting as a battery on the presence of oxygen ions, is generally used in a mixture of air and steam. The sensor can be mounted directly in a hot gas stream (600 °C/1700 °C). Acceptable accuracies are reached at dew points of 70 °C or higher.
- The frequency of a signal, generated by an acoustic source, depends on the mixing ratio. Measurements in gases up to 250 °C, to dew points of about 70 °C (0–30 vol%, in special cases to 100 vol%, Mahlo).
- The Lyman alpha hygrometer uses the 121 nm emission line of hydrogen, which is strongly absorbed by water vapor. Extremely small response times (milliseconds) can be obtained. The instrument is relatively expensive.
- The difference in thermal conductivity of dry and wet air allows the measurement of absolute humidity with two sensitive temperature sensors in a Wheatstone bridge (Shibaura).

80.2 Liquids and Solids

80.2.1 Gravimetric

Drying of a material at a controlled temperature and taking the difference in weight before and after drying is the most fundamental method, greatly improved by microprocessor-based instruments. The assumption is that the loss in weight is caused by water only and that no other volatile components have been removed. Another problem can arise if water present by surface adsorption or if crystal water is removed.

80.2.2 Karl Fischer Method

A chemical method for the determination of water in solids and organic solvents is the Karl Fischer method. The Karl Fischer reagent is composed of iodine, sulfur dioxide, pyridine, and methanol. Addition of this reagent to water causes a chemical reaction in which, in excess of the other components, 1 mole of iodine is used for each mole of water. The reagent is added in a controlled way to a mixture of reagent and sample, while current between two electrodes is measured. If all the water has been used, a sudden change in the current through the mixture is observed.

80.2.3 Infrared Techniques

The infrared technique is applied to liquids and solids as well, in the wavelength bands of 1.45, 1.94, and 2.95 μm. For liquids, the transmission mode described is used, leading to particular problems because of the small optical path needed. Even smaller transmittance paths would be necessary for solids, one of the reasons to choose reflectance from the surface as a measure for water content. The surface has to be representative for the material in question. The system needs to be calibrated for each material. Concentrations from 0.02% to 100% can be measured. In case of specular reflection, the method cannot be used. A relatively new development is the attenuated total reflectance (ATR) crystal method. The crystal is inserted

in the liquid, which may be opaque or semiopaque, or slurry. A beam with two wavelengths, for reference and measurement entering the crystal, is reflected on the internal surface, penetrating the solution one-half wavelength at each reflection point. The amplitude of the reflected signal decreases at each reflection. The number of reflections is determined by the length of the crystal and the angle of incidence, so the sensitivity can be changed. The measuring range is claimed 0%–100% water in solutions; measuring water in emulsions requires some precautions. The response time is negligible.

80.2.4 Microwave Absorbance

Microwave absorbance is generally used in materials with a more or less constant composition, apart from the moisture content. Microwave radiation from a low-power, solid-state generator is absorbed by the sample and detected by a solid-state detector. The commonly used frequencies where water strongly absorbs are 1–2 and 9–10 GHz, the latter being less dependent on the composition of the material. Operating ranges from 1% to 70% of water are mentioned, with achievable accuracies of ±0.5% of water. The attenuation is influenced by bulk density, bulk material, and temperature. The path between source and detector should not contain any metallic material.

80.2.5 Nuclear Magnetic Resonance

Hydrogen atoms in the field of a permanent magnet are allowed, according to quantum mechanics, to have some defined orientations in that field. To shift an atom from one orientation to another requires a defined amount of energy, dependent on the strength of the magnetic field. If electromagnetic radiation at the right frequency is applied, resonance of the hydrogen atoms occurs, and a loss in frequency power can be detected. It is specific for all hydrogen atoms, so interference with liquids other than water in the sample can be expected. Temperature and flow must be controlled. Magnetic materials must be avoided. Measuring ranges of 0.05%–100% have been reported [9].

80.2.6 Neutron Moderation

This method is, like NMR, specific to hydrogen atoms. Neutrons of high energy are slowed by nuclei of hydrogen atoms. The main components are a detector of slow neutrons, next to a source of fast neutrons. The measuring range goes from 0.5%. The sensor can be made very rugged. The measured volume is a sphere of up to tens of centimeters in diameter. The method is dependent on the bulk density of the material, but largely independent of the properties of the material being analyzed [9]. The method is not suitable for foodstuffs. It suffers from necessarily severe government regulations and low acceptance by the public and the operator.

80.2.7 Time Domain Reflectometry

Time domain reflectometry (TDR) measures the propagation velocity of electrical pulses, mainly between 1 MHz and 1 GHz. This method is well established, especially for the measurement of water content in soil. With certain limitations, it is proven suitable for automatic installations. The main disadvantage is the complexity of the data analysis [15].

80.2.8 Frequency Domain

The general features of the frequency domain (FD) technique are comparable to those of TDR; however, there are some important differences. The dielectric properties of the material (soil, concrete, grain, oil, etc.) can be measured at a single frequency. The ability to choose a whole range of frequencies makes the FD sensor suitable for spectroscopic measurements. A sensor of this type has recently been developed by IMAG-DLO, Wageningen (The Netherlands). It is simple and inexpensive, and available for many purposes. The sensor uses a single application-specific integrated circuit (ASIC) and is suitable for the measurement of other properties of materials as well [15].

80.2.9 Measurement of Thermal Conductivity

The thermal conductivity of a material is related to the amount of water it contains. Heat pulses are supplied by a needle probe, and the cooling of the needle after ending the pulse is measured. It is a simple and inexpensive method that needs calibration for the material in which it is going to be used.

80.2.10 Water Activity or Equilibrium Relative Humidity

A material enclosed in a measuring chamber is, after some time, in equilibrium with its environment. The moisture content of the material can be derived from the so-called adsorption isotherms for that specific material, which must be determined experimentally. The method is used for many materials, such as foodstuffs, chemicals, grains, seeds, etc., with electric humidity sensors described earlier. In cases where the water potential of living material like potatoes and leaves must be measured, thus at very high relative humidities, the junction of a small thermocouple is cooled by an electric current and, after the current has been turned off, used as an unventilated wet bulb psychrometer. It is an excellent method that requires skill.

80.3 Formulae

A relatively simple equation for the calculation of the saturation vapor pressure $e_w(t)$ in the pure phase with respect to water is the *Magnus formula*:

$$\ln e_w(t) = \ln 6.112 + \frac{17.62t}{(243.12 + t)} \tag{80.3}$$

where

t is the temperature in °C (on ITS-90)
$e_w(t)$ is in pascals

Equation 80.3 covers the range between −45 °C and +60 °C, with a maximum standard deviation of 0.3%. Over ice, Equation 80.3 changes to

$$\ln e_i(t) = \ln 6.112 + \frac{22.46t}{(272.62 + t)} \tag{80.4}$$

covering the range between −65 °C and 0 °C with a standard deviation of <0.5%.

Equation 80.3 can easily be converted for the calculation of the dew point t_d:

$$t_d = \frac{[243.12 \ln(e/6.112)]}{[17.62 - \ln(e/6.112)]} \tag{80.5}$$

where e is the saturation vapor pressure e_w at dew-point temperature t_d. The standard deviation in the range mentioned is <0.02 K. The *frost point* t_f can be calculated from the following equation:

$$t_f = \frac{[272.62 \ln(e/6.112)]}{[22.46 - \ln(e/6.112)]} \tag{80.6}$$

where e is the saturation vapor pressure e_i at frost-point temperature t_f, in the range mentioned within a standard deviation of 4 mK.

More accurate formulae, given by Hyland and Wexler, updated by Sonntag can be found in Ref. [7]. The uncertainties mentioned earlier, given by Sonntag [7], are valid for the pure water system. In the presence of air, the uncertainties can only be maintained if the water vapor enhancement factor is taken into account.

80.4 Calibration

This section explains a few words about calibration, a most important and too often forgotten subject in humidity and moisture measurement. The gravimetric method has already been described, as well as some principles of humidity generators, which could be used as standards. Another method is the humidity chamber, with both temperature and humidity control, where an instrument is compared with a calibrated standard instrument like a mirror dew-point meter or a psychrometer. Saturated (or diluted) salt solutions can be used to create a constant relative humidity in a confined space. Some values are listed in Table 80.2 (from Ref. [16]). The user should have knowledge of some critical factors like temperature, etc. for the application of this method. Permeation tubes are used where a repeatable, accurate, and low concentration flow is required. Unlike with temperature or pressure sensors, it is, except at the highest national level, not realistic to expect a reference or standard for humidity with an accuracy of a factor 5 or 10 times better than the required accuracy for a measuring instrument. A good calibration guarantees traceability to a higher standard. This means, in general, that the calibration should be performed by a national or accredited laboratory. A rule of thumb for the intervals of calibration of humidity meters is as follows: condensation dew-point meters and psychrometers require calibration once every 1–2 years; electric relative humidity sensors need calibration every 6–12 months; and less stable types like aluminum oxide sensors must be calibrated every 6 months or sooner if desired [8]. A comprehensive treatment of calibration of hygrometers and attainable accuracies has been given by Wiederhold [10].

80.5 Developments

- Fiber optics is beginning to find their way in hygrometry, resulting in explosion-proof models. Changes in refractive index by the use of micropores are used in an instrument recently developed by Ultrakust (Germany). Fiber lengths go to 1000 m. The measuring range is 0% to 20% r.h. in a dew-point range of –90 °C to 20 °C.
- A rapidly developing field is that of the monolithic integrated circuit sensors. Hycal (United States) manufactured a capacitive relative humidity sensor, while a recent commercial development in Germany reports the use of a monolithic integrated sensor instead of a mirror in a miniature dew-point meter, with an accuracy of better than 0.5 °C. Since the use of porous silicon allows the development of smart sensors, developments in that area will undoubtedly continue [17].
- The progress in the theoretical background of many water-related processes, made possible by an advanced FD sensor mentioned earlier, is of great importance for future development of simple, cheap, stable, and reliable sensors that can be used for many purposes.

P. Ottonello
Università di Genova

81.1 Ventilation

This chapter deals mainly with *spirometry*, i.e., with the measurement of volumes and flows associated with respiration. Spirometric tests (which embody useful information about parameters related to pulmonary function) are often used for diagnostic purposes in conjunction with other measurements. Figure 81.1 and Table 81.1 show spirometric quantities of clinical interest [1].

The classification of spirometric instruments may be based on different criteria. For example, one may consider *open-circuit* devices (the subject takes a full inspiration or expiration before connecting to the meter) and *closed-circuit* devices (the subject remains connected to the apparatus during one or several respiratory cycles). Another distinction concerns whether the instrument is a *portable* one and is mainly used for monitoring purposes or is a *diagnostic* one whose purpose is to provide an accurate value that may be compared with a reference value. As for the nature of the physical functions more directly investigated, a subdivision into *volume measurements* and *flow measurements* is important, even though, using some care, it is sometimes possible to shift from one class to the other by time-differentiation or time-integration procedures. Another technique deals with the direct evaluation (as a function of frequency) of the complex impedance of the respiratory system viewed as a suitable network of resistors, capacitors, and inductors. This method has been the subject of considerable investigation in the last two decades, due to the advent of computers and their use in the spectral analysis of signals. This topic will be discussed in the final section.

As a general comment about measurements associated with ventilation, it may be said that there are few other fields in applied science where a correct *operation procedure* is virtually as important as the reliability of the measuring instruments themselves. See for example a study conducted on nearly 6000 patients affected by some airflow obstruction (Ref. [2] and references therein, especially n. 26).

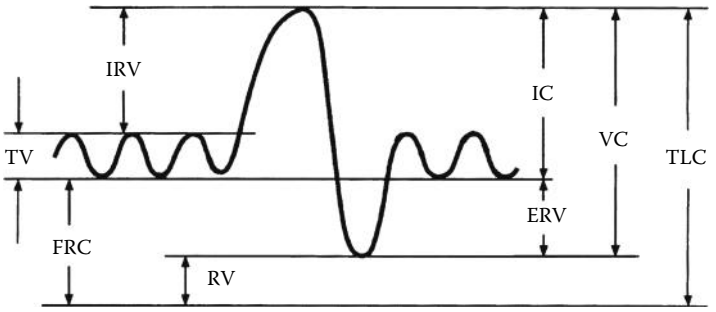

FIGURE 81.1 Spirometric trace illustrating the definitions of some significant quantities commonly evaluated in spirometry (see also Table 81.1).

TABLE 81.1 Common Spirometric Quantities

Vital capacity	VC
Inspiratory capacity	IC
Inspiratory reserve volume	IRV
Expiratory reserve volume	ERV
Tidal volume	TV
Functional residual capacity	FRC
Residual volume	RV
Total lung capacity	TLC

81.1.1 Volume Measurements

Here, gas volumes associated with the respiratory process are the main target of investigation; the principal instruments that have been used so far in the clinical routine and in research activity are [3]

1. *Spirometer*: An expandable chamber whose volume is monitored during inspiration or expiration. The subject is instructed to blow into a conduit communicating with the chamber; the latter may consist of a bell, a piston, or more often a bellows (as in the once ubiquitous Vitalometer®).
2. *Turbine meter*: Based on the principle that air blown through the inlet produces the rotation of a turbine connected to a revolution counter.
3. *Impedance plethysmograph*: Based on the measurement of resistance (*strain gage plethysmograph*) or of inductance (*inductance plethysmograph*); in both cases, the impedances of an elastic coil wrapped around the subject's chest and one wrapped around the subject's abdomen are monitored during respiration.
4. *Total-body plethysmograph*: A kind of sealed telephone booth inside which the subject sits; the pressure inside the box is sensed and converted to volume values.

81.1.2 Flow Measurements (Pneumotachometry)

In this case, the airflow through the upper airways is directly measured; in principle, the flow could be evaluated by time differentiating the spirometer records, but this method would suffer from limitations due to nonlinearity effects and to errors related both to poor frequency response and to some hysteresis of the volume meter. The reverse procedure is in fact more common: since they are normally connected to an electronic integrating device, flowmeters can be employed as volume-measuring instruments as well. Calibration is normally performed by discharging a syringe (of known capacity) through the flowmeter; the response of the latter is time integrated to check whether it corresponds to the calibration volume. It is convenient to repeat the calibration procedure a few times, with the

syringe discharged each time at a different speed, in order to detect possible effects due to deviations from linearity of the flow sensor.

A useful summary of standard specifications governing the performance of several types of pneumotachometers (PTM) together with a concise description of the more common PTM types can be found in Ref. [4]. Conventional devices for measuring respiratory flow are

1. *Linear resistance PTM* (LRPTM): Evaluates the pressure difference generated by the (laminar) airflow across a fixed hydrodynamic resistance. This procedure is based on the Poiseuille equation and is analogous to evaluating current by measuring voltage across a known resistor and using Ohm's law. The resistive element may consist either of a bundle of tubelets (Fleisch type) or of a wire mesh screen (Lilly type).
2. *Hot-wire PTM* (HWPTM): A very thin wire heated by an electric current, cooled by the flowing gas; the rate at which heat is conveyed away from the wire depends on the fluid flow; a variant of this instrument uses a heated film in lieu of the heated wire.
3. *Ultrasonic PTM* (UPTM): Based on the principle that the speed of a beam of ultrasounds exchanged between a pair of transducers is increased or decreased as it propagates through the moving air; the variations of the time of flight of the ultrasonic beam is related to the average speed of the flowing air.
4. *Vortex-shedding PTM* (VSPTM): Basically measures the frequency at which vortices are generated in the wake of a suitably shaped obstacle (the "bluff body") exposed to the flow.

81.1.3 Respiratory Impedance Measurements

In recent years, considerable interest has been devoted to the impedance of the respiratory system, a parameter that contains information about the morphology of our breathing apparatus and plays a role analogous to the impedance of an electrical circuit. *Respiratory impedance* may be obtained by connecting the patient's upper airways to an alternating pressure generator and by evaluating the ratio of the measured pressure to the measured flow; this can be done at several excitation frequencies, using a method that is referred to as the forced oscillation technique.

81.2 Instrumentation: Principles and Description

81.2.1 Measurements of Volume

81.2.1.1 Spirometer

A widely used spirometer is the bell type (see Figure 81.2): the volume of the lungs is monitored by the position of a light cylindrical bell (possibly equipped with counterweights) connected to the patient's mouth. The bell spirometer is rather cumbersome but, due to its great reliability, is an ideal tool for calibration purposes as well as for comparing data recorded at different centers. In its turn, the bell spirometer needs periodic calibration at least every 3 months; this may be performed by means of a 3 L syringe equipped with electronic volume readout [5]. The syringe must be accurate to within 25 mL and the spirometer should be able to measure volumes of at least 8 L with an accuracy of at least ±3% or 0.050 L, whichever is greater, with flows between zero and 14 L/s [6].

81.2.1.2 Turbine Meter

Its operating principle is quite straightforward. The revolutions of the turbine wheel, whose speed is proportional to the flow, are counted by electronic sensors (optoelectronics or Hall effect–based) and processed to give volume or flow values. The main limitation of the turbine meter is that low flow values are underestimated since a greater fraction of the air slips past the wheel as the flow rate decreases; it also displays poor frequency response and can be used only in unidirectional flows. Although these features

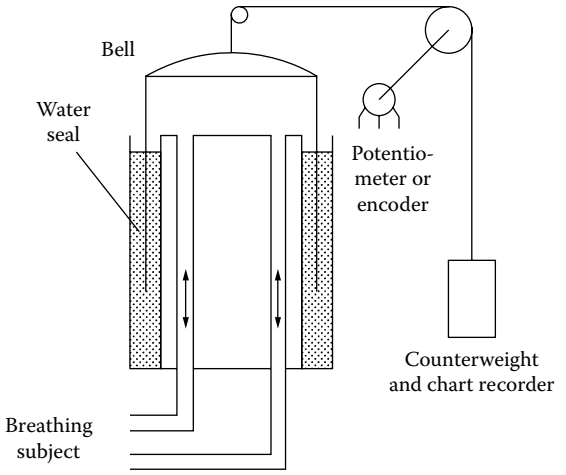

FIGURE 81.2 Schematic view of the classical bell spirometer.

make the device unsuitable for accurate laboratory measurements, it is used extensively to monitor the ventilation of patients in intensive care and in portable instruments, due to its overall (sensor and pulse processing) simplicity and low cost.

81.2.1.3 Inductance Plethysmograph

Like the spirometer, the PTM, and the total-body plethysmograph, this technique allows for noninvasive monitoring of human ventilation but it does not require a connection to the airways. Two elastic belts with serpentine inductors encircle the torso; the first around the rib cage and the other around the abdomen. Each inductor is part of the resonant tank circuit of a free-running oscillator (resonant frequency from 0.2 to 1 MHz) whose output is optically coupled to the demodulator circuit (for the purpose of electrical isolation of the subject from the equipment, usually operated by the ac power line). Ventilation causes the inductor cross-section areas to vary changing their inductances and thus varying the frequency of the two oscillators (FM modulation).

81.2.1.4 Strain Gage Plethysmograph

Its principle of operation is similar to that of the inductance plethysmograph; in this case, the sensing element consists of a strain gage whose resistance is varied as the gage is stretched and released during respiration.

81.2.1.5 Total-Body Plethysmograph (Constant-Volume Box)

This is a sealed chamber that allows the measurement of thoracic gas volume (TGV) by exploiting the pressure–volume relation of a fixed quantity of ideal gas. A schematic illustration of the method for a constant-volume plethysmograph is shown in Figure 81.3. The balloon-shaped object represents the subject's respiratory system, the volume of which varies during breathing. In the course of the measurement operation (which lasts only a few seconds), the shutter appearing in Figure 81.3 must remain closed in order that the alveolar pressure may be identified with the pressure measured at the mouth. In the following, the subscript A (for alveolar) denotes the gas in the lungs and the subscript C denotes the gas in the chamber.

For moderate respiratory acts, the air contained in the lungs at a given time can be treated as an approximately isothermal gas (temperature 37 °C, water vapor saturated) while the air in the chamber is more appropriately treated [1] as an adiabatic gas. By differentiating the ideal gas equation for the isothermal air in the lungs,

$$V_A = -P_A \frac{\Delta V_A}{\Delta P_A}$$

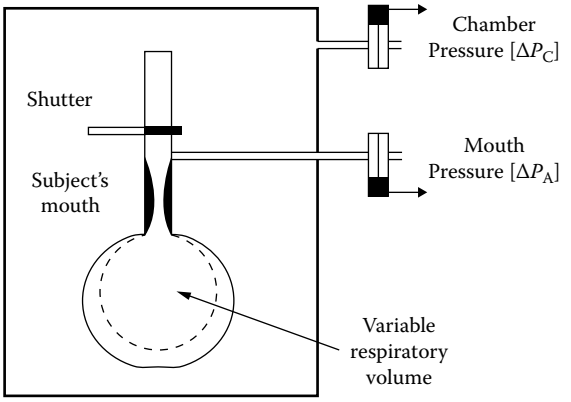

FIGURE 81.3 The respiratory system of a patient sitting inside an airtight chamber is schematized as an expandable balloon. The quantities of air inside and outside the balloon are separately constant: only their volumes and pressures change as the subject attempts to breathe against the closed shutter.

while for the adiabatic air in the chamber,

$$\Delta V_C = -V_C \frac{\Delta P_C}{\gamma P_C}$$

where γ is the usual ratio between molar heat capacities: $\gamma = c_p/c_v$.

Since the system is globally closed ($\Delta V_A = -\Delta V_C$), the lung volume V_A is related to the alveolar pressure P_A (which is taken to be the barometric pressure minus the water vapor pressure at 37 °C) and to the differential pressures ΔP_C and ΔP_A (equal to the chamber pressure fluctuation and to the alveolar pressure fluctuation, respectively) by the formula:

$$V_A = kP_A \frac{\Delta P_C}{\Delta P_A}$$

The coefficient k can be obtained through a calibration procedure that creates sinusoidal volume variations by means of a reciprocating pump. The pressure changes appearing on the right-hand side of the last equation may be measured by sending the outputs of the two sensors of Figure 81.3 to a data acquisition module installed in a host computer, typically a personal computer.

81.2.1.6 Correcting to Standard Conditions

Measurements of gas volumes make reference to lung BTPS (body temperature and pressure, saturated with water vapor) conditions. Volume measurements (V_A) made at ATP (ambient temperature and pressure) conditions should be corrected to BTPS conditions (V_B).

When bell or bellows spirometers are employed, the following formula [1] is often used:

$$V_B = \frac{310.2(P_B - P_W)}{(273.2 + t)(P_B - 6.3)} V_A \tag{81.1}$$

where

t is inside gas temperature (°C)
P_B is barometric pressure (kPa)
P_W is saturated water vapor pressure (kPa) of the gas

The temperature t of the air inside the spirometer should be measured accurately during each breathing maneuver (Table 3 in Ref. [7]).

81.2.2 Measurements of Flow

81.2.2.1 Linear Resistance PTM

The standard LRPTM contains the following elements (Figure 81.4a and b):

1. A fixed resistive load
2. A differential pressure sensor
3. Electronic instrumentation for processing and displaying the output of the pressure sensors

The relationship between flow rate and pressure difference should be linear within the range of useful flow rates; the maximum flow value, determined by the onset of turbulence, and the linearity range are given by the manufacturer's specifications.

It is good practice to calibrate the PTM periodically, by connecting it in series with a bell spirometer, and then use it without changing the geometry of the immediately adjacent tubing. In fact, accurate flow rate measurements are possible only if information about the flow pressure characteristics over the useful flow range is available; furthermore, this information should have been obtained in the same conditions in which the flowmeter will be used [8].

Figure 81.4a depicts the Fleisch PTM, whose resistive element consists of a bundle of capillary tubes. The function of the heater is to avoid the condensation of water vapor inside the tubes; the two chambers of the differential pressure sensor are connected at the two ends of the resistive element, whose resistance is lower than 0.1 kPa s/L (1 cm H_2O s/L). Since typical spirometric flows, for quiet breathing and slow maneuvers, are of the order of 1 L/s, they generate pressure differentials of about 1 cm H_2O. Considerably stronger flows, exceeding 10 L/s, may be produced by adults in some maneuvers; in these cases, Fleisch PTMs of larger dimensions should be employed in order to keep the spirometric flow within the linearity regime.

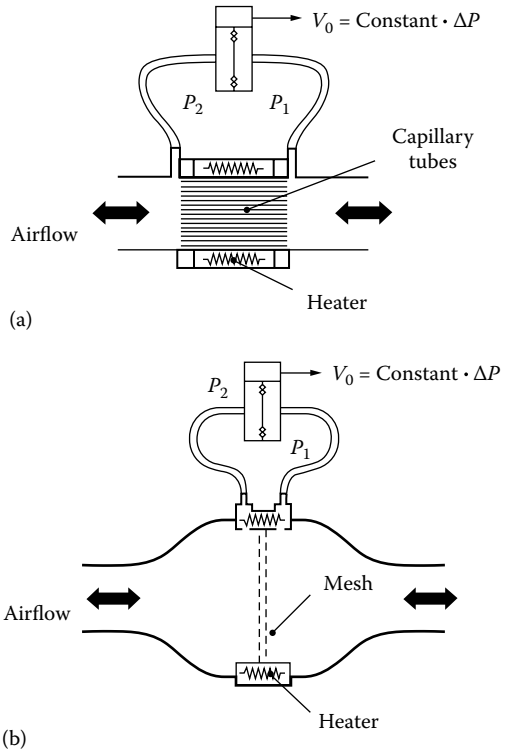

FIGURE 81.4 (a) The Fleisch (capillary) pneumotachograph and (b) the Lilly (wire-mesh screen) pneumotachograph. In both sensors, the task of the heater is to reduce water vapor condensation.

Figure 81.4b illustrates the Lilly PTM, whose resistive element consists of a wire mesh and is of the order of 0.05 kPa s/L (0.5 cm H_2O s/L) to which pressure differentials of the same order as the Fleisch are associated. The Lilly PTM is much less exposed than the Fleisch to the risk of nonlinearity at higher flow rates.

The linear resistance PTMs, in conjunction with an appropriate differential pressure transducer, an amplifier, and an analog or, more often, digital integrator, form the most widely used instrument for the combined measurement of flow and volume. In fact, recent recommendations on the standardization of lung function tests are limited to Fleisch and Lilly tachometers only [1].

81.2.2.2 Hot-Wire PTM

The HWPTM works on the principle that the cooling rate of a heated wire depends on the speed at which the surrounding fluid is flowing [9–11]. The rate at which thermal energy is lost by the wire may be written as

$$Q = hS(T_w - T) \tag{81.2}$$

where

Q is the heat transfer rate
S is the surface area of the wire
T_w is the wire mean temperature
T is the temperature of the fluid surrounding the wire
h is the transfer coefficient between sensor and fluid and is defined by Equation 81.2

The speed v of the fluid is linked to h by an important empirical relation whose analytical form has withstood the test of time; however, owing to the complexity of the formula and to the number of physical quantities involved in it, it is convenient to make direct reference to Ref. [11] where all necessary details can be found.

It is wise to remember, in fact, that from the operational point of view the last word on these instruments is always entrusted to a sound calibration procedure.

For spirometric purposes, it is recommended to use the HWPTM in the *constant-temperature* mode of operation, according to the diagram of Figure 81.5.

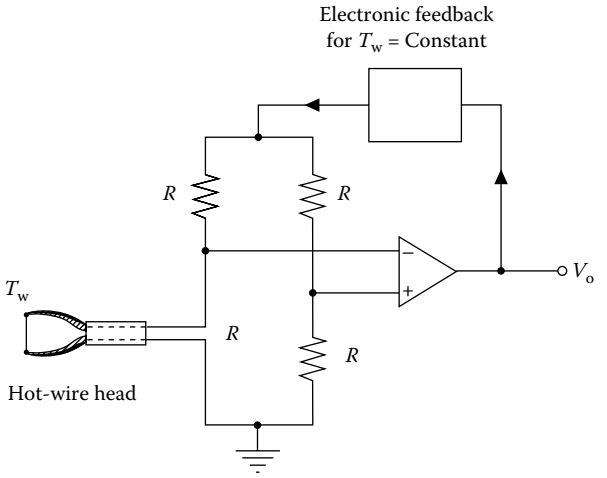

FIGURE 81.5 Block diagram of the constant-temperature hot-wire flowmeter. The electronic feedback system allows one to maintain the sensing wire temperature constant.

Using a suitable feedback system, the current is adjusted so as to maintain the wire temperature (hence, its resistance) at a constant value through the entire range of velocities allowed by the flowmeter. Once this condition is satisfied, the output voltage value is a measure of the heat transfer rate. The constant-temperature design has several advantages, e.g., the wire is protected against burnout and it is easy to compensate for environment temperature change either by using a temperature-sensitive element in the bridge or by measuring the actual temperature and correcting the results.

Accurate measurements require periodic calibration procedures (for example, using the syringe mentioned in connection with the spirometer) because dirt accumulating on the wire may significantly alter the heat transfer coefficient; it is easy, however, to remove dirt thoroughly from the sensor by manually superheating the wire for a few seconds or by immersing the sensor head into a suitable cleaning liquid. The calibration procedure should be repeated at intervals comparable to those of the LRPTM.

The setup in Figure 81.5 measures only unidirectional flows.

81.2.2.3 Hot-Film PTM

More recently, hot-film PTMs have been developed which can be used in place of the hot wire, the rest of the PTM remaining unchanged. The sensing element is deposited onto a nonconducting support (quartz) by vacuum sputtering, which ensures uniform thickness (about 0.1 μm) of the sensing element (platinum or nickel). In these sensors, heat can be conducted through the substrate and lost by convection to the ambient gas. The length-to-diameter ratio of the sensor is smaller; consequently, the temperature distribution along the sensor is less uniform. These drawbacks, which are more theoretical than real since calibration is always necessary, are largely compensated for by a lower fragility and sensitivity to particulate contamination.

81.2.2.4 Ultrasonic PTM

The basic working principles of UPTMs [10] are (1) sound is sped up or slowed down as it propagates through a moving medium and (2) the back and forth transit time of a sound signal is related to flow velocity and turns out to be largely independent of the acoustic velocity of the medium. UPTMs can be classified according to whether they use *pulsed* or *continuous* ultrasound signals.

In the first case, the transmitter is driven by a short pulse of sine waves; the round-trip transit time of individual pulses or sequences of pulses is measured.

In the second case, a continuous ultrasonic signal is transmitted along a closed path and either the phase shift or the frequency shift is measured. As a specific example, a pulsed transit time UPMT (Figure 81.6) is described.

Two piezoelectric crystal transducers are recessed into the wall of a conduit at an angle θ to the flow axis. Provisions are made in order to reduce the level of acoustical and electromagnetic

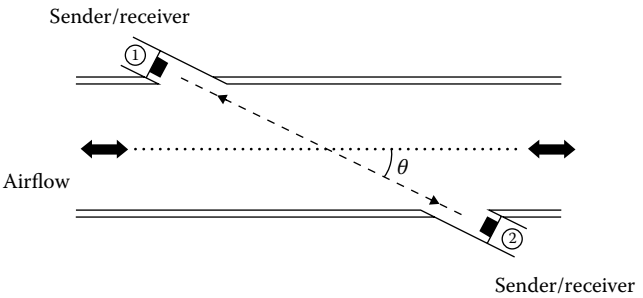

FIGURE 81.6 Transit time ultrasonic pneumotachograph. Owing to the large Q factor of the resonators, the central resonant frequencies of the two piezoelectric crystals should closely match.

external interferences. Moreover, moderate heating (at about 40 °C) prevents water from condensing on their surfaces. The two devices are made to function alternately as transmitter and receiver of a short burst of 50–200 kHz sound wave.

With no gas flowing through the conduit, the time required for sound transmission in either direction is the same. When gas is flowing, the two times are, respectively,

$$t_{12} = \frac{L}{(c + v \cdot \cos\theta)} \quad t_{21} = \frac{L}{(c - v \cdot \cos\theta)}$$

where

L is the transmitter–receiver distance

c is the speed of sound

The gas velocity v turns out to be independent of the actual value of c (which in turn depends on the gas type and on the working conditions and can range from around 200 to nearly 1000 m/s); an expression for v is easily obtained from the last equations by assuming $c^2 \gg v^2$

$$v \approx \frac{L}{2\cos\theta} \cdot \frac{\Delta t}{t_a^2} \tag{81.3}$$

where

$\Delta t = t_{21} - t_{12}$

$t_a = (t_{21} + t_{12})/2$

The flowmeter measures the average flow velocity of the gas along the path of the ultrasound beam.

In using the UPTM, it should be remembered that the working frequency is very close to the resonant frequencies of the two crystals which should be closely matched: small differences would cause a strong reduction of the instrument sensitivity owing to the sharpness of the resonance curves.

81.2.2.5 Vortex-Shedding PTM

When the Reynolds number is sufficiently high, vortices of regular periodicity are borne downstream of a bluff body located in the fluid flow (see Figure 81.7).

The frequency at which these eddies are generated is a linear function of flow velocity and depends weakly on the dimensionless Strouhal number [12,13]. Different types of VSPTMs use different methods for measuring the vortex frequency; to this end, ultrasonic beams and optical fibers are widely employed.

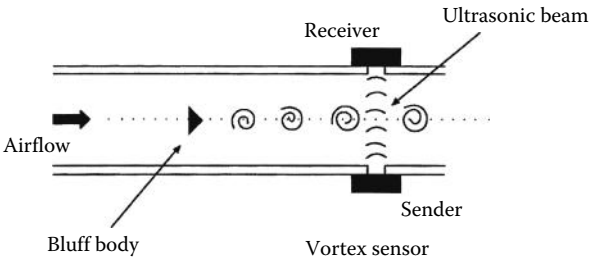

FIGURE 81.7 A vortex-shedding flowmeter equipped with an ultrasound vortex sensor. Vortices generated by the bluff body are sensed by the ultrasonic beam located downstream. In the optical model, the functions of vortex generation and counting are both taken on by an optical fiber.

Ultrasonic: An acoustic beam (Figure 81.7) is sent across the flow by an ultrasound transmitter located on one side of the tube (downstream of the bluff body); an ultrasound receiver is located on the opposite side of the tube. In this case, eddies generated by the bluff body act as modulators of the sound wave intensity. By doubling the setup [13], the ultrasonic VSPTM can also be used for bidirectional flows.

Optical fiber: In this model, an optical fiber is stretched across the tube and acts both as the bluff body and the vortex frequency sensor [14]. The light from an LED enters the fiber at one end, the other end being coupled to a photodiode. The intensity of the light propagating through the fiber is modulated by the mechanical vibrations of the fiber produced by the eddies moving with the fluid and fluctuates in step with the vortex generation frequency.

Both in the ultrasonic and the optical fiber VSPTM, the fluctuating intensity of the beam (respectively, sound and light) is processed to output a flow indication.

The main limitation of all types of VSPTMs is a "blind zone" at low fluid flows corresponding to the absence of vortices at low Reynolds numbers. In compensation, these devices are quite insensitive to the thermodynamic conditions of the gas and to the presence of particulate matter. Similarly to the case of HWPTMs, the last word on VSPTMs is entrusted to a sound calibration procedure.

81.2.2.6 Measurement of Volume Using a PTM Plus an Integrator

Another kind of plethysmograph can be built by combining a PTM and a digital integrator that calculates volume as follows:

$$V(\tau) = \int_0^{\tau} \dot{v}(t)dt \tag{81.4}$$

where $\dot{v}(t)$ is the instantaneous flow. The problems exhibited by this kind of instrument are the same as those of the PTM around which it is built, since the process of integration is invariably digital; moreover, correction to BTPS requires considerably more care [1]. Finally, when a heated PTM is employed, correction to BTPS is often done by assuming instantaneous thermalization of the gas within the tachometer (this means that the gas passing through the instrument assumes completely and without delay the same temperature of the tachometer [1]); this assumption may be quite unrealistic, especially in the case of the wire mesh screen type. The correction should thus be different for different types of PTMs.

81.2.3 Forced Oscillation Technique

The forced oscillation technique (FOT) is a modern tool [15] used to gain information on the structural and mechanical properties of the respiratory system by measuring how the latter responds to an externally imposed excitation. When linearity is assumed, well-known correlation techniques (borrowed from conventional signal analysis) can be exploited to measure the system complex impedance $Z_R(f)$, which is defined as the ratio of complex input pressure difference to complex output flow (i.e., the ratio of amplitudes and the difference of phases) and is equal to the inverse of the system transfer function $H_R(f)$.

Depending on the part of the respiratory system actually investigated, i.e., on the positions where the excitation pressure difference is applied and the flow is measured, different values for $Z_R(f)$ can be obtained:

- *Input impedance*: Both the excitation pressure (measured relatively to the pressure on the body) and flow are measured at the mouth.
- *Transfer impedance*: The excitation pressure is measured at the mouth, whereas flow is measured at the thorax (or vice versa) by means of a body plethysmograph.

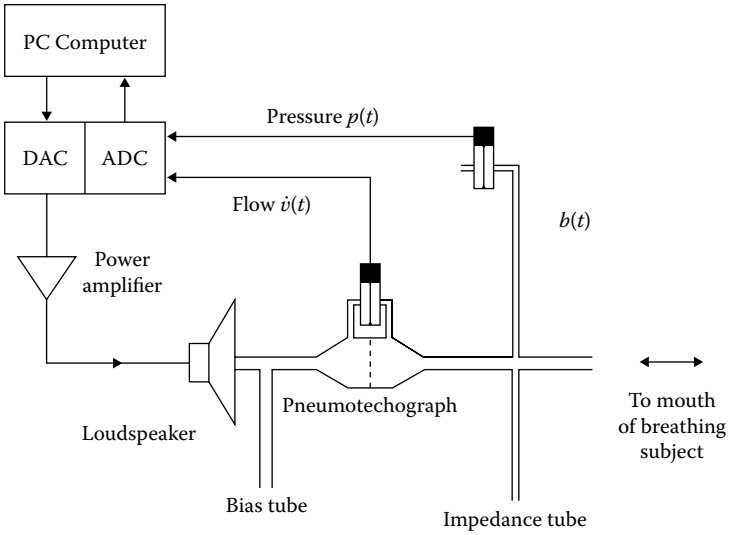

FIGURE 81.8 Experimental setup for the computer-based measurement of respiratory input impedance.

An experimental setup for the measurement of respiratory input impedance is shown in Figure 81.8. A suitable software provides

- Generation of a pseudorandom sequence (typically obtained by summing the first 25 harmonics of 2 Hz with random phases) which, after digital-to-analog conversion and proper power amplification, drives a large (20–30 cm diameter) loudspeaker
- Acquisition of two blocks of pressure and flow samples: 2 × 4096 data are collected in a 16 s run at a sampling rate of 256 samples/s
- Processing of data in order to obtain the desired $Z_R(f)$ function in the typical interval 2–48 Hz

The bias tube allows a flow of fresh air to be drawn through the system to minimize rebreathing of expired air. The impedance tube (2 m long, 2 cm diameter) allows spontaneous breathing; moreover, because its electrical equivalent is an inductor, it acts like a shunt for the low-frequency breathing components, thus reducing their level of disturbance on the pressure and flow measurements (noise), without affecting in a significant way the imposed pressure input (signal).

The respiratory apparatus is modeled as a system whose input is a random noise pressure $p(t)$ and whose output is a flow signal $\dot{v}(t)$, both corrupted by a breathing disturbance $b(t)$ uncorrelated to $p(t)$. Any text on random signal analysis [16] may provide useful information on the mathematical quantities employed in this section.

Using the following Fourier transform (FT) quantities,

- $P(f)$ = FT of the random noise pressure input $p(t)$
- $B(f)$ = FT of the subject's breathing noise $b(t)$

$$\dot{V}(f) = \text{FT of the linear system output } \dot{v}(t)$$

we have (Figure 81.9)

$$\dot{V}(f) = P(f) \cdot \frac{1}{Z_R(f)} + B(f) \tag{81.5}$$

A valid estimate of $Z_R(f)$ cannot be obtained from this relation because of the presence of the large breathing disturbance. According to the theory of signal processing, a nonbiased estimate of $Z_R(f)$ can be obtained by using autospectra and cross spectra of input [$p(t)$] and output [$\dot{v}(t)$] signals; if $G_{PP}(f)$ and

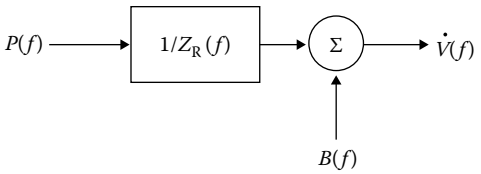

FIGURE 81.9 The respiratory system modeled in the frequency domain.

$G_{\dot{V}\dot{V}}(f)$ are the autopower spectra of pressure and flow, and $G_{\dot{V}P}(f)$ their cross power spectrum, the estimated impedance $Z_M(f)$ becomes

$$Z_M(f) = \frac{G_{PP}(f)}{G_{\dot{V}P}(f)} = \frac{G_{PP}(f)}{1/Z_R(f) \cdot G_{PP}(f) + G_{BP}(f)} \tag{81.6}$$

which becomes almost coincident with the true value $Z_R(f)$ when a long time average allows sensible reduction of the contribution of the $G_{BP}(f)$ term.

Moreover, since the systematic bias depends mainly on the presence of the breathing noise on both pressure and flow signals, all efforts should be made to reduce this disturbance as early as possible, i.e., at the sensor level. This is achieved by using the impedance tube and by keeping the value of the pneumotachograph impedance as low as possible. Further reduction is usually obtained by high-pass analog filtering (2 Hz corner frequency) before the ADC and/or by digital filtering before FFT calculations. It is worth noting that the choice of a pseudorandom excitation makes possible the use of a digital comb filter (a multiple narrow band pass, i.e., a band pass for each 2 Hz harmonic) [17].

When the FOT is used, it is necessary to ascertain that the coherence [16] between input and output, expressed by the γ^2 function defined as follows, is sufficiently large:

$$\gamma^2(f) = \frac{|G_{\dot{V}P}(f)|^2}{G_{\dot{V}\dot{V}}(f) \cdot G_{PP}(f)} \tag{81.7}$$

As a rule of the thumb, the calculated $Z_R(f_0)$ (the impedance for a particular value of frequency) is accepted only when the corresponding $\gamma(f_0)$ is larger than 0.9–0.95.

Actually, the value of $\gamma(f)$ is the only form of control used; at any rate, some care should be taken to interpret the coherence function as an index for the reliability of respiratory impedance data [18,19]. Obviously, higher values of the coherence function can be achieved by increasing the pressure input amplitude, but this may lead to an increase of nonlinearity effects [20].

In conventional setups, flow is evaluated by measuring the pressure drop ΔP that develops across the pneumotachograph, whose impedance is known and usually small with respect to the subject's input impedance Z_R. Since these two impedances are in series, the differential pressure ΔP measured by the pressure sensor is small compared with the pressure P applied to both sides of the transducer. Accurate measurements then require the use of highly symmetric sensors [21], where symmetry is expressed by the value of the common-mode rejection ratio, CMRR = 20 log$P/\Delta P$. In addition to this, however, other sources of error (such as the finite impedance of pressure sensors [22]) are usually present which render the correction procedure ineffective.

All these problems can be globally overcome by the following dynamic calibration procedure [23] that requires two simple preliminary measurements and the availability of a reference impedance Z_{REF}.

If Z_M^{∞} denotes the impedance measured when the measuring system is occluded, ($Z_R = \infty$), Z_M^{REF} denotes the impedance measured when a known reference impedance is used ($Z_R = Z_{REF}$) and Z_M denotes the impedance measured when the subject is connected to the measuring device, then the subject's corrected impedance is given by

$$Z_R = Z_{REF} \frac{1/Z_M^{REF} - 1/Z_M^{\infty}}{1/Z_M - 1/Z_M^{\infty}} \tag{81.8}$$

TABLE 81.2 Complex Values of Calibration Impedance

	Impedance (10^5 Pa s/m^3)		
Frequency (Hz)	Real	Imaginary	Modulus
0	3.09	0.00	3.09
5	3.11	1.11	3.30
10	3.14	2.17	3.82
15	3.20	3.22	4.54
20	3.28	4.26	5.37
25	3.37	5.28	6.26
30	3.47	6.29	7.18
35	3.58	7.28	8.12
40	3.70	8.26	9.05
45	3.82	9.23	9.98
50	3.94	10.17	10.91

Z_M^{∞} and Z_M^{REF} need not be evaluated each time a new subject is connected to the device, but only when some physical change (e.g., length variations of connecting tubes, replacements of sensors, etc.) has occurred since the last time the instrument was used.

81.2.3.1 Reference Impedance

The availability of a reference impedance is recommended [24]

1. To correct the measured impedance using the procedure described earlier
2. To compare measurements obtained by different devices, different techniques, and/or different groups

For these purposes, a compact calibrator [25] has been proposed which displays the following features:

- It is simply reproducible.
- Its impedance value is not too far from typical human values.
- It is tractable from the mathematical point of view.
- Its lowest resonances fall outside the usual working frequency range.

The calibrator consists of a bundle of 30 tubelets (each 20.0 cm long and of 2.00 mm inside diameter) and its complex impedance is given in Table 81.2.

81.3 Future Perspectives

Measurements in ventilation strongly depend on the availability of reliable sensors and detectors (pressure, temperature, optical and ultrasonic beams, etc.). The use of these components has been rising steadily in the last decade and this trend is expected to continue in the near future. The foreseeable consequences of this trend on the development of dedicated instrumentation may be

1. The increasing use of transducers of various kinds in all spirometric measurements
2. The universal use of personal computers (and specialized software) to process and display data
3. The growing importance of calibration procedures, because the accurate response of a particular transducer is usually reproducible but not always theoretically predictable; on the other hand, this is fundamental to all measurement systems

Defining Terms

Plethysmography: Method employed to evaluate volume variations, with particular reference to human organs.

Pneumotachography: Methodology for measuring gas flows.

Respiratory impedance: Complex ratio between input pressure difference and induced flow at a particular frequency, when the respiratory apparatus is viewed as a complex network of linear components (resistive, inductive, capacitive).

Spirometry: The measurement of volume changes of the ventilatory system (lungs and chest wall) usually inferred from the movement of gas to and from the system.

Ventilation: Physical interaction of a body of air with the respiratory system, either through spontaneous or mechanically assisted breathing.

Meteorological Measurement

John D. Garrison
San Diego State University

Stephen B.W. Roeder
San Diego State University

82.1 Introduction

Meteorological measurements are measurements of the physical properties of the atmosphere. These measurements are made at all elevations in the troposphere and the stratosphere. For measurements made at elevations above ground or tower level, instruments can be carried aloft by balloons, rockets, or airplanes. Ground radar is used to detect the presence of water in the form of droplets or ice crystals at all elevations and the winds associated with them. Lidar (optical radar) of selected wavelengths is used to detect the presence and amount of aerosols and other constituents of the atmosphere and to determine cloud height. Instruments on satellites measure properties of the atmosphere at all elevations.

Quantities measured are temperature, pressure, humidity, wind speed, wind direction, visibility, the presence and amount of precipitation, cloud amount, cloud opacity, cloud type, cloud height, broadband solar (or shortwave) radiation, long-wave radiation, ultraviolet radiation, and net radiation, sunshine duration, turbidity, and the amounts of trace gases such as NO, NO_2, SO_2, and O_3. Some of the methods and instruments used to measure a number of these variables are discussed in this chapter in the sections on pressure, temperature, humidity and moisture content, and air pollution monitoring. Additional information of interest is in the sections on resistive sensors, inductive sensors, capacitive sensors, satellite navigation, and radiolocation, and the sections under signal processing.

Meteorological measurements are made at individual sites, at several or many sites forming a local network, or at much larger networks. Much of the emphasis now is on global networks covering the entire northern and southern hemispheres. Individuals and groups can make measurements for their own purposes or they can use data provided by the various weather services. Weather service data are stored in archives that can cover many years of measurements. The U.S. National Climatic Data Center, Asheville, NC, has archived data produced from measurements at U.S. weather stations and other National Oceanic and Atmospheric Administration (NOAA) measurement sources, including satellites. It also has non-U.S. data. These data can be purchased. The website where information concerning NOAA data can be obtained is (http://www.ncdc.noaa.gov/). The U.S. National Renewable Energy

Laboratory has information on solar radiation and wind at website (http://www.rredc.nrel.gov/). Data at websites can often be retrieved by anonymous File Transfer Protocol (FTP).

Fabrication of meteorological instruments is usually done by companies specializing in these instruments. It is generally not economically feasible for individuals to fabricate their own instruments, unless their particular application cannot use commercially available instruments. The problem usually reduces to the determination of which commercial instruments to purchase. This determination depends on cost, durability, accuracy, maintenance requirements, ease of use, and the form of the output signal. A number of instrument manufacturers and distributors market complete weather stations.

The instruments used for meteorological measurements are fabricated for use in the special environment of the atmosphere. This environment varies with the latitude and longitude of the site and the elevation above the ground and above sea level. A common requirement is that the instruments be protected from adverse conditions that can cause errors in the measurement of the meteorological variables. For proper operation, some instruments (e.g., spectroradiometers) need to be in a temperature-controlled environment. The sun's heating can cause errors. Solar radiation can cause weathering of the instruments and shorten their useful life. Moisture from precipitation or dew can affect measurements adversely and also cause weathering and corrosion of the instruments. Blowing dust or sand can cause weathering of the instruments and affect the operation of mechanical parts. Insects, birds, and ice can also affect instruments adversely. Some gaseous constituents of the atmosphere can be corrosive. Packaging of the sensors and housing of the instruments in enclosures can protect them, but this protection must not interfere with the measurement of the meteorological variable. Packaging a sensor and putting the sensor in protective housing generally increases the response time of the sensor to changes in the meteorological variable it is measuring. Solar heating can be reduced by covering the sensor, its protective packaging, or housing with a white coating. Generally, housing or enclosures used to protect the instruments should be well ventilated. Sometimes, a fan is used to draw air through the housing or enclosure to reduce solar heating and make the air more representative of the outside air. Loss of measurement caused by loss of electric power can be avoided by having backup power from batteries or motor generators.

Another common requirement of meteorological measuring instruments is that they be calibrated before installation in the field. This is usually done by the manufacturer. For some applications, it may be important that the calibrations are traceable to National Institute of Standards and Technology (NIST) standards. The calibration should be checked routinely. Some instruments are constructed to be self-calibrating.

Generally, there is no reason to measure many of the meteorological variables to high precision. The temperature, humidity, and wind, for example, can vary in relatively short distances and sometimes in relatively short times by amounts that are large compared to the accuracy of the measuring instruments. This is especially true near ground level. The exact value of a meteorological variable at a particular site has little meaning unless the density of measuring sites is very high. A mesoscale network with high density of measuring sites over a relatively small area might be of interest for ecological studies. Larger-scale or global networks have widely separated sites. For these networks, it is important to install all of the instruments in a standard manner so as to reduce the effect of local fluctuations on the variation of the meteorological variables from site to site. Usually, this is done by placing them on a level, open area away from surrounding buildings and other obstructions and at a fixed distance above the ground. The ground should be drained ground and not easily heated to high temperature by the sun. In comparing temperatures, one must be aware of the "heat island effect" of large cities; furthermore, an increase in the degree of urbanization of a given site over time may affect the interpretation of the temperature trends observed.

The current trend is toward automatic measurement of meteorological variables at unattended sites with automatic data retrieval and computer processing and analysis of the data. Large-scale networks consisting of many stations covering a large area (e.g., the Northern Hemisphere) are used for regional, national, and global weather forecasting.

82.2 Measurement of the Atmospheric Variables

82.2.1 Temperature

The mean temperature of the atmosphere for each hour of the day at a particular site has a fairly regular annual and a diurnal variation when this mean temperature is an average over many years for each hour and day of the year. The temperature at a given site and time is a superposition of the mean temperature and the fluctuations from this mean temperature caused by current cloud and wind conditions, the past history of the air mass passing over the site, and interannual variations that are not yet well understood.

More detailed sources of information on temperature measurement include Refs. [1–5]. Common methods of measuring atmospheric temperature include electric resistance thermometer, thermistors, bimetallic strips, and liquid in glass thermometer.

82.2.1.1 Electric Resistance Thermometer

The variation of the resistance of a metal with temperature is used to cause a variation in the current passing through the resistance or the voltage across it. The electric circuit used for the measurement of temperature can utilize a constant current source, and temperature is determined from the voltage across the resistance after the circuit is calibrated. Alternatively, a constant voltage source can be used with the current through the resistance determining the temperature. Once the instrument is calibrated, it is generally expected to keep its calibration as long as electric power is supplied to the instrument. Commonly, platinum electric resistance thermometer (RTD) thermometers are made of a fixed length of fine platinum wire or a thin platinum film on an insulating substrate. The variation of the resistance as a function of temperature is approximately linear over the range of temperature found in meteorological measurements. The quadratic correction term is quite small. The accuracy and reproducibility of the measurements and the ease of using an electric signal for transmission of data from remote unmanned sites make electric resistance thermometers desirable for meteorological applications. Platinum is the best metal to use. With careful calibration and good circuit design, platinum resistance thermometers can measure temperature to a small fraction of a degree, much better than the accuracy needed for meteorological measurements.

82.2.1.2 Thermistors

Thermistors usually consist of an inexpensive mixture of oxides of the transition metals. The log of their resistance varies inversely with temperature. The change in resistance with temperature can be 10^3–10^6 times that of a platinum resistance thermometer. Their change in resistance with temperature is used to determine temperature in the same manner as metal resistance thermometers. They are somewhat lower in cost and are somewhat less stable than platinum resistance thermometers.

82.2.1.3 Bimetallic Strips

Bimetallic strips are normally used for casual monitoring of inside and outside temperatures at dwellings and office buildings and for heating and cooling controls. The accuracy is generally about ±1°C. They are low in cost.

82.2.1.4 Liquid in Glass Thermometer

These are a well-known method of measuring temperature. They are normally used for casual monitoring of inside and outside temperatures at dwellings or office buildings. These thermometers are more difficult to read than meter or dial readings of temperature, do not lend themselves to electric transmission of their readings, and are easily broken. Their cost can be low.

82.2.2 Pressure

One standard atmosphere of pressure corresponds to 1.01325×10^5 Pa (N/m^2) (14.6960 pounds per square inch, 1.01325 bars, 1013.25 mbars, 760.00 mm Hg, or 29.920 in. Hg). This is approximately

the mean atmospheric pressure at sea level. Atmospheric pressure at sea level usually does not deviate more than ±5% from one standard atmosphere. Atmospheric pressure decreases with altitude. Altitude measurements in airplanes are based on air pressure measuring instruments called altimeters. At about 5500 m (18,000 ft), the atmospheric pressure is half its sea level value. The following instruments are used to measure atmospheric pressure.

82.2.2.1 Mercury Manometer

Originally, barometric pressure was measured with a mercury manometer. This is a tube, about 1 m in length, filled with mercury and inverted into an open dish of mercury. The height of the column of mercury that the external pressure maintains in the tube is a measure of the external air pressure. Hence, one standard atmosphere is 760 mm Hg. While accurate, this device is awkward and has been replaced for general use.

82.2.2.2 Aneroid Barometer

It consists of a partially evacuated chamber that can expand or contract in response to changing external pressure. The evacuated chamber is often a series of bellows, so that the expansion and contraction occurs in one dimension. Basic aneroid barometers, which are still in use, have a mechanical linkage to a pointer giving a reading on a dial calibrated to read air pressure. High-quality mechanical barometers can achieve an accuracy of 0.1% of full scale. Aneroid barometers can also give electronic readout and eliminate the mechanical linkage; this is more the standard for serious meteorological measurements. In one method, a magnet attached to the free end of the bellows is in proximity to a Hall effect probe. The Hall probe output is proportional to the distance between the magnet and the Hall probe.

Barometric pressure is also measured with an aneroid type of device that consists of a rigid cylindrical chamber with a flexible diaphragm at its end. A capacitor is created by mounting one fixed plate close to the diaphragm and a second plate mounted on the diaphragm. As the diaphragm expands or contracts, the capacitance changes. Calibration determines the pressure associated with each value of capacitance. A range of 800 to 1060 mbars with an accuracy of ±0.3 mbars for ground-based measurements is typical. Setra Corporation produces this type of instrument for the U.S. National Weather Service ASOS network, the latter produced by AAI Systems Management Incorporated. The ASOS network is discussed later. Measurement of pressure is also discussed elsewhere in this chapter.

82.2.3 Humidity

Instruments that determine the density or pressure of water in vapor form in the atmosphere generally measure either relative humidity or dew-point temperature. The pressure of water vapor just above a liquid water surface when the vapor is in equilibrium with the liquid water is the saturated vapor pressure of the water. This saturated vapor pressure increases with the temperature and equals atmospheric pressure at the boiling temperature of water. Relative humidity is the ratio of the vapor pressure in air to the saturated vapor pressure at the temperature of the air. Relative humidity is usually expressed in percent, which is this ratio times 100. The dew-point temperature is the temperature to which the air must be lowered, so the vapor pressure in the air is the saturated vapor pressure with the relative humidity at 100%. Knowledge of water vapor density is used in weather prediction and in global climate modeling. It also affects light transmission through the atmosphere. Relative humidity is an important meterological variable. The temperature dew-point difference is an indicator of the likelihood of fog formation and can be used to estimate the height of clouds. More detailed sources of information on humidity measurement include Refs. [6–9]. Three common methods of measuring the vapor density in the atmosphere are given in the following sections.

82.2.3.1 Chilled Mirror Method

Chilled mirror instruments for measuring the dew-point temperature are not sold by most instrument companies. A chilled mirror instrument developed by Technical Services Laboratory is used in the U.S. National Weather Service ASOS network discussed later. It has a mirror cooled by a solid-state

thermoelectric cooler (using the Peltier effect) until water vapor in the air just starts condensing on the mirror. This condensation is detected using a laser beam reflecting from the mirror. When the reflected beam is first affected by the condensed water vapor, the temperature of the mirror is the dew-point temperature. The mirror temperature is controlled to remain at the dew-point temperature by an optic bridge feedback loop. The mirror is a nickel chromium surface plated on a copper block. The temperature of the block is measured to ±0.02% tolerance by a platinum resistance thermometer imbedded in the block. An identical platinum resistance thermometer measures ambient air temperature. Outside air is drawn through the protective enclosure surrounding the instrument by a fan, so that the effect of solar heating on the measured values of the dew-point temperature and ambient temperature is negligible and so that outside air is tested. The dew-point temperature and ambient temperature are measured between −60 °C and +60 °C to an accuracy of 0.5 °C rms. Dew-point errors are somewhat larger below 0 °C. To avoid errors that might arise from deterioration of the reflective properties of the mirror, the mirror should be inspected periodically, particularly in dirty or salty environments. This method is of higher cost than other methods of measuring the amount of water vapor in the atmosphere.

82.2.3.2 Thin Film Polymer Capacitance Method

The capacitance is formed with a thin polymer film as dielectric placed between two vapor-permeable electrodes. Water vapor from the air diffuses into the polymer, changing the dielectric constant of the dielectric and thus the capacitance. The capacitance can be measured electrically by comparison to fixed capacitance reference standards. The measured value of the capacitance is related to the relative humidity by calibration. Instruments using these capacitive sensors can measure relative humidity between 0% and 100% at temperatures between about −40 °C and +60 °C to about ±2% of relative humidity. These sensors can be made very small for incorporation into integrated circuits on silicon chips [9]. They are low in cost. Usually, instruments measuring humidity also measure temperature separately. The circuits used to measure relative humidity using a thin polymer capacitance yield an electric output signal (often 0–5 V), which lends itself to remote transmission of the relative humidity.

82.2.3.3 Psychrometric Method

Errors are introduced if the water is contaminated, if the water level in the reservoir supplying water to the wick becomes low, or if the reservoir runs dry. In extremely dry environments, it can be difficult to keep the wick wet, while salty environments can change the wet bulb reading. Accuracy is affected by air speed past the wet bulb. Because of these disadvantages, psychrometers have generally been replaced by more convenient methods of measuring humidity.

82.2.4 Wind Speed, Wind Direction, and Wind Shear

82.2.4.1 Anemometer

Weather stations commonly employ a three-cup anemometer. This consists of a vertical axis rotating collar with three vanes in the form of cups. The rotation speed is directly proportional to wind speed. Figure 82.1 shows an instrument of this type. An alternative to the cup anemometer is a propeller anemometer in which the wind causes a propeller to rotate. There are several ways to obtain an electrical signal indicating the speed: a magnet attached to the rotating shaft can induce a sinusoidal electrical impulse in a pickup coil; a Hall effect sensor can be used; or the rotating shaft can interrupt a light beam, generating an electric pulse in a photodetector. Rotating anemometers can measure wind velocities from close to 0 up to 70 m/s (150 mph).

82.2.4.2 Ultrasonic Wind Sensor

This sensor has no moving parts. Wind speed determination is as follows. An ultrasonic pulse emitted by a transducer is received by a nearby detector and the transit time calculated. Next, the transit time is

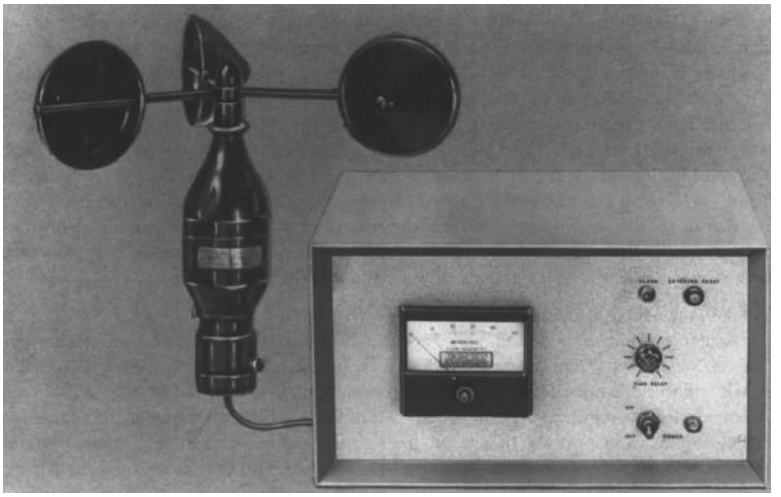

FIGURE 82.1 A cup-type anemometer for measuring wind speed. (Courtesy of Kahl Scientific Instrument Corporation.)

measured for the return path. In the absence of wind, the transit times are equal; but in the presence of wind, the wind component along the direction between the transmitter and receiver affects the transit time. Three such pairs, mounted 120° apart, enable calculation of both the wind speed and direction. Heaters in the transducer heads minimize problems with ice and snow buildup. The absence of moving parts eliminates the need for periodic maintenance.

82.2.4.3 Wind Direction

Wind direction sensors are generally some variant of the familiar weather vane. Sensitivity is maintained by constructing the weather vane to rotate on bearings with minimal resistance. Electronic readout can be achieved using a potentiometer (a "wiper" contact connected to the vane slides over a wire-wound resistor). The resistance between the contact and one end of the wire resistor indicates the position of the vane. Alternative methods of readout include optical and magnetic position sensors. Positional accuracy is ±5%.

82.2.4.4 Combination Wind Speed and Direction Sensor

A combination wind speed and direction sensor can be made in which a propeller anemometer is mounted on a weather vane. The vane keeps the propeller device pointed into the wind. Alternatively, two propeller anemometers, rigidly mounted in a mutually perpendicular arrangement, can be used to determine direction and magnitude of the horizontal wind simultaneously. Rotating anemometers and weather vanes are susceptible to ice and snow buildup and can be purchased with heaters. They need periodic maintenance.

82.2.4.5 Wind Shear

Wind shear occurs when wind direction and/or strength changes significantly over a short distance. This can occur in horizontal or vertical directions or sometimes in both. Measurement of wind shear conditions is particularly important at airports. Wind shear is determined by comparing readings made at the center of the airfield with measurements made at the periphery. An automated system to perform this function, entitled Low Level Wind Shear Alert System (LLWAS), is found at some airports. Wind shear can also be detected by Doppler radar. Doppler radar used by the U.S. National Weather Service is discussed later.

82.2.5 Precipitation

Precipitation measuring instrumentation includes devices that measure the presence of precipitation (precipitation sensors), those that determine the quantity of precipitation, those that measure rate of precipitation, and those that measure both quantity and rate.

82.2.5.1 Precipitation Presence Sensors

These sensors usually consist of two electric contacts in close proximity. Moisture causes electric conduction that is detected by a circuit monitoring conductance. A typical application consists of a circuit board consisting of a grid of two arrays of strips separated by small gaps. If the surface of the detector is heated, then only current precipitation will be detected and dew will not form to affect the measurement.

82.2.5.2 Rain Gages

These instruments measure amount of rainfall. A simple rain gage can consist of a cylinder, a funnel, and an inner collection tube of much smaller diameter than the funnel for amplification of the height of rain accumulation. The height of the water column in the inner tube is converted to total rainfall. Typical graduations on the tube enable determining rain accumulation to 0.025 cm (0.01 in.) of rain.

A tipping-bucket rain gage enables the measurement of both volume and rate of rainfall. A large funnel concentrates the precipitation, which is directed into one of two small buckets. When that bucket fills, it tips out of the way and empties, closing a switch to record the event, and another empty bucket moves into its place. Typical tipping-bucket gages respond to each 0.025 cm (0.01 in.) of rain. In conditions of snow and freezing rain, tipping-bucket rain gages can be equipped with heaters on the funnel to reduce snow and ice to water. The internal components are also heated to prevent refreezing. Reported accuracy for tipping-bucket rain gages is ±0.5% at 1.2 cm/h (0.5 in./h). Frise Engineering Company produces a tipping-bucket rain gage used in the ASOS network discussed later.

Highest accuracy rain gages that collect and concentrate precipitation should have their collection surfaces made of a plastic with a low surface tension for water. This minimizes losses from surface wetting.

Rain gages exist that do not rely on collection methods. Optical rain gages utilize an infrared beam. Drops falling through this beam induce irregularities in the beam that can be interpreted in terms of precipitation rate. This type of sensor is used for the precipitation identification or present weather sensor used in the ASOS network discussed later.

82.2.6 Solar Radiation

The mean annual intensity of solar radiation above the atmosphere (extraterrestrial solar radiation) continues to be measured to obtain a more precise value and to look for variations in the sun's energy output. It is called the solar constant. The solar constant is close to 1367 W/m^2. The intensity of solar radiation above the atmosphere varies approximately sinusoidally over the year with amplitude of close to 3.3% of the solar constant and a maximum near the first of January. This variation arises from the variation of the distance of the Earth from the sun. The sun has a spectral distribution that is roughly that of a blackbody at 5777 K with a peak of the spectrum at a wavelength of about 500 nm. Solar radiation is attenuated by scattering and absorption in the atmosphere. Attenuation is greater at wavelengths corresponding to absorption bands of certain gases in the atmosphere. On a clear day near noon, the solar intensity at the Earth's surface can be as high as 1000 W/m^2. Figure 82.2 shows a typical sea level solar spectrum with the sun about 48° away from the vertical (see, for example, Refs. [10,11]). This is called an air mass 1.5 spectrum, because the distance the radiation travels through the atmosphere is 1.5 times the distance when the sun is vertical. About 99% of the spectrum is in the range of wavelengths shown by the figure. Measurements of the solar constant and the solar spectrum are scientific measurements made with specialized instruments. Additional information can be found in Iqbal [11] and Coulson [12].

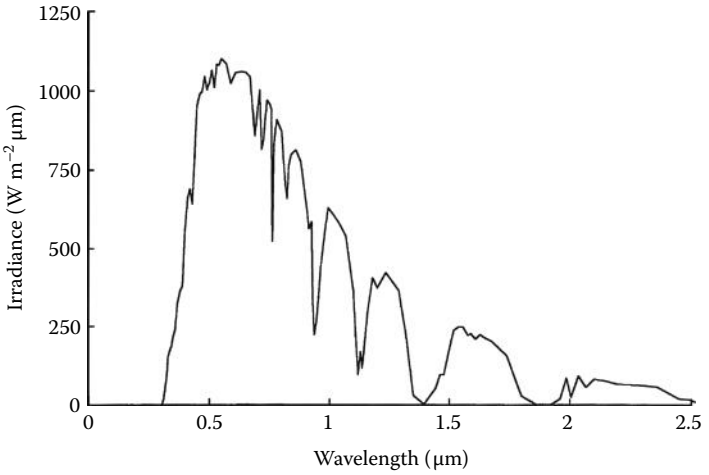

FIGURE 82.2 The intensity of solar radiation as a function of wavelength for a path length through the atmosphere of 1.5 times the vertical path length. The dips in the spectrum are molecular absorption bands.

Solar radiation instruments for general use in the field measure direct radiation from the sun, total or global radiation coming from the sky hemisphere, and diffuse or sky radiation (global radiation with the direct radiation removed). Solar radiation measuring instruments can be broadband instruments that measure the combined solar intensity (irradiance) at all wavelengths, or they can be spectrally selective instruments that measure the intensity at different wavelengths or in different wavelength bands. Only the much more common broadband instruments are discussed here. The instruments used for everyday measurement are field instruments. Field instruments are first class if they are of higher quality and provide greater accuracy and reliability (at higher cost).

Direct radiation is radiation coming directly from the sun without scattering in the atmosphere. Instruments measuring direct solar radiation usually include radiation coming from the sky out to an angular distance of about 3° away from the center of the sun's disk. They are called pyrheliometers. The radiation coming from clear sky near the sun, rather than from the solar disk, is the circumsolar radiation. This radiation can be subtracted from the pyrheliometer measurement for a more precise determination of direct radiation. This correction is often not made for routine measurements. The clear sky correction is calculated using the angular distribution of the intensity of the circumsolar radiation [13,14].

Instruments measuring global radiation are installed in a level position with a plane sensor facing up toward the sky. These instruments measure solar radiation coming from the whole sky hemisphere. They are called pyranometers. Global radiation measuring instruments should be sited in a level elevated area with no obstructions obscuring the sky hemisphere.

Diffuse radiation is the radiation coming from the sky hemisphere with the direct radiation subtracted. Pyranometers are used for measuring diffuse solar radiation and should be mounted in the same manner as pyranometers used for measurement of global radiation. They have an occulting (shade) disk or shadow band to prevent direct solar radiation from reaching the radiation sensor. The measurement of diffuse radiation involves correcting the pyranometer measurement for the part of the sky radiation shielded from the sensor by the occulting disk or shadow band. For clear skies, the occulting disk correction is calculated using the angular distribution of intensity of the circumsolar radiation. Corrections for partially cloudy and cloudy skies depend on the particular cloud conditions. Corrections for the shadow band are often determined by temporarily replacing the shadow band with an occulting disk when the sky is clear and when it is overcast. Corrections for measurements under other sky conditions can be determined by interpolation. The shadow band correction is discussed by LeBaron et al. [15]. The occulting disk

must have a tracking system to make the disk follow the sun over the sky. The shadow band removes solar radiation received from a narrow swath of the sky along the path the sun follows during the day. The shadow band must be adjusted regularly during the year as the path of the sun changes over the seasons. The more common solar radiation measuring instruments include the pyranometer and pyrheliometer.

82.2.6.1 Pyranometer

The sensor is usually a thermopile, consisting of a number of thermocouples in series, with alternate junctions heated by the sun. The unheated junctions are near ambient temperature. This is sometimes arranged by putting the unheated junctions in thermal contact with a white surface. Heating by the sun is accomplished by placing the junctions in contact with a matte black surface of high heat conductivity or by a black coating on the junctions. The blackened surface has a constant high solar absorptance (usually ~99%) over the solar spectrum. A constant high solar absorptance over the solar spectrum is important. The solar spectrum at the surface of the Earth varies with the time of day and year and the amount of clouds, because of the spectrally dependent scattering and absorption of solar radiation by the atmosphere. An absorbing surface whose absorption of solar radiation varies with wavelength will cause the sensor to have a different sensitivity for different wavelengths of the solar spectrum. Some less expensive pyranometers use a silicon photovoltaic sensor (solar cell) to measure solar radiation. These sensors have zero sensitivity above about 1.2 μm and the spectral response below 1.2 μm is not constant. This limits the accuracy of measurements of solar intensity with photovoltaic sensors. Instruments with a thermopile sensor can use a combination of thermopiles and resistors to compensate for the variation of the output of a single thermopile with temperature. The hemispherical windows of pyranometers are usually made of a special glass which transmits solar radiation of wavelengths between about 0.3 and 2.8 μm. This includes ~99% of the solar intensity. The absorbing surface must have a cosine response as a function of angle away from the normal to the surface (Lambert law response), and a flat response as a function of azimuth around the normal to the absorbing surface, for the global radiation to be measured correctly. The degree to which the pyranometer response is linear follows the cosine law, is temperature-, spectrum-, and azimuthally independent, and determines whether the instrument is a first-class instrument. Figure 82.3 shows a Kipp and Zonen (The Netherlands) first-class pyranometer.

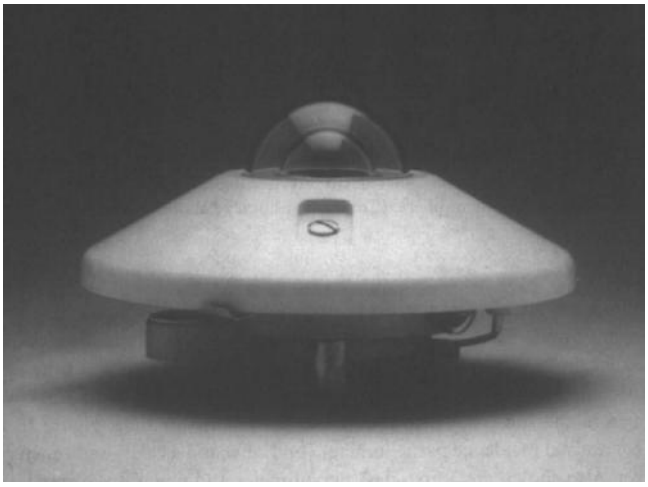

FIGURE 82.3 A class 1 pyranometer used for the measurement of global and diffuse solar radiation. (Courtesy of Kipp & Zonen Division of Enraf-Nonius Corporation.)

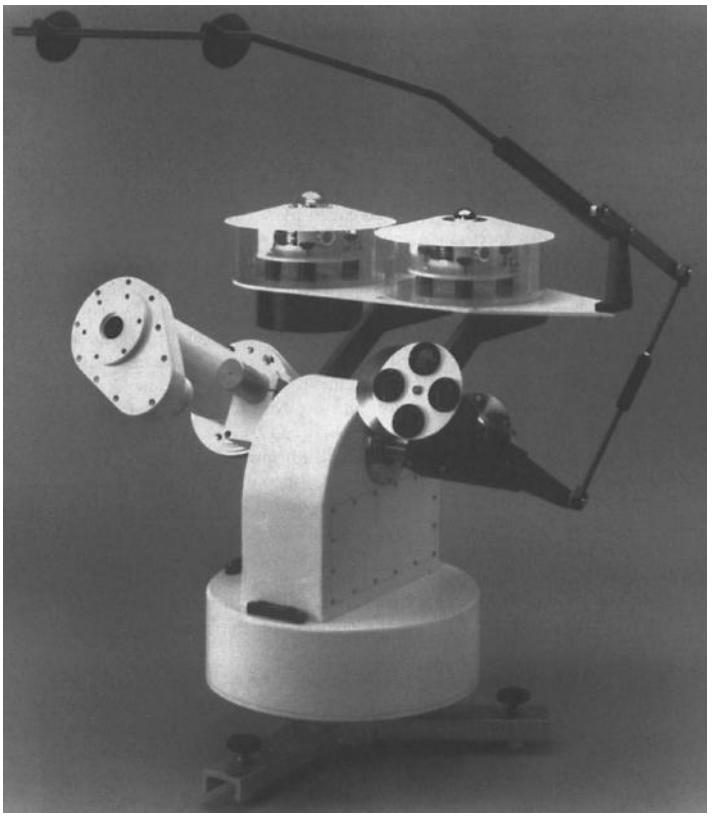

FIGURE 82.4 An automatic solar tracker with normal incidence pyrheliometer and cavity radiometer mounted on it. The tracker is coupled to two shade disks that shield direct sunlight from a first-class pyranometer and precision infrared radiometer facing the sky hemisphere. (Courtesy of Eppley Laboratories.)

82.2.6.2 Pyrheliometer

The field pyrheliometers usually have temperature-compensated thermopile sensors with flat spectral response and linear output. The sensor is placed at the bottom of an internally blackened, diaphragmed, collimator tube that limits the angular acceptance for solar radiation to be in the range of about 5° or 6° total acceptance angle. The pyrheliometer is mounted on an equatorial mount tracker that keeps the direct radiation from the sun parallel to the axis of the collimator tube. Figure 82.4 shows an Eppley Laboratory (United States) normal incidence pyrheliometer (on right) and a cavity radiometer (on left) mounted on a solar tracker. Also shown are a first-class pyranometer and precision infrared radiometer shielded from direct radiation from the sun by shade disks coupled to the tracker.

82.2.7 Visibility

Visibility in meteorology is a measure of how far one can see through the atmosphere.

82.2.7.1 Visibility Sensors

Measurement of forward scattering of light by aerosols in a given sample volume is used to determine visibility. A pulsed beam of near-infrared light (typically 850–880 nm wavelength) generated by an infrared-emitting diode is projected into the ambient air. A detector (usually a silicon photodiode), placed between 1 and 2 m away and oriented between 30° and 40° off the axis of the pulsed beam, samples the scattered light. The intensity of scattering is proportional to the atmospheric extinction coefficient.

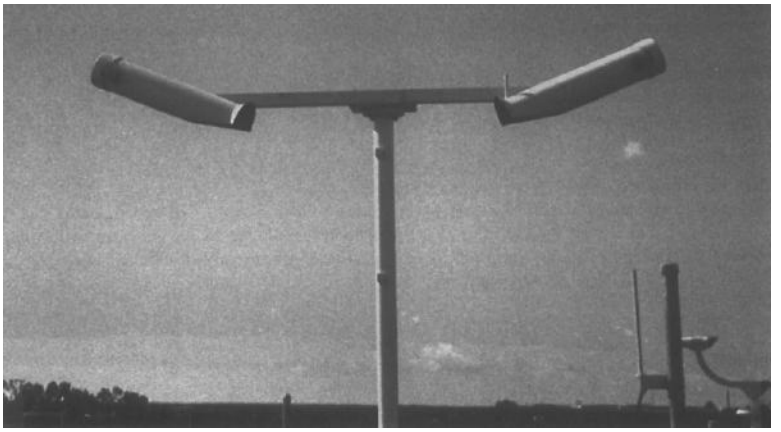

FIGURE 82.5 The xenon flash instrument that determines atmospheric visibility at an ASOS system station. This system is produced by AAI Systems Management Incorporation.

The extinction coefficient (k) is related to visual range (VR) by VR = 5/k (km). VR measurable by such a system lie between about 0.3 and 60 km. Figure 82.5 shows the visibility sensor used in the ASOS network. A xenon flash lamp source is used with this system.

82.2.7.2 Transmissometers

These measure the attenuation of a light beam to determine visibility.

82.2.8 Lidar Measurements

Lidar is optical radar in which a laser emits pulses of electromagnetic radiation. Scattered radiation that returns to an optimally tuned detector at the laser site for observation is called echos. The time from emission of the pulse to return of the echo determines the distance of the scatterer. The echos are sampled at all times between pulses, and thus all distances up to the maximum range. This provides information about the atmosphere along the pulse path. The strength of the echo is connected with the density, size, and shape of the scattering particles. Laser pulses are linearly polarized. Spherical scatterers return echos that have the same linear polarization. Nonspherical scatterers depolarize the echos. Thus, polarization of the echo also provides information concerning the scatterers. Using high spectral resolution lidar (HSRL), the scattering by air molecules can be separated from the scattering by aerosols. Differential absorption lidar (DIAL) measures the concentration of gaseous species in the atmosphere. Stephens [16] discusses the HSRL and DIAL methods. Zhao et al. [17] present an application of the DIAL method to the determination of O_3 concentration in the atmosphere. Because of their high power output, ruby, dye, neodymium, yttrium–aluminum–garnet (YAG), and CO_2 lasers are commonly used for lidar. The use of lidars in the observation of aerosols injected into the stratosphere by volcanic eruption, and their subsequent decay has become quite common (see Post et al. [18] and Jager [19] and other articles in the same journal issue).

82.2.9 Clouds

82.2.9.1 Observer Estimation

For many years, observers at weather stations have estimated the amount, type, and sometimes the opacity of low clouds, middle clouds, and high clouds. Estimation is usually every hour or similar period with the estimate in tenths or eighths (octa) of the sky covered. Satellite, radar, and ceilometer data are replacing observer estimation. Observer estimates have been archived.

Note: T, Temperature; P, pressure, RH, relative humidity; W, wind; PR, precipitation; SOL, solar radiation; VIS, visibility; LID, lidar; CEIL, ceilometer; RADS, radiosonde.

[a] Complete weather station available.

82.2.9.2 Ceilometers

Ceilometers measure the altitude of clouds. Most ceilometers are based on lidar technology using an infrared pulsed laser diode, usually GaAs. Laser pulses are reflected back (echos) to a receiver, usually a Si diode detector. The round-trip time is converted into cloud height. Common ceilometers can measure cloud base altitudes to 4,000 m (12,000 ft). Recent instruments developed by Vaisala can measure cloud bases up to 23,000 m (75,000 ft) with an error of ±1%. The Vaisala ceilometer is used in the ASOS network discussed later. Maintenance includes cleaning of the window. Heaters and blowers respond to automatic sensing units to clear precipitation from the window and control instrument temperature.

Companies producing and marketing meteorological instruments are presented in Table 82.1. For information on additional companies marketing meteorological instruments in the United States, see *Thomas Register of American manufacturer's* and *Thomas Register Catalog File* found in most major libraries. For manufacturers in other countries, search library catalog files under "manufacturers."

82.3 U.S. Weather Service Facilities

The U.S. National Weather Service, the U.S. Federal Aviation Administration, and the U.S. Department of Defense have joined in an upgrade of weather instrumentation and analysis for U.S. weather stations. Other national weather services are upgrading their facilities. The new U.S. National Weather Service system has four components to obtain weather data throughout the United States and its possessions:

1. The Automated Surface Observing Systems (ASOS): These systems, produced by AAI Systems Management Incorporated, are installed at over 850 sites. Each system usually measures visibility, surface temperature, dew-point temperature, pressure, wind speed and direction, visibility, cloud height, precipitation identification, freezing rain, and precipitation accumulation. Instruments used for each ASOS site are discussed earlier with other meteorological measuring instruments. Figure 82.6 shows the arrangement of instruments at an ASOS site.
2. Doppler weather surveillance radar (NEXRAD—WSR-88D): Doppler radar are produced by Lockheed-Martin Corporation and installed at ~160 sites in the U.S. Doppler radar surveys the weather out to about 300 km from the radar. The standard radar scans angles above the horizon up to about 6° in six ~1° intervals with a 360° azimuth. Rain scans go up to about 20°. Radar echos are reflection of the pulsed radar microwave signal from water drops in the form of rain or cloud. Ice crystals and snow reflect radar pulses with lower echo strength. Doppler radar can detect short-lived, possibly catastrophic events such as tornados, downbursts, and flash floods in real time. The Doppler shift of the echo determines the radial component of the wind velocity at the height and distance of the source of the reflected echo. The strength of the echo provides information on the precipitation rate. Powerful computers and sophisticated computer programs are used to analyze the radar signals. Additional discussion of the use of radar for weather observations can be found in Stephens [16]. NEXRAD is discussed in Refs. [20–23], for example.
3. Radiosonde upper air sounding: The northern hemisphere has a network of about 700 radiosonde sites, including the U.S. network, where soundings are generally made twice daily. The northern hemisphere is largely decoupled from the southern hemisphere for weather development. Radiosondes provide information on wind velocity, temperature, and humidity at all elevations up to 30–40 km. A temperature sensor, humidity sensor, and pressure sensor are carried aloft by balloon at 0000 and 1200 UTC (±1 h). The wind velocity at different altitudes is measured by determining the radiosonde position at all times during the flight. The horizontal position of the radiosonde can be obtained by OMEGA, LORAN, or VLF global positioning systems. Additional information on global positioning is found in Section 76.3 (Chapter 76 of this book) on satellite navigation and radiolocation. Pressure can indicate the altitude of the radiosonde. Radar or GPS can measure the radiosonde position in three dimensions. Radiotheodolites can track the radiosonde to receive the data transmitted by radio transmitter. The radiosonde manufactured by Viz

FIGURE 82.6 A view of an ASOS system sited at an airport near San Diego. The instrument of Figure 82.5 is seen in the foreground. A stand for the freezing rain sensor is not used. The next instrument is the ceilometer. Behind that is a metal box containing connections to the sensors and instruments to transmit the data to a remote collection and processing station. Along the same line of instruments beyond this is the precipitation identification or present weather sensor. This is followed along the same line by the sensor measuring ambient and dewpoint temperatures and a tipping-bucket rain gage. To the north of the line of instruments is a pole with a cup anemometer, weather vane, flashing red lights, and lightning rod at the top.

Manufacturing Co. called Bsonde is used by the U.S. National Weather Service. The instruments are mounted on a lightweight white styrofoam container. The temperature sensor is a thin, 50 mm long rod thermistor painted white to minimize heating by solar radiation. It is mounted outside the container. It measures temperature to ±0.5 °C. The container has an air flow duct for ventilation of the relative humidity sensor mounted inside. The relative humidity sensor consists of an insulating strip coated with a film of carbon that measures relative humidity from 0% to 100% to ±5%. The pressure sensor is a nickel, C-span aneroid pressure sensor coupled mechanically to a 180 contact baroswitch providing the output pressure signal. Pressure is measured from 1060 to 5 mb with an accuracy of ±0.5 mb. Sensor signals are sent to the receiving station by an amplitude modulated transmitter operating from 1660 to 1700 MHz. The Vaisala Inc. radiosonde sensors used by the U.S. National Weather Service differ from Bsonde by use of a capacitance temperature sensor, a capacitance with polymer dielectric humidity sensor, and a capacitive aneroid pressure sensor.

4. Satellite remote sensing: Meteorological variables are deduced from measurements of the electromagnetic radiation coming from the atmosphere and the surface of the Earth using satellite-based sensors. Usually, three or more different detector wavelength bands are used. The interpretation is difficult because the electromagnetic radiation can come from many levels of the atmosphere or the Earth's surface, all at different temperatures, and may have undergone multiple scattering in the atmosphere and Earth reflection. The energy coming from the atmosphere and the Earth's

surface is mostly reflected and scattered solar radiation for wavelengths up to about 4 μm. Longer wavelength energy is mostly associated with thermal emission from the Earth and its atmosphere. Thermal emission from the atmosphere and the surface of the Earth consists of overlapping blackbody spectra of different temperatures. Absorption spectra characteristic of various gases in the atmosphere and their temperatures are superimposed on the overlapping blackbody spectra. Visible wavelengths from about 0.4 to 0.7 μm are useful for determining cloud coverage and cloud type. Infrared wavelengths from about 6 to 7 μm can be used to determine water vapor density. Infrared in the range from about 10 to 12 μm can be used to look at high clouds. It is also useful for night observation. Satellite measurements show the motion and development of the clouds and storm systems. More detailed discussion is available [16,24–27].

Robotics and Sensors: Environmental Applications

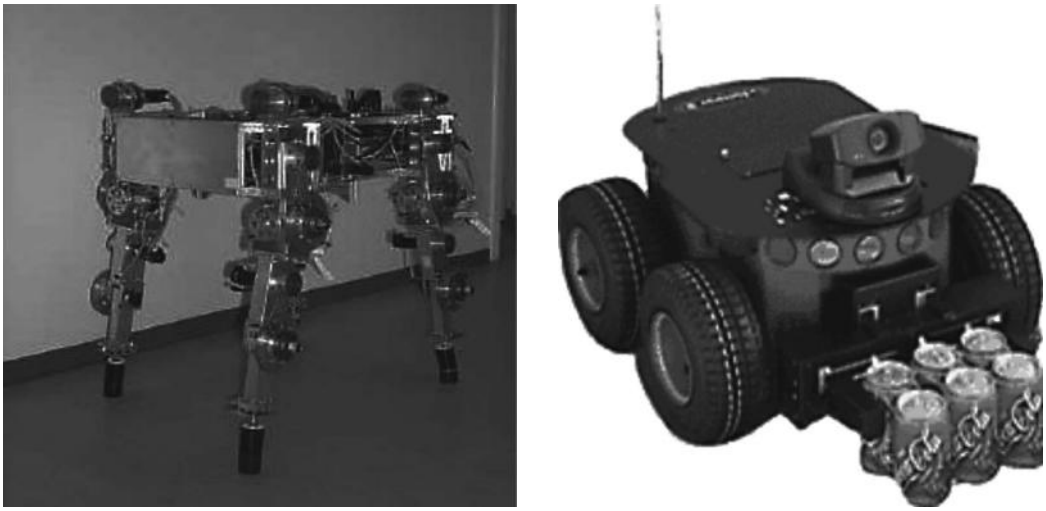
Gourab Sen Gupta
Massey University

83.1 Introduction

A robot is an automatically operated machine that replaces human effort, though it may not resemble human beings in appearance or perform functions in a humanlike manner. It is capable of being programmed in advance and is designed to execute one or more tasks repeatedly, with speed and precision.

Robots have changed the way we work, play, live, and unfortunately fight wars. Robots invaded the workplace many decades ago, initially for factory automation. They are increasing their presence in the home at a very rapid pace, primarily for assisted living. Wars are being fought using robots on the ground, above and below the waters, and in the air. In the next decade, the world will witness the largest growth of robots in the service industry. From the days of industrial automation using monstrous robots, the world has advanced to micro and nano robots traversing the veins of a human body to deliver drugs.

What makes the robots so capable and versatile as they are today? Will they ever be able to attain the full functionality, intelligence, and versatility of human beings? Or is it a wishful thinking? What will be the breakthrough technology that will enable the robots to make that quantum jump in their capabilities?



(a) (b)

FIGURE 83.1 Robots employing different types of locomotion methods: (a) a quadruped robot and (b) a wheeled robot.

For successful completion of tasks, robots have to perceive the world around them, the workspace in which they operate. At the heart of this perception are the inputs from a gamut of sensors. Accurate measurement of physical parameters and fusion of sensory data has a profound influence on the accuracy of the perception model. While a lot of energy and resources are still being expended for research into robot locomotion and actuators for motion, it is the advancement in sensors and measurement technology that will catapult the robots to the next level of versatility and acceptance. Miniaturization of sensors and precision measurement will be the flavor of research in the next decade.

Robots come in many different forms and sizes. Based on the method used for the locomotion of a robot, it can be classified as wheeled robot (including track robots) or legged robot. Legged robots may be two-legged humanoid or multilegged. Hybrid robots combine the aspects of wheeled and legged locomotion. Yet there are others types which cannot be classified as either wheeled or legged such as hovercrafts, underwater floating robots, and robots employing snakelike movements. A few different types of robots are shown in Figure 83.1.

Sensors are a very important element of a closed-loop robot control system (Figure 83.2). Sensors provide the robot the "awareness" of its surroundings—what's ahead, around, and "out there"? Sensors augment the capabilities of a robot to interact with the environment. For example, a robot lawn mower can "see" grass in its workspace. Sensors also give the robots the capability to goal seek such as by finding colored objects. Robots also need to employ sensors for protection and self-preservation. Localization in structured and unstructured environments is an important task of an autonomous robot for which sensors are required.

Sensors and measurement techniques increase the versatility of robots. Nature is a rich source of inspiration for the development of sensing and measurement systems. Sensors can be categorized based on nature—exteroceptive, proprioceptive, and interoceptive sensors.

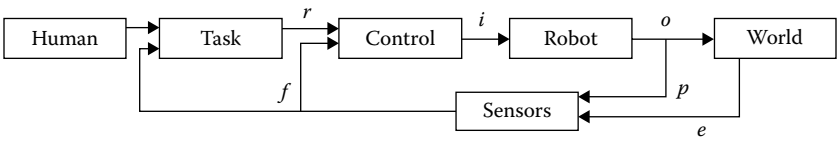


FIGURE 83.2 System blocks of a generic closed-loop control system of a robot.

Exteroceptive sensors deal with the external world and are used to find where is something, how does it look, and how big is it? Common exteroceptive sensors are camera, laser rangefinder, haptic sensors, etc. *Proprioceptive sensors* deal with self, for example, is the robot perfectly horizontal, where is it, how much is the joint bent, which way it is facing, how fast is it turning, etc. Common exteroceptive sensors are inclinometer, GPS, encoders, flex sensors, compass, and gyroscope. *Interoceptive sensors* deal with self, although without conscious perception, such as the amount of battery charge left for which a voltmeter may be used as the measurement device.

As shown in Figure 83.2, outputs from exteroceptive sensors (e) and proprioceptive sensors (p) are frequently combined to generate the feedback signal (f) for the robot controller. The feedback signal from the sensors is compared with the reference signal (r) in the control block to generate the inputs (i) for the robot.

83.2 Sensors for General Robotic Systems

Whole gamuts of sensors are used in robotic systems, from simple to very complex and sophisticated. These are detailed in this section.

83.2.1 Position and Velocity Encoders

Encoders measure displacement, both rotary and linear, and are used in odometry of a robot. The position information may also be used to calculate velocities. An encoder is an electromechanical device that can monitor position, motion, or direction of motion. It can be constructed with sensing mechanisms which can be mechanical, magnetic, or optical. There are two basic kinds of encoder information: absolute and incremental. Absolute encoders provide a code, which indicates the exact position of the shaft/wheel. Incremental encoders measure how far the wheel has moved and are normally used for measuring robot wheel velocity.

83.2.1.1 Magnetic Encoders

A magnetic encoder consists of a rotating gear (disk) made of ferrous metal and a magnetic pickup that contains a permanent magnet and the sensing element. The gear, which is mounted on the rotating shaft, has precisely machined teeth that provide the code pattern. As the disk rotates, these teeth disturb the magnetic flux emitted by the permanent magnet, causing the flux field to expand and collapse. These changes in the field are sensed by the sensing element, which generates a corresponding digital or pulse signal output. Two kinds of magnetic pickups exist—*Hall effect pickups* use a semiconducting sensing element that relies on the Hall effect to generate a pulse for every gear tooth that passes the pickup; *variable reluctance pickups* use a simple coil of wire in the magnetic field. As the gear teeth pass by the pickup and disturb the flux, they cause a change in the reluctance of the gear/magnet system. This induces a voltage pulse in the sensing coil that is proportional to the rate of flux change. Figure 83.3 shows the construction of a magnetic encoder.

83.2.1.2 Optical Encoders

The most popular type of encoder is the optical encoder, which consists of a rotating disk, a light source, and a photo detector (light sensor) as shown in Figure 83.4. The disk, which is mounted on the rotating shaft, has coded patterns of opaque and transparent sectors. As the disk rotates, these patterns interrupt the light emitted onto the photo detector, generating a digital or pulse signal output.

The encoding disk is made from glass for high-resolution applications (11 to >16 bits) and plastic (Mylar) or metal for applications requiring more rugged construction (resolution of 8 to 10 bits).

83.2.2 Flex or Bend Sensors

Flex or bend sensors are used to measure bend or angle. They are particularly of use in anthropomorphic robotic arms or exoskeleton devices used for control of robotic arms. These sensors are made of resistive

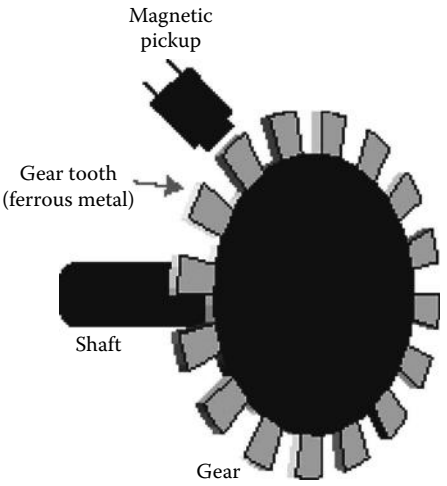

FIGURE 83.3 Magnetic encoder.

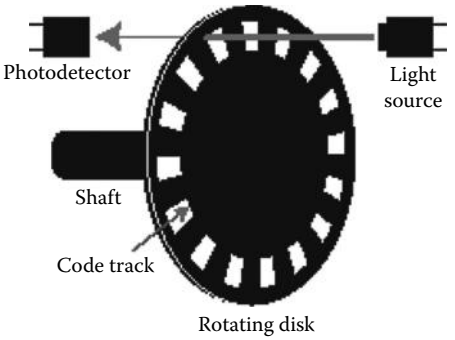

FIGURE 83.4 Optical encoder.

FIGURE 83.5 A resistive bend sensor.

strips as shown in Figure 83.5. The resistance changes when the strip is bent. While they are easy to integrate in a control system, they are however not very accurate.

83.2.3 Accelerometers

These sensors measure acceleration (as long as there is no rotation). They are frequently used to sense orientation, acceleration, vibration shock, falling, and for high-precision control of linear actuators of a robot and for joint feedback control. Unit of measurement is gram. A MEMS accelerometer can also be used as a tilt sensor. Available accelerometers can measure acceleration in 2-axis or 3-axis to detect magnitude and direction of the acceleration as a vector quantity. The output of the accelerometer can be analog signals or digital signals, usually on a serial interface. Often they are available commercially on a PCB breakout board, as shown in Figure 83.6, which makes it very easy to integrate with the rest of the electronic system of a robot.

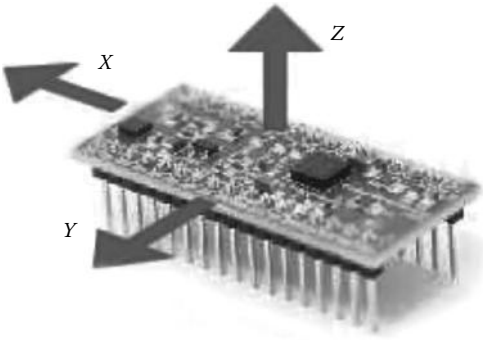

FIGURE 83.6 Three-axis accelerometers.

Apart from being incorporated in robots, micromachined and MEMS accelerometers are increasingly present in portable electronic devices (phones, tablet PC, cameras) and video game controllers (WII Console), to detect the position of the device or provide for game input.

There are many different ways to make an accelerometer. Accelerometers built using piezoelectric effect contain microscopic crystal structures that get stressed by accelerative forces, which cause a voltage to be generated. Another technique used is to sense the change in capacitance. If you have two microstructures next to each other, they have a certain capacitance between them. If an accelerative force moves one of the structures, then the capacitance will change. Additional circuitry is required to convert from capacitance to voltage. Commercially available accelerometer chips combine the processing circuitry on the chip itself and provide a voltage signal proportional to the acceleration. Other methods used are piezoresistive effect, hot air bubbles, and light.

83.2.4 Gyroscopes

A gyroscope has the capability of measuring the rate of rotation around a particular axis (angular rate or rotational speed). The unit of measurement is degree/second. It can be used for navigation on unmanned aerial vehicles (UAV), and radio-controlled helicopters. A gyroscope is essential for the stability of flying robots and is used to measure yaw, pitch, and roll of the robot. A difference between a gyroscope and an accelerometer is that a gyroscope gives an indication of the angular rate whereas an accelerometer measures the linear acceleration.

83.2.5 Electronic Compass

A digital compass sensor measures direction and bearing of a robot or autonomous mobile platforms. Often, the four cardinal (N, E, S, W) directions and the four intermediate (NE, NW, SE, SW) directions are measured. These sensors are essential for robots that navigate an unknown terrain. It uses a magnetic field sensor and a tilt sensor for compensation of inclination.

83.2.6 Two-Axis Tilt Sensors (Inclinometers)

A tilt sensor or inclinometer measures inclination, i.e., angles of slope (or tilt), single or dual axis. It measures elevation or inclination of an object with respect to gravity. Inclinometers measure both inclines (positive slopes, as seen by an observer looking upward) and declines (negative slopes, as seen by an observer looking downward). It is also known as a tilt meter, slope gauge, gradient meter, gradiometer, level gauge, declinometer, and pitch and roll indicator. Figure 83.7 shows an inclinometer.

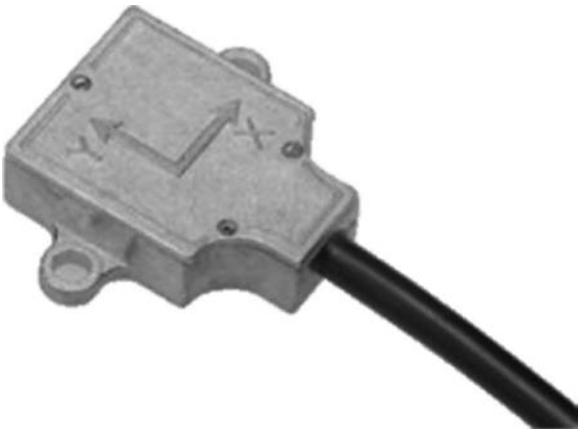

FIGURE 83.7 An inclinometer.

The output of these sensors can be analog signals or serial digital data. Common sensor technologies for inclinometers are MEMS, accelerometer, liquid capacitive, electrolytic, gas bubble in liquid, and pendulum.

83.2.7 Range Finders

For navigation and obstacle avoidance, robots need to detect the distance of objects from them. Range-finding sensors are used to measure range or distance. There are several technologies available to make such sensors, namely sensors based on infrared (IR) signals, ultrasonic signals, and lasers beams. The sensor has a transmitter–receiver pair. An IR light, sound, or laser beam is sent by the transmitter and reflected off the target, the distance of which is being measured. The time it takes for the signal to be returned to the receiver is a measure of how far the object is from the source.

83.2.8 GPS Sensors

More and more robots are being equipped with global positioning system (GPS) modules. The module can determine the latitude, longitude, and altitude of a receiver on earth by computing the time difference for signals from different satellites to reach the GPS receiver. The calculation to ascertain the location is based on a simple arithmetic theory known as trilateration. Especially in outdoor operations, where the GPS module has a direct line of sight to four or more orbiting satellites, GPS helps to localize the robot while navigating an unknown terrain. An added advantage of the GPS module is that it works in any weather condition and also provides additional information such as time, speed, bearing, trip distance, distance to destination, sunrise, and sunset time. Most GPS modules implement the NMEA 0183 standard which is a simple ASCII, serial communications protocol that defines how data is transmitted in a "sentence."

83.2.9 Vision Sensors (Camera)

Cameras give the robot the sense of sight. Cameras are very popular exteroceptive sensors, especially with mobile robots, for perceiving the external world. The image captured by the camera is processed to extract features of the surrounding and identify objects. The hardware to process images has become very cheap, fast, and small in form factor. This has made it very easy and cost-effective to integrate cameras in robotic systems (Figure 83.8). Primarily, there are two types of cameras based on the output

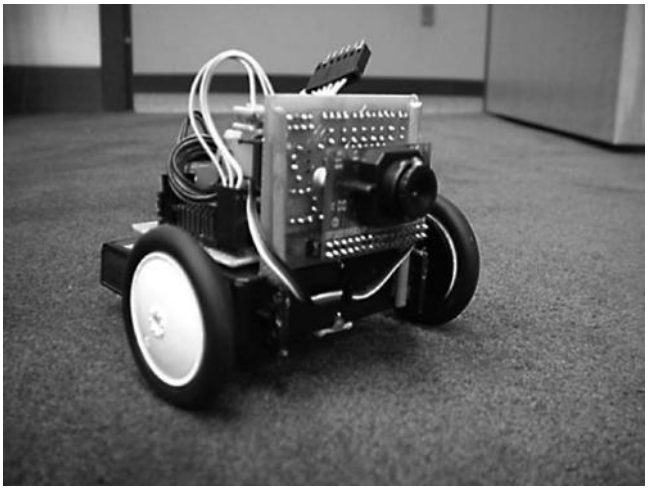

FIGURE 83.8 Use of camera in a robot.

signal—analog and digital. Digital cameras come with many different interfaces, namely USB, FireWire (IEEE 1394), TCP/IP, and SmartLink. Cameras with RF wireless transmitter built-in are also popular and can invariably be found on autonomous flying vehicles such as a Quadrotor and rescue robots.

83.2.10 Haptic (Tactile) Sensor

Haptic technology gives the robot the sense of touch by using tactile sensing which provides feedback by measuring forces and pressure. Research in the area of haptic sensing is in its infancy but is gaining momentum. Haptic sensors are employed in such scenarios where the robot has to manipulate objects. It helps the robot to discriminate between rigid and soft objects so that the gripping forces can be adjusted accordingly. Tactile sensors also give a feel of the object's profile (shape) which in turn helps the robot to decide on the optimal orientation for gripping. The integration of haptic sensors to refine information provided by vision sensors is a very promising approach in the development of autonomous robotic systems.

83.3 Sensors for a Humanoid Robot

A two-legged humanoid robot requires several types of sensors for balancing and gait generation. High accuracy and resolution of these sensors is of paramount importance for successful control of the humanoid. In this section, a couple of the sensors used in a typical humanoid robot are detailed. Primarily, there are three main types of sensors which are of utmost importance for humanoid control, namely foot pressure sensors, gyroscopes, and an Attitude Heading Reference System (AHRS).

83.3.1 Force Sensing Resistors

Along with a wide range of motion and acceleration sensors, force sensing resistors (FSRs) are very common devices in robotics applications. Due to their wide availability, ease of use, and low cost, designers have extensively relied on FSRs for force feedback in humanoid applications. FSRs are thin isometric force sensors whose resistance decreases, in a nonlinear way, with the force applied.

At least three commercial force sensors are currently available in the market—the Interlink FSR, the LuSense PS3, and the Tekscan FlexiForce sensor. The choice of the FSR is based on the application.

The FlexiForce sensors present better response in terms of linearity, repeatability, time drift, and dynamic accuracy, while the Interlink FSRs are more robust. If large changes in force are applied at a relatively high frequency, the Interlink or LuSense sensors should be selected, whereas if large slowly varying forces are applied infrequently for long durations, the Tekscan sensor should be selected. In a humanoid application, changes are short and changes in force are applied at a relatively high frequency; therefore, the Interlink FSRs are best suited. Due to nonconstant terrain, the ability to maintain a consistent and accurate area and position of the applied force will be the limiting factor in terms of sensor accuracy and precision.

The most basic FSR consists of two membranes separated by a thin air gap. The air gap is maintained by a spacer around the edges and by the rigidity of the two membranes. One of the membranes has two sets of interdigitated fingers that are electrically distinct, with each set connecting to one trace on a tail. The other membrane is coated with FSR ink. When pressed, the FSR ink shorts the two traces together with a resistance that depends on applied force.

The Interlink 402 FSR comprises of two polymer films: one with a conductive surface and the other with printed electrodes facing the first. Contact between the two surfaces causes the conductive layer to short circuit the printed electrodes, thereby reducing the electric resistance of the component. Typically, its resistance will drop from >1 MΩ to about 10 kΩ for an applied load of 100 (a force of roughly 1 N) to 10,000 g.

83.3.2 Three-Axis AHRS

To monitor the position of the body and pelvis, some form of sensor must be implemented. An AHRS consists of three gyroscopes, three accelerometers, and three magnetometers. These systems are currently used in intelligent gait humanoids. An on-board processor calculates the rate of change with respect to time outputting an absolute position in hexadecimal. The magnetometer is used as a horizontal reference to compute the rotational angle whereas the gravity is used for the roll and pitch.

Gyros are used to measure angular rates; accelerometers are used to determine initial attitude of the AHRS and to correct gyro drifts in the pitch and roll angles. The magnetometers essentially perform the same task where they correct gyro drift in the heading angle.

Gyro values are fed into the block named "numeric integration of the orientation equations" which is used to measure the rate of change in gyro angle. These values are fed into the block function "computation of correction signals" which reviews accelerometer and magnetometer values to produce and error value to be combined with the gyro value. Finally, an estimation of the heading pitch and roll angles is produced which combined with the other functional blocks is filtered using extended Kalman filtering. This filtering further increase the accuracy of the estimated orientation angles of the AHRS.

A major disadvantage of using MEMS systems for navigation/positioning is that they typically suffer from drift. Drift is the expression for an accumulated error in the position calculations. Because the system is continually adding minute changes to its previously calculated position, any error in measurement, however small, is accumulated resulting in a gradual drift effect.

To try and reduce the possibility of drift, there are several algorithms and filters that can be implemented. The CH 6 dm has a built-in extended Kalman filter (EKF) which through statistical models simulates the potential error in calculated value and actual value. EKF performance can be tuned by adjusting the process noise covariance matrix and the measurement noise covariance matrices (there are two measurement noise matrices—one for the accelerometers and other for the magnetometer).

The process noise matrix is used to specify how much the EKF "trusts" data from the gyros with respect to data from the magnetic sensors and accelerometers. The lower the values along the diagonal of the matrix, the more the rate gyros are trusted. Conversely, if the diagonal elements are large, the gyros are trusted less and the accelerometers and magnetometers are weighted more heavily.

83.4 Anthropomorphic Robotic Arm for Plant Health Monitoring Using RGB Color Sensor

Robots are increasingly finding applications in agriculture. Robots are employed to monitor the growth and health of plant tissues in a modified in vitro clonal plant propagation system. The color of the plant leaves is an indicator of its health. To monitor the color of plant material, and in particular to determine the RGB color content, a RGB color sensor that can interpret the color of an object can be used.

Colored objects that exhibit a particular color, as seen by humans, absorb certain wavelengths and reflect others back to the observer. Therefore, a red object would absorb all the green and blue wavelengths, but reflect back only the red wavelengths, thus giving its red appearance to the human. Currently, there are a number of color sensors available globally from numerous suppliers. Color sensors vary in price, size, sophistication, and the color space they use.

83.5 Sensors for Mobile Robotic Platforms in Environmental Applications

83.5.1 Greenhouse Applications

Various environmental factors influence the quality and productivity of plant growth in a greenhouse. Continuous monitoring of these environmental parameters gives valuable information to the grower to better understand how each factor affects the quality and the rate of plant growth, and how to maximize crop yield. The environmental parameters that are important are atmospheric temperature, humidity, carbon dioxide (CO_2), light intensity, and soil moisture. In this section, technologies for various environmental monitoring sensors have been reviewed.

83.5.2 Atmospheric Temperature Sensing

Temperature sensing technology is one of the most widely used sensing technologies in the world of sensors. It allows for the measurement of temperature in various applications and provides protection from excessive temperature excursions. Five different families of temperature sensors are available on the market. Each family of temperature sensors has its advantages and disadvantages. Depending on the application, one sensor may be more suitable than the other.

83.5.2.1 Thermocouples

A thermocouple is a junction between two wires of dissimilar metals. The point of contact between the wires generates a voltage that is proportional to the temperature. Thermocouples are suitable for measuring over a large temperature range, up to 2300 °C. They are less suitable for applications where smaller temperature differences need to be measured with high accuracy. For such applications, thermistors and resistance temperature detectors (RTDs) are more suitable. Applications include temperature measurement for kilns, gas turbine exhaust, diesel engines, and other industrial processes.

Advantages: Wide temperature range (200 °C–1300 °C), relatively cheap, highly accurate, minimal long-term drift, and fast response time.

Disadvantages: The relationship between the temperature and the thermocouple's output signal is not linear, low output signal (mV), vulnerable to corrosion, and calibration of thermocouples can be tedious and difficult.

83.5.2.2 Resistance Temperature Detectors

RTDs are widely used in many industrial applications such as air conditioning, food processing, and textile production, processing of plastics, microelectronics, and exhaust gas temperature measurement.

RTDs are basically temperature-sensitive resistor devices. The resistance increases with temperature. Most RTD elements consist of a length of fine-coiled wire wrapped around a ceramic or glass core.

Advantages: Linear over a wide temperature range, relatively accurate, good stability, and repeatability at high temperature (65 °C–700 °C).

Disadvantages: Low sensitivity, higher cost than thermocouples, and vulnerable to shock and vibration.

83.5.2.3 Thermistors

Similar to RTDs, thermistors are also temperature-dependent resistor devices. Thermistors are not as accurate or stable as RTDs but they are easier to wire, cost less, and almost all automation panels accept them directly. Thermistors are made of semiconductor materials with a resistivity that is especially sensitive to temperature.

Advantages: Highly sensitive, low cost, accurate over small temperature range, and good stability.

Disadvantages: Nonlinear resistance temperature characteristics, self-heating, and limited temperature operating range.

83.5.2.4 Integrated Circuit Temperature Sensors

In low-cost applications, most of the sensors stated earlier either are expensive or require additional circuits or components to be used. However, integrated circuit (IC) temperature sensors are complete, silicon-based sensing circuits with either analog or digital output. IC temperature sensors are often used in applications where the accuracy demand is low.

Advantages: Low cost, excellent linearity, and easy-to-read output.

Disadvantages: Limited temperature range, self-heating, fragile, and slightly less accurate when compared to other types.

83.5.3 Humidity Sensing

When it comes to humidity sensing technology, there are three types of humidity sensors: capacitive, resistive, and thermal conductivity humidity sensors.

83.5.3.1 Capacitive Humidity Sensors

Capacitive humidity sensors (CHS) are widely used in industrial, commercial, and weather telemetry applications. CHSs consist of a substrate on which a thin film of polymer or metal oxide is deposited between two conductive electrodes. The sensing surface is coated with a porous metal electrode to protect it from contamination and exposure to condensation. The substrate is typically glass, ceramic, or silicon. The changes in the dielectric constant of a CHS are nearly directly proportional to the relative humidity (RH) of the surrounding environment.

Advantages: Able to function in high-temperature environments (up to 200 °C), near linear voltage output, wide RH range, high condensation tolerance, reasonable resistance to chemical vapors and contaminants, minimal long-term drift, high accuracy, small size, and low cost.

Disadvantages: Limited sensing distance and sensor interface can be tedious and difficult.

83.5.3.2 Resistive Humidity Sensors

Resistive humidity sensors (RHS) measure the changes in electrical impedance of a hygroscopic medium such as conductive polymer, salt, or treated substrate. These sensors are suitable for use in control and display products for industrial, commercial, and residential applications. RHS consists of noble metal electrodes either deposited on a substrate by photoresist techniques or wire-wound electrodes on a plastic or glass cylinder.

Advantages: Faster response time than CHS, near linear voltage output, high accuracy, small size, low cost, and wide RH range.

Disadvantages: Lower operating temperature when compared to CHS, sensitive to chemical vapors, low tolerance against contaminants, and low condensation tolerance.

83.5.3.3 Thermal Conductivity Humidity Sensors

Thermal conductivity humidity sensors (TCHS) measure the absolute humidity by quantifying the difference between the thermal conductivity of dry air and that of air containing water vapors. These sensors are suitable for applications such as kilns for drying wood; machinery for drying textiles, paper, and chemical solids; pharmaceutical production; cooking; and food dehydration. TCHS consists of two matched negative temperature coefficient (NTC) thermistor elements in a bridge circuit; one is hermetically encapsulated in dry nitrogen and the other is exposed to the environment.

Advantages: Very durable, able to operate in high-temperature environments (up to 600°C), excellent immunity to many chemical and physical contaminants, high accuracy, and high condensation tolerance.

Disadvantages: Respond to any gas that has thermal properties different from those of dry nitrogen; this will affect the measurements.

83.5.4 Soil Moisture Sensing

Excessive moisture is undesirable in agriculture, houses, textiles, packaging materials, electronic appliances, dry food process, etc. Moisture detection is important in a number of different situations. For example, measurement of soil moisture is useful for minimizing the amount of irrigation water applied to grow plants and for optimizing plant growth. Excess moisture also creates "wet feet" in plants and destroys them. Because of the importance of the moisture content of materials, various techniques have been developed to measure it. This section outlines a number of soil moisture detection technologies that are available on the market and lists their advantages and disadvantages.

83.5.4.1 Frequency Domain Reflectometry Soil Moisture Sensor

Frequency domain reflectometry (FDR) is sometimes referred to as capacitance sensor. Soil sensor probes that use the FDR method of soil moisture measurement employ an oscillator to generate an electromagnetic signal that is propagated through the unit and into the soil. Part of this signal will be reflected back to the unit by the soil. This reflected wave is measured by the FDR probe, telling the user what the water content of the soil is.

Advantages: Highly accurate, fast response time, and inexpensive.

Disadvantages: Need to be calibrated for the type of soil they will be buried in.

83.5.4.2 Time Domain Reflectometry Soil Moisture Sensor

Time domain reflectometry (TDR) sensors propagate a pulse down a line into the soil, which is terminated at the end by a probe with wave guides (Figure 83.9). TDR systems measure water content of the soil by measuring how long it takes the pulse to come back.

Advantages: Highly accurate and fast response.

Disadvantages: Calibration can be tedious, difficult, and expensive.

FIGURE 83.9 Time domain reflectometry soil moisture sensors.

83.5.4.3 Gypsum Blocks

Gypsum blocks use two electrodes placed into a small block of gypsum to measure soil water tension. Wires connected to the electrodes are connected to either a portable handheld reader or a data logger. The amount of water in the soil is determined by the electrical resistance between the two electrodes within the gypsum block. More water present in the soil will reduce the resistance, while less water will increase it.

Advantages: Inexpensive and easy to install.

Disadvantages: Have to be replaced periodically and sensitive to the saline content of water.

83.5.4.4 Neutron Probes

Using neutron probes is another way to measure soil moisture content (Figure 83.10). A probe which is inserted in the ground emits low-level radiation in the form of neutrons. These neutrons collide with the

FIGURE 83.10 Use of neutron probes.

hydrogen atoms contained in water, which is detected by the probe. More the water content in the soil, the more neutrons are scattered back at the device.

Advantages: Very accurate and fast response.

Disadvantages: Expensive and users have to be registered with the government due to radioactive elements used to emit the neutrons.

83.5.5 Carbon Dioxide Sensing

Measuring carbon dioxide is important in monitoring indoor air quality and many industrial processes. Two types of CO_2 detectors are available to measure the CO_2 level in the surrounding environment—electrochemical CO_2 sensors and nondispersive IR (NDIR) CO_2 sensors.

83.5.5.1 Electrochemical CO_2 Sensors

The CO_2-sensitive element consists of a solid electrolyte formed between two electrodes, together with a heater substrate. By monitoring the changes in the electromotive force (EMF) generated between the two electrodes, it is possible to measure CO_2 gas concentration.

Advantages: Cheap, accurate, real-time sensing, high tolerance against contaminants, and small in size.

Disadvantages: Require a significant amount of power because they operate at high temperature.

83.5.5.2 NDIR CO_2 Sensors

NDIR sensors are spectroscopic sensors to detect CO_2 in a gaseous environment by its absorption characteristics. The key components are an IR source, a light tube, an interference (wavelength) filter, and an IR detector. The gas is pumped or diffused into the light tube and the electronics measures the absorption of the characteristic wavelength of light.

Advantages: High speed, real-time sensing, low power consumption, high contamination tolerance, and small in size.

Disadvantages: Carbon monoxide often coexists with CO_2 and absorbs a similar wavelength range as CO_2 which results in inaccurate readings. They are also very expensive.

83.5.6 Light Sensing

Light from the sun is responsible for nearly all life on the earth. Sunlight fuels the process of photosynthesis where plants convert carbon dioxide and water into carbohydrates. Plants use light in the range of 400–700 nm. This range is most commonly referred to as photosynthetically active radiation (PAR). Monitoring PAR is important to ensure that plants are receiving adequate light for photosynthesis. Typical applications include forest canopies, greenhouse monitoring, etc. PAR is also measured to estimate evaporation in bodies of water, as it plays a key role in surface water temperature. This section will present some of the popular light sensors on the market that can be used for environmental monitoring applications.

83.5.6.1 Photometric Sensors

Photometric sensors measure visible radiation or light as seen by the human eye.

Advantages: Highly sensitive, good stability, fast response time (10 μs), low temperature dependency, excellent linearity, and small size.

Disadvantages: Expensive and these sensors are mostly used to measure indoor lighting conditions. For environmental applications, PAR and solar radiation sensor are preferred.

83.5.6.2 Light-Dependent Resistor

Similar to photometric sensors, light-dependent resistors (LDRs) measure visible light as seen by the human eye. A LDR is basically a resistor; the internal resistance increases or decreases dependent on the level of light intensity impinging on the surface of the sensor.

Advantages: Very cheap, fast response, linear output, and small in size.

Disadvantages: Like photometric sensors, LDRs are mostly used to measure indoor lighting conditions.

83.5.6.3 Pyranometers

Pyranometers measure total solar radiation. These sensors are commonly used for agriculture, meteorology, and solar energy applications. The sensor is composed of a silicon photovoltaic detector mounted in a miniature head. The sensor output current is directly proportional to the level of solar radiation.

Advantages: Highly accurate, excellent linearity, good stability, and fast response time.

Disadvantages: Bulky and expensive.

83.5.6.4 Quantum Sensors

Quantum sensors measure the photosynthetic photon flux density (PPFD) of PAR. They are one of the most popular types of light sensors used in agriculture and environmental industries.

Advantages: Very sensitive, fast response, highly accurate, excellent linearity, good stability, and small in size.

Disadvantages: Expensive.

83.6 Biomimetic Sensor Design

Concepts from a nonengineering domain such as biology have sparked inspiration and innovation for a variety of technologies. Bacteria, plants, insects, mammals, reptiles, and the like have diverse forms, solving a variety of engineering functions. Elegant methods of sensing and communication are used in biological systems which may be considered as sophisticated adaptive systems. A biology-inspired branch of sensor research has emerged called biomimicry.

Biological systems offer exemplary methods of flight, imaging, sensing, adaptation to environment, and locomotion. Engineers have learned from these and created novel technologies. Biological domain provides inspiration at many levels, such as cellular, organism, and species. Nature has been developing biological sensors for billions of years. Lasting solutions have evolved to fulfill unique ecological niches, which make them ideal for study and imitation. Not only it is nature rich with sensing methods, but also it provides strategies to use these sensors. Biological sensors typically exhibit low-energy requirements, high sensitivity, and redundancy. They exhibit parallel sampling and processing of sensory information. Having tens or even hundreds of parallel receptor cells improves the signal-to-noise ratio through averaging. This also reduces the likelihood of error due to loss of or failure of a receptor organ. A great lesson from nature is redundancy; in most biological systems, there are many instances of redundancy.

Signal Processing

84

Modulation

David M. Beams
The University of Texas at Tyler

84.1 Introduction

It is often the case in instrumentation and communication systems that an information-bearing signal may not be in an optimal form for direct use. In such cases, the information-bearing signal may be used to alter some characteristic of a second signal more suited to the application. This process of altering one signal by means of another is known as *modulation*; the original information is called the *baseband signal*, and the signal modulated by the baseband signal is termed the *carrier* (because it "carries" the information contained in the baseband signal). Recovery of the original information requires a suitable demodulation process to reverse the modulation process.

A prominent use of modulation techniques is found in communication systems. The extremely long wavelengths of electromagnetic waves at frequencies found in a typical audio signal make direct transmission impractical, because of constraints on realistic antenna size and bandwidth. Successful radio communication is made possible by using the original audio (baseband) signal to modulate a carrier signal of a much higher frequency and transmitting the modulated carrier by means of antennas of feasible size. Another example formerly in widespread use is that of modems used to transmit digital data through the telephone network. Digital data are not directly compatible with analog local subscriber connections, but audible signals modulated by digital data could be carried over local telephone lines. Instrumentation systems use modulation techniques for telemetry (where the distances may be on the order of centimeters for implanted medical devices to hundreds of millions of kilometers for deep-space probes), for processing signals in ways for which the original signals may be unsuited (such as avoiding $1/f$ noise in high-gain amplifiers by processing a high-frequency carrier modulated by a low-frequency signal), and for specialized amplification purposes (carrier and lock-in amplifiers).

Techniques that modulate the amplitude of the carrier are full-carrier *amplitude modulation* (AM), reduced- or suppressed-carrier double-sideband (DSB) AM, single-sideband (SSB) suppressed-carrier

modulation, vestigial-sideband (VSB) modulation, and on–off keying (OOK). Techniques that modulate the frequency or phase angle of the carrier include *frequency modulation* (FM), phase modulation (PM), frequency-shift keying (FSK), and phase-shift keying (PSK). Simultaneous variation of amplitude and phase are applied in quadrature AM (QAM). Each technique has its own particular uses. Full-carrier AM is used in radio broadcasting; VSB was formerly used in analog television broadcasting. DSB appears in instrumentation systems utilizing carrier amplifiers and modulating sensors, while SSB finds use in certain high-frequency radio communications. FM is used in broadcasting and point-to-point mobile communications. OOK is commonly used to transmit digital data in optical fiber links. FSK, PSK, and QAM are found in digital communications; analog QAM was formerly used to transmit chrominance (color) information in color television broadcasting. The emphasis of this particular chapter will be instrumentation systems; those interested principally in communications applications could begin by consulting Refs. [1–4].

Malmstadt et al. [5] list the purposes of modulation in instrumentation systems as using one signal to convey (carry) the information of another; of multiplexing; and of moving the spectrum of a signal to another band of frequencies to avoid noise or interference.

84.2 Generalized Modulation

Two assumptions are made at the outset: (1) the highest frequency present in the baseband signal is typically considerably less than the carrier frequency and (2) the results derived in the following section pertain to sinusoidal carriers but may be extended to other periodic carrier signals (such as square waves and triangle waves). The following equation gives a general expression as a function of time t for a modulated sinusoidal carrier signal of radian frequency ω_c:

$$f_s(t) = A_c(t)\cos[\omega_c t + \varphi(t)] \tag{84.1}$$

where

$f_s(t)$ is the modulated signal
$A_c(t)$ is the modulated signal's instantaneous amplitude
$\varphi(t)$ is the instantaneous modulation phase angle

Information may be carried by $f_s(t)$ by AM, *angle modulation*, or, in some cases, both. As will be shown later, both FM and PM may be seen as specific case forms of generalized angle modulation.

Equation 84.1 may be recast in an equivalent form:

$$f_s(t) = f_i(t)\cos(\omega_c t) - f_q(t)\sin(\omega_c t) \tag{84.2}$$

where

$f_i(t) = A_c(t)\cos[\varphi(t)]$
$f_q(t) = A_c(t)\sin[\varphi(t)]$

Equation 84.2 gives $f_s(t)$ as the sum of a cosinusoidal carrier term with time-varying amplitude $f_i(t)$ and a sinusoidal (quadrature) carrier term with time-varying amplitude $f_q(t)$; this formulation is known as the carrier-quadrature description of $f_s(t)$. The terms $f_i(t)$ and $f_q(t)$ are known, respectively, as the in-phase and quadrature components of $f_s(t)$. Carlson et al. [1] gives the Fourier transform of a signal in carrier-quadrature form:

$$F_s(\omega) = \frac{1}{2}[F_i(\omega - \omega_c) + F_i(\omega + \omega_c)] + \frac{j}{2}[F_q(\omega - \omega_c) + F_q(\omega + \omega_c)] \tag{84.3}$$

where $F_s(\omega) \leftrightarrow f_s(t)$, $F_i(\omega) \leftrightarrow f_i(t)$, and $F_q(\omega) \leftrightarrow f_q(t)$ are Fourier-transform pairs. The meaning of Equation 84.3 is that the spectrum of $F_s(\omega)$ contains the spectra of both $F_i(\omega)$ and $F_q(\omega)$,

each translated by $\pm\omega_c$. Time-varying modulation of the carrier in any sense causes energy to appear at frequencies (known as *sidebands*) other than the carrier frequency. Sidebands will be symmetrically distributed relative to the carrier in all but specialized cases (e.g., SSB) which are not found in instrumentation systems.

84.3 Amplitude Modulation

Doebelin [6] notes that interest in amplitude-modulated signals in instrumentation systems comes from two considerations:

1. Physical data are sometimes themselves amplitude-modulated.
2. AM may be intentionally introduced in some measurement systems to achieve one or more benefits.

AM in instrumentation systems usually takes the form of DSB suppressed-carrier AM. Examples of measurements using AM techniques will be given later.

84.3.1 DSB AM

AM applied to a sinusoidal carrier is described by

$$f_s(t) = A_c[k + \mu f_m(t)]\cos(\omega_c t) \tag{84.4}$$

where

A_c is the amplitude of the unmodulated carrier
k is the proportion of carrier present in the modulated signal
μ is the modulation index
$f_m(t)$ is the modulating baseband signal (presumed to be a real bandpass signal)
ω_c is the carrier radian frequency

The modulation index relates the change in amplitude of the modulated signal to the amplitude of the baseband signal. The value of k ranges from 1 in full-carrier AM to 0 in suppressed-carrier DSB AM. The instantaneous amplitude of the modulated signal is $k + \mu f_m(t)$, which may take on any positive value consistent with the dynamic range of the modulator and demodulating system. Phase reversal of the carrier occurs if the value of $k + \mu f_m(t)$ becomes negative. Recasting Equation 84.4 in carrier-quadrature form gives $f_i = A_c[k + \mu f_m(t)]$ and $f_q = 0$. The Fourier transform of this signal is

$$F_s(\omega) = \frac{A_c}{2}\left\{[k\delta(\omega - \omega_c) + k\delta(\omega + \omega_c)] + \mu[F_m(\omega - \omega_c) + F_m(\omega + \omega_c)]\right\} \tag{84.5}$$

where $\delta(\omega - \omega_c)$ and $\delta(\omega + \omega_c)$ are unit impulses at $+\omega_c$ and $-\omega_c$, respectively; these are the carrier components of $F_s(\omega)$. The frequency domain representation of $F_s(\omega)$ also contains symmetric sidebands about the carrier with the upper sideband arising from the positive-frequency component of $F_m(\omega)$ and the lower sideband from the negative-frequency component. A DSB AM signal thus has a bandwidth twice as large as that of the baseband signal.

Figure 84.1 represents a full-carrier AM signal resulting from modulation of a sinusoidal carrier by a sinusoidal modulating signal $f_m(t) = A_m \cos(\omega_m t)$, where A_m is the amplitude and ω_m is the radian frequency of the modulating signal. This waveform is said to show 100% sinusoidal AM because the smallest value of $k + \mu f_m(t)$ just reaches 0.

The spectra of the unmodulated sinusoidal carrier, the sinusoidal modulating signal, and the composite AM signal are shown in Figure 84.2 which shows the presence of symmetric sidebands spaced at $\pm\omega_m$ with respect to the carrier components (which themselves remain unchanged when modulation is applied).

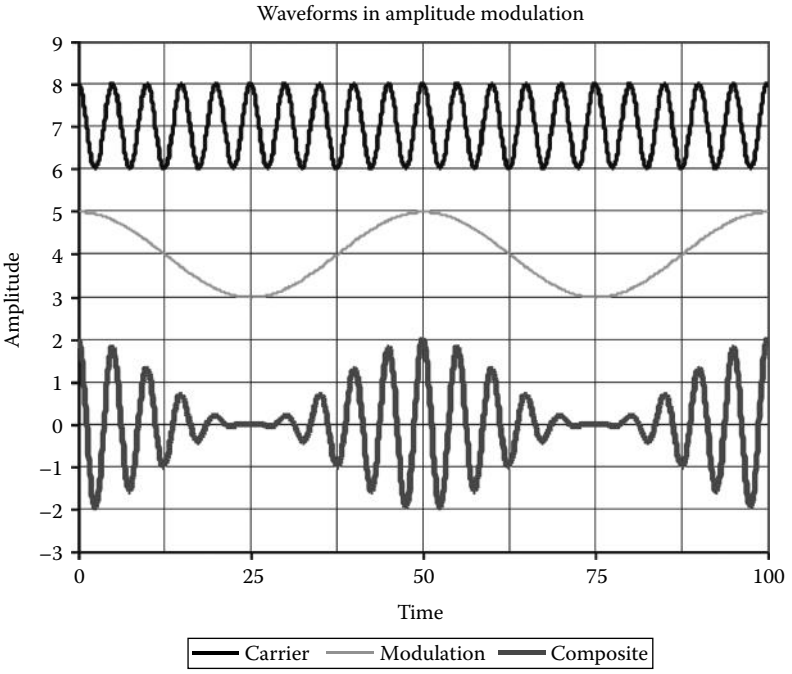

FIGURE 84.1 Full-carrier amplitude modulation showing 100% modulation of a sinusoidal carrier by a sinusoidal baseband modulating signal. The composite signal and the unmodulated carrier are in-phase throughout the modulation cycle. The time scale is arbitrary, and the carrier and modulation waveforms have been offset for clarity.

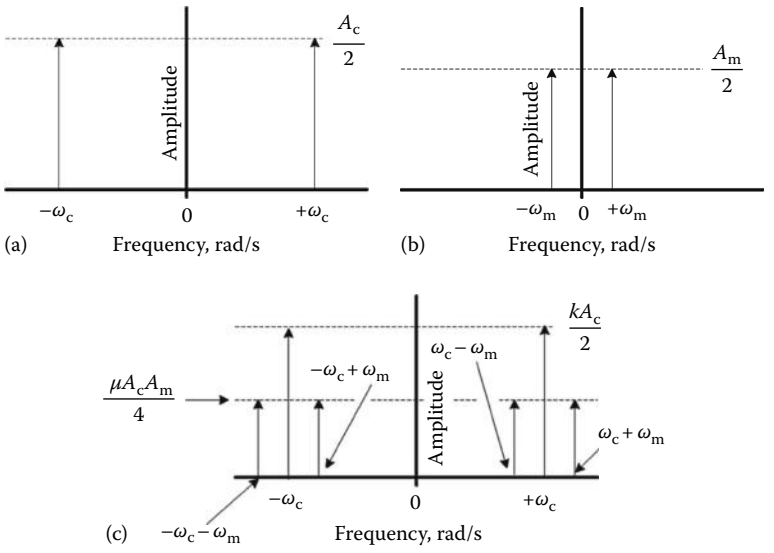

FIGURE 84.2 Double-sided spectra of (a) the unmodulated carrier, (b) the sinusoidal baseband signal, and (c) the amplitude-modulated signal.

The time-domain expression for a suppressed-carrier DSB signal is found by setting k to 0 in Equation 84.4. The phase of the suppressed-carrier DSB signal with respect to the unmodulated carrier undergoes phase reversal whenever $\mu f_m(t)$ goes negative, in contrast to full-carrier AM. The spectrum of a suppressed-carrier DSB signal is similarly found from Equation 84.5 by setting k to 0.

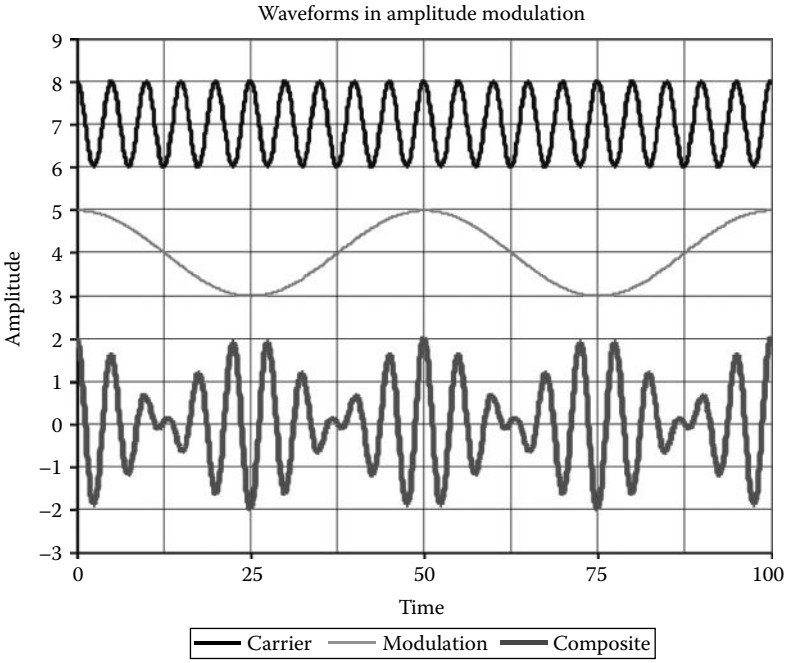

FIGURE 84.3 Suppressed-carrier double-sideband amplitude modulation of a sinusoidal carrier by a sinusoidal modulating signal; $k = 0$, $\mu = 2.0$, $A_c = 1.0$, and $A_m = 1.0$. The unmodulated carrier and the composite waveform are in phase on the positive half cycle of the modulating waveform, but the phase of the composite signal reverses with respect to the carrier on the negative half cycle. The time scale is arbitrary, and the carrier and modulation waveforms have been offset for clarity.

Figure 84.3 shows a time-domain representation of a suppressed-carrier DSB signal with the same sinusoidal baseband modulation as in Figure 84.1. The information in a full-carrier AM signal is found solely in the time-varying amplitude of the modulated signal, but the information carried by the suppressed-carrier DSB signal is found both in the amplitude and instantaneous phase of the modulated signal. (The phase of the DSB signal is inverted relative to the carrier when the baseband signal is negative and in phase when the baseband signal is positive.)

AM is a linear modulation technique; the sum of multiple AM signals produced from a common carrier by different baseband signals is the same as one AM signal produced by the sum of the baseband signals.

84.3.2 Generation of DSB AM Signals

Generation of AM signals in radio transmitters is frequently performed by applying the modulating waveform to the supply voltage to a nonlinear radio-frequency power amplifier with a resonant-circuit load as described by Carlson et al. [1]. Low-level AM may be achieved by direct multiplication of the carrier signal by $[k + \mu f_m(t)]$. Suppressed-carrier DSB signals often arise in instrumentation systems as the result of the use of an ac drive signal to a modulating sensor. Figure 84.4 shows examples of this. In Figure 84.4a, a sinusoidal drive voltage $v_{in}(t)$ is applied to the primary winding L_p of a linear variable differential transformer (LVDT). The magnitude of the output voltage $v_{out}(t)$ is proportional to the displacement $x(t)$ of the LVDT core from its center (null) position between the two secondary windings L_{x1} and L_{s2}; the output voltage is zero when the core is centered. The phase of $v_{out}(t)$ relative to $v_{in}(t)$ indicates the direction of displacement relative to the null position. In Figure 84.4b, an ac signal is applied to a resistive Wheatstone bridge. The differential output voltage $v_{out}(t)$ is zero when the bridge is balanced; the magnitude of $v_{out}(t)$ indicates the degree of unbalance in the bridge, and the phase of $v_{out}(t)$ relative

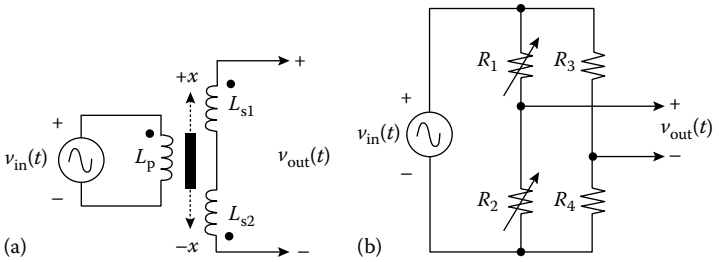

FIGURE 84.4 Balanced sensors producing suppressed-carrier DSB signals from ac excitation and physical measurands. In (a), an LVDT measures displacement x; in (b), a resistive Wheatstone bridge is unbalanced by a physical variable (e.g., mechanical strain).

to $v_{in}(t)$ indicates the direction of imbalance. In sensors like these, the modulating signal $f_m(t)$ is physical variable being measured. The use of ac excitation to a sensor is required for sensors containing reactive elements (inductances and/or capacitances); it may also be desirable in the case of resistive sensors (such as strain-gage bridges) requiring high-gain amplifiers. In these circumstances, amplification of an ac signal minimizes both $1/f$ noise and dc-offset problems associated with high-gain dc-coupled amplifiers.

84.3.3 Envelope Demodulation of DSB AM Signals

Full-carrier AM signals are readily demodulated by the simple envelope detector shown in Figure 84.5. The components of the RC low-pass filter are chosen such that $\omega_m << (1/RC) << \omega_c$. Envelope detection, however, cannot discriminate phase and is thus unsuitable for demodulation of signals in which phase reversal of the carrier occurs (such as reduced-carrier or suppressed-carrier signals). Synchronous demodulation is required for such signals.

84.3.4 Synchronous Demodulation of DSB AM Signals

Figure 84.6 shows three methods of synchronous demodulation of AM signals. In Figure 84.6a, the modulated signal $f_s(t)$ is multiplied by $A_d\cos(\omega_c t)$. In Figure 84.6b, the modulated signal $f_s(t)$ is gated by a square wave synchronous with $\cos(\omega_c t)$ so that the signal $f_s(t)$ is multiplied by a positive gain A during the positive half cycle of the carrier signal and by a negative gain $-A$ during the negative half cycle. Figure 84.6c shows a variation of this method in which the signal $f_s(t)$ is gated by a square wave such that it is amplified by a gain of A during the positive half cycle of $\cos(\omega_c t)$ and by 0 during the negative half cycle.

In the multiplying circuit of Figure 84.6a, the Fourier transform $F'_d(\omega)$ of the demodulated signal $f'_d(t) = f_s(t)A_d\cos(\omega_c t)$ is given by

$$F'_d(\omega) = \frac{A_d A_c k}{4}[\delta(\omega - 2\omega_c) + \delta(\omega + 2\omega_c) + 2\delta(\omega)] + \cdots$$

$$\cdots \frac{\mu A_d A_c}{4}[F_m(\omega - 2\omega_c) + F_m(\omega + 2\omega_c) + 2F_m(\omega)] \tag{84.6}$$

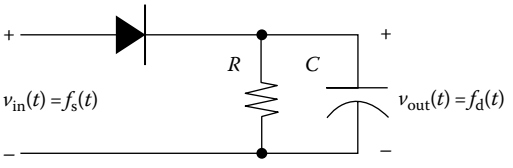

FIGURE 84.5 Simple envelope detector for full-carrier AM signals. The waveform $f_d(t)$ is the time-varying demodulated output.

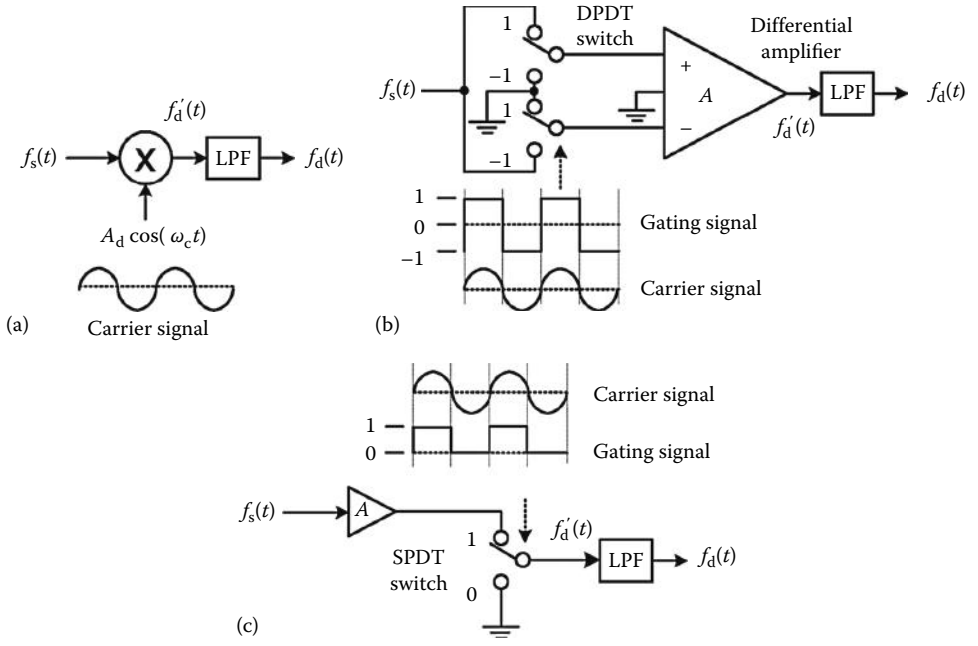

FIGURE 84.6 Synchronous detection methods for AM signals. The method of (a) is known as multiplying synchronous detection; those of (b) and (c) are methods of switching synchronous detection. The waveform $f_d'(t)$ is the time-varying demodulated output prior to filtering by the low-pass filter (labeled "LPF"). The waveform $f_d(t)$ is the filtered demodulated output. Switches are usually implemented with MOSFET transmission gates rather than mechanical switches.

It is assumed in Equation 84.6 that the input signal $f_s(t)$ is a generalized AM signal described by Equation 84.4. Suitable low-pass filtering after the multiplier removes the spectral components centered about $\pm 2\omega_c$. The Fourier transform $F_d(\omega)$ of the demodulated signal after filtering is

$$F_d(\omega) = \frac{A_d A_c k}{2}\delta(\omega) + \frac{\mu A_d A_c}{2} F_m(\omega) \tag{84.7}$$

Translating Equation 84.7 to the time domain gives

$$f_d(t) = \frac{A_d A_c}{2}[k + \mu f_m(t)] \tag{84.8}$$

The output of the multiplying synchronous detector consists of a dc term $A_d A_c k/2$ and the original baseband signal multiplied by a scale factor $\mu A_d A_c/2$. In the case of suppressed-carrier DSB ($k = 0$), the filtered detector output lacks the dc term and contains only a scaled version of the original baseband signal.

Figure 84.7 gives typical waveforms in a multiplying synchronous detector with a constant-amplitude sinusoidal signal. (This situation arises in balanced sensors when static measurand inputs are applied). It is of note that the output of the multiplier contains a dc term and a sinusoidal output at $2\omega_c$.

The gating action of the circuit of Figure 84.6b is equivalent to multiplying the original baseband signal by a square wave with levels $\pm A$. The Fourier-series representation of this square wave gating signal, $f_g(t)$, is

$$f_g(t) = \frac{4A}{\pi}\sum_{n=0}^{\infty}\frac{(-1)^n}{(2n+1)}\cos[(2n+1)\omega_c t] \tag{84.9}$$

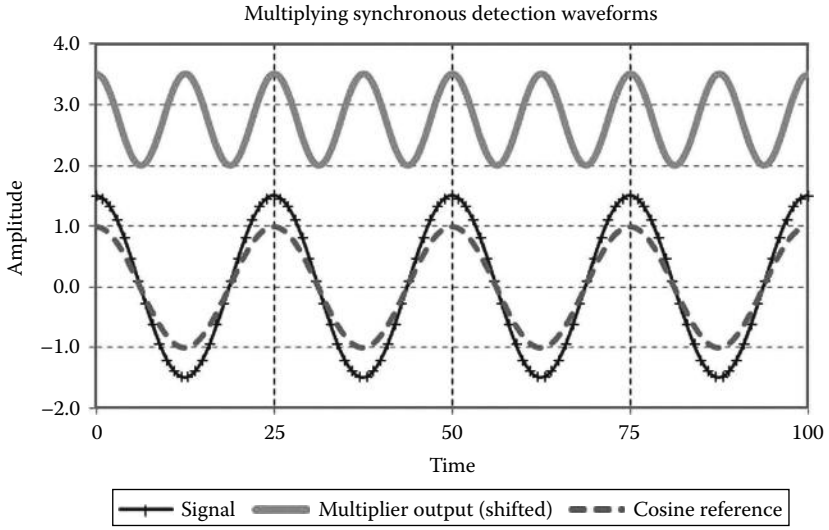

FIGURE 84.7 Waveforms in a multiplying synchronous demodulator when the signal to be demodulated is a constant-amplitude sinusoid in phase with the reference signal. The reference signal has been offset for clarity.

Multiplying an AM signal given by Equation 84.4 by the gating signal of Equation 84.9 and passing the product through a suitable low-pass filter gives

$$f_d(t) = \frac{2AA_c}{\pi}[k + \mu f_m(t)] \tag{84.10}$$

Comparison of Equation 84.10 with Equation 84.8 shows that synchronous detection of AM signals by multiplication or by switching produces similar results except for scaling factors.

Figure 84.8 shows typical waveforms in a switching-type synchronous demodulator of the type of Figure 84.6b when the input is a constant-amplitude sinusoid and the gain of the differential amplifier

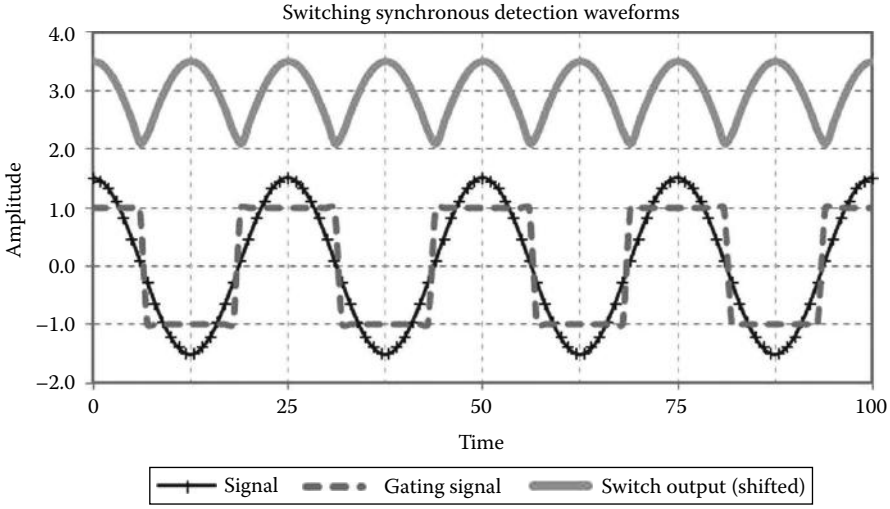

FIGURE 84.8 Waveforms in a full-wave synchronous demodulator when the input signal is a constant-amplitude sinusoid. The minimum value of the switch output waveform is 0; it has been offset for clarity.

is assumed to be 1. The output waveform of the switch has the form of a full-wave rectified sinusoid; this circuit is thus also known as a full-wave synchronous rectifier. The switch output waveform is periodic and nonsinusoidal with a fundamental frequency of $2\omega_c$. Low-pass filtering will extract the average (dc) value of the switch output while attenuating the time-varying components.

The gating function $f_g(t)$ of the circuit of Figure 84.6c is a square wave with levels A and 0. Its Fourier-series representation is

$$f_g(t) = \frac{A}{2} + \frac{2A}{\pi}\sum_{n=0}^{\infty}\frac{(-1)^n}{(2n+1)}\cos[(2n+1)\omega_c t] \tag{84.11}$$

Multiplication of this gating function with an AM signal described by Equation 84.4 and passing the product through a suitable low-pass filter gives

$$f_d(t) = \frac{AA_c}{\pi}[k + \mu f_m(t)] \tag{84.12}$$

Figure 84.9 shows typical waveforms in a switching-type synchronous demodulator of the type of Figure 84.6c when the input is a constant-amplitude sinusoid and the gain A of the amplifier is assumed to be 1. The output waveform of the switch has the form of a half-wave rectified sinusoid; this circuit is thus also known as a half-wave synchronous rectifier. The switch output waveform is periodic and non-sinusoidal with a fundamental frequency of ω_c.

Until this point, the implicit assumption has been made that the demodulating signal, whether sinusoidal (as in the case of the multiplying synchronous detector) or gating square wave (as in the case of switching synchronous detectors), is perfectly synchronized with the carrier of the modulated signal. However, perfect synchronization may not always be assumed. Multiplying a signal in carrier-quadrature form (as in Equation 84.2) by a demodulating signal $\cos(\omega_c t + \theta)$ and passing the result through a suitable low-pass filter gives

$$f_d(t) = \frac{f_i(t)}{2}\cos(\theta) + \frac{f_q(t)}{2}\sin(\theta) \tag{84.13}$$

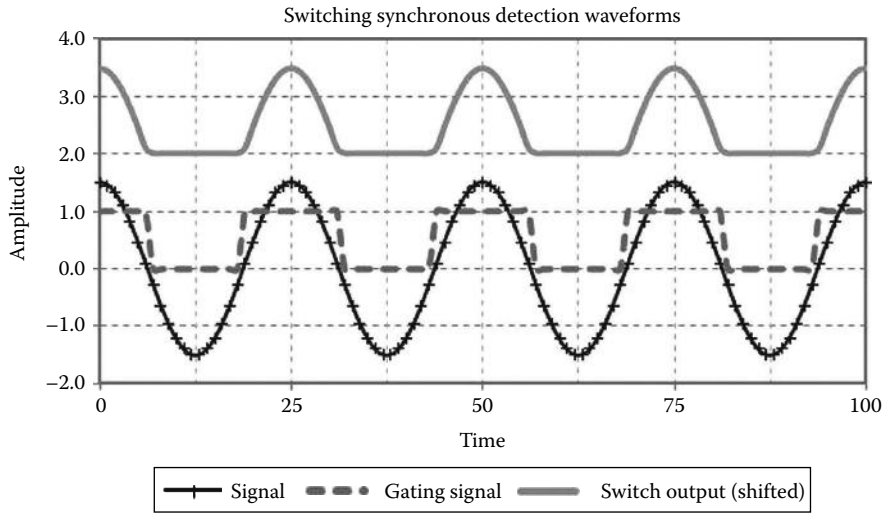

FIGURE 84.9 Waveforms in a half-wave synchronous demodulator when the input signal is a constant-amplitude sinusoid. The minimum value of the switch output waveform is 0; it has been offset for clarity.

Equation 84.13 is an important result; it demonstrates that both the magnitudes and the polarities of the components of the demodulated signal are functions of the synchronization in phase between the demodulating signal and the modulated carrier. Synchronous demodulation is thus often called phase-sensitive demodulation.

Balanced sensors with sinusoidal excitation (such as the LVDT and resistive Wheatstone bridge of Figure 84.4) produce modulated signals that are either in phase or inverted with respect to the carrier. In some measurements (e.g., electrical impedance), however, the phase between the modulated signal and the unmodulated carrier may take on a continuum of values, and information about the measurand may be contained in either or both the amplitude and phase of $f_s(t)$. A pair of phase-sensitive demodulators (PSD) may be employed to recover both amplitude and phase of $f_s(t)$; one uses a reference signal synchronous with $\cos(\omega_c t)$ while the other uses a reference signal synchronous with $\sin(\omega_c t)$. An example using half-wave synchronous rectifiers is shown in Figure 84.10.

Let $f_s(t)$ take the form $A_s\cos(\omega_c t + \theta)$ and be processed through the circuit of Figure 84.10. The in-phase gating signal $f_{GI}(t)$ has transitions synchronous with the zero crossings of $\cos(\omega_c t)$; quadrature gating signal $f_{GQ}(t)$ is synchronous with zero crossings of $\sin(\omega_c t)$. These gating signals may be expressed in terms of their Fourier series:

$$f_{GI}(t) = 0.5 + \frac{2}{\pi}\left[\cos(\omega_c t) - \frac{1}{3}\cos(3\omega_c t) + \frac{1}{5}\cos(5\omega_c t) - \frac{1}{7}\cos(7\omega_c t) + \cdots\right]$$

$$f_{GQ}(t) = 0.5 + \frac{2}{\pi}\left[\sin(\omega_c t) + \frac{1}{3}\sin(3\omega_c t) + \frac{1}{5}\sin(5\omega_c t) + \frac{1}{7}\sin(7\omega_c t) + \cdots\right] \tag{84.14a,b}$$

Multiplying $f_s(t)$ by the gating signals gives the switch output signals before filtering:

$$f_{I'}(t) = 0.5AA_s\cos(\omega_c t + \theta) + \cdots$$

$$\frac{AA_s}{\pi}\left\{\left[\cos(2\omega_c t + \theta) + \cos(\theta)\right] - \frac{1}{3}\left[\cos(4\omega_c t + \theta) + \cos(-2\omega_c t + \theta)\right] + \cdots\right\}$$

$$f_{Q'}(t) = 0.5AA_s\cos(\omega_c t + \theta) + \cdots \tag{84.15a,b}$$

$$\frac{AA_s}{\pi}\left\{\left[\sin(2\omega_c t + \theta) - \sin(\theta)\right] + \frac{1}{3}\left[\sin(4\omega_c t + \theta) - \sin(-2\omega_c t + \theta)\right] + \cdots\right\}$$

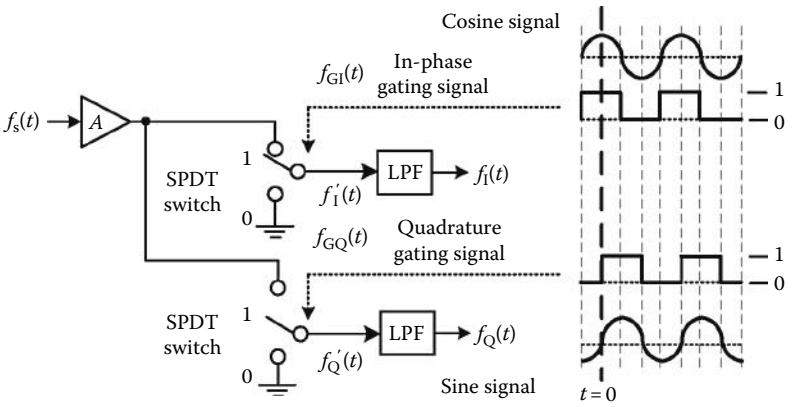

FIGURE 84.10 Phase-sensitive demodulator for arbitrary phase shifts between the unmodulated carrier and the modulated signal. Outputs $f_I(t)$ and $f_Q(t)$ are called the in-phase and quadrature outputs, respectively; the unfiltered signals at the outputs of the switches are designated as $f_I'(t)$ and $f_Q'(t)$.

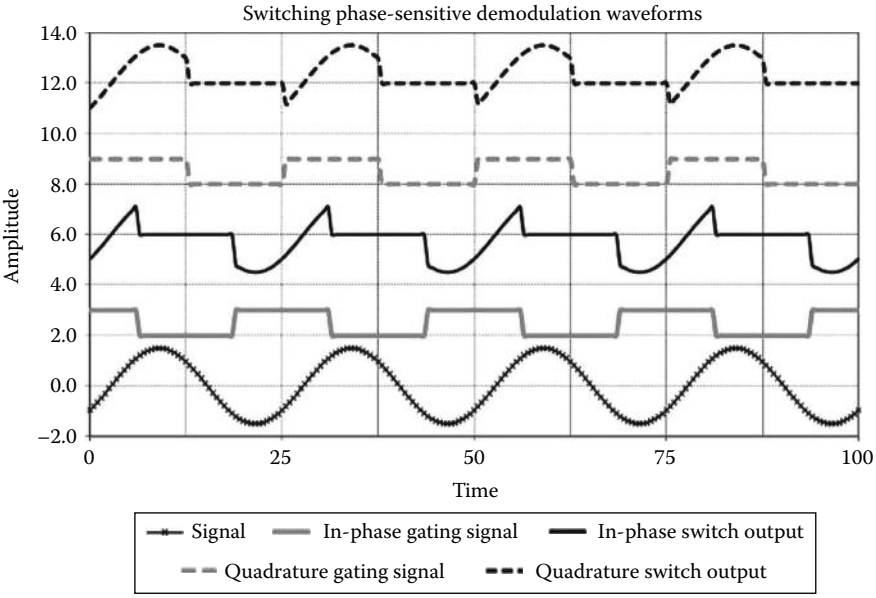

FIGURE 84.11 Example waveforms in the phase-sensitive demodulator of Figure 84.10. From bottom to top, the waveforms are the signal $f_s(t)$; the in-phase gating function $f_{GI}(t)$; the in-phase switch output prior to filtering $f_I'(t)$; the quadrature gating function $f_{GQ}(t)$; and the quadrature switch output prior to filtering $f_Q'(t)$. All waveforms except the signal waveform have been shifted vertically for clarity.

Equation 84.15 was derived using the trigonometric identities $\cos(a)\cos(b) = 0.5 \times [\cos(a + b) + \cos(a - b)]$ and $\cos(a)\sin(b) = 0.5 \times [\sin(a + b) - \sin(a - b)]$. Passing $f_I'(t)$ and $f_Q'(t)$ through low-pass filters having cutoff frequencies well below ω_c removes all but the dc components from the outputs $f_I(t)$ and $f_Q(t)$. The dc components are

$$f_I = \frac{AA_s}{\pi}\cos(\theta) \quad f_Q = -\frac{AA_s}{\pi}\sin(\theta) \tag{84.16}$$

The amplitude and phase of the modulated signal are found by the following equation:

$$A_s = \frac{\pi}{A}\sqrt{f_I^2 + f_Q^2} \quad \theta = \tan^{-1}\left(\frac{-f_Q}{f_I}\right) \tag{84.17a,b}$$

Figure 84.11 illustrates example waveforms in the PSD of Figure 84.10. In this case, the gain of the amplifier $A = 1$, the amplitude of the signal $A_s = 1.5$, and its phase θ relative to $\cos(\omega_c t)$ is –130. The calculated dc components of the switch output waveforms in Figure 84.11 are $f_I = -0.308$ and $f_Q = 0.367$. Using these values in Equation 84.17a,b gives a calculated amplitude of 1.505 and a phase angle of –130°.

Additional material on phase-sensitive demodulation in AM systems may be found in Pederson and Mayaram [7].

84.3.5 Applications of Phase-Sensitive Demodulation in Instrumentation Systems

It would be difficult to overstate the importance of phase-sensitive demodulation in instrumentation applications. There are numerous applications and developments described in the literature. For example, Munteanu et al. [8] describe the application of PSD to the measurement of electrical impedance.

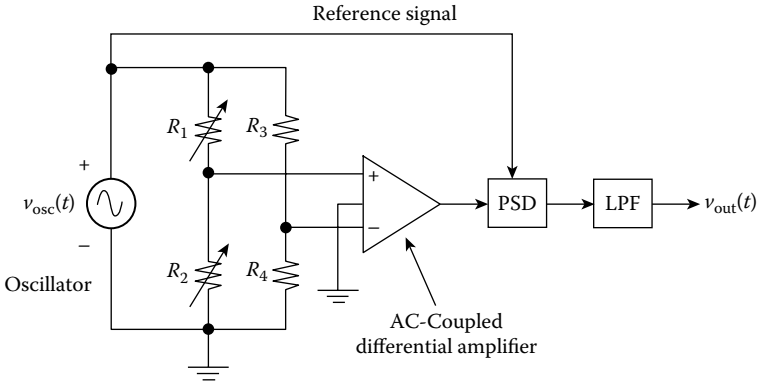

FIGURE 84.12 Carrier amplifier applied to measurement of imbalance in a resistive Wheatstone bridge. The oscillator provides a signal to operate the sensor, which itself may be measuring a number of possible measurands (e.g., mechanical strain). The block marked "PSD" is the phase-sensitive detector; "LPF" denotes a low-pass filter.

Syndenham [9] describes the use of PSD with LVDTs; Tarrant describes the use of PSD in optical systems, such as Faraday polarimeters and chopped optical systems [10]. The use of PSD to separate transformer voltage from signal voltage in electromagnetic flowmeters is described in [11]. A digital implementation of PSD for electrical capacitance tomography (ECT) applications is described in [12]. Ge and Lifeng [13] describe a digital PSD system for electric impedance tomography (EIT) applications. Tapson [14] describes a mixed-signal approach to PSD that provides benefits of precise bandwidth control, the ability to use square wave reference signals without problems of harmonic content, and elimination of need for a separate antialiasing filter that is required in a purely digital approach.

A particularly important application is the carrier amplifier. According to Pallàs-Areny and Webster [15], the carrier amplifier is a circuit that includes an oscillator circuit, ac-coupled amplification, phase-sensitive demodulation, and low-pass filtering. Figure 84.12 shows a carrier amplifier used for signal processing of the Wheatstone bridge of Figure 84.4. They further define a lock-in amplifier as a carrier amplifier in which the oscillator drives the system being measured rather than the sensor.

An example of a lock-in amplifier is the system for electrical-impedance plethysmography shown in Figure 84.13. In this case, a high-frequency ac current of constant magnitude is forced to flow through a part of the body. The current flow through the tissue produces a voltage which is picked up by sensing electrodes, amplified, and demodulated. Changes in perfusion in a limb or ventilation in the thorax provide small, but measurable, changes in electrical impedance $\Delta z(t)$ with respect to a much larger baseline impedance Z.

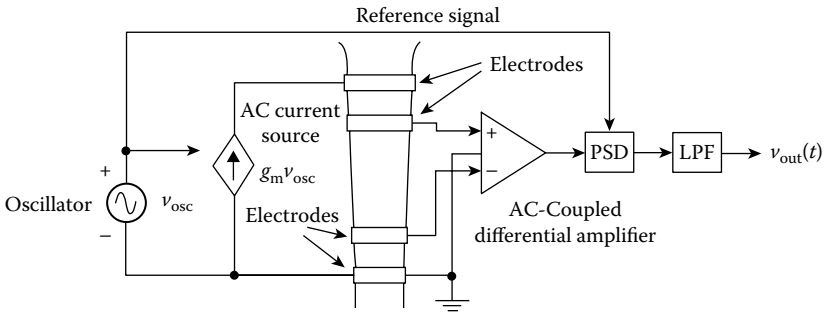

FIGURE 84.13 Lock-in amplifier employed for electrical-impedance plethysmography. The oscillator both controls the ac current source and provides a reference signal for the phase-sensitive demodulator.

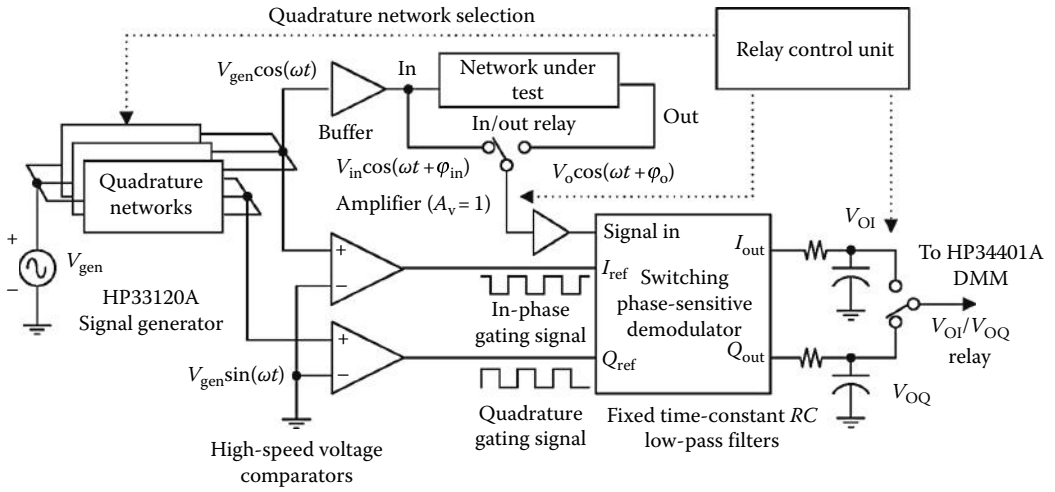

FIGURE 84.14 Lock-in amplifier methods using half-wave switching phase-sensitive demodulation in the Project TUNA instrument developed at the University of Texas at Tyler. The block labeled "Relay Control Unit" selects the appropriate quadrature network for the frequency of measurement, switches the input of the switching PSD between the input and output of the network under test, and switches the external DMM between the output voltage of the in-phase channel of the PSD (V_{OI}) and the output voltage of the quadrature channel (V_{OQ}).

As noted by Webster [16], high-frequency ac current passing through $Z + \Delta z(t)$ generates a full-carrier AM signal. This is unlike the signals produced by ac drive of balanced sensors, which are suppressed-carrier DSB signals. The full-carrier AM signal may be demodulated by a simple envelope detector. Phase-sensitive demodulation, however, gives superior performance because of its ability to reject interfering sources (e.g., pickup from 60 Hz power lines).

This ability to reject extraneous signals separated from the oscillator frequency allows carrier amplifiers to detect signals otherwise lost in noise or interfering signals. If the carrier oscillator frequency is ω_c and the bandwidth of the LPF extends from dc to an upper cutoff frequency ω_b, the carrier amplifier will reject all signals except those in the range $(\omega_c - \omega_b) < \omega < (\omega_c + \omega_b)$.

An example of lock-in amplifier methods coupled with quadrature detection is found in the Project TUNA (Texas Universal Network Analyzer) [17] and Project TUNA II [18] laboratory instruments developed for the electrical engineering laboratory at the University of Texas at Tyler. Both instruments use custom hardware and a LabVIEW (National Instruments, Austin, TX) virtual-instrument (VI) program. Both measure the frequency response (magnitude and phase shift) of the voltage gain of a linear network under sinusoidal, steady-state ac excitation, and both display these measurements in a Bode plot. Figure 84.14 shows the topology of the Project TUNA instrument. A signal generator (Agilent 33120A) generates a sinusoidal signal with frequency and amplitude controlled by the LabVIEW VI. The generator signal V_{gen} drives a quadrature network, an analog network that produces two sinusoidal outputs that maintain a 90° phase relationship over a wide range of frequencies. One output of the quadrature network is $V_{gen}\cos(\omega t)$ and the other output is $V_{gen}\sin(\omega t)$. The cosine signal is buffered and used to drive the network under test. Both the cosine and sine signals are passed through high-speed voltage comparators to produce square waves in-phase quadrature; these are the in-phase and quadrature gating signals of a half-wave switching phase-sensitive quadrature demodulator like that shown in Figure 84.10. The in-phase and quadrature output voltages of the PSD are read by an external digital multimeter (DMM) and these measurements are used to determine both the magnitude and the phase (relative to the cosine signal) of the signal input of the PSD. The magnitude and phase of both the input voltage $V_{in}\cos(\omega t + \varphi_{in})$ and output voltage $V_o\cos(\omega t + \varphi_o)$ of the network under test are measured, and the gain is computed and displayed. The switches of the PSD are implemented with ADG201HS

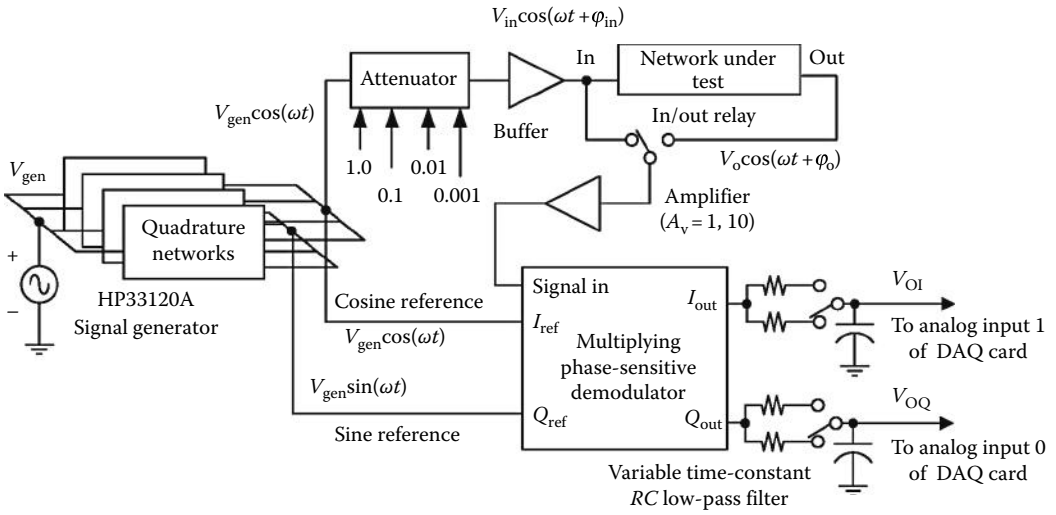

FIGURE 84.15 Lock-in amplifier methods using multiplying phase-sensitive demodulation in the Project TUNA II instrument developed at the University of Texas at Tyler. Improvements included a digitally controlled attenuator, a variable-gain amplifier, and variable time-constant low-pass filters.

high-speed analog switches (Analog Devices, Norwood, MA). A relay control unit, acting under control of the LabVIEW VI, activates the quadrature network appropriate to the frequency of the measurement, switches the input of the PSD to either the input or output of the network under test, and switches the DMM between the two outputs of the PSD.

The Project TUNA II instrument was an improved version of Project TUNA. Its chief differences were the use of a multiplying quadrature phase-sensitive detector, a variable-gain amplifier, and a variable attenuator under computer control. Analog Devices AD734 precision multipliers were used in the PSD. The topology of Project TUNA II is shown in Figure 84.15. The chief reason for the change to a multiplying PSD was to extend the maximal operating frequency of the instrument; charge injection in the analog switches of Project TUNA instrument limited the maximal usable frequency of Project TUNA to ~100 kHz.

Other topologies for lock-in amplifiers are also possible. The Analog Devices AD630 balanced modulator-integrated circuit makes a simple lock-in amplifier. It has on-chip precision resistances which allow the device to be used with a minimal number of external components. High-speed CMOS switches (such as the 74HC4053 or the ADG201HS mentioned in connection with Project TUNA) may be used in switching demodulators. Meade [19] provides detailed analysis of lock-in amplifiers; further information regarding lock-in amplifiers is found in [20,21].

84.4 Angle (Frequency and Phase) Modulation

In the preceding section, attention was paid to modulating the amplitude of a carrier signal. Information may be transmitted, however, by varying the phase angle in accordance with the baseband signal. Consider a signal of the form:

$$f_s(t) = A_c \cos[\omega_c t + \Delta\varphi \cdot x_m(t)] \tag{84.18}$$

The instantaneous phase of $f_s(t)$ is $\omega_c t + \Delta\varphi x_m(t)$; the phase relative to the unmodulated carrier is $\Delta\varphi x_m(t)$. The parameter $\Delta\varphi$ is the phase-modulation index (Carlson et al. [1]). The carrier is thus phase-modulated by $x_m(t)$. The instantaneous frequency of $f_s(t)$ is $\omega_c + \Delta\varphi[dx_m(t)/dt]$; phase modulation of the carrier also produces modulation of the carrier frequency unless $x_m(t)$ is a constant.

Assume that the modulating signal $x_m(t)$ is the time integral of the baseband signal $f_m(t)$. Then Equation 84.18 may be rewritten

$$f_s(t) = A_c \cos\left[\omega_c t + \Delta\varphi \cdot \int_0^t f_m(\tau)d\tau\right] \tag{84.19}$$

The instantaneous frequency $\omega_s(t)$ of $f_s(t)$ is $\omega_c + \Delta\varphi f_m(t)$. The instantaneous deviation in frequency in $\Delta\varphi f_m(t)$ is proportional to the baseband signal; the carrier is thus frequency-modulated by $f_m(t)$. This method of generating a frequency-modulated signal using a phase modulator controlled by the time integral of the baseband signal is known as indirect FM [22].

It is also possible to directly modulate the frequency of the carrier; in the case of the so-called direct FM, the expression for instantaneous frequency becomes

$$\omega_s(t) = \omega_c + \Delta\omega \cdot f_m(t) \tag{84.20}$$

Consider a baseband signal of the form $f_m(t) = A_m\cos(\omega_m t)$. Substituting this into Equation 84.19 gives

$$f_s(t) = A_c \cos\left[\omega_c t + \Delta\varphi \cdot A_m \int_0^t \cos(\omega\tau)d\tau\right] \tag{84.21}$$

Carrying out the integration in Equation 84.21 gives

$$f_s(t) = A_c \cos\left[\omega_c t + \frac{\Delta\varphi \cdot A_m}{\omega_m}\sin(\omega_m t)\right] = A_c \cos\left[\omega_c t + \beta\sin(\omega_m t)\right] \tag{84.22}$$

where β (called the modulation index) has replaced $\Delta\varphi A_m/\omega_m$. Figure 84.16 shows the time-domain representation of an FM signal and the original baseband signal. In this particular waveform, the unmodulated carrier frequency is 10 times the frequency of the sinusoidal baseband signal and the modulation index is 4.0.

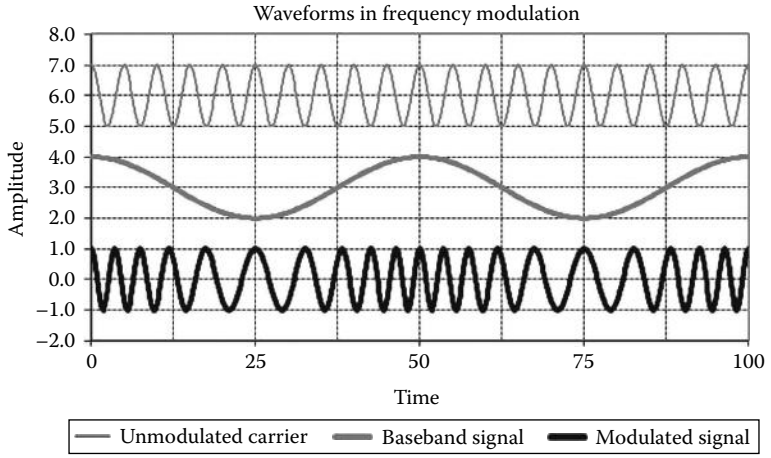

FIGURE 84.16 Frequency-modulated waveform. A_c = 1.0, A_m = 1.0, $\Delta\varphi$ = 0.5. The time scale is arbitrary, and the carrier and modulation waveforms have been offset for clarity.

The carrier-quadrature form of Equation 84.22 is

$$f_s(t) = A_c\left\{\cos[\beta\sin(\omega_m t)]\cos(\omega_c t) - \sin[\beta\sin(\omega_m t)]\sin(\omega_c t)\right\} \tag{84.23}$$

Unlike AM, an FM signal contains both in-phase and quadrature components, and the amplitudes of both are nonlinear functions of the modulation index. The terms $\cos[\beta\sin(\omega_m t)]$ and $\sin[\beta\sin(\omega_m t)]$ are generally expanded in terms of Bessel functions (see Schwartz [3] for detailed analysis). The Bessel function expression of an FM signal is

$$f_s(t) = A_c\sum_{n=-\infty}^{\infty} J_n(\beta)\cos[(\omega_c + n\omega_m)t] \tag{84.24}$$

where $J_n(\beta)$ represents a Bessel function of the first kind of order n. Beyer [23] provides tables of $J_0(\beta)$ and $J_1(\beta)$ and gives formulae for computing higher-order Bessel functions. Amplitudes for the carrier and sidebands through the fifth for modulation of a sinusoidal carrier with a sinusoidal baseband signal for selected values of β are given in Table 84.1.

It is also noted that $J_{-n}(\beta) = (-1)^n J_n(\beta)$. The approximations $J_0(\beta) = 1$ and $J_1(\beta) = \beta/2$ are valid for small values of the modulation index ($\beta < 0.2$). A carrier with sinusoidal FM and a low modulation index will show sidebands spaced at $\pm\omega_m$ about the carrier. Thus narrowband FM would be indistinguishable from full-carrier AM on a spectrum analyzer (which shows the amplitudes of spectral components, but not their phase relationships). As modulation index increases, however, new sideband pairs appear at $\pm2\omega_m$, $\pm3\omega_m$, $\pm4\omega_m$, etc., as the higher-order Bessel functions become more significant. The amplitude of the carrier component of $f_s(t)$ varies with $J_0(\beta)$; the carrier, in fact, disappears completely for certain values of the modulation index. These characteristics are unlike AM in which the carrier component of the modulated signal is constant and in which only one sideband pair is produced for each spectral component in the baseband signal. FM is inherently a nonlinear modulation process; the sum of multiple FM signals derived from a single carrier with multiple baseband signals does not give the same result as frequency modulation of the carrier by the sum of the baseband signals. The spectrum of a phase-modulated signal is similar to that of an FM signal, but the modulation index of a phase-modulated signal does not vary with ω_m.

TABLE 84.1 Carrier and Sideband Amplitudes for Frequency Modulation with a Sinusoidal Baseband Signal

Modulation Index	Carrier	f_1	f_2	f_3	f_4	f_5
0	1.0	—	—	—	—	—
0.25	0.98	0.12	0.01	—	—	—

84.4.1 Generation of Phase- and Frequency-Modulated Signals

Variable-frequency signals may arise directly in instrumentation applications from sources like turbine-type flowmeters or Doppler velocity sensors. Direct FM signals may be generated by applying the baseband signal to a voltage-controlled oscillator; Sherwin and Regan [24] apply this technique in a system using the LM566 VCO to transmit analog information over 60 Hz power lines. In radio-frequency applications, the oscillator frequency may be varied by application of the baseband signal to a voltage-variable reactance (typically a varactor diode). Indirect FM may be generated by PM of the carrier with the baseband signal integrated with respect to time as in Equation 84.21; DeFrance [25] and Comer and Comer [26] give examples of phase-modulator circuits.

84.4.2 Demodulation of Phase- and Frequency-Modulated Signals

PM signals may be demodulated by phase-sensitive detectors. Limiter circuits may be employed to transform analog signals to digital waveforms prior to the phase detector. This has the advantage of making the output of the phase detector insensitive to variations in amplitude of the signal prior to the limiter. The use of digital waveforms in a PSD also makes linear the relationship of output voltage to phase difference.

Simple digital circuits like those of Figure 84.17 can serve to detect the phase difference between two digital signals. In Figure 84.17a, an exclusive OR (XOR) logic gate produces logic 1 at its output Y only if

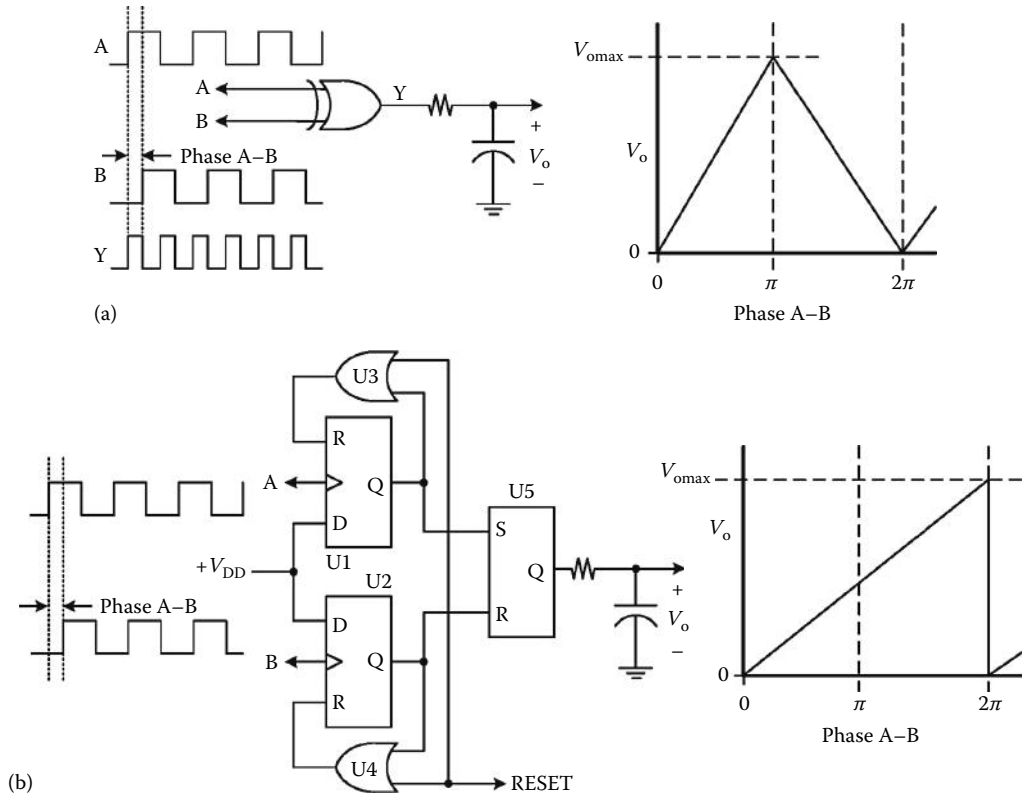

FIGURE 84.17 Examples of digital phase detectors. In both cases, the maximal output voltage V_{omax} is equal to the high-level output voltage of the logic devices. In each circuit, it is assumed that signals A and B have been hard-limited to suppress amplitude variations and to produce digital waveforms of the appropriate logic levels.

logic inputs A and B are different. The low-pass filter produces from the pulse train at output Y at voltage proportional to phase difference between signals A and B. However, the proportionality becomes negative for phase shifts between π and 2π radians. In Figure 84.17b, flip-flop U1 and OR-gate U3 produce a short logic 1 pulse on the rising edge of A; this pulse sets SR flip-flop U5. Flip-flop U2 and OR-gate U4 likewise produce a short pulse on the rising edge of B, causing U5 to be reset. The low-pass filter produces a voltage proportional to the phase difference between signals A and B. The RESET input may be used to force the initial states of U1 and U2.

Figure 84.18 shows examples of three common FM detectors. Figure 84.18a is a quadrature detector of the type frequently used in integrated-circuit FM receivers. Figure 84.18b is a frequency-to-voltage converter utilizing a monostable multivibrator, while Figure 84.18c shows a block diagram of a phase-locked loop (PLL).

In the quadrature detector of Figure 84.18a, a limiter circuit suppresses amplitude variations in the modulated signal and the amplitude-limited signal is passed to a PSD as its reference signal. The limiter output signal is also coupled (via a small capacitor C_1) to a resonant network consisting

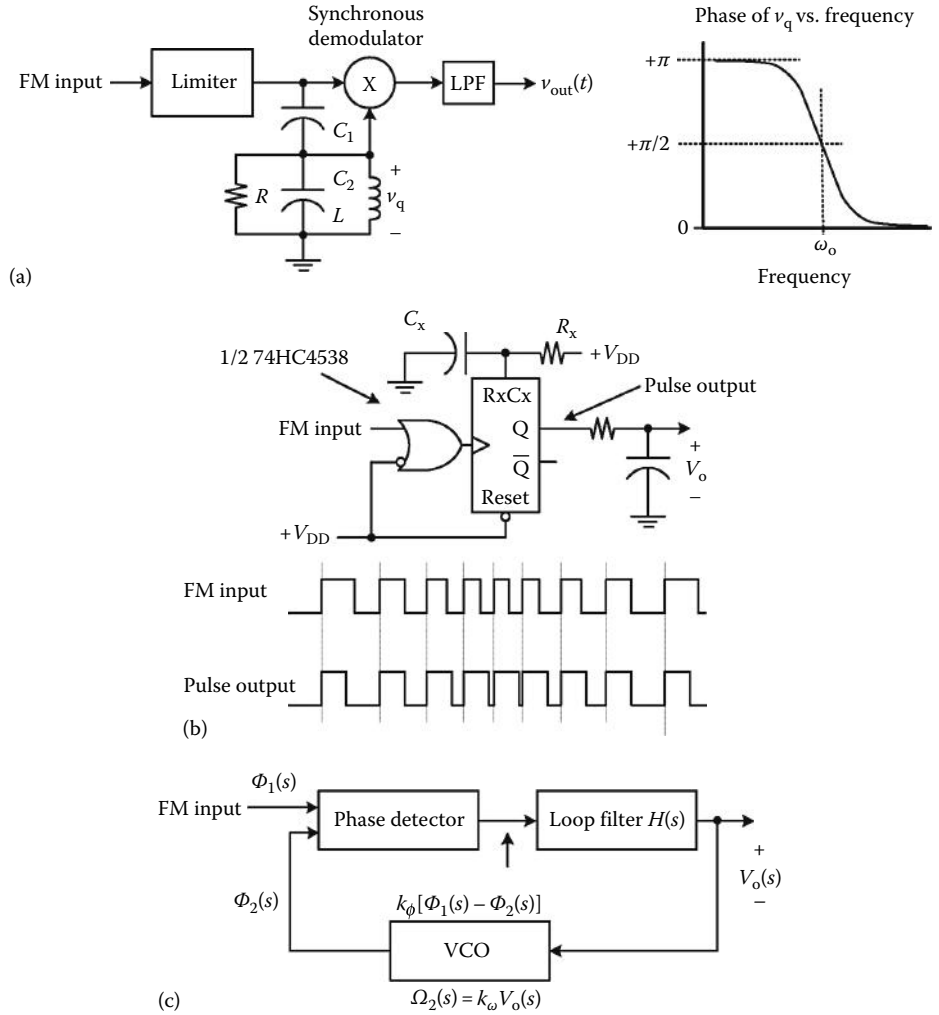

FIGURE 84.18 Examples of FM demodulators.

of L, R, and C_2. The phase of the voltage across the quadrature network relative to the limiter output, $\varphi(\omega)$, is given by

$$\varphi(\omega) = \pi - \tan^{-1} \frac{\omega L/R}{[1-(\omega/\omega_0)^2]} \tag{84.25}$$

where ω_0 is

$$\omega_0 = \frac{1}{\sqrt{L(C_1 + C_2)}} \tag{84.26}$$

This relationship is illustrated in the graph associated with Figure 84.18b. The variation in phase is nearly linear for frequencies close to ω_0. The baseband signal is recovered from the output of the phase-sensitive detector. The voltage across the quadrature network also varies with frequency, but there is generally sufficient voltage across the quadrature network to force the PSD into a nonlinear regime in which its output voltage is relatively insensitive to the amplitude of the voltage across the quadrature network.

Figure 84.18b shows a frequency-to-voltage converter consisting of a monostable multivibrator (one-shot) triggered on each rising edge of the digital input waveform; the low-pass filter recovers the baseband signal from the resulting pulse train.

Figure 84.18c shows FM demodulation by means of a PLL. The phase-comparator circuit produces an output voltage proportional to the difference in phase between the input signal and the output signal of the VCO. The output voltage of the phase comparator is filtered and used to drive the VCO; the filtered output voltage of the phase comparator is also the demodulated output signal.

The operation of the PLL may be explained in the following. The phase and frequency of the FM input signal are designated as $\varphi_1(t)$ and $\omega_1(t)$, respectively, and have Laplace transforms $\Phi_1(s)$ and $\Omega_1(s)$. The phase and frequency of the VCO output are represented by $\varphi_2(t)$ and $\omega_2(t)$; their Laplace transforms are $\Phi_2(s)$ and $\Omega_2(s)$. The phase detector produces an output voltage $v_\varphi(t)$ given by

$$v_\varphi(t) = k_\varphi[\varphi_1(t) - \varphi_2(t)] \tag{84.27}$$

The Laplace transform of $v_\varphi(t)$ is designated $V_\varphi(s)$ and is given by

$$V_\varphi(s) = k_\varphi[\Phi_1(s) - \Phi_2(s)] \tag{84.28}$$

This voltage is filtered by the loop filter having transfer function $H(s)$ and is applied to the control voltage input of the VCO. The VCO produces an output signal with a frequency proportional to the control voltage. The Laplace transform of the VCO frequency is

$$\Omega_2(s) = k_\omega k_\varphi H(s)[\Phi_1(s) - \Phi_2(s)] \tag{84.29}$$

Since $\Phi_1(s) = \Omega_1(s)/s$ and $\Phi_2(s) = \Omega_2(s)/s$, appropriate substitutions and rearrangement of Equation 84.29 gives

$$\Omega_2(s) = \left[\frac{k_\omega k_\varphi H(s)}{s + k_\omega k_\varphi H(s)}\right]\Omega_1(s) \tag{84.30}$$

If the input frequency to the PLL is a step function of magnitude ω_1, the Laplace transform of the VCO frequency is

$$\Omega_2(s) = \left[\frac{k_\omega k_\varphi H(s)}{s + k_\omega k_\varphi H(s)}\right]\frac{\omega_1}{s} \tag{84.31}$$

Application of the final-value theorem of the Laplace transform to Equation 84.31 gives $\omega_2 = \omega_1$. In other words, the output frequency of the VCO matches the input frequency. The VCO input voltage is ω_1/k_ω and is directly proportional to the input frequency. If the input signal is a carrier frequency-modulated by some baseband signal, the filtered phase-detector output follows that baseband signal. Taub and Schilling [2] give an extensive analysis of the PLL, as do Pederson and and Mayaram [7] and O'Dell [27].

The simplest loop filter simply applies the output of the phase detector to the input of the VCO and has $H(s) = 1$. If this were done, the transfer function $\Omega_2(s)/\Omega_1(s)$ would have a single-pole low-pass response with a cutoff frequency $\omega_{-3\text{dB}} = k_\omega k_\varphi$. The VCO output frequency tracks slowly varying input frequencies well, but the response to rapidly varying input frequencies is limited by the low-pass transfer function of the loop. Baseband spectral components which lie beyond the cutoff frequency of the loop are attenuated. A single-pole *RC* network is frequently used as the loop filter in a PLL. The transfer function of a PLL with such a loop filter is

$$\frac{\Omega_2(s)}{\Omega_1(s)} = \left[\frac{k_\omega k_\varphi \omega_\text{f}}{s^2 + s\omega_\text{f} + k_\omega k_\varphi \omega_\text{f}}\right] \tag{84.32}$$

where $\omega_\text{f} = 1/(RC)$ is the cutoff frequency of the *RC* low-pass filter. It is noted that the loop transfer function $\Omega_2(s)/\Omega_1(s)$ is a second-order system and thus may exhibit dynamics such as resonance and underdamped transient response, depending upon the values of the parameters k_φ, k_ω, and ω_f.

84.4.3 Examples

Two common applications in instrumentation involving FM signals are Doppler radar velocimetry and distance measurement using FM continuous-wave (FMCW) radar.

Doppler radar velocimetry measures relative velocity between an emitter of microwave energy and a reflecting object by taking advantage of the Doppler frequency shift. Figure 84.19 shows a simple Doppler radar velocity sensor. A microwave source (typically a MOSFET or Gunn diode) supplies energy to the feedpoint of a high-gain microwave antenna. Some of the emitted energy is

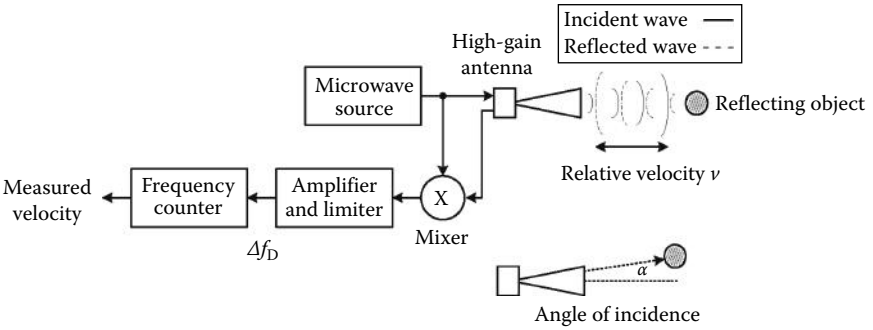

FIGURE 84.19 Microwave Doppler velocity sensor.

reflected from nearby objects, and the reflected signal is mixed with the emitted signal to produce the sum and difference of the transmitted and received frequencies. If the object and the microwave emitter are in relative motion, the reflected signal returns to the emitter shifted in frequency by the Doppler shift frequency Δf_D:

$$\Delta f_D = 2\left(\frac{v}{c}\right) f_c \cos(\alpha) \tag{84.33}$$

where

v is the relative velocity of the source and the reflecting object (m/s)
c is the speed of light in air (3.0×10^8 m/s)
f_c is the frequency of the microwave (carrier) source (Hz)
α is the angle of incidence between the source and the reflector

For K-band microwave sources (24 GHz) and head-on incidence ($\alpha = 0$), the Doppler frequency shift is 160 Hz/(m/s). One drawback of the system of Figure 84.19 is that it cannot distinguish whether the Doppler shift is positive (indicating that the source and reflector are approaching each other) or negative (indicating that the source and reflector are moving away from each other).

The Doppler velocity sensor uses a constant-frequency carrier; modulation of the carrier frequency takes place through nonelectronic means. The Doppler velocity sensor may be used to measure distance traveled through integration of the measured velocity, but it cannot measure distance or detect stationary objects. FMCW radar uses a frequency-modulated carrier and detects the difference between the instantaneous transmitted frequency and the received frequency. An example of an FMCW distance-measurement system is shown in Figure 84.20.

The frequency of the carrier is swept between its minimum and maximum frequency values f_{cmin} and f_{cmax} in a triangular pattern at a rate $\pm\Delta f_c/\Delta t$. The transmitted signal strikes the reflecting object

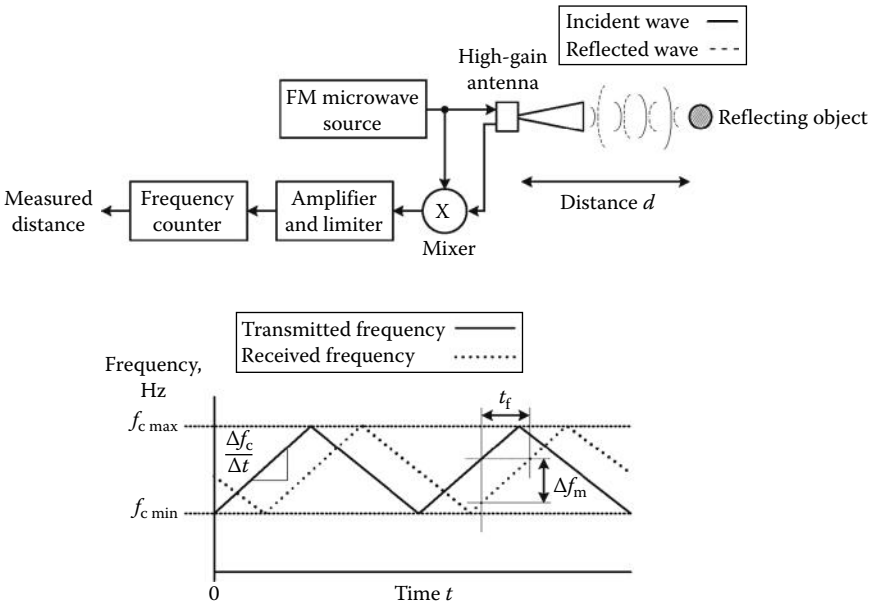

FIGURE 84.20 FMCW distance sensor. (The diagram of carrier frequency vs. time is adapted from Daniewicz, J.L. and Boyes, W.H., in Lipták, B.G., Ed., *The Instrument Engineer's Handbook. Process Measurement and Analysis*, 4th ed., Vol. 1, CRC Press, Boca Raton, FL, 2003.)

at a distance d from the source and returns to the source after a total time of flight t_f, which is the time required for the signal to traverse a distance of $2d$. During the time of flight, the carrier frequency will have changed by $(\pm\Delta f_c/\Delta t)t_f$, assuming that the carrier frequency sweep has not changed polarity during that time. Mixing the transmitted and received signals produces a measured difference frequency Δf_m:

$$\Delta f_m = t_f \frac{\Delta f_c}{\Delta t} \tag{84.34}$$

Since $t_f = 2d/c$ (where c is the speed of light in air), the distance may be expressed as

$$d = \frac{c\Delta f_m}{2\left(\Delta f_c/\Delta t\right)} \tag{84.35}$$

However, as Figure 84.20 makes evident, Equations 84.34 and 84.35 are valid only during those times that the frequency sweep rates of both the transmitted and reflected signals have the same polarity. FMCW distance sensors find wide use in material-handling applications (e.g., sensing the liquid level in a tank or reservoir).

Cohen et al. [29] in Figure 84.21 describe a novel use of a direct FM technique to perform noninvasive monitoring of human ventilation. Elastic belts with integral serpentine inductors encircle the chest and

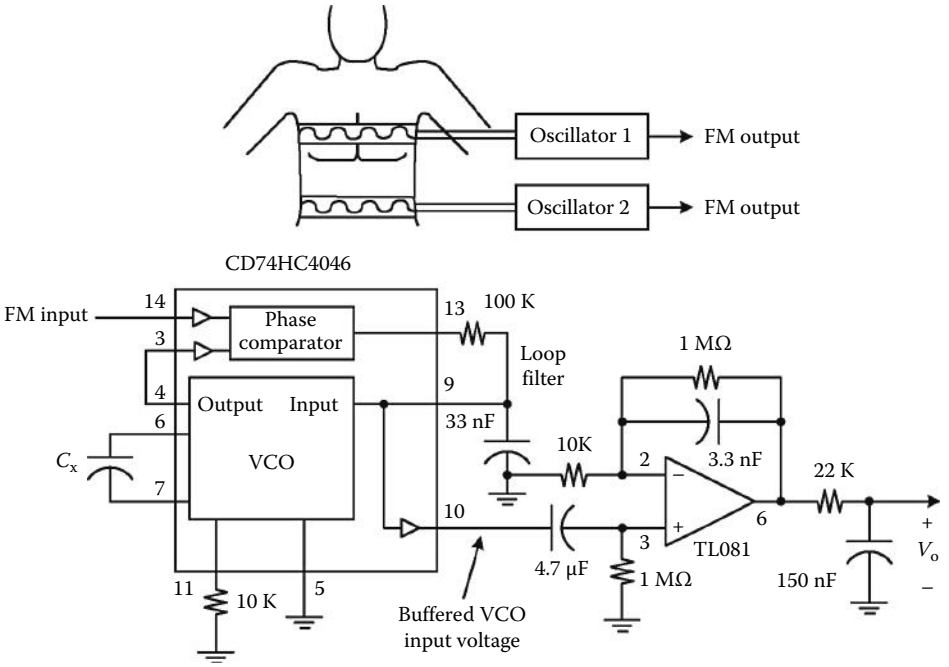

FIGURE 84.21 Direct FM techniques applied to the measurement of human ventilation. (Adapted from Cohen, K.P. et al., *Physiol. Meas.*, 15, 217, 1994.) One of two PLL demodulator circuits is shown. The capacitor C_x was chosen specifically for each demodulator depending upon the nominal frequency of each VCO. Pin numbers are shown adjacent to each integrated circuit. Optical coupling was used between the oscillator outputs and demodulator inputs to provide electrical isolation between the subject and the measurement system.

abdomen of the subject; these inductors are components of resonant tank circuits of free-running radio-frequency oscillators. Changes in chest and abdominal volume during respiration cause the inductors' cross-sectional areas to vary, changing their inductances and thus varying the frequencies of the oscillators. Figure 84.21 also shows one of the two PLL demodulator circuits. The PLLs utilize single-pole *RC* low-pass loop filters.

84.5 Components and Instrumentation

84.5.1 Integrated Circuits

Table 84.2 lists certain integrated circuits which may be used in application of the modulation techniques covered in this chapter. This is neither an exhaustive list of all useful types nor of all manufacturers. Most integrated circuits are available in a number of packages and performance grades; the prices given are indicative of the pricing of the least expensive versions purchased in small quantities. The AD532, AD633, AD734 four-quadrant multipliers may be used to make balanced modulator and multiplying demodulator circuits. The AD650 may be used as either a voltage-to-frequency or a frequency-to-voltage converter. The ADG201HS is the high-speed analog switch used as the switching element of the PSD of the Project TUNA instrument described earlier. Depending upon the maximal frequency, any number of analog switches from various sources may be suitable.

Lock-in amplifiers for general laboratory instrumentation purposes are available from several manufacturers, as listed in Table 84.3.

A partial list of instruments using modulation techniques is given in Table 84.4. A partial list manufactures of integrated circuits for modulation is given in Table 84.5 and manufacturers that make modulated sources and analyzers can be found in Table 84.6.

TABLE 84.2 Integrated Circuits Used in Modulation Applications

Designation	Function	Manufacturer

Filters

Rahman Jamal
National Instruments Germany

Robert Steer
Frequency Devices

85.1 Introduction

In its broadest sense, a filter can be defined as a signal-processing system whose output signal, usually called the *response*, differs from the input signal, called the *excitation*, such that the output signal has some prescribed properties. In more practical terms, an electric filter is a device designed to suppress, pass, or separate a group of signals from a mixture of signals according to the specifications in a particular application. The application areas of filtering are manifold, for example to band-limit signals before sampling to reduce aliasing, to eliminate unwanted noise in communication systems, to resolve signals into their frequency components, to convert discrete-time signals into continuous-time signals, to demodulate signals, etc. Filters are generally classified into three broad classes: *continuous-time*, *sampled-data*, and *discrete-time* filters depending on the type of signal being processed by the filter. Therefore, the concepts of signals are fundamental in the design of filters.

A *signal* is a function of one or more independent variables such as time, space, temperature, etc. that carries information. The independent variables of a signal can either be continuous or discrete. Assuming that the signal is a function of time, in the first case the signal is called continuous time and in the second, discrete time. A continuous-time signal is defined at every instant of time over a given interval, whereas a discrete-time signal is defined only at discrete-time instances. Similarly, the *values* of a signal can also be classified in either continuous or discrete.

In real-world signals, often referred to as analog signals, both amplitude and time are continuous. These types of signals cannot be processed by digital machines unless they have been converted into discrete-time signals. In contrast, a digital signal is characterized by discrete signal values that are defined only at discrete points in time. Digital signal values are represented by a finite number of digits, which are usually binary-coded. The relationship between a continuous-time signal and the corresponding discrete-time signal can be expressed in the following form:

$$x(kT) = x(t)_{t=kT}, \quad k = 0, 1, 2, \ldots \tag{85.1}$$

where T is called the sampling period.

Filters can be classified on the basis of the input, output, and internal operating signals. A continuous data filter is used to process continuous-time or analog signals, whereas a digital filter processes digital signals. Continuous data filters are further divided into *passive* or *active* filters, depending on the type of elements used in their implementation. Perhaps, the earliest type of filters known in the engineering community are *LC* filters, which can be designed by using discrete components like inductors and capacitors, or crystal and mechanical filters that can be implemented using *LC* equivalent circuits. Since no external power is required to operate these filters, they are often referred to as *passive* filters. In contrast, *active* filters are based on active devices, primarily *RC* elements, and amplifiers. In a sampled-data filter, on the other hand, the signal is sampled and processed at discrete instants of time. Depending on the type of signal processed by such a filter, one may distinguish between an *analog sampled-data* filter and a *digital* filter. In an analog sampled-data filter, the sampled signal can principally take any value, whereas in a digital filter the sampled signal is a digital signal, the definition of which was given earlier. Examples of analog sampled-data filters are switched capacitor (SC) filters and charge-transfer device (CTD) filters made of capacitors, switches, and operational amplifiers.

85.2 Filter Classification

Filters are commonly classified according to the filter function they perform. The basic functions are low pass, high pass, bandpass, and bandstop. If a filter passes frequencies from zero to its cutoff frequency Ω_c and stops all frequencies higher than the cutoff frequencies, then this filter type is called an ideal *low-pass filter*. In contrast, an ideal *high-pass filter* stops all frequencies below its cutoff frequency and passes all frequencies above it. Frequencies extending from Ω_1 to Ω_2 are passed by an ideal *bandpass filter*, while all other frequencies are stopped. An ideal bandstop filter stops frequencies from Ω_1 to Ω_2 and passes all other frequencies. Figure 85.1 depicts the magnitude functions of the four basic *ideal filter* types.

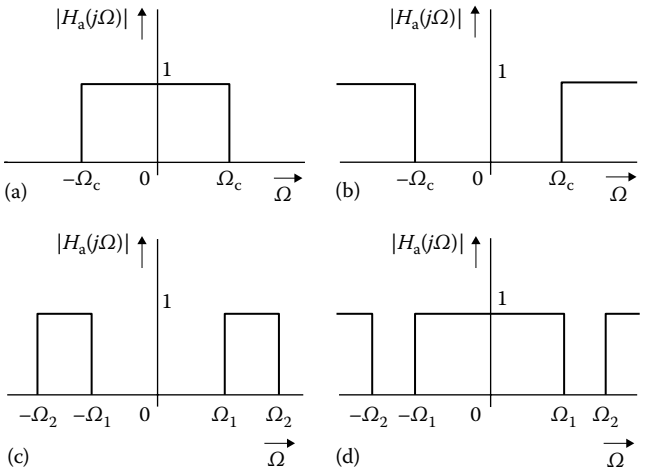

FIGURE 85.1 The magnitude function of an ideal filter is 1 in the passband and 0 in the stopband as shown for (a) low-pass, (b) high-pass, (c) bandpass, and (d) stopband filters.

So far, we have discussed ideal filter characteristics having rectangular magnitude responses. These characteristics, however, are physically not realizable. As a consequence, the ideal response can only be approximated by some nonideal realizable system. Several classical approximation schemes have been developed, each of which satisfies a different criterion of optimization. This should be taken into account when comparing the performance of these filters characteristics.

85.3 Filter Approximation Problem

Generally, the input and output variables of a linear, time-invariant, causal filter can be characterized either in the time domain through the convolution integral given by

$$y(t) = \int_0^t h_a(t-\tau)x(t)d\tau \tag{85.2}$$

or, equivalently, in the frequency domain through the transfer function

$$H_a(s) = \frac{Y(s)}{X(s)} = \frac{\sum_{i=0}^{N} b_i s^i}{1 + \sum_{i=0}^{N} a_i s^i} \Leftrightarrow H_a(s) = \frac{b_N}{a_N} \prod_{i=1}^{N} \left(\frac{s - s_{0i}}{s - s_{\infty i}} \right) \tag{85.3}$$

where

$H_a(s)$ is the Laplace transform of the impulse response $h_a(t)$ and $X(s)$
$Y(s)$ are the Laplace transforms of the input signal $x(t)$ and the output or the filtered signal $y(t)$
$X(s)$ and $Y(s)$ are polynomials in $s = \sigma + j\Omega$
The overall transfer function $H_a(s)$ is a real rational function of s with real coefficients

The zeroes of the polynomial $X(s)$ given by $s = s_{\infty i}$ are called the poles of $H_a(s)$ and are commonly referred to as the *natural frequencies* of the filter. The zeros of $Y(s)$ given by $s = s_{0i}$ which are equivalent to the zeroes of $H_a(s)$ are called the *transmission zeros* of the filter. Clearly, at these frequencies the filter output is zero for any finite input. Stability restricts the poles of $H_a(s)$ to lie in the left half of the s-plane excluding the $j\Omega$-axis, that is, $\mathrm{Re}\{s_{\infty i}\} < 0$. For a stable transfer function, $H_a(s)$ reduces to $H_a(j\Omega)$ on the $j\Omega$-axis, which is the continuous-time Fourier transform of the impulse response $h_a(t)$ and can be expressed in the following form:

$$H_a(j\Omega) = |H_a(j\Omega)|\, d^{j\theta(\Omega)} \tag{85.4}$$

where

$|H_a(j\Omega)|$ is called the magnitude function
$\theta(\Omega) = \arg H_a(j\Omega)$ is the phase function

The gain magnitude of the filter expressed in decibels (dB) is defined by

$$\alpha(\Omega) = 20\log|H_a(j\Omega)| = 10\log|H_a(j\Omega)|^2 \tag{85.5}$$

Note that a filter specification is often given in terms of its attenuation, which is the negative of the gain function also given in decibels. While the specifications for a desired filter behavior are commonly given

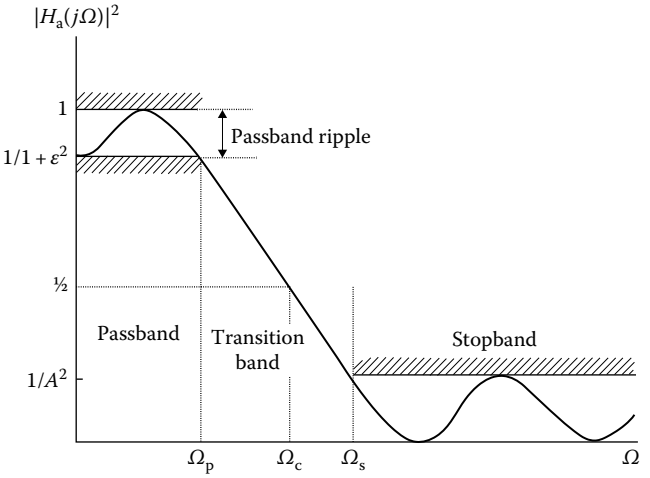

FIGURE 85.2 The squared magnitude function of an analog filter can have ripple in the passband and in the stopband.

in terms of the loss response $\alpha(\Omega)$, the solution of the filter approximation problem is always carried out with the help of the characteristic function $C(j\Omega)$ giving

$$\alpha(\Omega) = 10\log[1+|C(j\Omega)|^2] \tag{85.6}$$

Note that $\alpha(\Omega)$ is not a rational function, but $C(j\Omega)$ can be a polynomial or a rational function and approximation with polynomial or rational functions is relatively convenient. It can also be shown that frequency-dependent properties of $|C(j\Omega)|$ are in many ways identical to those of $\alpha(\Omega)$. The approximation problem consists of determining a desired response $|H_a(j\Omega)|$ such that the typical specifications depicted in Figure 85.2 are met. This so-called tolerance scheme is characterized by the following parameters:

- Ω_p Passband cutoff frequency (rad/s)
- Ω_s Stopband cutoff frequency (rad/s)
- Ω_c –3 dB cutoff frequency (rad/s)
- ε Permissible error in passband given by $\varepsilon = (10^{r/10} - 1)^{1/2}$, where r is the maximum acceptable attenuation in dB; note that $10\log(1)/(1+\varepsilon^2)^{1/2} = -r$
- $1/A$ Permissible maximum magnitude in the stopband, i.e., $A = 10^{\alpha/20}$, where α is the minimum acceptable attenuation in dB; note that $20\log(1/A) = -\alpha$

The *passband* of a low-pass filter is the region in the interval $[0, \Omega_p]$ where the desired characteristics of a given signal are preserved. In contrast, the *stopband* of a low-pass filter (the region $[\Omega_s, \infty]$) rejects signal components. The *transition* band is the *region* between $(\Omega_\times - \Omega_p)$ which would be 0 for an ideal filter. Usually, the amplitudes of the permissible ripples for the magnitude response are given in decibels.

The following sections review four different classical approximations: Butterworth, Chebyshev Type I, elliptic, and Bessel.

85.3.1 Butterworth Filters

The frequency response of an Nth-order Butterworth low-pass filter is defined by the squared magnitude function:

$$|H_a(j\Omega)|^2 = \frac{1}{1+(\Omega/\Omega_c)^{2N}} \tag{85.7}$$

It is evident from Equation 85.7 that the Butterworth approximation has only poles, i.e., no finite zeros and yields a maximally flat response around zero and infinity. Therefore, this approximation is also called maximally flat magnitude (MFM). In addition, it exhibits a smooth response at all frequencies and a monotonic decrease from the specified cutoff frequencies.

Equation 85.7 can be extended to the complex *s*-domain, resulting in

$$H_a(s)H_a(-s) = \frac{1}{1+(s/j\Omega_c)^{2N}} \tag{85.8}$$

The poles of this function are given by the roots of the denominator

$$s_k = \Omega_c e^{j\pi[1/2+(2k+1)/2N]}, \quad k = 0, 1, \ldots, 2N-1 \tag{85.9}$$

Note that for any N, these poles lie on the unit circle of radius Ω_c in the s-plane. To guarantee stability, the poles that lie in the left half-plane are identified with $H_a(s)$. As an example, we will determine the transfer function corresponding to a third-order Butterworth filter, i.e., $N = 3$.

$$H_a(s)H_a(-s) = \frac{1}{1+(-s^2)^3} = \frac{1}{1-s^6} \tag{85.10}$$

The roots of denominator of Equation 85.10 are given by

$$s_k = \Omega_c e^{j\pi[1/2+(2k+1)/6]}, \quad k = 0, 1, 2, 3, 4, 5 \tag{85.11}$$

Therefore, we obtain

$$\begin{aligned}
s_0 &= \Omega_c e^{j\pi 2/3} = -1/2 + j\sqrt{2}/2 \\
s_1 &= \Omega_c e^{j\pi} = -1 \\
s_2 &= \Omega_c e^{j\pi 4/3} = -1/2 - j\sqrt{3}/2 \\
s_3 &= \Omega_c e^{j\pi 5/3} = 1/2 - j\sqrt{3}/2 \\
s_4 &= \Omega_c e^{j2\pi} = 1 \\
s_5 &= \Omega_c e^{j\pi/3} = 1/2 + j\sqrt{3}/2
\end{aligned} \tag{85.12}$$

The corresponding transfer function is obtained by identifying the left half-plane poles with $H_a(s)$. Note that for the sake of simplicity we have chosen $\Omega_c = 1$:

$$H_a(s) = \frac{1}{(s+1)(s+1/2-j\sqrt{3}/2)(s+1/2+j\sqrt{3}/2)} = \frac{1}{1+2s+2s^2+s^3} \tag{85.13}$$

Table 85.1 gives the Butterworth denominator polynomials up to $N = 5$.

Table 85.2 gives the Butterworth poles in real and imaginary components and in frequency and Q.

TABLE 85.1 Butterworth Denominator Polynomials

Order (N)	Butterworth Denominator Polynomials of $H(s)$
1	$s + 1$
2	$s^2 + \sqrt{2}s + 1$
3	$s^3 + 2s^2 + 2s + 1$
4	$s^4 + 2.6131s^3 + 3.4142s^2 + 2.6131s + 1$
5	$s^5 + 3.2361s^4 + 5.2361s^3 + 5.2361s^2 + 3.2361s + 1$

	−0.195	0.981	1.000	2.563	−0.893	1.998	2.189	1.226

In the next example, the order N of a low-pass Butterworth filter is to be determined whose cutoff frequency (–3 dB) is $\Omega_c = 2$ kHz and stopband attenuation is greater than 40 dB at $\Omega_s = 6$ kHz. Thus the desired filter specification is

$$20\log|H_a(j\Omega)| \le -40, \quad \Omega \ge \Omega_s \tag{85.14}$$

or equivalently,

$$|H_a(j\Omega)| \le 0.01, \quad \Omega \ge \Omega_s \tag{85.15}$$

It follows from Equation 85.7

$$\frac{1}{1+(\Omega_s/\Omega_c)^{2N}} = (0.01)^2 \tag{85.16}$$

Solving the earlier equation for N gives $N = 4.19$. Since N must be an integer, a fifth-order filter is required for this specification.

85.3.2 Chebyshev Filters or Chebyshev I Filters

The frequency response of an Nth-order Chebyshev low-pass filter is specified by the squared-magnitude frequency response function:

$$|H_a(j\Omega)|^2 = \frac{1}{1+\varepsilon^2 T_N^2(\Omega/\Omega_p)} \tag{85.17}$$

where

$T_N(x)$ is the Nth-order Chebyshev polynomial

ε is a real constant <1 which determines the ripple of the filter

Specifically, for nonnegative integers N, the Nth-order Chebyshev polynomial is given by

$$T_N(x) = \begin{cases} \cos(N\cos^{-1}x), & |x| \le 1 \\ \cosh(N\cos h^{-1}x), & |x| \ge 1 \end{cases} \tag{85.18}$$

High-order Chebyshev polynomials can be derived from the recursion relation:

$$T_{N+1}(x) = 2xT_N(x) - T_{N-1}(x) \tag{85.19}$$

where

$T_0(x) = 1$
$T_1(x) = x$

The Chebyshev approximation gives an *equiripple* characteristic in the passband and is maximally flat near infinity in the stopband. Each of the Chebyshev polynomials has real zeros that lie within the interval (–1, 1) and the function values for $x\varepsilon[-1, 1]$ do not exceed +1 and –1.

The pole locations for Chebyshev filter can be determined by generating the appropriate Chebyshev polynomials, inserting them into Equation 85.17, factoring, and then selecting only the left half plane roots. Alternatively, the pole locations P_k of an Nth-order Chebyshev filter can be computed from the relation, for $k = 1 \rightarrow N$

$$P_k = -\sin\Theta_k \sin h\beta + j\cos\Theta_k \cos h\beta \tag{85.20}$$

where

$\Theta_k = (2k - 1)\pi/2N$
$\beta = \sin h^{-1}(1/\varepsilon)$

Note: P_{N-k+1} and P_k are complex conjugates and when N is odd there is one real pole at

$$P_{N+1} = -2\sin h\beta$$

For the Chebyshev polynomials, Ω_p is the last frequency where the amplitude response passes through the value of ripple at the edge of the passband. For odd N polynomials, where the ripple of the Chebyshev polynomial is negative going, it is the $[-1/(1 + \varepsilon^2)]^{(1/2)}$ frequency and for even N, where the ripple is positive going, it is the 0 dB frequency.

The Chebyshev filter is completely specified by the three parameters: ε, Ω_p, and N. In a practical design application, ε is given by the permissible passband ripple and Ω_p is specified by the desired passband cutoff frequency. The order of the filter, i.e., N, is then chosen such that the stopband specifications are satisfied.

85.3.3 Elliptic or Cauer Filters

The frequency response of an Nth-order elliptic low-pass filter can be expressed by

$$|H_a(j\Omega)|^2 = \frac{1}{1 + \varepsilon^2 F_N^2(\Omega/\Omega_p)} \tag{85.21}$$

where $F_N(\cdot)$ is called the Jacobian elliptic function. The elliptic approximation yields an equiripple passband and an equiripple stopband. Compared with the same-order Butterworth or Chebyshev filters, the elliptic design provides the sharpest transition between the passband and the stopband. The theory of elliptic filters, initially developed by Cauer, is involved; therefore for an extensive treatment, refer to Ref. [1].

Elliptic filters are completely specified by the parameters ε, α, Ω_p, Ω_s, and N where ε is passband ripple, α is stopband floor, Ω_p is the frequency at the edge of the passband (for a designated

passband ripple), Ω_s is the frequency at the edge of the stopband (for a designated stopband floor), and N is the order of the polynomial.

In a practical design exercise, the desired passband ripple, stopband floor, and Ω_s are selected and N is determined and rounded up to the nearest integer value. The appropriate Jacobian elliptic function must be selected and $H_a(j\Omega)$ must be calculated and factored to extract only the left plane poles. For some synthesis techniques, the roots must be expanded into polynomial form.

This process is a formidable task. While some filter manufacturers have written their own computer programs to carry out these calculations, they are not readily available. However, the majority of applications can be accommodated by use of published tables of the pole/zero configurations of low-pass elliptic transfer functions. An extensive set of such tables for a common selection of passband ripples, stopband floors, and shape factors is available in Ref. [2].

85.3.4 Bessel Filters

The primary objectives of the preceding three approximations were to achieve specific loss characteristics. The phase characteristics of these filters, however, are nonlinear. The Bessel filter is optimized to reduce nonlinear-phase distortion, i.e., a maximally flat delay. The transfer function of a Bessel filter is given by

$$H_a(s) = \frac{B_0}{B_N(s)} = \frac{B_0}{\sum_{k=0}^{N} B_k s^k}, \quad B_k = \frac{(2N-k)!}{2^{N-k}k!(N-k)!} \quad k = 0, 1, \ldots, N \tag{85.22}$$

where $B_N(s)$ is the Nth-order Bessel polynomial. The overall squared-magnitude frequency response function is given by

$$|H_a(j\Omega)|^2 = 1 - \frac{\Omega^2}{2N-1} + \frac{2(N-1)\Omega^4}{(2N-1)^2(2N-3)} + \cdots \tag{85.23}$$

To illustrate Equation 85.22, the Bessel transfer function for $N = 4$ is given as follows:

$$H_a(s) = \frac{105}{105 + 105s + 45s^2 + 10s^3 + s^4} \tag{85.24}$$

Table 85.2 lists the factored pole frequencies as real and imaginary parts and as frequency and Q for Bessel transfer functions that have been normalized to $\Omega_c = -3$ dB.

85.4 Design Examples for Passive and Active Filters

85.4.1 Passive *R, L, C* Filter Design

The simplest and most commonly used passive filter is the simple, first-order ($N = 1$) RC filter shown in Figure 85.3. Its transfer function is that of a first-order Butterworth low-pass filter. The transfer function and −3 dB Ω_c are

$$H_a(s) = \frac{1}{RCs + 1} \quad \text{where } \Omega_c = \frac{1}{RC} \tag{85.25}$$

While this is the simplest possible filter implementation, both source and load impedance change the dc gain and/or corner frequency and its roll-off rate is only first order, or −6 dB/octave.

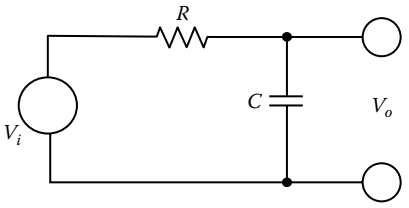

FIGURE 85.3 A passive first-order *RC* filter can serve as an antialiasing filter or to minimize high-frequency noise.

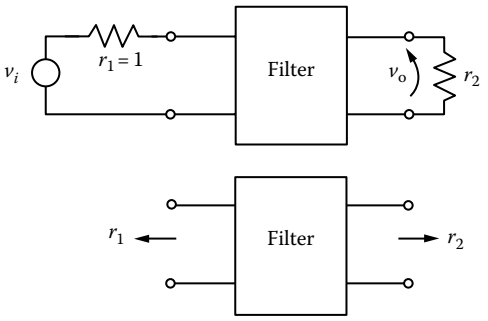

FIGURE 85.4 A passive filter can have the symbolic representation of a doubly terminated filter.

To realize higher-order transfer functions, passive filters use *R*, *L*, *C* elements usually configured in a ladder network. The design process is generally carried out in terms of a doubly terminated two-port network with source and load resistors R_1 and R_2 as shown in Figure 85.4. Its symbolic representation is given later.

The source and load resistors are normalized in regard to a reference resistance $R_B = R_1$, i.e.,

$$r_i = \frac{R_1}{R_B} = 1, \quad r_2 = \frac{R_2}{R_B} = \frac{R_2}{R_1} \tag{85.26}$$

The values of *L* and *C* are also normalized with respect to a reference frequency to simplify calculations. Their values can be easily scaled to any desired set of actual elements:

$$l_v = \frac{\Omega_B L_v}{R_B}, \quad c_v = \Omega_B C_v R_B \tag{85.27}$$

Low-pass filters, whose magnitude-squared functions have no finite zero, i.e., whose characteristic functions $C(j\Omega)$ are polynomials, can be realized by lossless ladder networks consisting of inductors as the series elements and capacitors as the shunt elements. These types of approximations, also referred to as *all-pole approximations*, include the previously discussed Butterworth, Chebyshev Type I, and Bessel filters. Figure 85.5 shows four possible ladder structures for even and odd *N*, where *N* is the filter order.

In the case of doubly terminated Butterworth filters, the normalized values are precisely given by

$$a_v = 2\sin\left(\frac{(2v-1)\pi}{2N}\right), \quad v = 1, \ldots, N \tag{85.28}$$

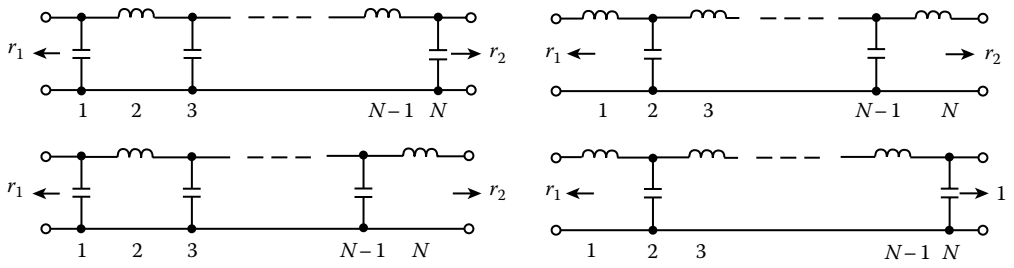

FIGURE 85.5 Even and odd N passive all-pole filter networks can be realized by several circuit configurations. N odd, above; N even, below.

where a_v is the normalized L or C element value. As an example, we will derive two possible circuits for a doubly terminated Butterworth low pass of order 3 with $R_B = 100\ \Omega$ and a cutoff frequency $\Omega_c = \Omega_B = 10$ kHz. The element values from Equation 85.28 are

$$l_1 = 2\sin\left(\frac{(2-1)\pi}{6}\right) = 1 \Rightarrow L_1 = \frac{R_B}{\Omega_c} = 1.59 \text{ mH}$$

$$c_2 = 2\sin\left(\frac{(4-1)\pi}{6}\right) = 2 \Rightarrow C_2 = \frac{2}{\Omega_c R_B} = 3.183 \text{ nF} \tag{85.29}$$

$$l_3 = 2\sin\left(\frac{(6-1)\pi}{6}\right) = 1 \Rightarrow L_3 = \frac{R_B}{\Omega_c} = 1.59 \text{ mH}$$

A possible realization is shown in Figure 85.6.

Table 85.3 gives normalized element values for the various all-pole filter approximations discussed in the previous section up to order 3 and is based on the following normalization:

1. $r_1 = 1$
2. All the cutoff frequencies (end of the ripple band for the Chebyshev approximation) are $\Omega_c = 1$ rad/s
3. r_2 is either 1 or ∞, so that both singly and doubly terminated filters are included

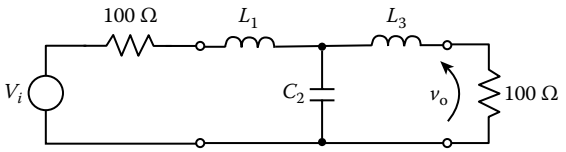

FIGURE 85.6 A third-order passive all-pole filter can be realized by a doubly terminated third-order circuit.

TABLE 85.3 Element Values for Low-Pass Filter Circuits

		$N = 2$, Element Number		$N = 3$, Element Number		
Filter Type	r_2	1	2	1	2	3
Butterworth	∞	1.4142	0.7071	1.5000	1.3333	0.5000
	1	1.4142	1.4142	1.0000	2.0000	1.0000
Chebyshev Type I	∞	0.7159	0.4215	1.0895	1.0864	0.5158
0.1 dB ripple	1	—	—	1.0316	1.1474	1.0316
Chebyshev Type I	∞	0.9403	0.7014	1.3465	1.3001	0.7981
0.5 dB ripple	1	—	—	1.5963	1.0967	1.5963
Bessel	∞	1.0000	0.3333	0.8333	0.4800	0.1667
	1	1.5774	0.4227	1.2550	0.5528	0.1922

The element values in Table 85.3 are numbered from the source end in the same manner as in Figure 85.4. In addition, empty spaces indicate unrealizable networks. In the case of the Chebyshev filter, the amount of ripple can be specified as desired, so that in the table only a selective sample can be given. Extensive tables of prototype element values for many types of filters can be found in Ref. [3].

The example given earlier, of a Butterworth filter of order 3, can also be verified using Table 85.3. The steps necessary to convert the normalized element values in the table into actual filter values are the same as previously illustrated.

In contrast to all-pole approximations, the characteristic function of an elliptic filter function is a rational function. The resulting filter will again be a ladder network but the series elements may be parallel combinations of capacitance and inductance and the shunt elements may be series combinations of capacitance and inductance.

Figure 85.6 illustrates the general circuits for even and odd N, respectively. As in the case of all-pole approximations, tabulations of element values for normalized low-pass filters based on elliptic approximations are also possible. Since these tables are quite involved, the reader is referred to Ref. [3].

85.4.2 Active Filter Design

Active filters are widely used and commercially available with cutoff frequencies from millihertz to megahertz. The characteristics that make them the implementation of choice for several applications are small size for low-frequency filters because they do not use inductors; precision realization of theoretical transfer functions by use of precision resistors and capacitors; high input impedance that is easy to drive and for many circuit configurations the source impedance does not effect the transfer function; low output impedance that can drive loads without effecting the transfer function and can drive the transient, switched capacitive, loads of the input stages of A/D converters and low (N+THD) performance for pre-A/D antialiasing applications (as low as −100 dBc).

Active filters use R, C, A (operational amplifier) circuits to implement polynomial transfer functions. They are most often configured by cascading an appropriate number of first- and second-order sections.

The simplest first-order ($N = 1$) active filter is the first-order passive filter of Figure 85.3 with the addition of a unity gain follower amplifier. Its cutoff frequency (Ω_c) is the same as that given in Equation 85.25. Its advantage over its passive counterpart is that its operational amplifier can drive whatever load that it can tolerate without interfering with the transfer function of the filter.

The vast majority of higher-order filters have poles that are not located on the negative real axis in the s-plane and therefore are in complex conjugate pairs that combine to create second-order pole pairs of the form:

$$H(s) = s^2 + \frac{\omega_p}{Q}s + \omega_p^2 \Leftrightarrow s^2 + 2as + a^2 + b^2 \tag{85.30}$$

where

$$p_1,\ p_2 = a \pm jb$$

$$\omega_p^2 = a^2 + b^2$$

$$Q = \frac{\omega_p}{2a} = \frac{\sqrt{(a^2 + b^2)}}{2a}$$

The most commonly used two-pole active filter circuits are the *Sallen and Key* low-pass resonator, the *multiple feedback* bandpass, and the *state variable* implementation as shown in Figure 85.7a–c. In the analyses that follow, the more commonly used circuits are used in their simplest form. A more comprehensive treatment of these and numerous other circuits can be found in Ref. [4].

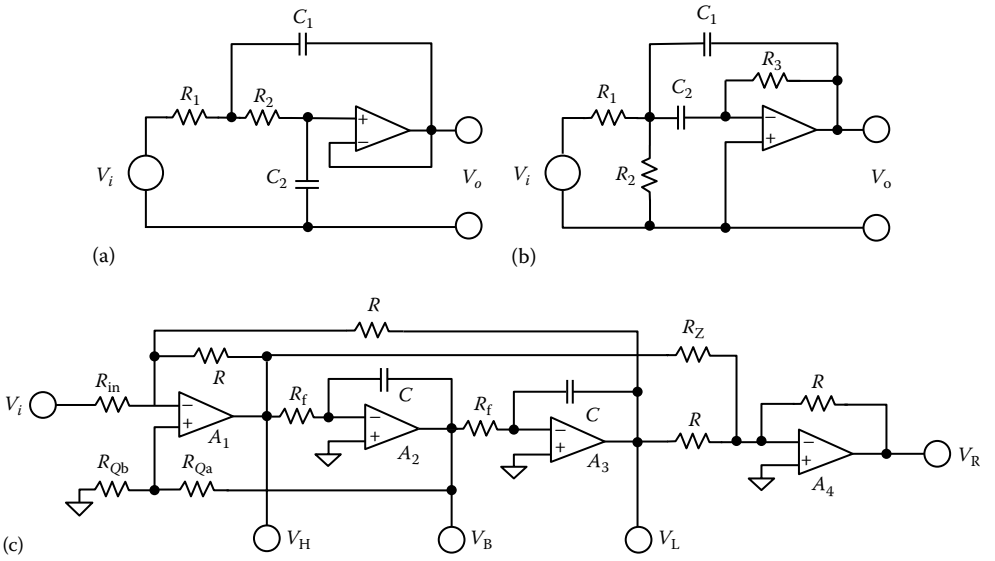

FIGURE 85.7 Second-order active filters can be realized by common filter circuits: (a) Sallen and Key low pass, (b) multiple feedback bandpass, and (c) state variable.

The Sallen and Key circuit of Figure 85.7a is used primarily for its simplicity. Its component count is the minimum possible for a two-pole active filter. It cannot generate stopband zeros and therefore is limited in its use to monotonic roll-off transfer functions such as Butterworth and Bessel filters. Other limitations are that the phase shift of the amplifier reduces the Q of the section and the capacitor ratio becomes large for high Q circuits. The amplifier is used in a follower configuration and therefore is subjected to a large common mode input signal swing which is not the best condition for low distortion performance. It is recommended to use this circuit for a section $Q < 10$ and to use an amplifier whose gain bandwidth product is greater than $100 f_p$.

The transfer function and design equations for the Sallen and Key circuit of Figure 85.7a are

$$H(s) = \frac{1/R_1R_2C_1C_2}{s^2 + (1/R_1C_2)s + 1/R_1R_2C_1C_2} = \frac{\omega_p^2}{s^2 + (\omega_p/Q)s + \omega_p^2} \tag{85.31}$$

from which obtains

$$\omega^2 = \frac{1}{R_1R_2C_1C_2}, \quad Q = \omega_pR_1C_2 = \sqrt{\frac{R_1C_2}{R_2C_1}} \tag{85.32}$$

$$R_1,\ R_2 = \frac{1}{4\pi f_pQC_2}\left[1 \pm \sqrt{1 - \frac{4Q^2C_2}{C_1}}\right] \tag{85.33}$$

which has valid solutions for

$$\frac{C_1}{C_2} \geq 4Q^2 \tag{85.34}$$

In the special case where

$$\begin{aligned} &R_1 = R_2 = R, \text{ then} \\ &C = 1/2\pi Rf_p, \quad C_1 = 2QC, \quad \text{and} \quad C_2 = C/2Q \end{aligned} \tag{85.35}$$

The design sequence for Sallen and Key low pass of Figure 85.7a is as follows.

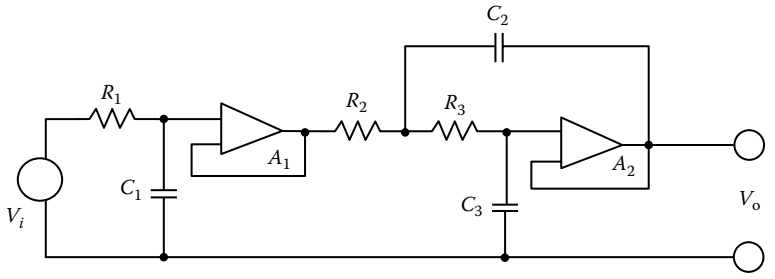

FIGURE 85.8 A three-pole Butterworth active can be configured with a buffered first-order *RC* in cascade with a two-pole Sallen and Key resonator.

For a required f_p and Q, select C_1 and C_2 to satisfy Equation 85.34. Compute R_1 and R_2 from Equation 85.33 (or Equation 85.35 if R_1 is chosen to equal R_2) and scale the values of C_1 and C_2 and R_1 and R_2 to desired impedance levels.

As an example, a three-pole low-pass active filter is shown in Figure 85.8. It is realized with a buffered single-pole *RC* low-pass filter section in cascade with a two-pole Sallen and Key section.

To construct a three-pole Butterworth filter, the pole locations are found in Table 85.2 and the element values in the sections are calculated from Equation 85.25 for the single real pole and in accordance with the Sallen and Key design sequence listed earlier for the complex pole pair.

From Table 85.2, the normalized pole locations are

$$f_{p1} = 1.000, \quad f_{p2} = 1.000, \quad \text{and} \quad Q_{p2} = 1.000$$

For a cutoff frequency of 10 kHz and if it is desired to have an impedance level of 10 kΩ, then the capacitor values are computed as follows:

For R_1 = 10 kΩ:

$$\text{From Equation 85.25, } C_1 = \frac{1}{2\pi R_1 r_{p1}} = \frac{1}{2\pi(10{,}000)(10{,}000)} = \frac{10^{-6}}{200\pi} = 0.00159\ \mu\text{F}$$

For $R_2 = R_3 = R$ = 10 kΩ:

$$\text{From Equation 85.35, } C = \frac{1}{2\pi R f_{p2}} = \frac{1}{2\pi(10{,}000)(10{,}000)} = \frac{10^{-6}}{200\pi} = 0.00159\ \mu\text{F}$$

from which

$$C_2 = 2QC = 2(0.00159)\ \mu\text{F} = 0.00318\ \mu\text{F}$$

$$C_3 = \frac{C}{2Q} = 0.5(0.00159)\ \mu\text{F} = 0.00795\ \mu\text{F}$$

The *multiple feedback* circuit of Figure 85.7b is a minimum component count, two-pole (or one-pole pair), bandpass filter circuit with user definable gain. It cannot generate stopband zeros and therefore is limited in its use to monotonic roll-off transfer functions. Phase shift of its amplifier reduces the Q of the section and shifts the f_p. It is recommended to use an amplifier whose open-loop gain at f_p is $>100Q^2H_p$.

The design equations for the *multiple feedback* circuit of Figure 85.4b are

$$H(s) = \frac{s/R_1C_1}{s^2 + s/R_3\left(1/C_1 + 1/C_2\right) + (R_1 + R_2)/R_1R_2R_3C_1C_2} = -\frac{s\omega_p H_p/Q}{s^2 + s\omega_p/Q + \omega_p^2} \tag{85.36}$$

when $s = j\omega_p$, the gain H_p is

$$H_p = \frac{R_3C_2}{R_1(C_1 + C_2)} \tag{85.37}$$

From Equations 85.36 and 85.37 for a required set of ω_p, Q, and H_p

$$R_1 = \frac{Q}{C_1H_p\omega_p}, \quad R_2 = \frac{Q}{\omega_p}\left(\frac{1}{Q^2(C_1 + C_2) - H_pC_1}\right), \quad R_3 = \frac{R_1H_p(C_1 + C_2)}{C_2} \tag{85.38}$$

For R_2 to be realizable,

$$Q^2(C_1 + C_2) \geq H_pC_1 \tag{85.39}$$

The design sequence for a *multiple feedback* bandpass filter is as follows.

Select C_1 and C_2 to satisfy Equation 85.39 for the H_p and Q required. Compute R_1, R_2, and R_3. Scale R_1, R_2, R_3, C_1, and C_2 as required meeting desired impedance levels.

Note that it is common to use $C_1 = C_2 = C$ for applications where $H_p = 1$ and $Q > 0.707$.

The *state variable* circuit of Figure 85.7c is the most widely used active filter circuit. It is the basic building block of programmable active filters and of SC designs. While it uses three or four amplifiers and numerous other circuit elements to realize a two-pole filter section, it has many desirable features. From a single input, it provides low-pass (V_t), high-pass (V_H), and bandpass (V_B) outputs and by summation into an additional amplifier (A_4) (or the input stage of the next section) a band reject (V_R) or stopband zero can be created. Its two integrator resistors connect to the virtual ground of their amplifiers (A_2, A_3) and therefore have no signal swing on them. Therefore, programming resistors can be switched to these summing junctions using electronic switches. The sensitivity of the circuit to the gain and phase performance of its amplifiers is more than an order of magnitude less than single amplifier designs. The open-loop gain at f_p does not have to be multiplied by either the desired Q or the gain at dc or f_p. Second-order sections with Q up to 100 and f_p up to 1 MHz can be built with this circuit.

There are several possible variations of this circuit that improve its performance at particular outputs. The input can be brought into several places to create or eliminate phase of inversions; the damping feedback can be implemented in several ways other than the R_{Qa} and R_{Qb} that are shown in Figure 85.7c and the f_p and Q of the section can be or adjusted independently from one another. The dc offset adjustment components can be added to allow the offset at any one output to be trimmed to zero.

For simplicity of presentation, Figure 85.7c makes several of the resistors equal and identifies others with subscripts that relate to their function in the circuit. Specifically, the feedback amplifier A_1 that generates the V_H output has equal feedback and input resistor from the V_L feedback signal to create unity gains from that input. Similarly, the "zero-summing" amplifier, A_4 has equal resistors for its feedback and input from V_L to make the dc gain at the V_R output the same as that at V_L. More general configurations with all elements included in the equation of the transfer function are available in numerous reference texts including Ref. [4].

The *state variable* circuit, as configured in Figure 85.7c, has four outputs. Their transfer functions are

$$V_{\mathrm{L}}(s) = -\frac{R}{R_1(R_{\mathrm{f}}C)^2}\left(\frac{1}{D(s)}\right) \tag{85.40a}$$

$$V_{\mathrm{B}}(s) = \frac{R}{R_1}\left(\frac{s/(R_{\mathrm{f}}C)}{D(s)}\right) \tag{85.40b}$$

$$V_{\mathrm{H}}(s) = -\frac{R}{R_1}\left(\frac{s^2}{D(s)}\right) \tag{85.40c}$$

$$V_{\mathrm{R}}(s) = \frac{R}{R_1(R_{\mathrm{f}}C)^2}\left(\frac{(R_z/R)s^2+1}{D(s)}\right) \tag{85.40d}$$

where

$$D(s) = s^2 + \frac{a}{R_{\mathrm{f}}C}s + \frac{1}{(R_{\mathrm{f}}C)^2} = s^2 + \frac{\omega_{\mathrm{p}}}{Q}s + \omega_{\mathrm{p}}^2 \quad a = \frac{R_{\mathrm{Qb}}}{(R_{\mathrm{Qa}}+R_{\mathrm{Qb}})}\left(2+\frac{R}{R_1}\right) \tag{85.41}$$

Note that the dc gain at the low-pass output is

$$V_{\mathrm{L}}(0) = -\frac{R}{R_1} \tag{85.42a}$$

from which obtains

$$\omega_{\mathrm{p}} = \frac{1}{R_{\mathrm{f}}C} \quad \text{and} \quad \frac{1}{Q} = \frac{R_{\mathrm{Qb}}}{(R_{\mathrm{Qa}}+R_{\mathrm{Qb}})}\left(2+\frac{R}{R_1}\right) \tag{85.42b}$$

The design sequence for the state variable filter of Figure 85.7c is to select the values of R_{f} and C to set the frequency ω_{p}, set the values of R_i for the desired dc gain, and adjust R_{Qa} and R_{Qb} for the desired Q and dc gain.

85.5 Discrete-Time Filters

A digital filter is a circuit or a computer program that computes a discrete output sequence from a discrete input sequence. Digital filters belong to the class of discrete-time linear time-invariant (LTI) systems, which are characterized by the properties of causality, recursibility, and stability, and may be characterized in the time domain by their impulse response and in the transform domain by their transfer function. The most general case of a discrete-time LTI system with the input sequence denoted by $x(kT)$ and the resulting output sequence $y(kT)$ can be described by a *set of linear difference equations with constant coefficients*:

$$y(kT) = \sum_{\mu=0}^{N} b_\mu x(kT-\mu T) - \sum_{\mu=1}^{N} a_\mu y(kT-\mu T) \tag{85.43}$$

where $a_0 = 1$. An equivalent relation between the input and output variables can be given through the convolution sum in terms of the impulse response sequence $h(kT)$:

$$y(kT) = \sum_{\mu=0}^{N} h(kT)x(kT - \mu T) \tag{85.44}$$

The corresponding transfer function is given by

$$H(z) = \frac{Y(z)}{X(z)} = \frac{\sum_{\mu=0}^{N} b_\mu z^{-\mu}}{1 + \sum_{\mu=1}^{N} a_\mu z^{-\nu}} \Leftrightarrow H(z) = b_0 \prod_{\mu=1}^{N} \left(\frac{z - z_{0\mu}}{z - z_{\infty\mu}} \right) \tag{85.45}$$

where

$H(z)$ is the z-transform of the impulse response $h(kT)$

$X(z)$ and $Y(z)$ are the z-transform of the input signal $x(kT)$ and the output or the filtered signal $y(kT)$

As can be seen from Equation 85.44, if for at least one μ, $a_\mu \neq 0$, the corresponding system is recursive; its impulse response is of infinite duration—*infinite impulse response (IIR) filters*. If $a_\mu = 0$, the corresponding system is nonrecursive—*finite impulse response (FIR) filter*; its impulse response is of finite duration and the transfer function $H(z)$ is a polynomial in z^{-1}. The zeros of the polynomial $X(z)$ given by $z = z_{\infty i}$ are called the poles of $H(z)$ and are commonly referred to as the *natural frequencies* of the filter. The condition for the stability of the filter is expressed by the constraint that all the poles of $H(z)$ should lie inside the unit circle, that is $|z_{\infty i}| < 1$. The zeros of $Y(z)$ given by $z = z_{0t}$ which are equivalent to the zeros of $H(z)$ are called the *transmission zeros* of the filter. Clearly, at these frequencies the output of the filter is zero for any finite input.

On the unit circle, the transfer function frequency $H(z)$ reduces to the frequency response function $H(e^{j\omega T})$, the discrete-time Fourier transform of $h(kT)$, which in general is complex and can be expressed in terms of magnitude and phase

$$H(e^{j\omega T}) = |H(e^{j\omega T})| e^{j\theta(\omega)} \tag{85.46}$$

The gain function of the filter is given as

$$\alpha(\Omega) = 20\log_{10} |H(e^{j\omega T})| \tag{85.47}$$

It is also common practice to call the negative of the gain function of the attenuation. Note that the attenuation is a positive number when the magnitude response is <1.

Figure 85.9 gives a block diagram realizing the difference equation of the filter, which is commonly referred to as the *direct-form I* realization. Notice that the element values for the multipliers are obtained directly from the numerator and denominator coefficients of the transfer function. By rearranging the structure in regard to the number of delays, one can obtain the canonic structure called *direct-form II* shown in Figure 85.10, which requires the minimum number of delays.

Physically, the input numbers are samples of a continuous signal and real-time digital filtering involves the computation of the iteration of Equation 85.43 for each incoming new input sample. Design of a filter consists of determining the constants a_μ and b_μ that satisfies a given filtering requirement. If the filtering is performed in real time, then the right side of Equation 85.46 must be computed in less than the sampling interval T.

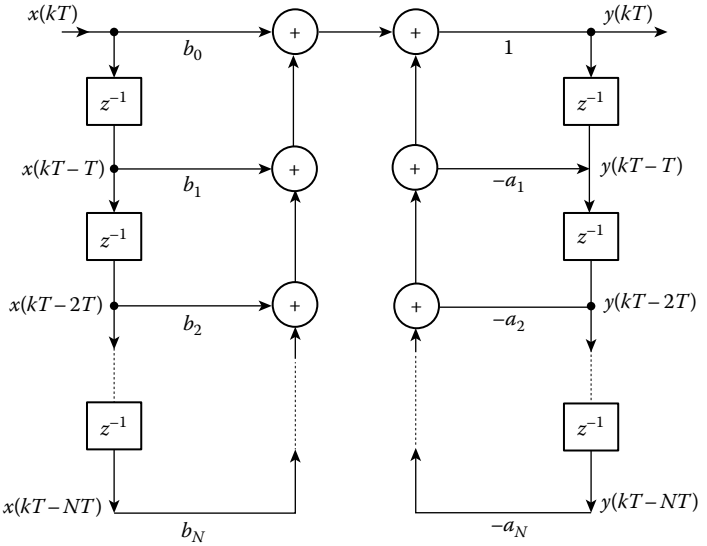

FIGURE 85.9 The difference equation of a digital filter can be realized by a direct-form I implementation that uses separate delay paths for the *X* and *Y* summations.

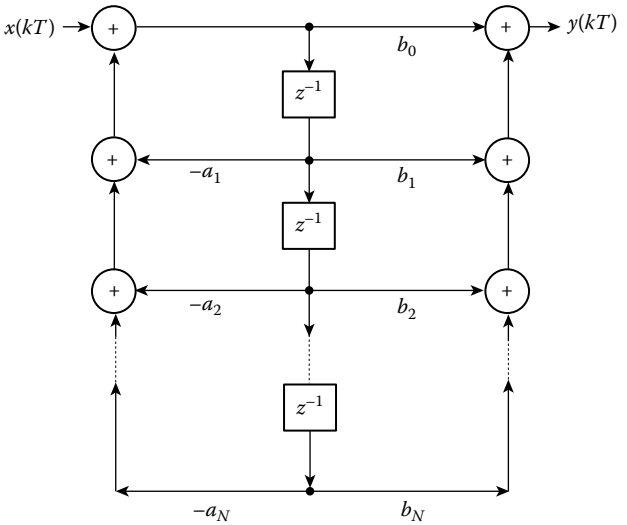

FIGURE 85.10 A direct-form II implementation of the difference equations minimizes the number of delay elements.

85.6 Digital Filter Design Process

The digital filter design procedure consists of the following basic steps:

1. Determine the desired response. The desired response is normally specified in the frequency domain in terms of the desired magnitude response and/or the desired phase response.
2. Select a class of filters (e.g., linear-phase FIR filters or IIR filters) to approximate the desired response.
3. Select the best member in the filter class.
4. Implement the best filter using a general-purpose computer, a DSP, or a custom hardware chip.
5. Analyze the filter performance to determine whether the filter satisfies all the given criteria.

85.7 FIR Filter Design

In many digital signal-processing applications, FIR filters are generally preferred over their IIR counterparts, because they offer a number of advantages compared with their IIR equivalents. Some of the good properties of FIR filters are a direct consequence of their nonrecursive structure. First, FIR filters are inherently stable and free of limit cycle oscillations under finite-word length conditions. In addition, they exhibit a very low sensitivity to variations in the filter coefficients. Second, the design of FIR filters with exactly *linear phase* (constant group delay) vs. frequency behavior can be accomplished easily. This property is useful in many application areas, such as speech processing, phase delay equalization, image processing, etc.

Finally, there exists number of efficient algorithms for designing optimum FIR filters with arbitrary specifications. The main disadvantage of FIR filters over IIR filter is that FIR filter designs generally require, particularly in applications requiring narrow transition bands, considerably more computation to implement.

An FIR filter of order N is described by a difference equation of the form

$$y(kT) = \sum_{\mu=0}^{N} b_\mu x(kT - \mu T) \tag{85.48}$$

and the corresponding transfer function is

$$H(z) = \frac{Y(z)}{X(z)} = \sum_{\mu=0}^{N} b_\mu z^{-\mu} \tag{85.49}$$

The objective of FIR filter design is to determine $(N \pm 1)$ coefficients given by

$$h(0), h(1), \ldots, h(N) \tag{85.50}$$

so that the transfer function $H(e^{j\omega T})$ approximates a desired frequency characteristic. Note that because Equation 85.47 is also in the form of a convolution summation, the impulse response of an FIR filter is given by

$$h(kT) = \begin{cases} b_\mu, & k = 0, 1, \ldots, N \\ 0, & \text{otherwise} \end{cases} \tag{85.51}$$

Two equivalent structures for FIR filters are given in Figure 85.11.

The accuracy of an FIR approximation is described by the following parameters:

δ_p Passband ripple
δ_s Stopband attenuation
$\Delta\omega$ Transition bandwidth

These quantities are depicted in Figure 85.12 for a prototype low-pass filter. δ_p and δ_s characterize the permissible errors in the passband and stopband, respectively. Usually, the passband ripple and stopband attenuation are given in decibels, in which case their values are related to the parameters δ_p and δ_s by

$$\text{Passband ripple (dB): } A_p = -20\log_{10}(1 - \delta_p) \tag{85.52}$$

$$\text{Stopband ripple (dB): } A_s = -20\log_{10}(\delta_s) \tag{85.53}$$

Note that due to the symmetry and periodicity of the magnitude response of $|H(e^{j\omega T})|$, it is sufficient to give the filter specifications in the interval $0 \le \omega \le \pi$.

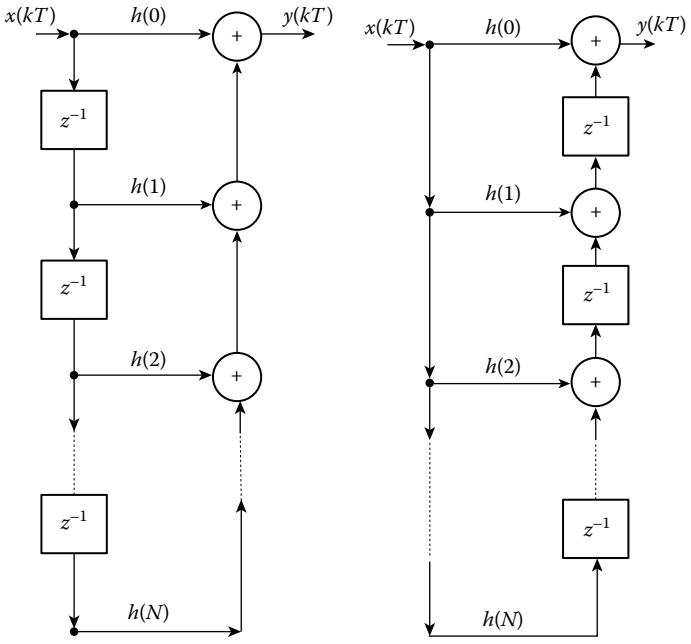

FIGURE 85.11 The sequence of the delays and summations can be varied to produce alternative direct-form implementations.

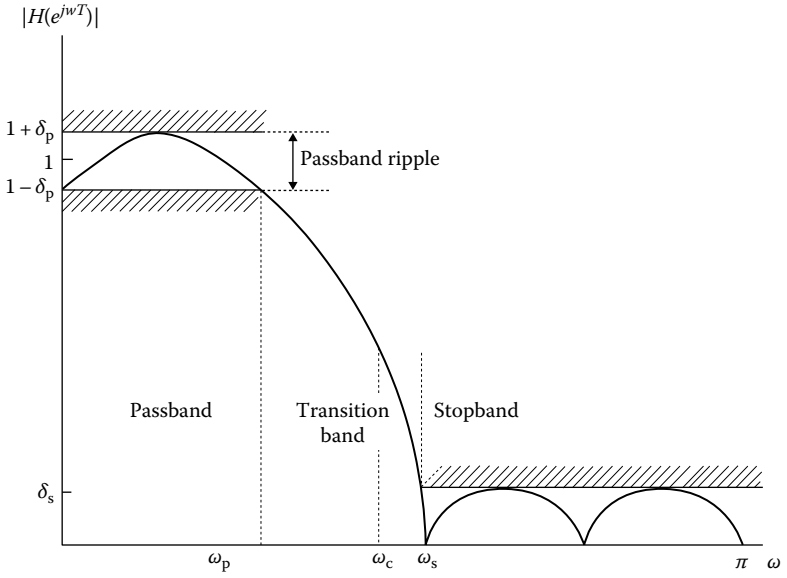

FIGURE 85.12 Tolerance limits must be defined for an FIR low-pass filter magnitude response.

85.7.1 Windowed FIR Filters

Several design techniques can be employed to synthesize linear-phase FIR filters. The simplest implementation is based on *windowing*, which commonly begins by specifying the ideal frequency response and expanding it in a Fourier series and then truncating and smoothing the ideal impulse response by means of a window function. The truncation results in large ripples before and after the discontinuity of

the ideal frequency response known as the Gibbs phenomena, which can be reduced by using a window function that tapers smoothly at both ends. Filters designed in this way possess equal passband ripple and stopband attenuation, i.e.,

$$\delta_p = \delta_s = \delta \tag{85.54}$$

To illustrate this method, let us define an ideal desired frequency response that can be expanded in a Fourier series:

$$H_d(e^{jwT}) = \sum_{k=-\infty}^{\infty} h_d(kT) e^{-jk\omega T} \tag{85.55}$$

where $h_d(kT)$ is the corresponding impulse response sequence, which can be expressed in terms of $H_d(e^{j\omega T})$ as

$$h_d(kT) = \frac{1}{2\pi} \int_{-\pi}^{\pi} H_d(e^{jwT}) e^{jk\omega T} d\omega \tag{85.56}$$

The impulse response of the desired filter is then found by weighting this ideal impulse response with a window $w(kT)$ such that

$$h(kT) = \begin{cases} w(kT) h_d(kT), & 0 \le k \le N \\ 0, & \text{otherwise} \end{cases} \tag{85.57}$$

Note that for $w(kT)$ in the earlier given interval we obtain the rectangular window. Some commonly used windows are Bartlett (triangular), Hanning, Hamming, Blackmann, etc., the definitions of which can be found in Ref. [5].

As an example of this design method, consider a low-pass filter with a cutoff frequency of ω_c and a desired frequency of the form:

$$H_d(e^{j\omega T}) = \begin{cases} e^{-j\omega NT/2}, & |\omega| \le \omega_c \\ 0, & \omega_c < |\omega| \le \pi \end{cases} \tag{85.58}$$

Using Equation 85.56, we obtain the corresponding ideal impulse response:

$$h_d(kT) = \frac{1}{2\pi} \int_{-\omega_c}^{\omega_c} e^{-j\omega TN/2} e^{jk\omega T} d\omega = \frac{\sin[\omega_c(kT - TN/2)]}{\pi(kT - TN/2)} \tag{85.59}$$

Choosing $N = 4$, $\omega_c = 0.6\pi$ and a Hamming window defined by

$$w(kT) = \begin{cases} 0.54 - 0.46\cos(2\pi kT/N), & 0 \le k \le N \\ 0, & \text{otherwise} \end{cases} \tag{85.60}$$

we obtain the following impulse response coefficients:

$$\begin{aligned} h(0) &= -0.00748 \\ h(1) &= 0.12044 \\ h(2) &= -0.54729 \\ h(3) &= 0.27614 \\ h(4) &= -0.03722 \end{aligned} \tag{85.61}$$

85.7.2 Optimum FIR Filters

As mentioned earlier, one of the principal advantages of FIR filters over their IIR counterparts is the availability of excellent design methods for optimizing arbitrary filter specifications. Generally, the design criterion for the optimum solution of an FIR filter design problem can be characterized as follows. The maximum error between the approximating response and the given desired response has to be minimized, i.e.,

$$E(e^{j\omega T}) = W_{\mathrm{d}}(e^{j\omega T})\left\| H_{\mathrm{d}}(e^{j\omega T})\right| - \left|H(e^{j\omega T})\right\| \tag{85.62}$$

where

$E(e^{j\omega T})$ is the weighted error function on a close range X of $[0, \pi]$

$W_{\mathrm{d}}(e^{j\omega T})$ is a weighting function, which emphasizes the approximation error parameters in the design process

If the maximum absolute value of this function is less than or equal ε on X, i.e.,

$$\varepsilon = \max_{\omega \varepsilon X} \left| E(e^{j\omega T}) \right| \tag{85.63}$$

the desired response is guaranteed to meet the given criteria. Thus, this optimization condition implies that the best approximation must have an equiripple error function. The most frequently used method for designing optimum magnitude FIR filters is the Parks–McClellan algorithm. This method essentially reduces the filter design problem into a problem in polynomial approximation in the Chebyshev approximation sense as discussed earlier. The maximum error between the approximation and the desired magnitude response is minimized. It offers more control over the approximation errors in different frequency bands than is possible with the window method. Using the Parks–McClellan algorithm to design FIR filters is computationally expensive. This method, however, produces optimum FIR filters by applying time-consuming iterative techniques. A FORTRAN program for the Parks–McClellan algorithm can be found in the IEEE publication Programs for DSP in Ref. [6]. As an example of an equiripple filter design using the Parks–McClellan algorithm, a sixth-order low-pass filter with a passband $0 \le \omega \le 0.6\pi$, a stopband $0.8\pi \le \omega \le \pi$, and equal weighting for each band was designed by means of this program.

The resulting impulse response coefficients are

$$\begin{aligned} h(0) &= h(6) = -0.00596 \\ h(1) &= h(5) = -0.18459 \\ h(2) &= h(4) = 0.25596 \\ h(3) &= 0.70055 \end{aligned} \tag{85.64}$$

85.7.3 Design of Narrowband FIR Filters

When using conventional techniques to design FIR filters with especially narrow bandwidths, the resulting filter lengths may be very high. FIR filters with long filter lengths often require lengthy design and implementation times, and are more susceptible to numerical inaccuracy. In some cases, conventional filter design techniques, such as the Parks–McClellan algorithm, may fail the design altogether. A very efficient algorithm called the interpolated finite impulse response (IFIR) filter design technique can be employed to design narrowband FIR filters. Using this technique produces narrowband filters that require far fewer coefficients than those filters designed by the direct application of the Parks–McClellan algorithm. For more information on IFIR filter design, see Ref. [7].

85.8 IIR Filter Design

The main advantage of IIR filters over FIR filters is that IIR filters can generally approximate a filter design specification using a lower-order filter than that required by an FIR design to perform similar filtering operations. As a consequence, IIR filters execute much faster and do not require extra memory, because they execute in place. A disadvantage of IIR filters, however, is that they have a nonlinear-phase response. The two most common techniques used for designing IIR filters will be discussed in this section. The first approach involves the transformation of an analog prototype filter. The second method is an optimization-based approach allowing the approximation of an arbitrary frequency response.

The transformation approach is quite popular because the approximation problem can be reduced to the design of classical analog filters, the theory of which is well established, and many closed-form design methods exist. Note that this is not true for FIR filters, for which the approximation problems are of entirely different nature. The derivation of a transfer function for a desired filter specification requires the following three basic steps:

1. Given a set of specifications for a digital filter, the first step is to map the specifications into those for an equivalent analog filter.
2. The next step involves the derivation of a corresponding analog transfer function for the analog prototype.
3. The final step is to translate the transfer function of the analog prototype into a corresponding digital filter transfer function.

Once the corresponding analog transfer function for the analog prototype is derived, it must be transformed using a transformation that maps $H_a(s)$ into $H(z)$. The simplest and most appropriate choice for s is the well-known bilinear transform of the z-variable

$$s = \frac{2(1-z^{-1})}{T_d(1+z^{-1})} \Leftrightarrow z = \frac{1+(T_d/2)s}{1-(T_d/2)s} \tag{85.65}$$

which maps a stable analog filter in the s-plane into a stable digital filter in the z-plane. Substituting s with the right-hand side of Equation 85.63 in $H_a(s)$ results in

$$H(z) = H_a\left(\frac{2(1-z^{-1})}{T_d(1+z^{-1})}\right) \Rightarrow H(e^{j\omega T})\Big|_{z=e^{j\omega T}} = H_a\left(\frac{2j}{T_d}\tan\left(\frac{\omega T}{2}\right)\right) \tag{85.66}$$

As it can be seen from Equation 85.66, the analog frequency domain (imaginary axis) maps onto the digital frequency domain (unit circle) nonlinearly. This phenomenon is called frequency warping

and must be compensated in a practical implementation. For low frequencies, Ω and ω are approximately equal. We obtain the following relation between the analog frequency Ω and the digital frequency ω:

$$\Omega = \frac{2}{T_d}\tan(\omega T/2) \tag{85.67}$$

$$\omega = \frac{2}{T}\arctan(\Omega T_d/2) \tag{85.68}$$

The overall bilinear transformation procedure is as follows:

1. Convert the critical digital frequencies (e.g., ω_p and ω_s for low-pass filters) to the corresponding analog frequencies in the s-domain using the relationship given by Equation 85.67.
2. Derive the appropriate continuous prototype transfer function $H_a(s)$ that has the properties of the digital filter at the critical frequencies.
3. Apply the bilinear transform to $H_a(s)$ to obtain $H(z)$ which is the required digital filter transfer function.

To illustrate the three-step IIR design procedure using the bilinear transform, consider the design of a second-order Butterworth low-pass filter with a cutoff frequency of $\omega_c = 0.3\pi$. The sampling rate of the digital filter is to be $f_s = 10$ Hz, giving $T = 0.1$ s. First, we map the cutoff frequency to the analog frequency

$$\Omega_c = \frac{2}{0.1}\tan(0.15\pi) = 10.19 \text{ rad/s} \tag{85.69}$$

The poles of the analog Butterworth filter transfer function $H_a(s)$ are found using Equation 85.11. As explained earlier, these poles lie equally spaced in the s-plane on a circle of radius Ω_c:

$$H_a(s) = \frac{1}{s^2 + \sqrt{2\Omega_c s + \Omega_c^2}} \tag{85.70}$$

Application of the bilinear transformation

$$S = \frac{2(1 - z^{-1})}{0.1(1 + z^{-1})} \tag{85.71}$$

gives the digital transfer function

$$H(z) = \frac{0.00002 + 0.00004z^{-1} + 0.00002z^{-2}}{1 - 1.98754z^{-1} + 0.98762z^{-2}} \tag{85.72}$$

The earlier computations were carried out using Ref. [8], which greatly automates the design procedure.

85.8.1 Design of Arbitrary IIR Filters

The IIR filter design approach discussed in the previous section is primarily suitable for frequency-selective filters based on closed-form formulas. In general, however, if a design other than standard low pass, high pass, bandpass, and stopband is required, or if the frequency responses of arbitrary specifications are to be matched, in such cases it is often necessary to employ algorithmic methods implemented on computers. In fact, for nonstandard response characteristics, algorithmic

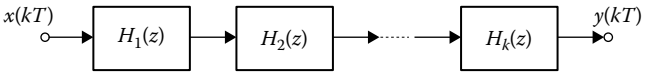

FIGURE 85.13 An IIR filter can be implemented by a cascade of individual transfer functions.

procedures may be the only possible design approach. Depending on the error criterion used, the algorithmic approach attempts to minimize the approximation error between the desired frequency response $H_d(e^{j\omega T})$ and $H(e^{j\omega T})$ or between the time-domain response $h_d(kT)$ and $h(kT)$. Computer software is available for conveniently implementing IIR filters approximating arbitrary frequency response functions [8,9].

85.8.2 Cascade-Form IIR Filter Structures

Recall that theoretically there exist an infinite number of structures to implement a digital filter. Filters realized using the structure defined by Equation 85.44 directly is referred to as direct-form IIR filters. The direct-form structure, however, is not employed in practice except when the filter order $N \leq 2$, because they are known to be sensitive to errors introduced by coefficient quantization and by finite-arithmetic conditions. Additionally, they produce large round-off noise, particularly for poles closed to the unit circle.

Two less-sensitive structures can be obtained by partial fraction expansion or by factoring the right-hand side of Equation 85.46 in terms of real rational functions of orders 1 and 2. The first method leads to *parallel connections* and the second one to *cascade connections* of corresponding lower-order sections, which are used as building blocks to realize higher-order transfer functions. In practice, the cascade form is by far the preferred structure, since it gives the freedom to choose the pairing of numerators and denominators and the ordering of the resulting structure. Figure 85.13 shows a cascade-form implementation, whose overall transfer function is given by

$$H(z) = \prod_{k=1}^{M} H_k(z) \tag{85.73}$$

where the transfer function of the kth building block is

$$H_k(z) = \frac{b_{0k} + b_{1k}z^{-1} + b_{2k}z^{-2}}{1 + a_{1k}z^{-2} + a_{2k}z^{-2}} \tag{85.74}$$

Note this form is achieved by factoring Equation 85.45 into second-order sections.

There are, of course, many other realization possibilities for IIR filters, such as state-space structures [8], lattice structures [10], and wave structures. The last is introduced in the next section.

85.9 Wave Digital Filters

It was shown earlier that for recursive digital filters the approximation problem can be reduced to classical design problems by making use of the bilinear transform. For wave digital filters (WDFs), this is carried one step farther in that the structures are obtained directly from classical circuits. Thus, to every WDF there corresponds an *LCR* reference filter from which it is derived. This relationship accounts for their excellent properties concerning coefficient sensitivity, dynamic range, and all aspects of stability under finite-arithmetic conditions. The synthesis of WDFs is based on the wave network characterization; therefore, the resulting structures are referred to as WDFs. To illustrate the basic idea behind the

theory of WDFs, consider an inductor L, which is electrically described by $V(s) = sLI(s)$. In the next step, we define wave variables $A_1(s)$ and $B_1(s)$ as

$$\begin{aligned} A_1(s) &= V(s) + RI(s) \\ B_1(s) &= V(s) - RI(s) \end{aligned} \tag{85.75}$$

where R is called the port resistance. Substituting $V(s) = sLI(s)$ in the earlier relation and replacing s in $A_1(s)$ and $B_1(s)$ with the bilinear transform given by Equation 85.65, we obtain

$$B(z) = \frac{(1-z^{-1})L - (1+z^{-1})R}{(1-z^{-1})L + (1+z^{-1})R} A(z) \tag{85.76}$$

Letting $R = L$, the earlier relation reduces to

$$B(z) = -z^{-1}A(z) \tag{85.77}$$

Thus an inductor translates into a unit delay in cascade with an inverter in the digital domain. Similarly, it is easily verified that a capacitance can be simulated by a unit delay and a resistor by a digital sink. Figure 85.14 shows the digital realizations of impedances and other useful one-port circuit elements.

To establish equivalence with classical circuits fully, the interconnections are also simulated by the so-called wave adaptors. The most important of these interconnections are series and parallel connections, which are simulated by series and parallel adaptors, respectively. For most filters of interest, only two- and three-port adaptors are employed. For a complete design example, consider Figure 85.15.

For a given LC filter, one can readily derive a corresponding WDF by using the following procedure. First, the various interconnections in the LC filter are identified as shown in Figure 85.15. In the next

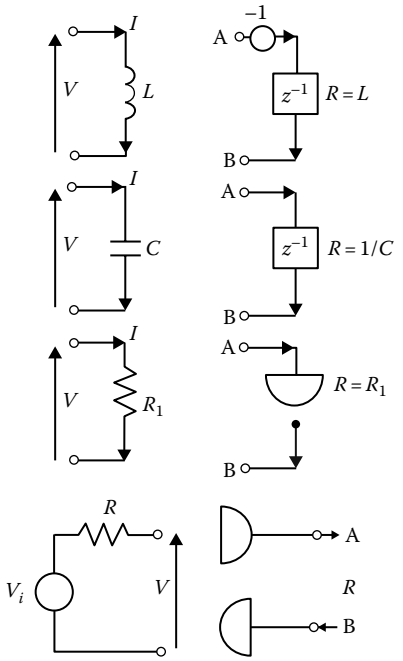

FIGURE 85.14 Digital filter implementations use functional equivalents to one-port linear filter elements.

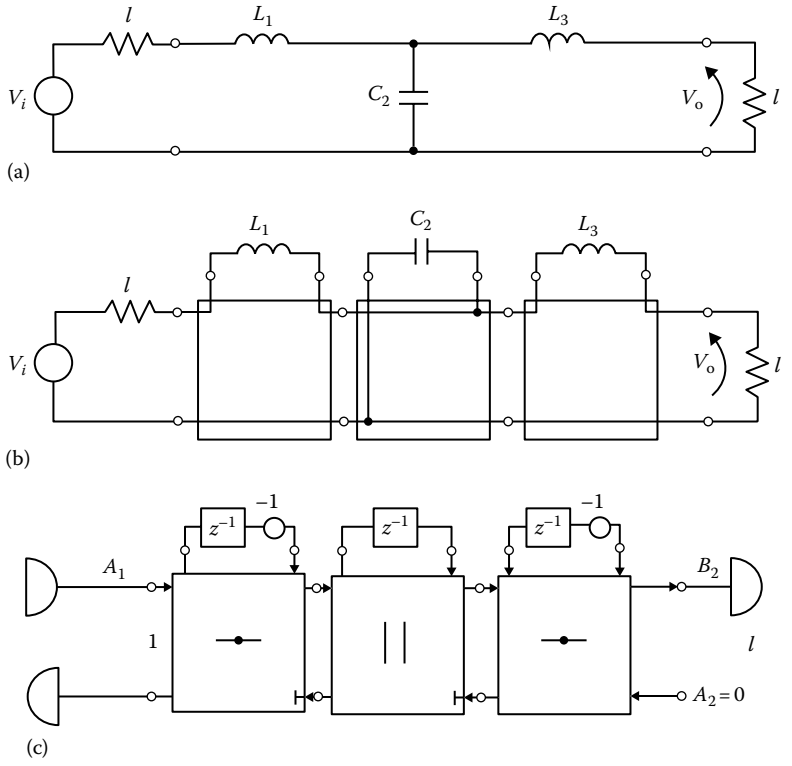

FIGURE 85.15 Digital wave filters establish equivalence with classical filter circuits by use of wave adapter substitutions: (a) LC reference low pass; (b) identification of wire interconnections; and (c) corresponding wave digital filter.

step, the electrical elements in the *LC* filter are replaced by its digital realization using Figure 85.15. Finally, the interconnections are substituted using adaptors. Further discussions and numerical examples dealing with WDFs can be found in Refs. [11–13].

85.10 Antialiasing and Smoothing Filters

In this section, two practical application areas of filters in the analog conditioning stage of a data acquisition system are discussed. A block diagram of a typical data acquisition system is shown in Figure 85.16, consisting of an *antialiasing filter* before the analog-to-digital converter (ADC) and a smoothing filter after the digital-to-analog converter (DAC).

For a complete discrete reconstruction of a time-continuous, band-limited input signal having the spectrum $0 \le f \le f_{max}$, the sampling frequency must be, according to the well-known Shannon's sampling theorem, at least twice the highest frequency in the time signal. In our case, in order to be able to represent frequencies up to f_{max}, the sampling frequency $f_s = 1/T > 2f_{max}$. The necessary band limiting to $f \le f_{max}$ of the input time-continuous signal is performed by a low-pass filter, which suppresses higher

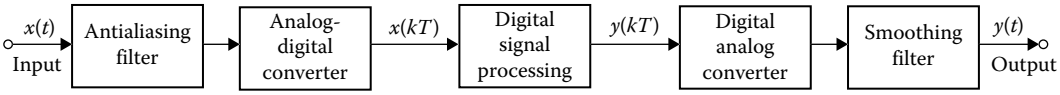

FIGURE 85.16 A data acquisition system with continuous-time inputs and outputs uses antialias prefiltering, an A/D converter, digital signal processing, a D/A converter, and an output smoothing filter.

spectral components greater than f_{max}. Violation of this theorem results in alias frequencies. As a result, frequency components above $f_x/2$, the so-called Nyquist frequency, appear as frequency components below $f_x/2$. Aliasing is commonly addressed by using antialiasing filters to attenuate the frequency components at and above the Nyquist frequency to a level below the dynamic range of an ADC before the signal is digitized. Ideally, a low-pass filter with a response defined by

$$H(j\Omega) = \begin{cases} 1, & |\Omega| \le \pi/T \\ 0, & |\Omega| \ge \pi/T \end{cases} \tag{85.78}$$

is desired to accomplish this task. In practice, a variety of techniques based on the principles of continuous-time analog low-pass filter design can be employed to approximate this "brick-wall" type of characteristic. Antialiasing filters typically exhibit attenuation slopes in the range from 45 to 120 dB/octave and stopband rejection from 75 to 100 dB. Among the types of filters more commonly used for antialias purposes are the Cauer elliptic, Bessel, and Butterworth. The optimum type of filter depends on which kinds of imperfections, e.g., gain error, phase nonlinearity, passband and stopband ripple, etc., are most likely to be tolerated in a particular application. For example, Butterworth filters exhibit very flat frequency response in the passband, while Chebyshev filters provide steeper attenuation at the expense of some passband ripple. The Bessel filter provides a linear-phase response over the entire passband but less attenuation in the stopband. The Cauer elliptic filter, with its extremely sharp roll-off, is especially useful as an antialiasing filter for multichannel digitizing data acquisition systems. However, the large-phase nonlinearity makes it more appropriate for applications involving analysis of the frequency content of signals as opposed to phase content or waveform shape.

Many considerations discussed earlier also apply to smoothing filters. Due to the sampling process, the frequency response after the digital-to-analog conversion becomes periodic with a period equal to the sampling frequency. The quantitization steps that are created in the DAC reconstruction of the output waveform and are harmonically related to the sampling frequency must be suppressed through a low-pass filter having the frequency response of Equation 85.78 also referred to as a smoothing or reconstruction filter. While an antialiasing filter on the input avoids unwanted errors that would result from undersampling the input, a smoothing filter at the output reconstructs a continuous-time output from the discrete-time signal applied to its input.

Consideration must be given to how much antialiasing protection is needed for a given application. It is generally desirable to reduce all aliasable frequency components (at frequencies greater than half of the sampling frequency) to less than the LSB of the ADC being used. If it is possible that the aliasable input can have amplitude as large as the full input signal range of the ADC, then it is necessary to attenuate it by the full 2^N range of the converter. Since each bit of an ADC represents a factor of 2 from the ones adjacent to it, and 20 log(2) = 6 dB, the minimum attenuation required to reduce a full-scale input to less than a LSB is

$$\alpha < -20N(6\text{ dB}) \tag{85.79}$$

where N is the number of bits of the ADC.

The amount of attenuation required can be reduced considerably if there is knowledge of the input frequency spectrum. For example, some sensors, for reasons of their electrical or mechanical frequency response, might not be able to produce a full-scale signal at or above the Nyquist frequency of the system and therefore "full-scale" protection is not required. In many applications, even for 16 bit converters that, in the worst case, would require 96 dB of antialias protection, 50–60 dB is adequate.

Additional considerations in antialias protection of the system are the noise and distortion that are introduced by the filter that is supposed to be eliminating aliasable inputs. It is possible to have a perfectly clean input signal which, when it is passed through a prefilter, gains noise and harmonic distortion

components in the frequency range and of sufficient amplitude to be within a few LSBs of the ADC. The ADC cannot distinguish between an actual signal that is present in the input data and a noise or distortion component that is generated by the prefilter. It is necessary that both noise and distortion components in the output of the antialias filter must also be kept within LBS of the ADC to ensure system accuracy.

85.11 SC Filters

SC filters, also generally referred to as analog sampled-data filters, provide an alternative to conventional active *RC* filters and are commonly used in the implementation of adjustable antialiasing filters. SC filters comprise switches, capacitors, and op amps. Essentially, an SC replaces the resistor in the more traditional analog filter designs. Because the impedance of the SC is a function of the switching frequency, one can vary the cutoff frequency of the SC filter by varying the frequency of the clock signal controlling the switching. The main advantage of SC filters is that they can be implemented in digital circuit process technology, since the equivalent of large resistors can be simulated by capacitors having small capacitance values.

When using SC filters, one must also be aware that they are in themselves a sampling device that requires antialias protection on the input and filtering on their outputs to remove clock feedthrough. However, since clock frequencies are typically 50–100 times f_c of the filter, a simple first or second *RC* filter on their inputs and outputs will reduce aliases and noise sufficient to permit their use with 12–14 bit ADCs. One also need to consider that they typically have dc offset errors that are large, vary with time, temperature, and programming or clock frequency. Interested readers may refer to Refs. [13,14].

85.12 Adaptive Filters

Adaptive filtering is employed when it is necessary to realize or simulate a system whose properties vary with time. As the input characteristics of the filter change with time, the filter coefficients are varied with time as a function of the filter input. Some typical applications of adaptive filtering include spectral estimation of speech, adaptive equalization, echo cancellation, and adaptive control, to name just a few. Depending on the application, the variations in the coefficients are carried out according to an optimization criterion and the adaptation is performed at a rate up to the sampling rate of the system. The self-adjustment capability of adaptive filter algorithms is very valuable when the application environment cannot be precisely described. Some of the most widely used adaptive algorithms are least-mean square (LMS), recursive least squares (RLS), and frequency domain, also known as block algorithm. The fundamental concept of an adaptive filter is depicted in Figure 85.17.

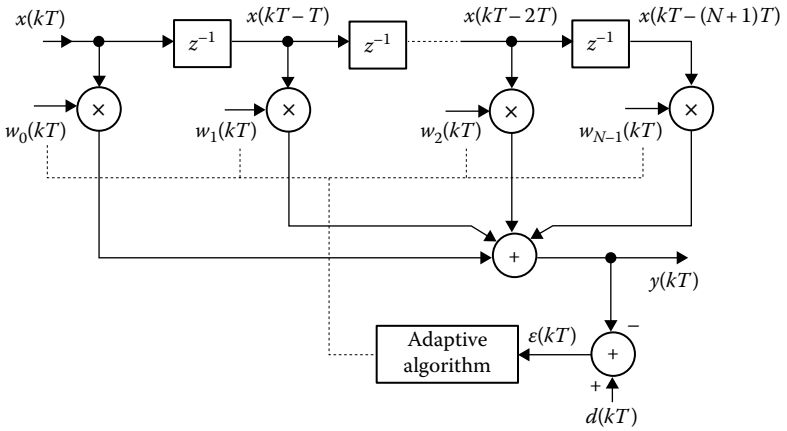

FIGURE 85.17 An adaptive filter uses an adaptive algorithm to change the performance of a digital filter in response to defined conditions.

An adaptive filter is characterized by the filter input $x(kT)$ and the desired response $d(kT)$. The error sequence $\varepsilon(kT)$ formed by

$$\varepsilon(kT) = \sum_{\mu=0}^{N-1} w_\mu(kT)x(kT - \mu T) \tag{85.80}$$

and $x(kT)$, …, $x(kT - T(N-1))$ serve as inputs to an adaptive algorithm that recursively determines the coefficients $w_0(kT + T)$, …, $w_{N-1}(kT + T)$. A number of adaptive algorithms and structures can be found in the literature that satisfies different optimization criteria in different application areas. For more detailed developments, refer to Refs. [1,5,15].

Defining Terms

Antialiasing filter: Antialiasing filters remove any frequency elements above the Nyquist frequency. They are employed before the sampling operation is conducted to prevent aliasing in the sampled version of the continuous-time signal.

Bandpass filter: A filter whose passband extends from a lower cutoff frequency to an upper cutoff frequency. All frequencies outside this range are stopped.

Equiripple: Characteristic of a frequency response function whose magnitude exhibits equal maxima and minima in the passband.

Finite impulse response (FIR) filter: A filter whose response to a unit impulse function is of finite length, i.e., identically zero outside a finite interval.

High-pass filter: A filter that passes all frequencies above its cutoff frequency and stops all frequencies below it.

Ideal filter: An ideal filter passes all frequencies within its passband with no attenuation and rejects all frequencies in its stopband with infinite attenuation. There are five basic types of ideal filters: low pass, high pass, bandpass, stopband, and all pass.

Infinite impulse response (IIR) filter: A filter whose response to a unit impulse function is of infinite length, i.e., nonzero for infinite number of samples.

Low-pass filter: A filter that attenuates the power of any signals with frequencies above its defined cutoff frequency.

Passband: The range of frequencies of a filter up to the cutoff frequency.

Stopband: The range of frequencies of a filter above the cutoff frequency.

Transition region: The range of frequencies of a filter between a passband and a stopband.

Spectrum Analysis and Correlation

Ronney B. Panerai
University of Leicester

86.1 Introduction

Most sensors and instruments described in the previous chapters of this handbook can produce continuous measurements in time or sequential measurements at fixed or variable time intervals, as represented in Figure 86.1. The temporal patterns resulting from such measurements are usually referred to as *signals*. Signals can either be *continuous* or *discrete in time*. The main objective of *spectral analysis* is to provide an estimate of the distribution of signal power at different frequencies. Spectral analysis and correlation techniques are an aid to the interpretation of signals and to the systems that generate them. These methods are now widely used for the analysis and interpretation of measurements performed in medicine, geophysics, vibration analysis, communications, and several other areas.

Although the original concept of a *signal* involves measurements as a function of time (Figure 86.1), this term has been generalized to include measurements along other dimensions, e.g., distance. In addition, signals can have multiple dimensions—the instantaneous velocity of an airplane can be regarded as a four-dimensional signal since it depends on time and three spatial coordinates.

With the growing availability of signal-processing computer packages and dedicated instruments, most readers will perform spectral analysis and correlation at the "touch of a button," visualizing results on a screen or as a computer plot. These "black-box" systems are useful for saving time and money, but users should be aware of the limitations of the fundamental techniques and circumstances in which inappropriate use can lead to misleading results. This chapter presents the basic concepts of spectral analysis and correlation based on the *fast Fourier transform* (FFT) approach. FFT algorithms allow the most efficient computer implementation of methods to perform spectral analysis and correlation and have become the most popular option. Nevertheless, other approaches, such as parametric techniques, wavelet transforms (WT), and time-frequency analysis, are also available. These will be

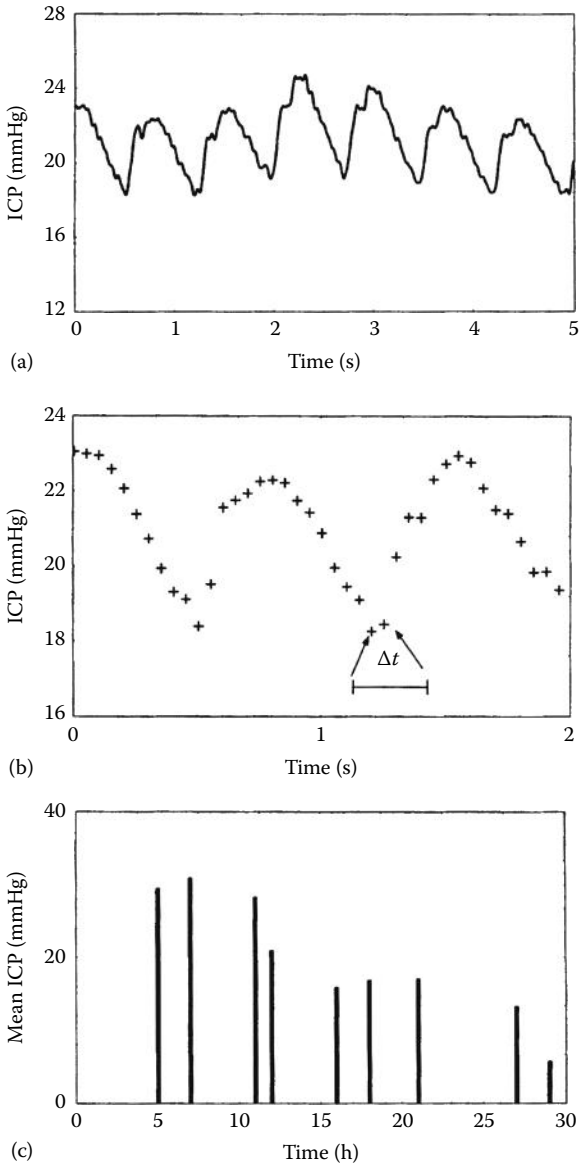

FIGURE 86.1 Examples of continuous and discrete-time signals. briefly discussed and the interested reader will be directed to the pertinent literature for applications that might benefit from alternative approaches.

86.2 Fundamental Concepts

86.2.1 Spectral Analysis

Practical applications of spectral and correlation analysis are performed on discrete-time signals (Figure 86.1). These are obtained either from a sequence of discrete measurements or from the transformation of a continuous signal to digital format using an analog-to-digital converter (ADC).

When the latter is adopted to allow computer analysis of an originally continuous signal, two main characteristics of the ADC must be considered. The first is the number of bits available to represent each sample, as this will determine the resolution and accuracy of the sampled signal. The second important consideration is the *sampling interval* Δt (Figure 86.1). From the *Nyquist theorem* [1], the maximum value of Δt must be such that the *sampling frequency* $f_s - 1/\Delta t$ is at least twice the highest frequency of interest in the original signal. If this rule is not followed, spectral and correlation estimations might be considerably distorted by a phenomenon called *aliasing* [2]. Low-pass filtering before ADC is always recommended to limit the bandwidth of the continuous signal to allow the correct choice of f_s or Δt. In practice, the sampling frequency is usually much higher than the minimum required by the Nyquist theorem to provide a better visual representation of the sampled data.

Let x_n represent a discrete-time signal with samples at $n = 0, 1, 2, \ldots, N-1$. The Fourier theorem [1,2] states that it is possible to decompose x_n as a sum of cosine and sine waveforms of different frequencies using an appropriate combination of amplitude coefficients. Therefore,

$$x_n = a_0 + \sum_{k=1}^{N-1} a_k \cos\left(\frac{2\pi kn}{N}\right) + \sum_{k=1}^{N-1} b_k \sin\left(\frac{2\pi kn}{N}\right) \tag{86.1}$$

where $k = 1, 2, \ldots, N-1$ determines the frequency of each cosine and sine waveforms as $f_k = k/N\Delta t$. The corresponding coefficients are calculated from

$$a_0 = \frac{1}{N}\sum_{n=0}^{N-1} x_n \tag{86.2a}$$

$$a_k = \frac{1}{N}\sum_{n=0}^{N-1} x_n \cos\left(\frac{2\pi kn}{N}\right) \tag{86.2b}$$

$$b_k = \frac{1}{N}\sum_{n=0}^{N-1} x_n \sin\left(\frac{2\pi kn}{N}\right) \tag{86.2c}$$

Note that Equation 86.2a represents the mean value of x_n and that the argument $2\pi kn/N$ is the same for the *direct* (Equation 86.2) and *inverse* (Equation 86.1) *discrete Fourier transforms* (DFT).

From Euler's formula [3], it is possible to combine the cosine and sine terms to express the DFT in exponential form:

$$e^{j\theta} = \cos\theta + j\sin\theta \tag{86.3}$$

leading to

$$x_n = \sum_{k=0}^{N-1} c_k e^{j(2\pi kn/N)} \tag{86.4}$$

with

$$c_k = \frac{1}{N}\sum_{n=0}^{N-1} x_n e^{-j(2\pi kn/N)} \tag{86.5}$$

where c_k is now a complex value related to the original cosine and sine coefficients by

$$c_0 = a_0 \tag{86.6a}$$

$$c_k = a_k - jb_k \quad k = 1, 2, \ldots, N-1 \tag{86.6b}$$

A graphic representation of the a_k, b_k, or c_k coefficients for each value of k (or f_k) constitutes the frequency spectrum of x_n, expressing the relative contribution of different sinusoidal frequencies to the composition of x_n (Equation 86.4). Since c_k is complex (Equation 86.6b), a more meaningful physical interpretation of the spectrum is obtained with the *amplitude* and *phase* spectra, defined as

$$A_k = \left(a_k^2 + b_k^2\right)^{1/2} = |\, c_k \,| \tag{86.7a}$$

$$\theta_k = \tan^{-1}\left(-\frac{b_k}{a_k}\right) \tag{86.7b}$$

Figure 86.2 shows the amplitude (or magnitude) and phase spectra for the signal in Figure 86.1a, sampled at intervals Δt = 20 ms. The signal was low-pass-filtered at 20 Hz before ADC. The total duration is

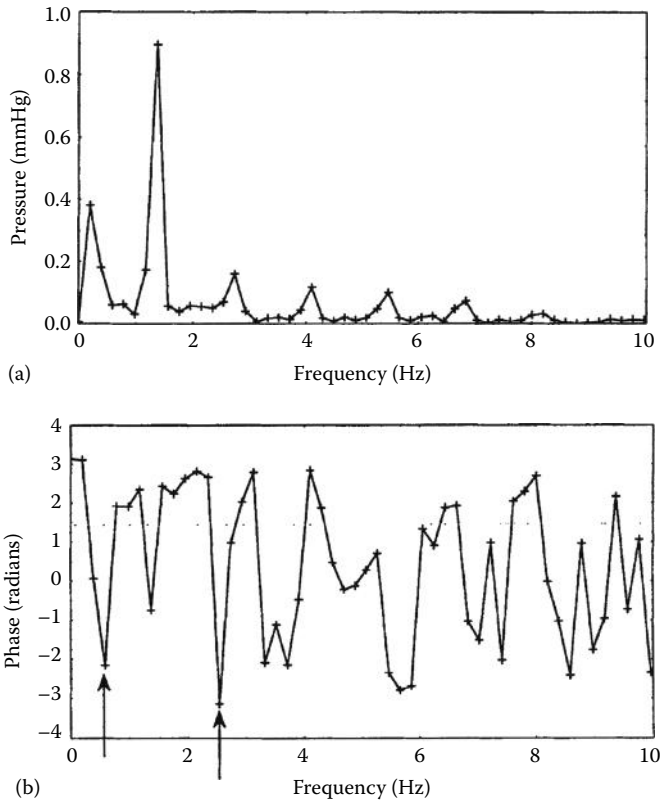

FIGURE 86.2 (a) Amplitude, and (b) phase spectra of the intracranial pressure signal represented in Figure 86.1a after analog-to-digital conversion with a sampling interval of 20 ms. The main peak in the amplitude spectrum corresponds to the frequency of the cardiac cycle in Figure 86.1a. Wraparound of the phase spectrum is apparent in the third and 13th harmonics (arrows). Both spectra have been plotted to 10 Hz only.

given by $T = N\Delta t = 5$ s, corresponding to $N = 250$ samples. Before calculating the spectral coefficients, the mean value of the complete record was removed (dc term) and any linear trends were removed by fitting a straight line to the data (detrending). As will be discussed later, it is also important to apply a window to the data, to minimize the phenomenon of leakage. For $k > N/2$, both spectra present symmetrical values. This can be easily demonstrated from the fact that cosine (and sine[2]) functions have even symmetry while sine has odd symmetry. From Equation 86.7, it follows that A_k and θ_k have *even* and *odd* symmetry, respectively [4]. Consequently, only half the spectral components ($k < N/2$) are required to give a complete description of x_n in the frequency domain.

The amplitude spectra indicate the combined amplitude of the cosine and sine terms to reconstruct x_n; the phase spectra reflect the relative phase differences (or time delays) between the sinusoidal waveforms to generate the temporal pattern of x_n. The amplitude spectra also reflect the signal power at different frequencies. For simplicity, the power spectrum can be defined as

$$P_k = A_k^2 = |c_k|^2 \tag{86.8}$$

Direct implementation of Equation 86.8, however, leads to spectral power estimates which are biased and inconsistent. More appropriate procedures for estimating the *power spectrum* (or *power density spectrum*) will be discussed later.

Parseval's theorem [5] demonstrates that the total signal energy can be computed in either time or frequency domain:

$$\frac{1}{N}\sum_{n=0}^{N-1} x_n^2 = \sum_{k=0}^{N-1} P_k \tag{86.9}$$

If x_n has zero mean, the left-hand side of Equation 86.9 is the biased estimator of signal variance [6]. Although most applications of spectral analysis concentrate on the characteristics of the amplitude or power spectra, it is important to bear in mind that the phase spectrum is also responsible for the temporal pattern of x_n. As an example, both the Dirac impulse function and white noise have a flat, constant amplitude (or power) spectra [6], it is the difference in the phase spectra which accounts for the different morphologies in the time domain.

Interpretation of the amplitude and phase spectra of both theoretical functions and sampled data is facilitated by taking into account several properties of the DFT (Equations 86.4 and 86.5), namely, *symmetry*, *linearity*, *shifting*, *duality*, and *convolution* [7]. To these, a very important property of Equations 86.1 and 86.4 must be added. Since cosine and sine functions are periodic, and exist for $-\infty < t < \infty$, Equations 86.1 and 86.4 will reconstruct x_n not only in the interval of interest ($0 \le t \le$ T) but also at all other multiple intervals $pT \le t \le (p + 1)T (p = 0, \pm 1, \pm 2, \ldots)$. As a consequence, spectral estimations obtained with the DFT inherently assume that x_n is *periodic* with period $T = T/\Delta t$. As discussed in the following sections, this property needs to be taken into account when performing spectral analysis with the DFT and FFT.

86.2.2 Correlation Analysis

The basic concept of the correlation coefficient, as a measure of the strength of linear relationship between two variables [6], can be extended to signal analysis with the definition of the *cross-correlation function* (CCF) as [5]

$$r_{xy}(p) = \frac{1}{N}\sum_{n=0}^{N-1} x_n y_{n-p} \quad p = 0, \pm 1, \pm 2, \ldots \tag{86.10}$$

where x_n and y_n are zero-mean, discrete-time signals defined in the interval $n = 0, 1, 2, \ldots, N-1$. For each value of p, the cross correlation is computed by shifting y_n by $p\Delta t$ and calculating the average product in Equation 86.10. If x_n and y_n are unrelated, the sum of positive and negative products will tend to zero. Conversely, y_n tends to follow x_n, but with a time delay D, $r_{xy}(p)$ will show a peak at $p = D/\Delta t$. This property of the CCF is illustrated in Figure 86.3. As noted by Bergland [8], cross correlation can be viewed as "one signal searching to find itself in another signal."

For $y_n = x_n$, $r_{xx}(p)$ becomes the *autocorrelation function* (ACF):

$$r_{xx}(p) = \frac{1}{N}\sum_{n=0}^{N-1} x_n x_{n-p} \tag{86.11}$$

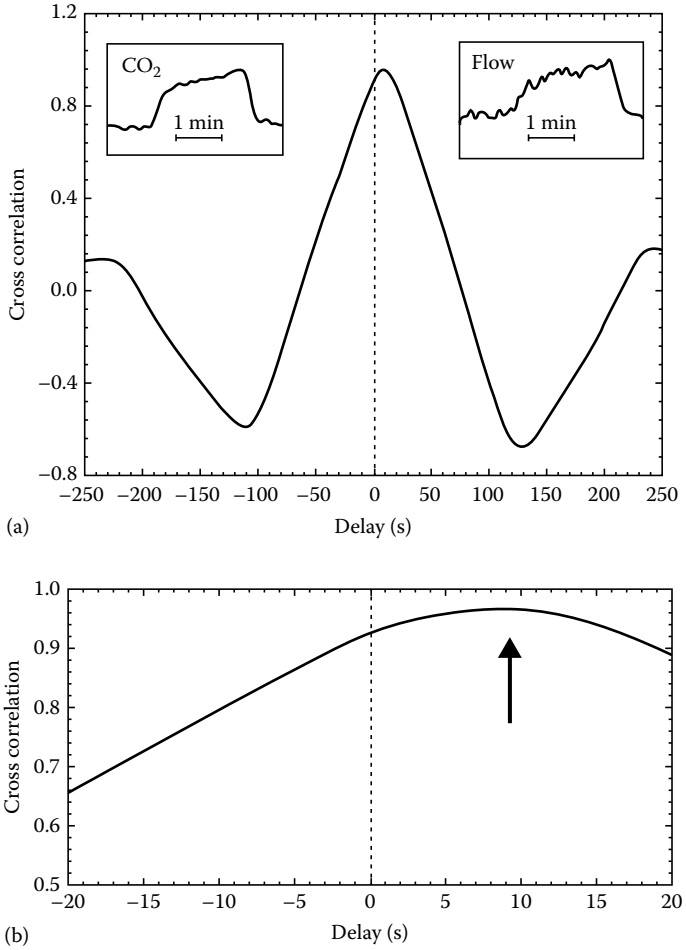

FIGURE 86.3 CCF between changes in arterial CO_2 and blood flow to the brain. Arterial CO_2 was estimated from end-tidal measurements and cerebral blood flow with Doppler ultrasound in the middle cerebral artery. (a) CCF and original signals (inserts). The cross-correlation value of ~1.0, observed at time delays near zero, reflects the similar temporal patterns between the two measurements. The negative cross correlations are obtained when either signal is shifted by approximately the duration of the plateau phase, which lasts 2 min. (b) Enlarging the scale around delay = 0 shows that the peak cross correlation occurs at 10 s, reflecting the time it takes for the flow to respond to the CO_2 change. (Data kindly provided by Dr. Joanne Dumville, Mr. A. Ross Naylor, and Prof. David H. Evans, University of Leicester, Leicester, U.K.)

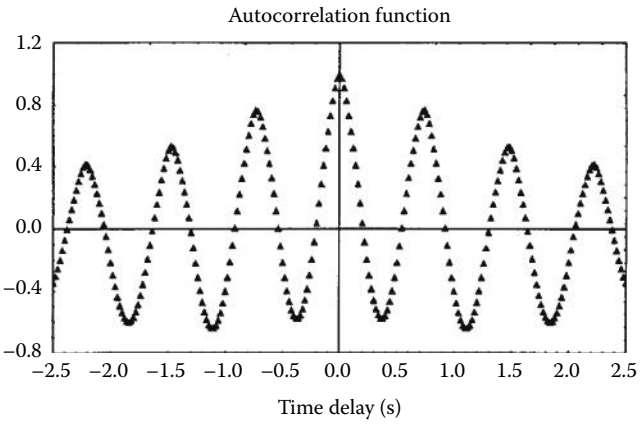

FIGURE 86.4 ACF of the discrete-time version of the signal in Figure 86.1a. The periodicity of the ACF reflects the quasi-periodic pattern of the intracranial pressure signal (Figure 86.1a).

and it is intuitive that the maximum value of $r_{xx}(p)$ occurs for $p = 0$ with

$$r_{xx}(0) = \frac{1}{N}\sum_{n=0}^{N-1} x_n^2 \tag{86.12}$$

which represents the signal variance or total energy. Therefore, for signals with unit standard deviation, the autocorrelation peak is equal to 1.

The Wiener–Khintchine theorem [9] demonstrates that the ACF and the power spectrum constitute a Fourier transform pair, that is,

$$S_k = \sum_{p=0}^{N-1} r_{xx}(p) e^{-j(2\pi kp/N)} \tag{86.13}$$

where S_k is usually called the autospectra of x_n. Equation 86.13 indicates that it is possible to estimate the power spectra from a previous estimate of the ACF. As a transform pair, the ACF can also be derived from the autospectra by substituting S_k for c_k in Equation 86.4.

From Equation 86.11, it is clear that $r_{xx}(p)$ has even symmetry, that is, $r_{xx}(+p) = r_{xx}(-p)$. This property is apparent in Figure 86.4, which shows the estimated ACF for the signal in Figure 86.1a. Another characteristic of ACF, which can be visualized in Figure 86.4, is the occurrence of secondary peaks reflecting the presence of an oscillatory component in x_n (Figure 86.1a).

86.3 Fast Fourier Transform

The FFT is not a single algorithm but rather a large family of algorithms which can increase the computational efficiency of the DFT. The main ideas behind the formulation of FFT algorithms are discussed later. A detailed description of the different algorithms that have been proposed is beyond the scope of this introduction; this can be found in Refs. [5–7,10–14].

For both software and hardware implementations of Equations 86.4 and 86.5, the computational efficiency is usually expressed by the number of complex multiplications and additions, or simply, by the *number of* operations [10]. Straight implementation of either Equation 86.4 or 86.5 leads to N^2 operations. Typically, FFT algorithms can reduce this number to $N\log_2 N$. For $N = 1024$, the FFT algorithm is 100 times faster than the direct implementation of Equation 86.4 or 86.5.

The essence of all FFT algorithms is the periodicity and symmetry of the exponential term in Equations 86.4 and 86.5, and the possibility of breaking down a transform into a sum of smaller transforms for subsets of data. Since n and k are both integers, the exponential term is periodic with period N. This is commonly represented by

$$W_N = e^{-j(2\pi/N)} \tag{86.14}$$

and Equation 86.5 can be written as

$$c_k = \frac{1}{N}\sum_{n=0}^{N-1} x_n W_N^{kn} \quad k = 0, 1, 2, \ldots, N-1 \tag{86.15}$$

In many applications, the terms W_N^{kn} are called *twiddle factors*. Assuming $N = 8$, calculation of the DFT with Equation 86.15 will require 64 values of w_8^{kn}. Apart from the minus sign, a simple calculation can show that there are only four different values of this coefficient, respectively: $1, j, (1+j)/\sqrt{2}$, and $(1-j)/\sqrt{2}$. Consequently, only these four complex factors need to be computed, representing a significant savings in number of operations.

Most FFT algorithms are based on the principle of *decimation-in-time*, involving the decomposition of the original time (or frequency) sequence into smaller subsequences. To understand how this decomposition can reduce the number of operations, assume that N is even. In this case, it is possible to show that Equation 86.15 can be written as [4,5,7,11]:

$$c_k = \frac{1}{N}\sum_{r=0}^{(N/2)-1} x_r^e \cdot W_{N/2}^{kr} + \frac{1}{N}\sum_{r=0}^{(N/2)-1} x_r^0 \cdot W_{N/2}^{kr} \tag{86.16}$$

where x_r^e and x_r^0 represent the even- and odd-order samples of x_n, respectively. Comparing Equations 86.15 and 86.16, it is clear that the latter represents two DFTs with dimension $N/2$, involving $2(N/2)^2$ operations rather than the N^2 operations required by Equation 86.15. This process of decimation-in-time can be carried out further to improve computational performance. In the general case, N can be decomposed into q factors:

$$N = \prod_{i=1}^{q} r_i = r_1 r_2 \ldots r_q \tag{86.17}$$

The number of operations required is then [6]

$$\text{Number of operations} = N\sum_{i=1}^{q} r_i \tag{86.18}$$

In the original algorithm of Cooley and Tukey [10], $r_i = 2$ and $N = 2^q$. In this case, the theoretical number of operations required would be $2Nq = 2N\log_2 N$. As pointed out in Ref. [6], further improvements in efficiency are possible because of the symmetry of the twiddle factors. The efficiency gain of most FFT algorithms using radix-2, i.e., $N = 2^q$ is

$$\text{Efficiency gain} = \frac{N^2}{N\log_2 N} = \frac{N}{\log_2 N} \tag{86.19}$$

For $N = 1024$, $q = 10$ and the efficiency gain is ~100. Specific applications might benefit from other decompositions of the original sequence. Cases of particular interest are radix-4 and radix-8 FFTs [14]. However, as shown by Rabiner and Gold [11] (p. 585), it is not possible to generalize the superiority of radix-8 over radix-4 algorithms.

In general, most FFT algorithms accept complex x_n sequences in Equation 86.5. By limiting x_n to the most common situation of real-valued signals, it is possible to obtain more efficient algorithms as demonstrated by Sorensen et al. [15]. Uniyal [16] performed a comparison of different algorithms for real-valued sequences showing that performance is architecture-dependent. For machines with a powerful floating point processor, the best results were obtained with Brunn's algorithm [17].

The application of FFT algorithms for spectral and correlation analysis is discussed in the following sections.

86.4 FFT Spectral Analysis

For some deterministic signals, x_n can be expressed by a mathematical function and the amplitude and phase spectra can be calculated as an exact solution of Equations 86.5 and 86.7. The same is true for the power spectra (Equations 86.8 and 86.13). Examples of this exercise can be found in many textbooks [1,2,4,5,7].

In most practical applications, there is a need to perform spectral analysis of experimental measurements, corresponding to signals which, in general, cannot be described by simple mathematical functions. In this case, the spectra have to be estimated by a numerical solution of Equations 86.5 through 86.8, which can be efficiently implemented on a digital computer with an FFT algorithm. For estimation of the power spectrum, this approach is often classified as *nonparametric*, as opposed to other alternatives which are based on parametric modeling of the data such as *autoregressive* methods [18]. Considerable distortions can result from applications of the FFT unless attention is paid to the following characteristics and properties of the measured signal and the DFT/FFT.

86.4.1 Limited Observation of Signal in Time

Limited observation of a signal x_n in time can be seen as the multiplication of the original signal x_n^∞ by a rectangular window of duration $T = N\Delta t$ as exemplified for a single sinusoid in Figure 86.5. The DFT assumes that x_n is periodic, with period T, as mentioned previously. Instead of a single harmonic at the frequency of the original sinusoid, the power spectrum estimated with the FFT will have power at other harmonics as indicated by the spectrum in Figure 86.5c. The spectral power, which should have been concentrated on a single harmonic (Figure 86.5c, dashed line), has "leaked" to neighboring harmonics and for this reason this phenomenon is usually called *leakage*. The morphology of the distorted spectrum of Figure 86.5c can be explained by the fact that the Fourier transform of a rectangular window function (Figure 86.5b) is given by a sin c function (sin x/x) which presents decreasing side lobes [1,2]. Multiplication in time corresponds to the convolution operation in the frequency domain. In the general case of signals comprising several harmonics, the sin c functions will superimpose and the resulting spectrum is then a distorted version of the "true" spectrum. As the individual *sine* functions superimpose to produce the complete spectrum, a *picket-fence* effect is also generated [8]. This means that spectral leakage not only adds spurious power to neighboring harmonics but also restricts the frequency resolution of the main spectral peaks. The effects of spectral leakage can be reduced by (1) increasing the period of observation and (2) multiplying the original signal x_n by a window function with a smooth transition as represented by the dashed line window in Figure 86.5b. The Fourier transform of a window function with tapered ends has smaller side lobes, thus reducing the undesirable effects leakage.

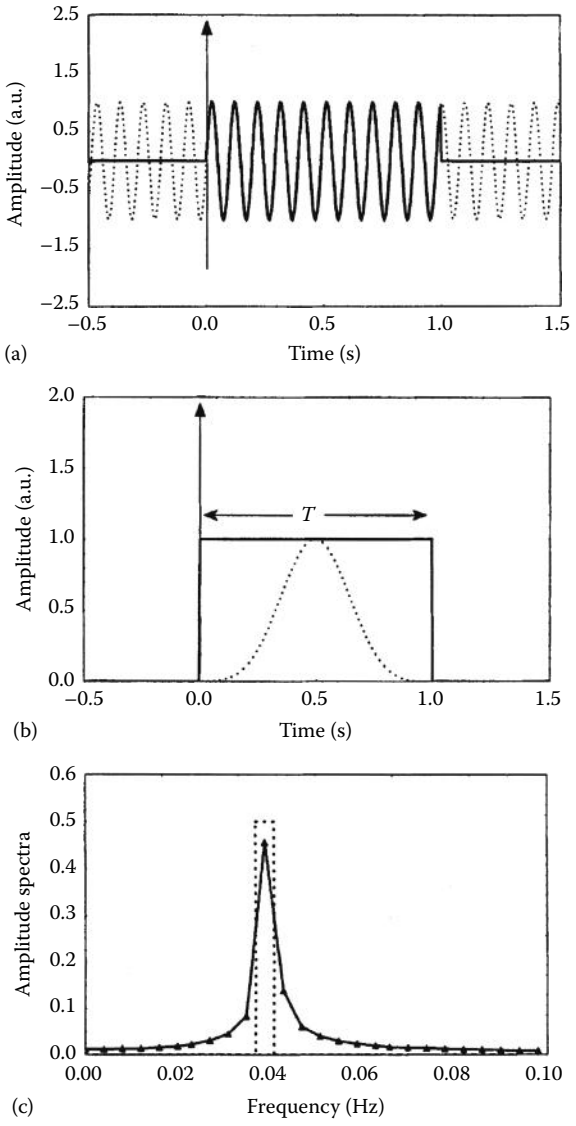

FIGURE 86.5 Effect of limited observation time T on the amplitude spectra of a sinusoidal component. (a) Observation of a single harmonic (dashed line) for a limited period of time T is equivalent to the multiplication for the rectangular function represented in (b). The Blackman–Harris window is also represented in (b) (dashed line). (c) Truncating a single harmonic produces spectral estimates smeared by *leakage* (solid line) as compared with the theoretical result (dashed line) with width equal to the frequency resolution ($f_r \approx 0.004$ Hz).

A large number of tapering windows have been proposed, as reviewed by Harris [19]. As an example, the four-term Blackman–Harris window, defined as

$$w_n = a_0 - a_1 \cos\left(\frac{2\pi n}{N}\right) + a_2 \cos\left(\frac{4\pi n}{N}\right) - a_3 \cos\left(\frac{6\pi n}{N}\right) \quad n = 0, 1, 2, \ldots, N-1 \tag{86.20}$$

produces side lobe levels of –92 dB if the a coefficients are chosen as $a_0 = 0.35875$, $a_1 = 0.48829$, $a_2 = 0.14128$, $a_3 = 0.01168$ [19]. Windows also play an important role in the sampling properties of power spectral estimates, as will be discussed later. Windowing attenuates the contribution of signal samples

at the beginning and end of the signal and, therefore, reduces its effective signal duration. This effect is reflected by the equivalent noise bandwidth (ENBW) defined as [19]

$$\text{ENBW} = \frac{\sum_{n=0}^{N-1} w_n^2}{\left[\sum_{n=0}^{N-1} w_n\right]^2} \tag{86.21}$$

For a rectangular window ENBW = 1.0 and for the Blackman–Harris window (Equation 86.20), the corresponding value is 2.0. The majority of other window shapes have intermediate values of ENBW [19].

86.4.2 Effects of "Zero Padding"

Most FFT algorithms operate with $N = 2^q$ samples, the choice of q is many times critical. Since frequency resolution is inversely proportional to N, in many circumstances a value of q leading to $2^q > N$ is preferable to the option of limiting the signal to $N' = 2^{q-1}$ samples with $N' < N$. The most common and simple way of extending a signal to comply with the $2q$ condition is by *zero padding*. For signals with zero mean and with first and last values around zero, this can be accomplished by complementing the signal with Q zeros to achieve the condition $N + Q = 2^q$. For signals with end points different from zero, these values can be used for padding. If initial and final values differ significantly, a linear interpolation from the last to the first point is also a practical option. However, with the application of windowing, most signals will have similar initial and final points and these can be used for zero padding. As discussed in the next section, zero padding has important applications for the estimation of correlation functions via FFT. For spectral analysis, it is relatively simple to demonstrate that adding Q zeros corresponds to over sampling the N point original spectrum with a new frequency resolution which is $(N + Q)/N$ times greater than the original resolution. Consequently, although zero padding does not introduce major distortions, it produces the false illusion of higher resolution than warranted by the available N measured signal samples.

86.4.3 Phase Spectrum Estimation

The use of Equation 86.7b to estimate the phase spectrum is fraught with a different kind of problem, resulting from the indetermination of the $\tan^{-1}$ function to discriminate between phase angles with absolute values greater than π. This problem is illustrated in Figure 86.2 showing that phase angles decrease continuously until reaching $-\pi$ and then "jump" to continue decreasing from the $+\pi$ value. This feature of the phase spectrum is called *wraparound*. Methods to "unwrap" the phase spectrum have been proposed [20], but a general satisfactory solution to this problem is not available. In some cases, the shifting property of the DFT [5,7] can be used to "rotate" the original signal in time, thus minimizing the slope of the phase spectrum and, consequently, the occurrence of wraparound.

86.4.4 Sampling Properties of Spectral Estimators

The most straightforward approach to computing the power spectrum is to use Equation 86.8. This method is known as the *periodogram* [5]. Application is limited to signals which are *stationary*, meaning stable statistical properties (such as the mean and the variance) along time. For measurements performed on *nonstationary* systems, such as speech or systems with time-varying parameters, other methods of spectral estimation are available and will be mentioned later. It is possible to demonstrate that when the period of observation T tends to infinity, Equation 86.8 gives an unbiased estimate of the power spectrum. In practice, due to finite values of T, the phenomenon of spectral leakage described earlier will lead to power spectral estimates which are *biased*.

The second inherent problem with the periodogram is the *variance* of the resulting spectral estimates. Assuming x_n to follow a Gaussian distribution, it follows that a_k and b_k will also be Gaussian because

Equation 86.2 represents a linear transformation. Since Equations 86.7a and 86.8 involve the sum of two squared Gaussian variates, P_k will follow a χ^2 distribution with two degrees of freedom [6]. In this case the mean and the standard deviation of the power spectral estimate will be the same, *independently of the frequency considered*. As a consequence, power spectral estimates obtained from Equation 86.8, using a simple sample x_n, should be regarded as highly unreliable. In addition, the variance or standard deviation of this χ^2 distribution does not decrease with increases in sample duration N. This indicates that the periodogram (Equation 86.8) is an *inconsistent* estimator of the power spectrum.

For a χ^2 distribution with m degrees of freedom, the coefficient of variation is given by

$$\mathrm{CV}\left[\chi_m^2\right] = \frac{\sqrt{2m}}{m} = \sqrt{\frac{2}{m}} \tag{86.22}$$

showing that it is possible to improve the reliability of power spectral estimates by increasing m. This can be achieved by replacing Equation 86.8 by [21]

$$\hat{P}_k = \frac{1}{L}\sum_{l=1}^{L} c_{k,l}^2, \quad k = 0, 1, 2, \ldots, N-1 \tag{86.23}$$

with L representing a number of separate samples x_n each with length $T = N\Delta t$. If only one record of x_n can be obtained under stationary conditions, it is possible to break down this record into L segments to obtain an improved estimate of the power spectrum with variance reduced by a factor of L. However, the spectral resolution, given by $f_r = 1/T$, will be reduced by the same factor L, thus indicating an inescapable compromise between resolution and variance.

A *modified periodogram* was introduced by Welch [21] consisting of the multiplication of x_n by a triangular, or other window shape, before computing the individual spectral samples with Equation 86.5. The application of a window justifies overlapping adjacent segments of data by as much as 50%. For a signal with a total duration of N samples, the combination of overlapping with segmentation (Equation 86.23) can lead to a further reduction of the spectral variance by a factor of 11/18.

Averaging L spectral samples as indicated by Equation 86.23 represents one approach to improve spectral estimation by means of *smoothing*. A similar effect can be obtained with the *correlogram*. Equation 86.13 indicates that it is possible to estimate the power spectrum from the ACF. Limiting the number of shifts of the ACF to $p \ll N$ becomes equivalent to smoothing the original spectrum by convolution with the Fourier transform of a Bartlett (triangular) window [22]. As discussed in the next section, the ACF can also be computed more efficiently with the FFT and it can be shown that in this case it involves a smaller number of numerical operations than the Welch method based on the periodogram [5].

86.5 FFT Correlation Analysis

Before considering the application of FFT algorithms to compute ACF and CCF, it is important to discuss their sampling properties using Equations 86.10 and 86.11 as estimators. Assuming that variables x_n and y_n are not defined outside the interval $0 \le n \le N-1$, it follows from Equation 86.10 that as p increases and the two functions "slide" past each other, the effective number of summed products is $N - |p|$ rather than N as implied by Equations 86.10 and 86.11. For this reason, these equations are often rewritten as

$$r_{xy}(p) = \frac{1}{N-|p|}\sum_{n=0}^{N-|p|-1} x_n y_{n-1}, \quad p = 0, \pm 1, \pm 2, \ldots \tag{86.24}$$

The main justification for this modification, however, is that Equations 86.10 and 86.11 lead to biased estimations of correlation functions while Equation 86.24 is *unbiased*.

Equation 86.24 normally assumes that x_n and y_n are standardized variables with zero mean and unit variance. If the mean values are different from zero, Equations 86.10 and 86.11 will produce distorted estimates with a "pyramid effect" due to the presence of the dc term. However, this effect is compensated for in Equation 86.24 and in this case the effect of the mean value is to add a constant term:

$$r_{xy}(p) = r'_{xy}(p) - m_x m_y \tag{86.25}$$

where $r'_{xy}(p)$ is the cross correlation of variables with mean values m_x and m_y, respectively.

Similarly to the DFT, Equations 86.10 and 86.11 involve N^2 operations and Equation 86.24 slightly less. Since the autocorrelation and the power spectra constitute a Fourier transform pair (Equation 86.13), the computation of correlation functions can also be sped up by means of an FFT algorithm. For the sake of generality, the cross *spectrum* of x_n and y_n can be defined as [6]

$$C_{xy}(f_k) = X(f_k)Y^*(f_k) \tag{86.26}$$

with $X(f_k)$ and $Y(f_k)$ representing the Fourier transforms of x_n and y_n, respectively. The generalized Wiener–Khintchine theorem then gives the CCF as

$$r_{xy}(p) = \sum_{k=0}^{N-1} C_{xy}(f_k) e^{-j(2\pi kp/N)} \tag{86.27}$$

Therefore, "fast" correlation functions can be computed [23] using the forward FFT to calculate $X(f_k)$ and $Y(f_k)$ and then the inverse FFT to obtain $r_{xy}(p)$ with Equation 86.27. Obviously, when ACF are being computed with this method, only one transform is necessary to obtain the autospectra (Equation 86.13) instead of the cross spectra (Equation 86.26).

When correlation functions are computed with the FFT, it is critical to pay attention again to the periodicity of the transformed variables as an intrinsic property of the DFT. When the two functions in either Equation 86.10 or 86.11 are displaced by p samples, for periodic functions there will be nonzero products outside the range $0 \le n \le N - 1$, thus leading to significant errors in the estimated ACF or CCF. In this case, the resulting estimates are called *circular* correlations [6]. This error can be avoided by zero padding the original signals from $n = N$ to $n - 2N - 1$ and computing the FFTs with $2N$ points. The resulting correlation functions will be noncircular and, in the range $0 \le p \le N - 1$ will agree with correlations computed with the original Equation 86.10 or 86.11. Finally, to remove bias the results of Equation 86.27 should also be multiplied by $NI(N - |p|)$ to agree with Equation 86.24.

86.6 Further Information

Software for FFT special analysis is available from multiple sources. Off-the-shelf software ranges from specialized packages for digital signal processing, such as DADiSP, to statistical packages which include FFT analysis of time series. Mathematical and engineering packages such as MATLAB® also include routines for FFT spectral and correlation analysis. For a review of available options, see Ref. [24]. For readers who want to implement their own software, FFT routines can be found in Refs. [4,13–15,18]. Additional references are [25–27].

Hardware implementations of FFT algorithms are common in areas requiring real-time spectral analysis as in the case of blood flow velocity measurement with Doppler ultrasound. For a review of hardware implementations, see Refs. [11,28]. Developments in this area follow the pace of change in VLSI technology [29].

One of the limitations of the FFT is the fact that frequency resolution is the inverse of the signal observation time. Improved resolution can be obtained with *parametric* methods of spectral analysis and their application is particularly relevant when only short segments of data are available or when it is necessary to discriminate between frequency harmonics which are closely spaced in the spectrum. Broadly speaking, parametric methods assume that the data follow spectral densities with a known pole–zero structure of variable complexity, characterized by a given *model order*. All-zero models correspond to the *moving average* structure while the all-pole version represents the *autoregressive* model. The general case is the autoregressive-moving average model (ARMA). For a comprehensive review of these methods, see Ref. [30]; further information and software implementations can be found in Refs. [18,27].

Nonstationary signals present a particular problem. In cases where the signal statistical properties change relatively slowly with time, it is possible to select short segments of quasi-stationary data and to use the DFT or parametric methods to estimate the spectra as mentioned previously. However, when these changes in systems parameters or statistical moments are fast in relation to the phenomenon under observation (e.g., speech or seismic data), this approach is not feasible because of the poor frequency resolution resulting from short observation times. Methods proposed to cope with signal nonstationarity often depend on the underlying cause of nonstationary behavior [9,31]. More general methods, known as *time-frequency distributions*, are now favored by most investigators [32]. The Wigner–Ville and Choi–Williams transforms are some of the more widely used of these time-frequency distributions. In each case the signal is described by a simultaneous function of time *and* frequency and hence is graphically represented by a three-dimensional plot having time and frequency as dependent variables.

A different approach to the analysis of nonstationary data is the application of *wavelets* [33]. This alternative also has advantages in the representation of fast transients and in applications requiring data compression and pattern classification. Similarly to the sine and cosine functions, which are the basis of Fourier analysis, wavelets are orthogonal functions which can be used to decompose and reconstruct signals using a finite set of coefficients obtained by a WT. The main difference between wavelets and sinusoids, however, is that the former are limited in time. In addition, the complete orthogonal set of wavelets can be obtained simply by expansion (or compression) and scaling of a single function, known as the *mother wavelet*. Because of their limited time duration, wavelets can provide a much more synthetic decomposition of fast transients, or sharp edges in image analysis, than it is possible to obtain with the DFT. Their property of expansion/contraction of a single mother wavelet can also overcome a major limitation of the DFT, that is, to allow good frequency resolution at both low and high frequencies. For applications of the WT and commercially available software, see Refs. [34,35].

Defining Terms

Analog-to-digital conversion: The process of converting a continuous signal to a discrete-time sequence of values usually sampled at uniform time intervals.

Autocorrelation function (ACF): A measure of longitudinal variability of a signal which can express the statistical dependence of serial samples.

Correlogram: Numerical calculation and graphical representation of the ACF or CCF.

Cross-correlation function (CCF): A measure of similarity between signals in the time domain which also allows the identification of time delays between transients.

Cross spectrum: The complex product of the power spectra of two different signals.

Decimation-in-time: The process of breaking down a time series into subsequences to allow more efficient implementations of the FFT.

Discrete Fourier transform (DFT): The usual method to obtain the Fourier series of a discrete-time signal.

Fast Fourier transform (FFT): Algorithm for the efficient computation of the DFT.

Periodogram: A family of methods to estimate the power spectrum using the DFT.

Power spectrum: The distribution of signal power as a function of frequency.

Signal: Continuous or discrete representation of a variable or measurement as a function of time or other dimension.

Stationarity: Property of signals which have statistical moments invariant with time.

Twiddle factors: Exponential term in the DFT whose periodicity allows repeated use and hence considerable savings of computation time in the FFT.

Wraparound: Overflow of phase spectral estimations above $|\pi|$ due to the uncertainty of the $\tan^{-1}$ function.

Zero padding: Extension of a signal with zeros, constant values, or other extrapolating functions.

University of South Australia

87.1 Introduction

For a variety of reasons, the signal that comes from the output of a sensor will usually need to be processed, as has been explained elsewhere. This may be needed for a single sensor alone, as found in the conversion from an electronic resistance temperature sensor into the equivalent digital display number.

Alternatively and increasingly so, as is now discussed, the outputs from several sensors need to be combined into a single signal to form a mapping of those sources from "many to one." An example of this would be when a set of sensors measuring many different variables is used to determine if a machine tool is correctly making a component.

There are now many ways that can be used to combine signals, each having its own features that make it the best to use in a given circumstance.

Signal-processing methods range from the well-proven and mostly used method using processing based on mathematical relationships that are very precise—these are explained elsewhere. These are generally executed using digital computation and are often referred to as digital signal-processing (DSP) methods.

Alternatively, it has now been shown conclusively that less quantitative methods can also be used to great effect despite their lack of complete formal mathematical formulation. These are here called the applied intelligence (AI) methods, a convention developed to distinguish man-made systems from the very broad, and oversold, use of the term *artificial intelligence* (AI).

Many seemingly different methods exist in the latter group but, as will be shown here, they are all part of a continuum of ways that range from use of subjective to exactly objective procedures. These are not well explained as a group because they are presented in the literature as different methods used in isolation of each other. This account shows how they all tie together, thus makes it easier to decide which is appropriate in a given application. They are particularly useful for handling highly nonlinear situations where algorithms cannot be realized.

While we appear to prefer the total objectivity of a mathematically formulated method of signal processing, it is now well proven that the AI methods often are better choices to use in terms of better speed of performance and often lower cost of processing. Often they are the only solution since the algorithmic approach cannot be deployed because of the lack of a suitable mathematical formulation or powerful enough processor to run the algorithm.

Signal processing in the modern instrument, therefore, will often make use of many different methods. This account is an introduction to the characteristics of the various forms and is written to assist selection. Space limitations prevent presentation of each kind in detail.

87.2 Overview of Algorithmic Methods

Traditionally the most popular method used to develop mapping models is that of mathematical modeling. The mathematical model is usually what is sought, as it provides the highest level of understanding about the subject and the most precise representation of the behavior. The major disadvantage of mathematical models is that they can quickly become so complex that implementation of these models in measurement systems is often impractical.

In this class, the single, or set of multiple, input signal(s) to the data processor is converted to the output form using tightly formulated mathematical description. This relationship is called the algorithm. Strict relationships hold; the relationship is said to be *formal*, meaning that for any given input the output will always be the same. The algorithm supports only one interpretation.

This method of signal processing is the most highly developed method and is certainly one to aim for because it is devoid of ambiguity. All will agree on how it will respond. It carries a comforting level of understanding and, thus, acceptance.

Algorithmic methods can be very accurate, traceable, and can be calibrated with relative ease and agreement. They are the basis of many instrumentation systems. The origin of their use in instrumentation goes back to the early days of computing using, first, mechanical computational machines (late 1800s to around 1930) and then analog electric devices (early 1900s to 1960s), all of which were mostly replaced by the use of digital computers commencing around 1950. All of these algorithmic methods of processing can be simplistically regarded as embodiments of a mathematical equation inside a suitable technological machine.

As the demanded complexity and performance requirements grew over time, so did the demands on the detail of the algorithm and the means to model it inside a computational machine. Mathematical description eventually reaches limits of definition as the models push the boundaries of mathematical methods and human development. Too often, this arises before adequate detail is able to be built into the model. The algorithm is then an inadequate model of the need.

As the algorithm increases in complexity, the processing power needed must be increased to maintain both fidelity and speed of processing.

Despite great advances being made in algorithm development and in computer power, the algorithmic methodology eventually encountered mathematical and technological barriers in many fields. The method is seen to not always be the best to use because of lack of an adequate algorithm or the high cost of computing.

In instrumentation, another factor also arises. Fast, detailed processing brings with it the need for increasing electrical bandwidth requirements in signal transmission. This increases implementation costs and also eventually reaches technological constraints.

87.3 Overview of Applied Intelligence Methods

Fortunately, the solutions that may overcome these limiting constraints in many circumstances were developing in other fields under the general name of AI (now called applied intelligence in engineering), as new forms of mathematics and in other fields, such as decision theory.

Principally, a key limitation of the algorithmic method is that its unforgiving level of formalism carries with it a depth of processing exactitude that is often not warranted.

Other methods have emerged that allow vaguely subjective, as opposed to tightly objective, processing to be applied to good effect.

These AI methods have gradually gained acceptance to the degree that many are now routinely used and are supported by dedicated applications software and electronic integrated circuitry.

At first, these many alternatives were seen to be isolated methods. Gradually, the literature has shown trends to merge them in pairs. Their use in a more widely mixed form is still limited. This account seeks to give a comprehensive appreciation of the commonly met AI processing methods by placing them into relative perspective.

It is interesting to contemplate that natural world computing in animals does not appear to make much use of algorithmic methods, but does make extensive use of the methods presented here in the AI class.

The paradigm invoked here is that experience has shown that informal methods based on knowledge-based systems (KBS) can produce mappings of many inputs to one by use of less than completely formal description.

The AI methods can yield surprisingly efficient solutions to previously unsolved needs. They often can outperform algorithmic methods or carry out a similar task with far less computing power. They are all associated with multiple input processing and can be applied to forming decisions from data supplied by sensors. Each situation has to be judged on the balance between use of computing effort and effective processing.

On the downside, they lack formality and thus may be very hard to calibrate and authenticate. They, not having adequate scientific foundation and a solid formal base of operation, are not easily accepted as "sound." They are often hard to comprehend by a second party, for their description is not always adequately documented or done to any agreed convention. As their principles vary widely, they must be well understood before application is developed.

For all of these negative factors, they often are able to provide "more performance for less cost" and thus will be increasingly adopted.

Their rising level of use should not suggest the algorithmic methods will become obsolete, but more that the instrument designer now has a much larger set of processing tools available.

87.4 Mapping, in General

The high-level purpose of most signal processing is to yield knowledge of a situation so that decisions can be made.

For example, consider a health-monitoring system installed on an aircraft engine. A set of sensors of different measurand types and locations is installed at various critical points on the engine—temperatures, pressures, flow rates, metal content of the lubricating oil, and more. The data from these are collected and transmitted to a central processor using a common digital bus. The many inputs then need to be combined in some way to decide such conditions as emergency states, when to change the oil, and engine efficiency. This combination is a "mapping of many to a few."

These are not always simple mappings, for there is no adequate algorithm available to give a mathematical description for such things as degradation of oil condition. However, human intuition can be used quite effectively to obtain answers—the human mind is very capable of carrying out such mapping functions. This form of natural processing makes use of what are technically called "heuristics"—but more commonly known as "rules of thumb."

Consider the question, "How could we decide, using an automated measurement system, when loaves being made in a bakery are satisfactory to sell?" As the way to decide, this almost all people asked would suggest that the weight, size, crustiness, appearance, and softness inside would be the parameters that must all be satisfactory (that is, lie within a small range of values for each) to be declared suitable. Weight and size are easily measured; the others are not for they are really heuristics, as is the choice of the set of parameters.

The thought process implemented here is that the designer starts with a desire to know something about a situation. Consider how we could automatically monitor the "risk of working in a hazardous place" in order to give an alarm at set levels. In this kind of situation, a study of the problem will lead to identification of key parameters. These parameters can each be assigned safety functions that express how each parameter varies with system changes. With this framework, it is then possible to set up a signal-processing system that continuously calculates the risk level. This form of solution is based on ideas embodied in the wide field of decision-making theory.

The heart of application of AI methods of signal processing in instrumentation lies with appreciation of decision theory methods.

A range of multivariable mappings methods using AI ideas have emerged. Those well established in instrumentation are

- Representational measurement theory and ways sets are mapped into other sets (whose usefulness is still emerging)
- Rule and frame representation of heuristic knowledge and ways they are used to form expert systems (ESs) and other KBSs
- Binary Boolean trees as crisp logical mappings, which is the foundation of the fuzzy logic method based on fuzzy set theory

Another class of AI methodology that does not fit the same sequence, yet includes powerful methods, is those that assist optimization of the mapping setup. There are two main methods in use:

1. Genetic algorithm (GA) and its use to optimize fuzzy logic and other multisensor setups
2. Artificial neural net, a mapping method that learns by itself, from experience, how to achieve an optimal mapping in a given situation that it has been taught to work in

87.5 Basics of Decision Theory

87.5.1 Rules about a Decision-Making Process

Before entering into the detail of the AI signal-processing methods, it is necessary to develop a foundation about the ways in which decisions can be made by computers using sensed information. It is not that well appreciated, but setting up a mapping-type signal-processing situation is actually implementing a decision-making information system. General appreciation of decision making can be found in the introductory work of Kaufmann [1].

Unlike the human brain decision maker which carries out smart thinking with ease to build a machine counterpart, an engineered object needs effective externalization of the process involved. This begins by developing appreciation of the basic rules that always apply about a decision-making situation. These have been summarized by Baker et al. [2] and condense to

1. There must be a clearly expressed criterion for making a judgment of the options available, which must be such that others will understand how the judgment was made.
2. All decisions will involve choosing alternative strategies to arrive at the best one to use. This will involve assigning score numbers to the selected parameters and deciding how to process the set of numbers.
3. A decision is made by a choice of competing alternatives in the face of given restraints. Decisions can only rarely be made in the general sense but will be made for a given set of circumstances. The complexity of a problem rises rapidly as the number of parameters rises.

4. The process used attempts to achieve some payoff as a value added or lost. It aims to rank the various mapping alternatives to advise the apparently best to use. Note that once a decision-making mapping is built, the information about alternatives is no longer available as it will only usually embed one set of parameters as a single process.
5. A decision matrix carrying the competing parameters results. A method of combining the matrix constituents is needed, and, again, there is no singularly definitive, absolutely correct way to process the matrix.

In setting up a signal-processing mapping, these rules will need to be addressed. They will be embedded in the software of the hardware processor as its operational strategy. Considerable creativity is needed by the designer of the processor, for much of the setup of decision-making methods requires subjective human interpretation in several steps of the process. Decision making is really only needed when there is no exact and obvious answer. The devices built to mimic the human process will never be perfect. There will be much debates about which are the best methods and parameters to use. Engineers must live with this situation and make machines that will make good decisions, that are as close to perfect as possible.

87.5.2 Extracting Parameters

The first step in setting up a decision mapping is to understand the need. That means researching it by observation and from literature on the topic. This sets up the specific knowledge base to allow one to progress to the next step.

Then comes the need to define the key parameters of the situation. There is no organized way to develop these. They arise from inventive and innovative thought processes that seem to be based on prior learning.

To streamline this intuitive step, it is useful to apply some ordered processes that assist in externalizing appropriate parameters. Three methods are now briefly described.

87.5.2.1 Slip Writing

A group of people familiar with the problem area are read a brief statement of the problem by a person independent from the problem. An example could be "What do you think are the main parameters that a person uses to decide if a loaf of bread is fresh?"

Without much time to reflect, the group is then asked to write down the key parameters that come to mind immediately as they work without talking about the problem as a group. They write down each parameter on a separate piece of paper, doing this as fast as ideas come to them. This only happens for a few minutes. The slips of paper are then collected and classified. The whole process takes around 10 min and is known as slip writing.

It will usually be found that there is common agreement about the majority of parameters with some quite unexpected ones also arising.

Slip writing is a good way to find consensus. It probes the mind well and can bring out appreciation of factors that open discussion might easily inhibit. It is important in this method to decouple the thoughts of each person during the process; otherwise, the real parameters may not be externalized because some people may exert influence on others of the group.

87.5.3 Brainstorming and Think Tanks

If participants are shown what others are thinking and are encouraged to debate issues, it is possible to gain consensus and also allow group participants the opportunity to help each other be innovative at the same time. This method works best when the participants are prepared to go into open discussion. Several similar processes are those known as brainstorming or carrying out a think-tank session.

Here a problem in need of solution is written down as a well-prepared statement by the session organizer. A team of experts, each covering the expected aspects of the problem area, are selected and sent the statement along with any supporting exhibits. Each person considers, over a few days, how he or she might contribute a solution.

The group is then assembled. The problem is first reviewed by the session leader and each person is then asked for ideas. As ideas are externalized they are recorded in very brief form—large sheets of butcher paper are suitable. These sheets must be readable by all in the group and be prepared instantly to keep up with the thoughts of the group.

It will be found that innovative ideas will arise as candidate solutions are put up and seen by others in the group. This method encourages group-driven inventiveness.

Gradually the group will settle on a few solutions that it feels have a good chance of succeeding. This list is then ordered in priority of likelihood of success. The session leader then writes up the outcomes, ready for further investigation.

87.5.4 Knowledge Trees

The final method to be described here for developing parameters of a decision, called knowledge trees, has the merit of ordering the relative place of parameters as well as encouraging inventiveness of solutions. It also provides a mapping structure. This procedure is based on age-old realization that we think problems through by breaking them down into ever smaller subproblems until we feel able to solve them. Overall solution is then very much a matter (but not entirely so in practice) of implementing the solution of all subproblems and combining them by a process called integration.

The need is first written down. For example, "How would we measure the quality of loaves of bread?" or in a shorter form "Is the loaf OK?"

This forms the top-level parameter of the tree given as Figure 87.1. Consideration of the situation at hand then leads to realization of the collection of parameters relevant to get this answer. These might be weight, size, crustiness, appearance, and softness. They may have been externalized by a group process, such as slip writing, or created by the individual.

Each branch on the tree is then visited to see how that parameter might be measured. Only one of these can be measured as it stands—it is reasonable to assume that weight can be measured with scales.

Size is not so easy to measure as it is expressed for there is inadequate definition. More thought will yield another level to the tree—length, width, and height—for this parameter. As linear measurements, these can also be measured with ease.

When building the branching downward, a thought process has decided how the parameters map upward and downward. Size dictates the mapping of three parameters into one, so there must also be a defined mapping model for that mapping.

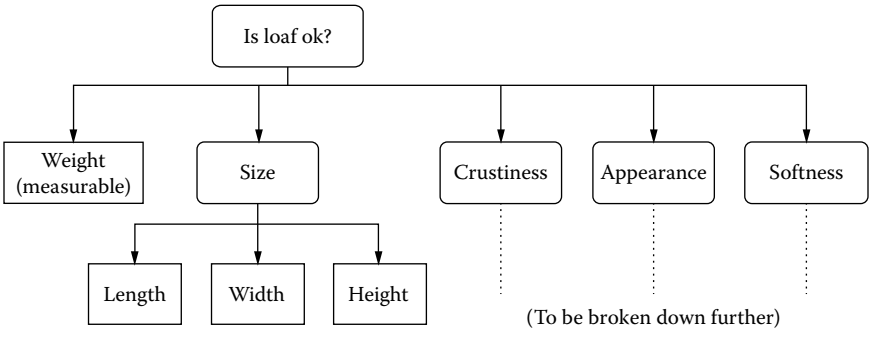

FIGURE 87.1 Knowledge trees allow facts and their relationships to be captured in pictorial form.

Note also that to branch downward, the thought process used has actually been driven by some heuristics. Each branching has been driven by rules of some kind—but more on that in the rule-based decision-making method covered later.

It is also easy to see why the other parameters could be measured with automated instrumentation. Softness could be assessed in terms of the squeeze factor, which is actually measurable as the compliance of the loaf at the center point of a side of the loaf. Appearance would map down the tree into color, texture, and graininess of the image. It is left to the reader to think up and draw a complete tree.

When all branch ends have been reticulated down to the point where they can be measured, the system mapping can be implemented with a human-made sensing system. The parameters are externalized and the mapping process is largely decided.

Use of tree-based thinking is a simple, yet powerful, way of keeping track of decision making for a complex situation. The recorded form also allows others to see the thought process used.

87.5.5 Two Examples of Decision Assistance Methods

87.5.5.1 Triangle of Pairs

Having now seen how to externalize parameters and how they might be interrelated using trees, we can move on to investigate how to set up a suitable decision-making process.

Knowing the parameters is not enough yet to design a multisensor mapping processor. The relative importance of the parameters is also a key factor. Furthermore, the tree is not the only way to combine sensor signals.

Two, of many, examples of decision assistance methods are now outlined to illustrate these points.

The first, the triangle of pairs (TOP) method, allows parameters to be ranked against others on the binary-only basis of which is preferred of each two compared. In the bread example, compare some of the parameters for their relative importance. Crustiness is preferred to weight. Softness is preferred to size and so on until all pairs have been considered. If all combinations are carried through and recorded as a matrix, a TOP results, as in Table 87.1.

Having formed a matrix of competing parameters, the next step is to decide how the matrix can be processed. This is where much debate can occur. For the TOP method, however, the binary nature of the choices means a simple count of first preferences gives the ordered preference of parameters—at least as that person assessed it!

TABLE 87.1 Triangle of Pair Assessment Is a Simple Way to Decide Which Choice to Make

Size	Crustiness	Appearance	Softness	Parameters
$\frac{\Rightarrow Si}{W}$	$\frac{C}{\Rightarrow W}$	$\frac{A}{\Rightarrow W}$	$\frac{\Rightarrow So}{W}$	Weight
	$\frac{\Rightarrow C}{Si}$	$\frac{A}{\Rightarrow Si}$	$\frac{\Rightarrow So}{Si}$	Size
		$\frac{\Rightarrow A}{C}$	$\frac{So}{\Rightarrow C}$	Crustiness
			$\frac{\Rightarrow So}{A}$	Appearance
Scores (number of times preferred)				
Si	*C*	*A*	*So*	*W*
2	2	1	3	2

Notes: This table gives the workings for the grading of bread as in the example of Figure 87.1. Si, size; Cr, crustiness; A, appearance; So, softness; W, weight.

We will see later how the idea is extended by giving parameters a varying degree of "preference" rather than the simple binary choice allowed here.

87.5.6 Utility Analysis

A more fully developed method for making decisions in complex and subjective situations is one called utility analysis (UA). This is a process that can be applied to find the usefulness of a design, piece of equipment, or any similar situation where one can externalize and prioritize a set of measurable parameters. Although mostly applied to decision making as a paper study, the process is amenable to the creation of a multisensor mapping processor.

Appreciation of this process is easily obtained by working through an example. Consider the need to set up a method for grading the quality of bread made in an automated bakery.

The first step is to decide the parameters that will affect the choice finally made. We select weight, size, and appearance as the key parameters to illustrate the method. (More parameters might be needed in a real situation.) We also decide that these are important according to the relative weighting ratios of 1.0:0.2:0.8.

Next utility curves must be set up, one for each parameter. These show how the usefulness of the parameter changes as the parameter ranges.

The simplest way to obtain these graphs is to use one's own intuition, but a better way is to make use of some form of consensus-forming procedure as discussed earlier. Figure 87.2 shows what these three functions might look like. As a guide to their construction, if the weight of the loaf is too low, it fails to comply with legal requirements and thus has zero utility as a product below the allowed uncertainty of weight. The size factor depends on the type of bread. Here it is assumed it is for sandwich making, in which case the size can be too small for sliced meats or too big for a toaster. Appearance can only be measured by mapping downward to a set of measurands; it is convenient to plot the function in more vaguely defined terms in this method.

Note that the weighting ratios have already been incorporated into the utility charts by setting their best values at the correct percentage.

It is necessary to reinforce the fact that the set of graphs is needed for the parameters, not for each case to be considered. With the charts setup, the selection process can begin.

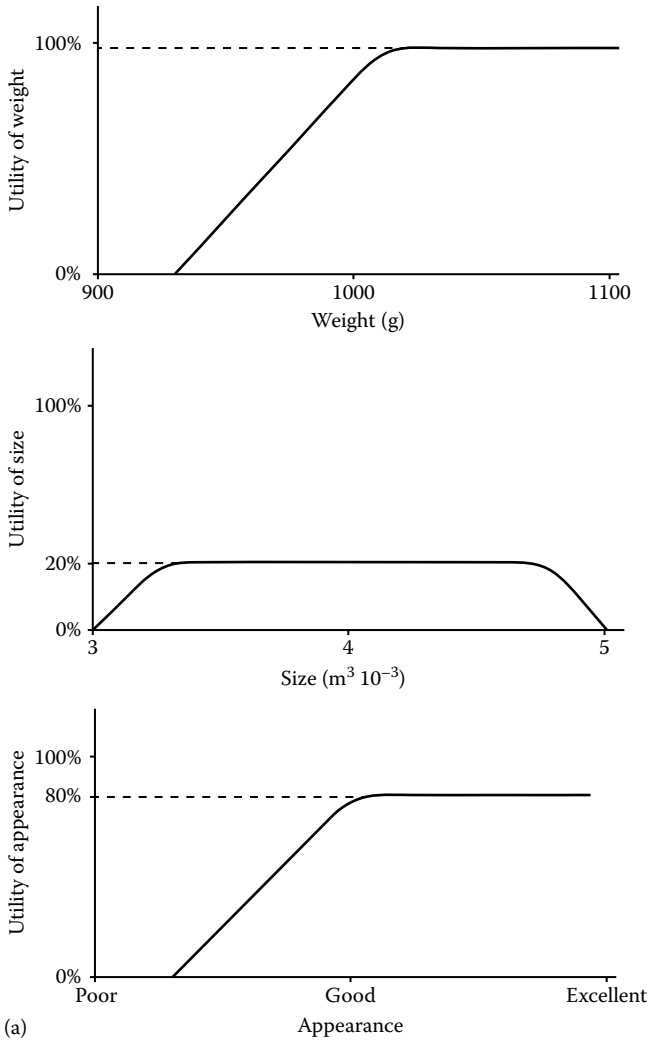
A matrix is now created, as also shown in Figure 87.2. The actual measured weight value (960 g) for loaf 1 (under automatic inspection) is compared with the graph of weight to yield a utility of 0.4. The size is done likewise, using the size graph to get 0.2, and the appearance sensor set tells us it is between poor and good to give us 0.4. Each loaf is subjected to the same process. The other two loaves have different sets of scores.

The combined usefulness of a given loaf is now to be decided by processing the set of numbers for that loaf. Here is where some difficulty arises, because there are many ways to combine the three scores for each loaf. One way often used is simply to sum the values, as is done in the example. Note that this can be satisfactory unless a zero or other unacceptable value arises, in which case more mapping processing is needed. Assume that an acceptable combined score has been determined to be 1.8 or higher (with the best, due to the weightings, 2.0).

Having carried out the processing of the matrix, we find that the first loaf is not acceptable and the other two are equally acceptable.

What we have done is to form an automatic measuring system that can make assisted and graded decisions. There is certainly a degree of human subjectivity inherent in the method, but by recording what is taking place the task can be automated and it can also be evaluated in the light of experience, correcting choices of parameters and weightings.

Other decision-making methods exist: they use elements of the earlier concepts in a variety of assemblages.



(a)

Object under Assessment \ Parameter	Weight (g)	Size (m^3 10^{-3})	Appearance (grade)	Score(Σ)
Loaf 1	(960)	(4)	(poor/good)	1.0
	0.4	0.2	0.4	
Loaf 2	(1000)	(3.5)	(good/excellent)	2.0
	1.0	0.2	0.8	
Loaf 3	(1100)	(4.9)	(excellent)	1.9
	1.0	0.1	0.8	
⋮	⋮	⋮	⋮	⋮
Loaf "*n*"	…	…	…	…

(b)

FIGURE 87.2 Utility analysis is a more-detailed way to automate loaf inspection with a set of sensors: (a) three possibilities of the utility functions for the example in Figure 87.1, and (b) scoring matrix for loaves passing the inspection point.

The earlier has been a very rapid introduction to decision-making methods. These are rarely taught as the foundation of the now popularized AI signal-processing methods given next. They are, however, the conceptual basis of the AI processes.

87.6 Principal AI Methods

87.6.1 Measurement Theory

Sensors observe a finite number of variables associated with real-world events. Measurement systems are required to convert the information from these sensors into knowledge. This process often involves what is known as mapping.

Depending on the loss or preservation of information, the mapping process can be classified as either transformation or abstraction.

If a rule exists that assigns every element of x in the set X (written $x \in X$) to precisely one element $y \in Y$, we say that a function exists that maps the set X to the set Y, and this is represented as Figure 87.3 and symbolically by

$$y = f(x)(x \in X)$$

A transformation defines a one-to-one mapping on the set of all elements of x into y, in which for all $x \in X$ there exists a unique value in Y; therefore, the inverse transformation is guaranteed, i.e., $x = f^{-1}(y)$.

An abstraction differs from a transformation in that it can map a number of elements $x_i \in X$ into the same y, or a many-to-one mapping; hence, no inverse operator can exist such that the inverse image of X can be uniquely retrieved from Y. Therefore, abstraction is usually characterized by a loss of information.

It is possible to define the set theoretical relationship as a formal mathematical model and then embed that in the signal processor. Although this is a clearly useful method of formalizing mappings, this approach is not commonly used at the time of writing but can be expected to find more favor in the future.

87.6.2 Rule- and Frame-Based Systems

In early stages of problem solving, we seem naturally to look to rules of thumb to get the solution started. Even the algorithmic methods start with this form of thinking, for one has to decide what the elements of the decision are and how they might be assembled into a strategy for implementation in the signal processor. As the rules are externalized, one's thought patterns also usually build knowledge trees that show the relationship between the rules.

Consideration of the knowledge supporting the structure of a tree will reveal that the decision needed about which way to branch as one moves through a tree is actually the implementation of a rule that has relevance at that junction. Rules link parameters together.

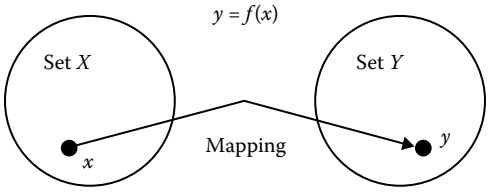


FIGURE 87.3 Pictorial representation of the set theoretical mapping process.

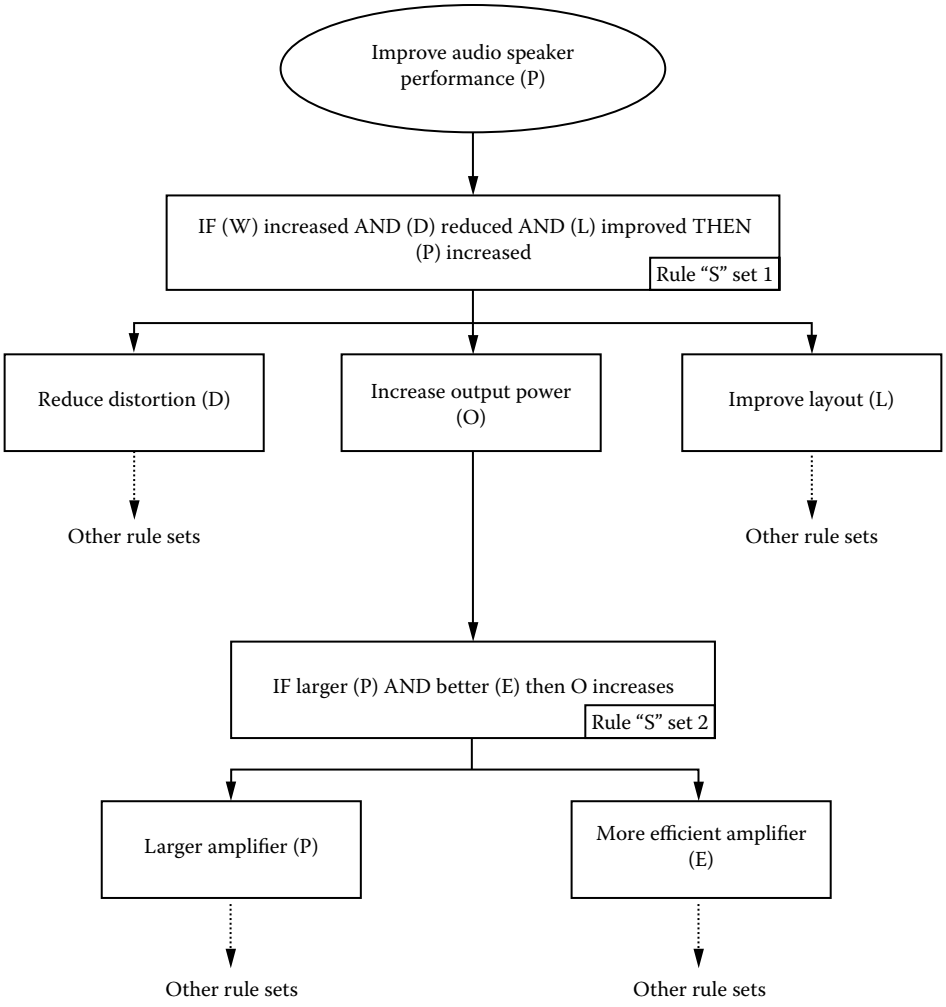

FIGURE 87.4 Part of a design knowledge tree for improving the performance of an audio speaker system.

Figure 87.4 is a tree giving some of the design options for improving the performance of an audio speaker system. This tree has been built by applying a designer's knowledge of speaker system design. The heuristic rule set for the top branch is stated as

IF	Speaker output (W) increases
AND	Distortion (D) is reduced
AND	Positioning (L) improved
THEN	Audio output (O) is improved

No part of the rule set could be first realized using formal mathematical or algorithmic thinking. Intuition, leap, common sense, and other terms that describe the human intelligence process must be applied to commence a solution.

At some stage a rule may become describable by an algorithm, when that occurs, a formal mathematical expression can be used to embed relationships. However, this is often not the case and so methods have been developed in computers to process heuristics.

The full set of AI techniques were originally all rolled into what became known as KBSs but this term is so overused that it has lost specific meaning.

Among the first AI processing methods were special computing ways to process the logic of a set of rules. These became known as ESs. In the example earlier, the rule tree is very sparse; a practical system for decision making is likely to have from 100 to several thousand rules.

The rules are considered by an inference engine (a software program) that is able to carry out Boolean logical operations of AND, OR, etc., to yield the outcome appropriate to the set of rules relevant to the problem at hand.

Trees can be traversed from the top down (downward chaining) or from the bottom up (upward chaining) and modern ES software applications carry out these operations with great sophistication.

KBS methods generally suffer from the feature that they seem to give answers all too easily, for they use only a few of the many rules available to come to a solution in a given situation. To help users feel more confident in their application, features are often offered that include plotting of the chaining used to get the solution or stating the rule set used.

Rule-based software applications are sold as empty shells. The user fills the shells with the rule set to make the application specific. These applications are now commonly used. They are relatively easy to use without the need for a competent computer programmer.

Rules are a primitive way to express knowledge. A better form of representation is the frame. This has the ability to hold more knowledge than a single rule and is a small database about a limited area of the system of interest. Frames are like objects in object-oriented programming. Advanced ES shells operate with frames.

ES shells are now very capable entities for decision making. They are a significant tool in the instrument signal processor's toolbox. Space restricts more explanation but enough has been stated here to allow further development of AI methods.

Some basic characteristics about rule- and frame-based processing are as follows (these apply variously):

- The software program is often self-explanatory as the rules can be read as (almost) normal language.
- They need considerable computer power as the rule number increases.
- They are relatively slow to yield a solution but are best used for cases where slow outcomes are applicable.
- They need special software.
- They are not that well known, so their application may be slow to find favor.

If the problem becomes complex, EAs soon run out of usefulness. The computer search becomes too slow because the number of rules needed rapidly rises with problem complexity. The approach used today for large problem-solving systems is to build an ES for each facet of the problem. These small-problem AI units are called agents. A set of agents is then combined using a conceptual software-based blackboard that calls on the agents to investigate a problem put to the system.

The chaining operation basically only carries out simple Boolean algebra operations using system parameters represented by a description called a rule. The system has no understanding of the wording of the rule. Thus, it is only processing as through the tree branching is either one way or the other. In its simplest form, it contains no concept of making that branching decision with a graded concept of which way to go.

Real life is full of unclear logical operations. The outcome of a decision will be clearly this way or that, but just where the change arises is problematic. The changeover point is unclear because the variables of the rule are fuzzy. It is desirable to process rules with regard of their likelihood of relevance depending on the state and selection of other rules. As is explained in the following section, the fuzzy logic method of carrying out a mapping is another way that allows the rule to have more variability than the two-state exactness of binary logic.

87.6.3 Fuzzy Logic

This explanation is not intended to be a rigorous mathematical examination of fuzzy sets and fuzzy logic but rather explain, through example, the application of fuzzy techniques in measurement systems, specifically in respect to mapping models. For more detail, see Mauris et al. [3].

The simple example used here is a measurement system (Figure 87.5) that maps two input sensors (temperature and humidity) into one output value (comfort index). Clearly, there is no formally accepted definition of comfort index as it is a subjective assessment. One of the advantages of fuzzy sets is that they are usually intended to model people's cognitive states.

In the mid-1960s, Professor Lofti Zadeh recognized the deficiencies of Boolean logic, in that its TRUE/FALSE nature did not deal well with the shades of gray that exist in real-life situations.

Boolean logic uses classical set theory where an element is either viewed as entirely true or completely false $A = \{0, 1\}$. These are often referred to as a crisp sets (Figure 87.6). In a crisp set the transition between sets is instantaneous, i.e., 36.9 °C is considered warm whereas 37.1 °C is considered hot. Hence, small changes in the input values can result in significant changes in the model output. Clearly, the real world is not like this.

Fuzzy logic uses a multivalued set where degrees of membership are represented by a number between 0 and 1, $A = [0, 1]$ μ_A:$U \rightarrow [0, 1]$, where μ_A is the membership function. With fuzzy logic, the transition between sets is gradual and small changes in input values result in a more graceful change in the model output (Figure 87.7).

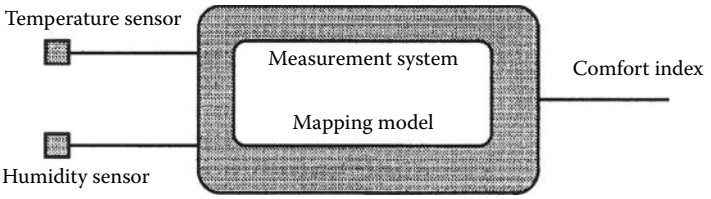

FIGURE 87.5 A simple comfort index measurement system uses temperature and humidity variables.

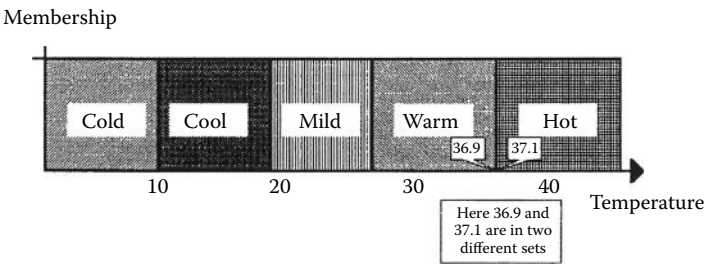

FIGURE 87.6 Conventional crisp set for the measurement system of Figure 87.5.

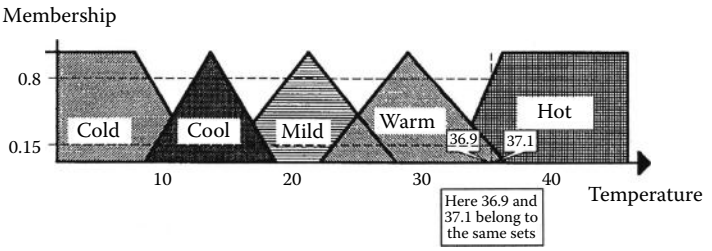

FIGURE 87.7 Fuzzy set representation temperature regimes in the comfort controller example.

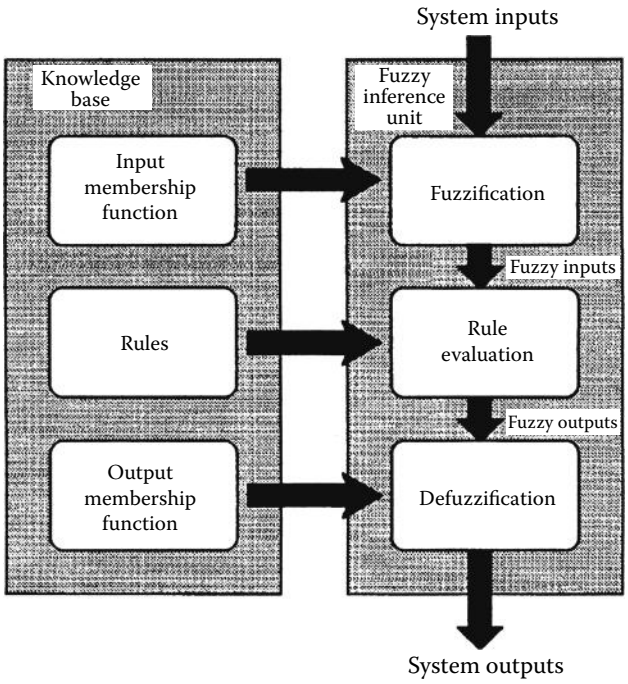

FIGURE 87.8 A fuzzy inference system combines rules in a way that allows them to be fuzzy in nature, that is, not crisp.

87.6.4 Fuzzy Expert Systems

A fuzzy ES (Figure 87.8) combines fuzzy membership functions and rules, in place of the often all-too-crisp Boolean logic, to reason about data. The fuzzy ES is usually composed of three processing sections:

Step 1: Fuzzification
Step 2: Rule evaluation
Step 3: Defuzzification

87.6.4.1 Step 1: Fuzzification

In fuzzification, crisp inputs from input sensors are converted into fuzzy inputs using the membership functions in the knowledge base. A fuzzy input value is generated for each linguistic label of each input. For example, in Figure 87.7, for an input temperature of 37°C the fuzzy input is COLD (0.0), COOL (0.0), MILD (0.0), WARM (0.15), HOT (0.80). A similar set of fuzzy inputs are generated for the humidity sensor (Figure 87.9).

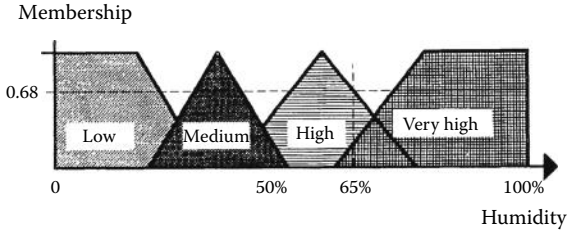

FIGURE 87.9 Humidity membership function for the controller example.

TABLE 87.2 Fuzzy Associative Matrix Links Inputs and Outputs

Humidity/ Temperature	Cold	Cool	Mild	Warm	Hot
Low	Uncomfortable	Uncomfortable	Uncomfortable	Uncomfortable	Uncomfortable
Medium	Uncomfortable	Acceptable	Comfortable	Acceptable	Uncomfortable
High	Uncomfortable	Acceptable	Acceptable	Acceptable	Uncomfortable
Very high	Uncomfortable	Uncomfortable	Uncomfortable	Uncomfortable	Uncomfortable

87.6.4.2 Step 2: Rule Evaluation

Rules provide a link between fuzzy inputs and fuzzy outputs. Rules are usually expressed in the form of IF … AND/OR … THEN … statements.

For example,

"IF" the TEMPERATURE is HOT "AND" the HUMIDITY is HIGH "THEN" it is UNCOMFORTABLE.

"IF" the TEMPERATURE is MILD "AND" the HUMIDITY is MEDIUM "THEN" it is COMFORTABLE.

"IF" the TEMPERATURE is WARM "AND" the HUMIDITY is LOW "THEN" it is UNCOMFORTABLE.

Rules can also be expressed in the form of a table or matrix, called the fuzzy associative matrix. This matrix (Table 87.2) provides a complete description of the system performance for all combinations of inputs.

The function of the rule evaluation step is to evaluate the relative strengths or truth of each of the rules in order to determine which rules dominate. In this example, the rules contain AND relationships and therefore the overall rule strength must be the minimum (MIN) value of the two strengths of the input values.

For example, at a temperature of 37 °C and a humidity of 65% the rule strengths of the three example rules are

"IF" the TEMPERATURE is HOT (0.8) "AND" HUMIDITY is HIGH (0.68) "THEN" it is UNCOMFORTABLE (Rule Strength = MIN (0.8,0.68) = 0.68).

"IF" the TEMPERATURE is MILD (0.0) "AND" the HUMIDITY is MEDIUM (0.0) "THEN" it is COMFORTABLE (Rule Strength = MIN (0.0,0.0) = 0.0).

"IF" the TEMPERATURE is WARM "AND" the HUMIDITY is LOW "THEN" it is UNCOMFORTABLE (Rule Strength = MIN (0.15,0.0) = 0.0).

All rules must be evaluated (in this case, all 20 in the matrix) to determine each rule strength. If two rule strengths exist for one fuzzy output label, then the maximum (MAX) rule strength is used because this represents the rule which is most true; that is, in the previous example the fuzzy output for UNCOMFORTABLE is the MAX(0.68,0.0) = 0.68.

87.6.4.3 Step 3: Defuzzification

Now that rule strengths exist for all the output fuzzy labels, a crisp output value can be determined from the fuzzy output values. The most common method used to defuzzify the fuzzy output value is the center of gravity (COG) method. The fuzzy rule strengths determined from rule evaluation are used to truncate the top of the output membership functions. Given this area curve, the COG or balance point can then be calculated. For example, in Figure 87.10, for fuzzy output values of

UNCOMFORTABLE = 0.68
ACCEPTABLE = 0.2
COMFORTABLE = 0

the COG or crisp "Comfort Index" evaluates to 25.

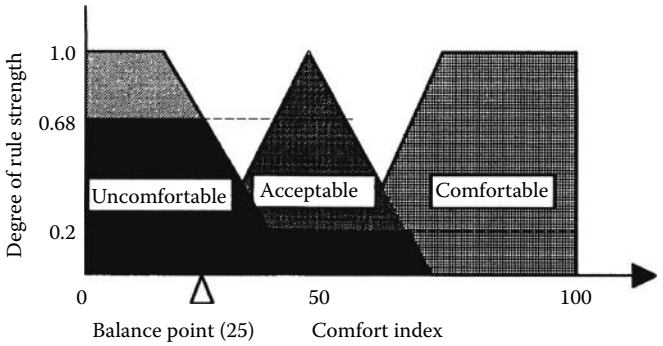

FIGURE 87.10 Output membership functions for controller. Each type of shaded area represents the three states of comfort.

Fuzzy logic signal processing is now a well-developed method. It is supported by copious teaching material including those on Internet and on CD ROMs provided by manufacturers of this form of special integrated circuit chip sets and setup software. Possibly, its best-known application has been in clothes washing machines where the wash parameters are set to suit the load. Although there are still limitations, this method can be considered to be a mature procedure.

87.6.5 Genetic Algorithms

The methods discussed thus far all have required the user to advise the system about the parameters to use. That is, they need to be taught efficient mappings.

In sharp contrast to these types of systems, there also exist other AI methods that possess the ability to learn, by themselves, what are the more optimal mapping configurations. Two main techniques are used—GAs and artificial neural networks (ANNs). These self-learning processes both work well in certain situations and are now commonly used in signal processing. On the face of it, both seem to possess magical properties because they defy logical thought processes and a clear understanding of how they actually operate.

We begin with an overview of GAs. These make use of the basic principles by which natural selection found in living things, that is, from genetics, is able to improve gradually the fitness of species. That the genetic principles found in nature can be used in human-made applications is accredited to pioneering work of John Holland in the mid-1970s. Today, it is large field in algorithm optimization research (see Tang et al. [4]). A very simplistic description now follows to give some insight.

The concept starts with the selection of a set of features (Figure 87.11) (these can take a wide range of forms and are not just measurement parameters) that represent the essential features of a system of interest. As examples, the DNA molecule carries the code of the characteristics of living beings and a computer string can carry a coded message that represents the features of the behavior of some human-devised system.

Various types of events (crossover, mutation, inversion are commonly encountered methods) can slightly alter the code of any particular string. When this happens, the new string then represents another closely similar, but different system having new properties. Consider, next, that a number of slightly different code strings have been formed.

When a change takes place in the code of a string, it is assessed against the other strings using rules for a predecided fitness test. If improvement has occurred in the overall properties, then it is adopted as one of the full set. If not better, then it is discarded. In this way the set of strings, and thus the total system capability, gradually improves toward an optimal state.

The operational aspects of such systems are beyond description here. Suffice to say that the technique is well established—but highly specialized—and is undergoing massive international research effort in hope of alleviating certain limitations.

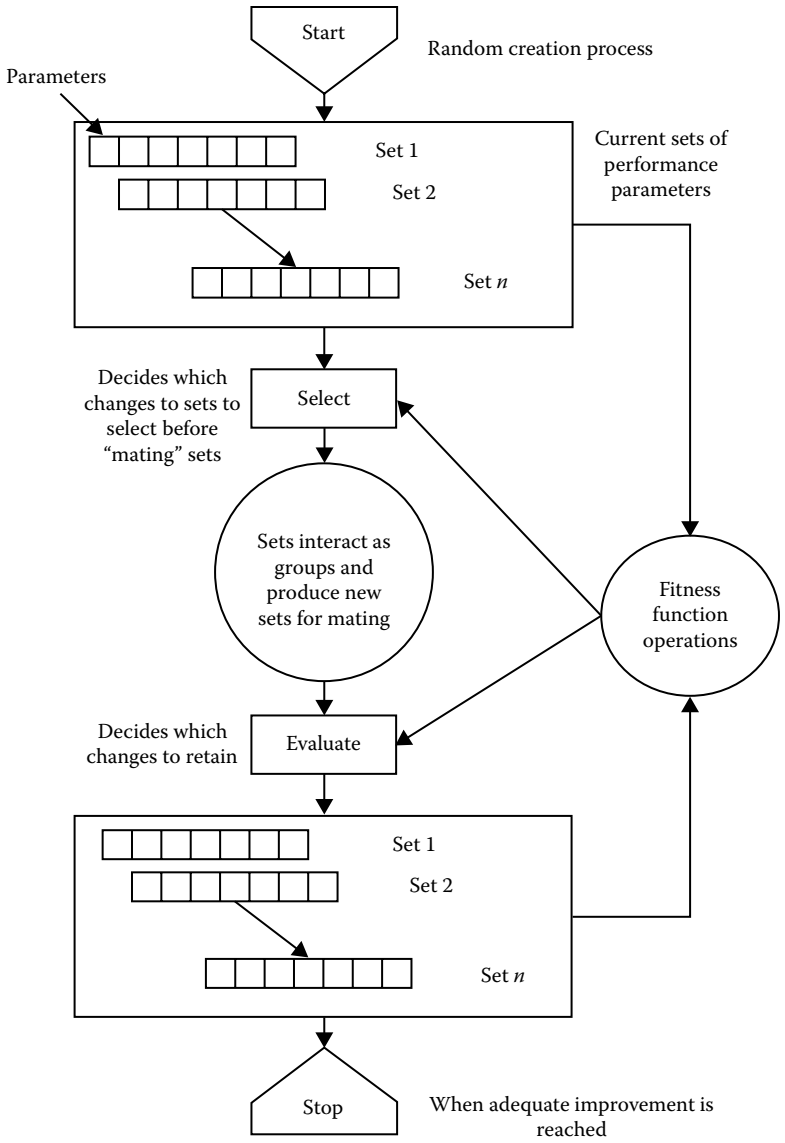

FIGURE 87.11 In the GA method, sets of code strings are first modified by some form of genetic operations. They are then intercompared using fitness functions to select a better code to use in the subsequent set of strings. This iterative process is continued until some event disrupts it.

The first limitation is that although it is generally agreed each adopted change for the better takes the overall system capability closer to the goal being sought, there is, as yet, no theory that can be applied to show the state of maximum optimization. GAs, therefore, always have doubt associated with their solutions as to how much more improvement might be possible.

The second limitation becomes obvious when the computational demands are considered in terms of the number of comparison operations needed to be run in the improvement process. This number can be truly huge, especially as the range of options rises with increase in string length. This kind of operation usually needs very large and fast computing power. In cases where there is plenty of time to determine an improvement, this is not a major limitation. An example of effective use would be finding how best to operate a wide range of functions in a complex system when the task is then fixed; this method

was used to set up more optimal use of power supplies in a space vehicle. In cases where the variables in a code string are fast changing, the method may not be applicable.

When running this form of computer program, it is essential to have a measure of the speed—the dynamic behavior—at which this highly iterative process is moving toward the optimization goal: the user can then decide if it is a viable method for obtaining improvement.

With this background, it is probably obvious why GAs are sometimes used to set up the membership functions of fuzzy logic systems. As explained earlier, the membership functions each are part of a set of individual functions that form the mapping for a multisensor system. The choice of the membership function is largely heuristic and thus may not be the best function to use. By setting up several sets of functions, it is then possible to apply GA computing methods iteratively to select a better set to use. Such systems have been used where the time of currency of a function set is longer than the time needed to improve the functions. Obviously, use of GAs increases system setup and operational complexity, but once implemented may yield worthwhile gains.

87.6.6 Artificial Neural Networks

The AI basket of potentially useful methods in signal processing is full of surprises. Attention is now directed to another method, which can learn, after an initial training period, how to better operate a given mapping process.

Neurocomputing or use of ANNs is another AI technique well suited to make a mapping processor in some circumstances. (These are sometimes called NNs but should not be used for human-devised systems as they can lead to confusion with life sciences research on living neural networks.) ANNs are particularly useful when mapping complex multidimensional information to a simpler representation. Because of their ability to deal with nonlinear relationships, they find application in areas where traditional statistical techniques are of limited use. Some application areas include pattern recognition and classification, categorization, function approximation, and control.

87.6.7 Biological Neuron

The ANN has been inspired by the biological structure of the brain, and it is an attempt to mimic processes within the biological nervous system. The neuron is an information-processing cell in the brain (Figure 87.12). It consists of

1. A body or *soma*
2. Input branches or *dendrites*
3. Output branch or *axon*

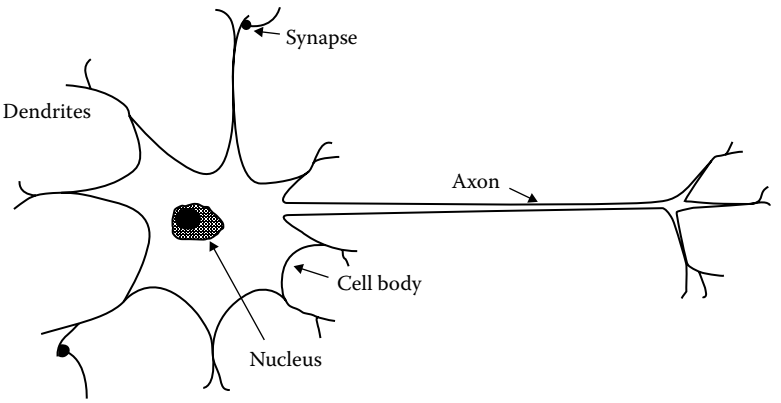

FIGURE 87.12 A biological neuron.

The neuron receives signals through its dendrites, and then transmits signals from its cell body along the axon. The neuron will generate an output (or fire) when the aggregation of the inputs reaches a threshold level. At the terminals of the axon are *synapses*. The synapse couples the signals from the axon of one neuron to the dendrites of another neuron. The strength with which these signals are transferred from the axon to the dendrite is controlled by the synapse and can be altered; hence, the synapses can learn from experience.

Desirable characteristics of neural systems include

- Massive parallelism
- Learning ability
- Ability to generalize
- Adaptability
- Fault tolerance

It is the attempt to construct machines that exhibit these characteristics that has led to the ANN methods of signal processing.

87.6.8 Artificial Neural Networks

In 1943, McCulloch and Pitts proposed the first model of an artificial neuron. This has formed the basis for the generally accepted form of synthetic neuron model or processing element (PE) (see Figure 87.13).

The output of the PE y is given by

$$y = g\left[\left(\sum\nolimits_i w_i \cdot x_i\right) - b\right]$$

where

x_i is the PE inputs with weights (synaptic strengths) w_i
b is the PE bias
g is the activation or transfer function

Many types of function have been proposed but the most popular is the sigmoid function, defined by

$$g(h) = \frac{1}{(1 + e^{(-\beta h)})}$$

where β is the slope parameter.

By themselves the PEs are very simple; however, when the individual elements are joined into large interconnected networks, complex relationships can be represented. Although a number of network architectures [5] exist, one of the most commonly discussed architectures found in the literature is the

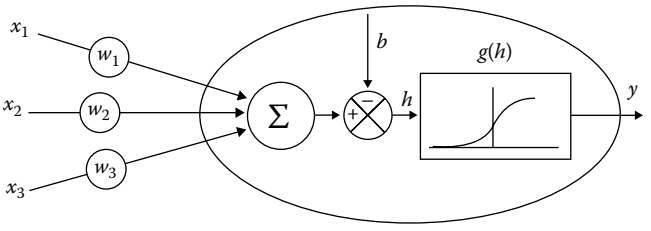

FIGURE 87.13 This neuron model is commonly used.

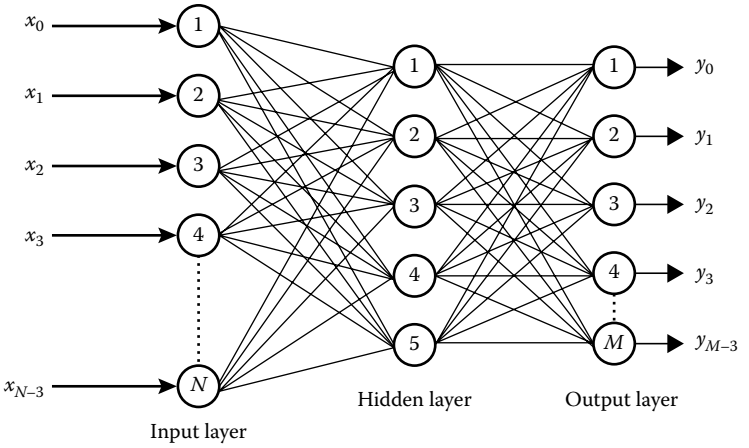

FIGURE 87.14 A typical three-layer neural network as is commonly used to create an optimal mapping from sensors to outputs.

feed-forward multilayered perceptron. Figure 87.14 provides a simple illustration of how a multilayered ANN maps a multidimensional input vector $x_0, \ldots, x_{N-1}$ in an input space to a vector $y_0, \ldots, y_{M-1}$ in an output space.

87.6.9 Learning

A fundamental characteristic of the ANN, once it has been set up as an operational tool in software form, is that it does not need to be programmed for the application. ANNs appear to learn rules from a representative set of examples, rather than having rules programmed in by an expert. The knowledge acquired by the system that controls how the system maps input to output is held within the connection weights of the network.

The focus of extensive ongoing research is the search for optimal training techniques. These techniques tend to fall into two broad categories—supervised and unsupervised learning.

In supervised learning, a representative set of inputs is presented to the network which then modifies its internal weights in order to achieve a desired output. With unsupervised learning, the input data only are presented to the network, following which the network organizes itself through self-modification of its internal weights so that it responds differently to each input stimulus.

It is beyond the scope of this chapter to review all the current learning techniques for ANNs. This is well documented in the literature [6]. One popular training algorithm—backpropagation—will be discussed as an example.

87.6.10 Backpropagation

Backpropagation is an example of a supervised learning paradigm commonly used with multilayer perceptron network architectures. Backpropagation follows the error-correction principle and uses the error signal {d (desired output) − y (actual output)} to modify the connection weights to reduce this error. The backpropagation algorithm is implemented as follows:

1. Initialize network weights to small random values.
2. Present an input vector $x_0, \ldots, x_{N-1}$ and the corresponding desired output vector $d_0, \ldots, d_{M-1}$
3. Calculate the actual output vector $y_0, \ldots, y_{M-1}$ by propagating the input through the network.

4. Use a recursive algorithm starting at the output layer and adjust the weights backward by

$$w_{ij}(t+1) = w_{ij}(t) + \eta \delta_j x_i'$$

where
$w_{ij}(t)$ is the weight from an input to node j at time t
x_i' is either the output of node i or an input
η is a gain term ($0.0 < \eta < 1.0$)
δ_j is an error term for node j

For the output layer $l = L$, the error is calculated:

$$\delta_j^L = g'\left(h_j^L\right)[d_j - y_j]$$

where
h_j^L is the net input to the jth unit in the L layer
g' is the derivative of the activation function g

For hidden layers $l = (L - 1), \ldots, 1$, the error is calculated:

$$\delta_j^L = g'\left(h_j^l\right)\sum_l w_{ij}^{l+1}\delta_j^{l+1}$$

where
h_j^l is the net input to the jth unit in the lth layer
g' is the derivative of the activation function g

5. Return to Step 2 and repeat for the next pattern until the error reaches a predefined minimum level.

Unfortunately, no method exists that allows the ANN to create or learn information that is not contained in the training data; that is, the ANN can only reproduce based on experience. Under certain conditions, however, the network can generalize, that is, approximate, output values for data not contained in the training set.

The neural network can be considered as a universal approximator. During supervised learning, the output eventually approximates a target value based on training data. While this is a useful function, the ability to provide output data for test cases not in the training data is more desirable. Loosely, generalization can be viewed in terms of interpolation and extrapolation based on training data. If a test case is closely surrounded by training data, then (as with interpolation) the output accuracy is generally reliable. If, however, the test case is outside of, and not sufficiently close to, training data, then (as with extrapolation) the accuracy is notoriously unreliable. Therefore, if the training cases are a sufficiently large sample of the total population of possible input data so that each test case is close to a training case, then the network will adequately generalize.

While multilayer feed-forward networks are finding increasing application in a wide range of products, many design issues such as determining an optimal number of layers, units, and training set for good generalization are research topics. Current theory provides loose guidelines and many of these

design issues are resolved by trial and error. Another disadvantage of ANNs is the high demand that many training algorithms can put on computing resources because of their recursive nature.

The ANN, then, provides another alternative for development of suitable mapping models for measurement systems. They can be used to describe complex nonlinear relationships using a network of very simple processing elements. The attraction of the ANN lies in its ability to learn. As long as there exists a sufficiently representative sample of input-to-output data available, the mathematical relationship of the mapping function need not be known. It is effectively taught to the network during a learning process.

Again, there exist important limitations. The worst is the time it might take to adjust the system nodes and weights to a nearly final state. This can often require considerably more time than the time-varying properties of the inputs allow. In many potential applications, they take too long to learn and are not effective. Again computational speed and power are governing factors.

Despite their shortcomings in some applications, ANNs are now a commonly used procedure to set up sensor mapping systems. Examples are banknote image detection and the increased sensitivity of the detection of aluminum in water.

87.7 Problems in Calibration of AI Processing Methods

Calibration of a measurement system is the result of using an agreed upon, often legally binding, process by which it is proven to possess a declared level of accuracy in its measurement outcome. In conventional instrument terms, this implies the system can be set up and compared with a measurement method of superior performance to give its error of accuracy plus its variance from the agreed value determined with a level of uncertainty. This kind of instrument system is then accepted to have a known behavior that could be explained by the laws of physics as causal and unique in performance. The prime example, the physical standard apparatus for a parameter, can and is defined such that it will always give very closely the same outcome, even if built in different laboratories. It will have predictable behavior. At the heart of this acceptability is that it can be modeled in terms of an algorithm. All parts in it follow formal laws and have the same outcomes from implementation to implementation.

Most of this notion has to be put aside because, as explained earlier, AI-based instrument signal processors are built on a raft of transformations that convert subjective situations into objective ones or they carry out unexplained processes. It is, therefore, not hard to see that calibration is a major issue with this type of processor.

Processes make use of heuristics to at least start them going. The designer, when invoking any of the decision-making methods, will almost certainly not select the same rules, processes, and parameters that another designer will choose. There is a lack of consistency in AI processors. The outcomes are fuzzy, not crisp as in instrumentation that complies with a physical law. They act like humans do in that they provide a range of solutions to the same problem.

At first sight, this seems to imply that we should ignore the AI possibilities for they cannot be calibrated according to long-standing metrological practices. However, their performance is often very worthy and will be workable where algorithmic methods are not. This calibration constraint must be considered in terms of human thinking, not so much in terms of physics and mathematical models.

At present, AI processing methods have been well proved in many fields, these tending to be fields in which performance does not need calibration with regard to the standards regime. Examples are the use of fuzzy logic in clothes washing machines to improve the wash by varying the wash cycle parameters, in neural network methods to aid the recognition of banknotes, and in rule-based controllers in industrial process plant controls. GAs have been used to schedule power supply and usage in space shuttles—said to be an impossible task by any other known means. These all are typified as being needs where much experience can be devoted to ensuring they work satisfactorily.

They should normally not be the critical processing element in safety-critical situations. They can certainly be used in routine management situations where they can outperform algorithmic methods, but there they should be backed up with conventional alarms. They are often used in off-line plant control

where the human and alarms are still the final arbiter. This, however, seems to be only a cautious step in our slow acceptance of new ideas.

The process of calibration here is more akin to that of conducting evaluation and validation. Does the system give the range of outcomes expected in given circumstances? Are the outcomes better than those without the processor? Could it be done as well or better by algorithmic-based processing? Is the speed it gives worth the problems it may bring? Problems in their testing, and thus calibration, are discussed by Sizemore [7]. The issues that need to be considered in the calibration of conventional instrumentation [8] are relevant to the calibration of AI-based processing but need much more care in their execution.

Such questions require consideration of the very same elements of decision theory upon which they are based to test them. They have been set up to think like humans so it is expected they will have to be calibrated and evaluated like humans—that is not at all easy.

At present, the calibration and validation of AI systems are not standardized well enough. This impedes acceptance, but standardization will improve as world knowledge of this relatively new method of processing develops to greater maturity inside instrumentation.

There will be opposition to the use of AI methods, but the performance gain they bring will ensure they are used. The forward-thinking academic measurement community is showing signs of addressing AI signal processing—but it will take time.

Analog-to-Digital Converters

E.B. Loewenstein
National Instruments

88.1 Introduction

Almost every modern instrumentation system includes some form of digitizer, or *analog-to-digital converter* (ADC). An ADC converts real-world signals (usually voltages) into digital numbers so that a computer or digital processor can (1) acquire signals automatically, (2) store and retrieve information about the signals, (3) process and analyze the information, and (4) display measurement results. A digitizing system can do these jobs with greater speed, reliability, repeatability, accuracy, and resolution than a purely analog system normally can.

The two main functions of an ADC are *sampling and quantization*. These two processes convert analog signals from the time and voltage continuums (respectively) into digital numbers having discrete amplitudes, at discrete times. To represent changing signals at every instant in time or at every possible voltage would take an infinite amount of storage. So for every system there is an appropriate *sampling rate* and degree of quantization (*resolution*) so that the system retains as much information as it needs about the input signals while keeping track of manageable amounts of data. Ultimately, the purpose of sampling and quantization is to reduce as much as possible the amount of information about a signal that a system must store in order to reconstruct or analyze it meaningfully.

88.2 Sampling

To prevent having to digitize an infinite amount of information, an analog signal must first be sampled. Sampling is the process of picking one value of a signal to represent the signal for some interval of time. Normally, digitizers take samples uniformly in time, e.g., every microsecond. It is not necessary to sample uniformly, but doing so has some interesting and convenient mathematical properties, which we will see later.

Sampling is done by a circuit called a *sample-and-hold* (S/H), which, at a sampling instant, transfers the input signal to the output and holds it steady, even though the input signal may still be changing. An S/H usually consists of a signal buffer followed by an electronic switch connected to a capacitor. At a sampling instant, the switch briefly connects the buffer to the capacitor, allowing the capacitor to charge to the input voltage. When the switch is disconnected, the capacitor retains its charge and thus keeps the sampled input voltage steady while the ADC that follows does its job. Quite often, sampling is actually done by a circuit called a *track-and-hold* (T/H), which differs from an S/H only slightly. Whereas the S/H holds the analog signal until the next sampling instant, the T/H holds the analog signal still only until the ADC has finished its conversion cycle. After the ADC is through, the T/H reconnects the buffer to the capacitor and follows the input signal until the next sampling instant. The result is more accurate sampling, because the buffer has more time to charge the capacitor and "catch up" with (track) the input signal, which has changed since the last sampling instant. Nearly every modern ADC chip has a built-in S/H or T/H, and virtually all data acquisition systems include them.

Of course, sampling necessarily throws away some information, so the art of sampling is in choosing the right sample rate so that enough of the input signal is preserved. The major pitfall of *undersampling* (sampling too slowly) is *aliasing*, which happens whenever the input signal has energy at frequencies greater than one-half the sample rate. In Figure 88.1a, a signal (the fast sine wave) is sampled at a rate *Fs*, shown by the hash marks at the bottom of the graph. The sine wave has a frequency of 0.8*Fs*, which is higher than one-half the sample rates (0.5*Fs*). Notice that sampling the lighter sine wave of 0.2*Fs* produces the same set of samples. The resulting sampled data are ambiguous in that we cannot tell from the data what the frequency of the incoming sine wave actually is. In fact, even though the data set appears to represent a sine wave of 0.2*Fs*, the actual signal could be any sine wave having a frequency of $(n)Fs \pm 0.2Fs$, where n is any integer, starting with 0. So the original signal could be 0.2*Fs*, 0.8*Fs*, 1.2*Fs*, 1.8*Fs*, 2.2*Fs*, etc. (or even more than one of those). We say that 0.2*Fs* is the *alias* of a signal that may actually be at another frequency entirely. During interpretation of sampled data, it is customary to treat signals as though they occurred in the baseband (0–0.5*Fs*), whether or not that is the case. In general, in a system sampling at *Fs*, a signal at a frequency *F* will alias into the baseband at

$$Fa = \text{abs}[(n)Fs - F] \tag{88.1}$$

where

abs denotes absolute value
$n \geq 0$
$(n)Fs$ is the closest integer multiple of *Fs* to *F*

Everyone has seen a demonstration of aliasing at the movies, in the form of "wagon wheeling." As the stagecoach or wagon takes off, the wheels begin to turn, slowly at first, then faster. As the wagon speeds up, the spokes suddenly appear to be turning backward, even though the wagon is moving forward. Sometimes, the spokes appear to be standing still. The reason for this is that a motion picture camera shooting film at 24 frames/s is a sampling system operating at 24 samples/s. The turning wagon wheel is a periodic signal that the camera undersamples. When the wheel begins turning just fast enough that one spoke travels at least half the distance to the next spoke in $\frac{1}{24}$th of a second, the spokes begin to

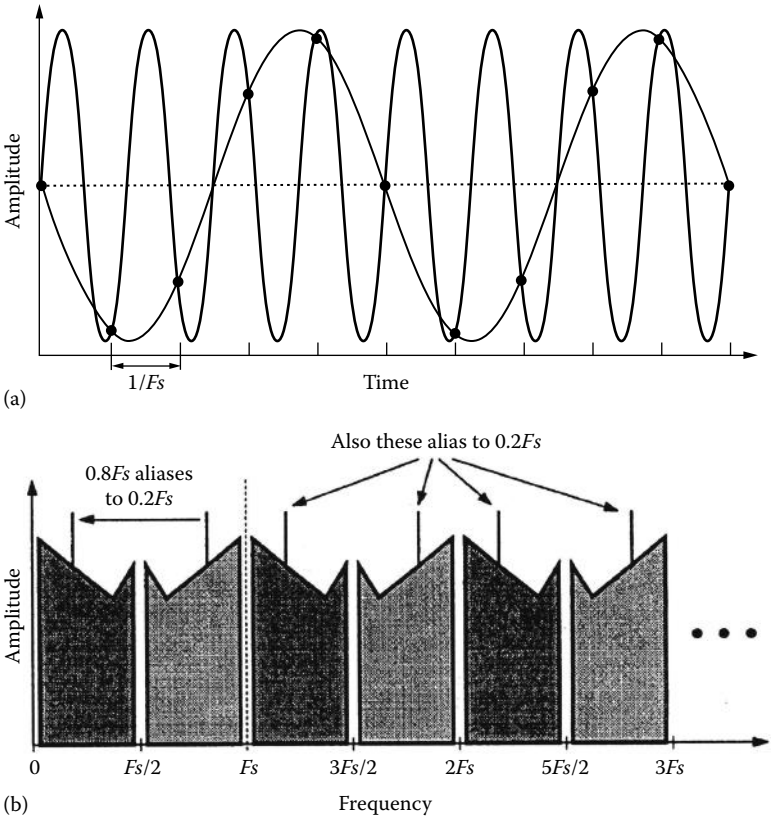

FIGURE 88.1 A demonstration of aliasing. An ADC sampling at rate *Fs* cannot distinguish between a 0.8*Fs* sine wave and a 0.2*Fs* sine wave: (a) a time-domain illustration and (b) a frequency-domain illustration. Theoretically, a sampler aliases an infinite number of 0.5*Fs* wide frequency bands into the baseband (0–0.5*Fs*). Practically, finite analog bandwidth eventually limits how far out in frequency aliases can come from.

appear to move backward, and the system is aliasing. When the wheel is turning so that a spoke moves exactly the distance between two spokes in $\frac{1}{24}$th of a second, the spokes appear to be standing still, since they all look the same to the camera.

It follows from Equation 88.1 that if we put into a sampler a signal with no energy at frequencies greater than one-half the sample rate (0.5*Fs*), then aliasing will not occur. This is the essence of the Shannon sampling theorem [1], which states that, with mathematical interpolation, the complete input waveform can be recovered *exactly* from the sampled data, at all times at and in between the sampling instants, as long as the sample rate is at least twice as high as the highest frequency content in the signal. Sometimes we refer to 0.5*Fs* as the *Nyquist frequency*, because Nyquist was concerned with the maximum bandwidth of signals [2]. Similarly, twice the highest frequency content of a signal (i.e., the minimum nonaliasing sample rate) is sometimes called the *Nyquist rate*. Sample rates are specified in samples/s, or S/s, and it is also common to specify rates in kS/s, MS/s, and even GS/s.

It is not always necessary to worry about aliasing. When an instrument is measuring slow-moving dc signals or is gathering data for statistical analysis, for instance, getting frequencies right is not important. In those cases, we choose the sample rate so that we can take enough data in a reasonable amount of time. On the other hand, if the instrument is a spectrum analyzer, where frequency does matter, or an oscilloscope, where fine time detail is needed, aliasing certainly is an issue. When aliased signals from beyond the

frequency band of interest can interfere with measurement, an instrument needs to have an *antialias filter* before the S/H. An antialias filter is a low-pass filter with a gain of 1 throughout most of the frequency band of interest. As frequency increases, it begins to attenuate the signal; by the Nyquist frequency, it must have enough attenuation to prevent higher-frequency signals from reaching the S/H with enough amplitude to disturb measurements. An efficient antialias filter must attenuate rapidly with frequency in order to make most of the baseband usable. Popular analog filters with rapid cutoff include elliptic and Chebyshev filters, which use zeros to achieve fast cutoff, and Butterworth filters (sixth order and above), which do not attenuate as aggressively, but have very flat passband response. A good book about filters is Ref. [3].

Some ADCs do not need a S/H or T/H at all. If the ADC is converting a slow-moving or dc signal and precise timing is not needed, the input may be stable enough during conversion that it is as good as sampled. There are also *integrating ADCs* (discussed later), which average the input signal over a period of time rather than sampling it. However, internally they actually sample the average.

88.3 Quantization

What sampling accomplishes in the time domain, quantization does in the amplitude domain. The process of digitization is not complete until the sampled signal, which is still in analog form, is reduced to digital information. An ADC quantizes a sampled signal by picking one integer value from a predetermined, finite list of integer values to represent each analog sample. Each integer value in the list represents a fraction of the total analog input range. Normally, an ADC chooses the value closest to the actual sample from a list of uniformly spaced values. This rule gives the *transfer function* of analog input-to-digital output a uniform "staircase" characteristic. Figure 88.2 represents a 3 bit quantizer, which maps a continuum of analog input values to only eight (2^3) possible output values. Each step in the staircase has (ideally) the same width along the *x*-axis, which we call *code width* and define as 1 *least significant bit* (LSB). In this case, 1 LSB is equal to 1 V. Each digital code corresponds to one of eight 1 LSB intervals making up the analog input range, which is 8 LSB (and also 8 V in this case).

Of course, we would like our measurement system to have a transfer function that is a straight line and has no steps at all. The bottom graph in Figure 88.2 is the ideal transfer function (a straight diagonal line) subtracted from the staircase function, or the *quantization error*. In an ideal ADC, the quantization error is bounded by ±½ LSB, and over the input range, the average error is 0 LSB and the standard deviation of error is $1/\sqrt{12}$ LSB. As the bottom graph shows, the quantization error at any point is a deterministic function of the input signal.

88.4 ADC Specifications

88.4.1 Range and Resolution

The *input range* of an ADC is the span of voltages over which a conversion is valid. The end points at the bottom and the top of the range are called *–full scale* and *+full scale*, respectively. When –full scale is 0 V the range is called *unipolar*, and when –full scale is a negative voltage of the same magnitude as +full scale the range is said to be *bipolar*. When the input voltage exceeds the input range, the conversion data are certain to be wrong, and most ADCs report the code at the end point of the range closest to the input voltage. This condition is called an *overrange*.

The *resolution* of an ADC is the smallest change in voltage the ADC can detect, which is inherently 1 LSB. It is customary to refer to the resolution of an ADC by the number of binary bits or decimal digits it produces; for example, "12 bits" means that the ADC can resolve one part in 2^{12} (=4096). In the case of a digital voltmeter that reads decimal digits, we refer to the number of digits that it resolves. A "6-digit" voltmeter on a 1 V scale measures from –0.999999 to +0.999999 V in 0.000001 V steps; it resolves one part in 2,000,000. It is also common to refer to a voltmeter measures from –1.999999 to +1.999999 as a "6½ digit" voltmeter. Table 88.1 compares the resolutions of common word lengths for ADCs.

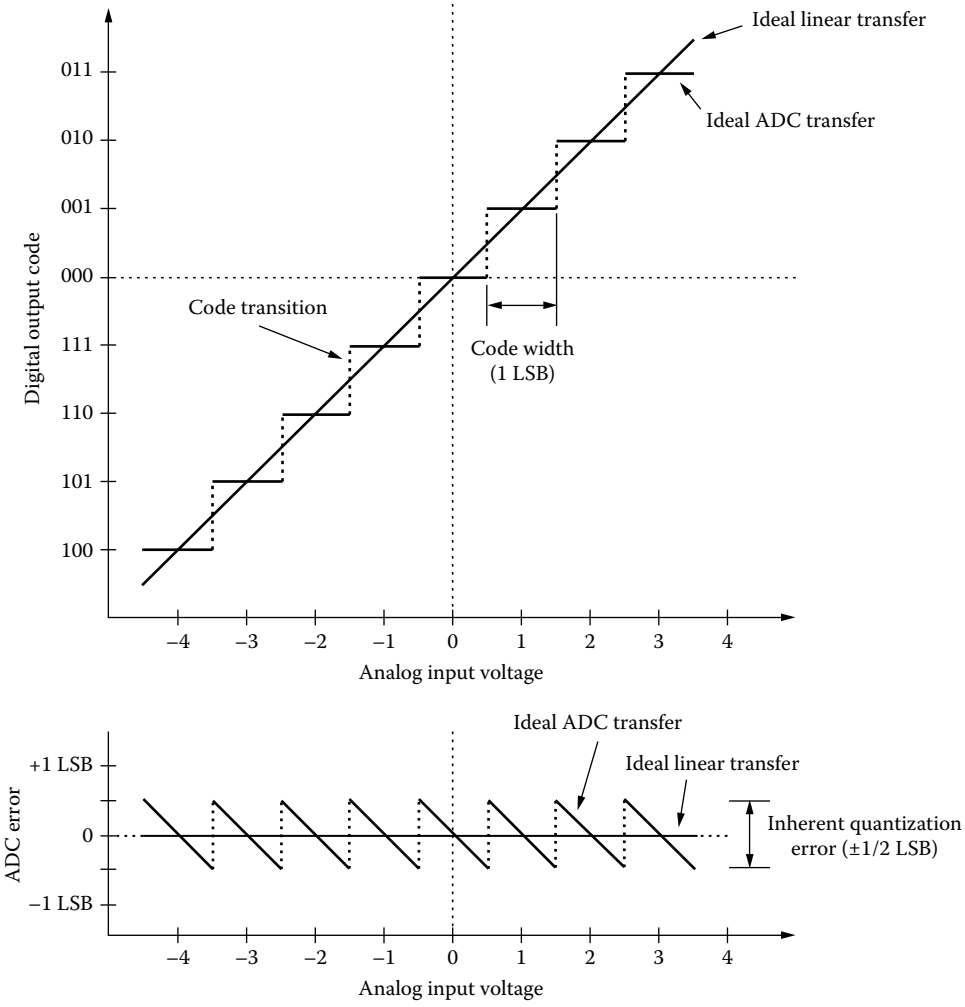

FIGURE 88.2 The ideal 3 bit quantizer has eight possible digital outputs. The analog input-to-digital output transfer function is a uniform staircase with steps whose width and height are 1 LSB exactly. The bottom graph shows the ideal transfer function (a straight line) subtracted from the staircase transfer function.

88.4.2 Coding Conventions

There are several different formats for ADC output data. An ADC using *binary* coding produces all 0s (e.g., 000 for the 3 bit converter) at –full scale and all 1s (e.g., 111) at +full scale. If the range is bipolar, so that –full scale is a negative voltage, binary coding is sometimes called *offset binary*, since the code 0 does not refer to 0 V. To make digital 0 correspond to 0 V, bipolar ADCs use *two's complement* coding, which is identical to offset binary coding except that the *most significant bit* (MSB) is inverted, so that 100 … 00 corresponds to –full scale, 000 … 00 corresponds to 0 V (*midscale*), and 011 … 11 corresponds to +full scale. All of the figures in this chapter depicting 3 bit ADC transfer functions use two's complement coding.

Decimal-digit ADCs, such as those used in digital voltmeters, use a coding scheme call *binary-coded decimal* (BCD). BCD data consist of a string of 4 bit groups of binary digits. Each 4 bit group represents a decimal digit, where 0000 is 0, 0001 is 1, and so on, up to 1001 for 9. The other six combinations (1010 through 1111) are invalid, or can be used for special information, such as the sign of the conversion.

TABLE 88.1 Comparison of Theoretical Resolutions of ADCs

Bits	Digits	Voltmeter "Digits"	Steps in FSR	Step Size (ppm)	Theoretical Dynamic Range (dB)
30	8.730		1,073,741,824	0.001	182.379
28.575	8.301	8½	400,000,000	0.003	173.802

Note: "Bits" refers to binary word length, and "digits" refers to decimal word length. * denotes popular binary word lengths. FSR is full-scale range, and theoretical dynamic range is computed from the formula $1.7609 + 6.0206n$, where n is the number of bits (see discussion on dynamic range).

88.4.3 Linear Errors

Linear errors are the largest and most common errors in an ADC and are easily corrected by simple calibrations or by additions with and multiplications by correction constants. Linear errors do not distort the transfer function; they only change somewhat the input range over which the ADC operates.

Figure 88.3 shows the transfer function of an ideal 3 bit ADC with some *offset error*. The straight line joining the centers of the code transitions is raised, or offset, by 0.6 LSB, and the bottom graph shows the resulting error. Figure 88.4 shows an ideal 3 bit ADC with a +25% *gain error*. The slope of the line through the code transitions is 1.25 times the ideal slope of 1.00. If the slope of the line was 0.75 instead, the gain error would be –25%. The bottom graph shows the error resulting from excessive gain. Offset errors can be compensated for simply by adding a correcting voltage in the analog circuitry or by adding a constant to the digital data. Gain errors can be corrected by analog circuitry like potentiometers or voltage-controlled amplifiers or by multiplying the digital data by a correction constant.

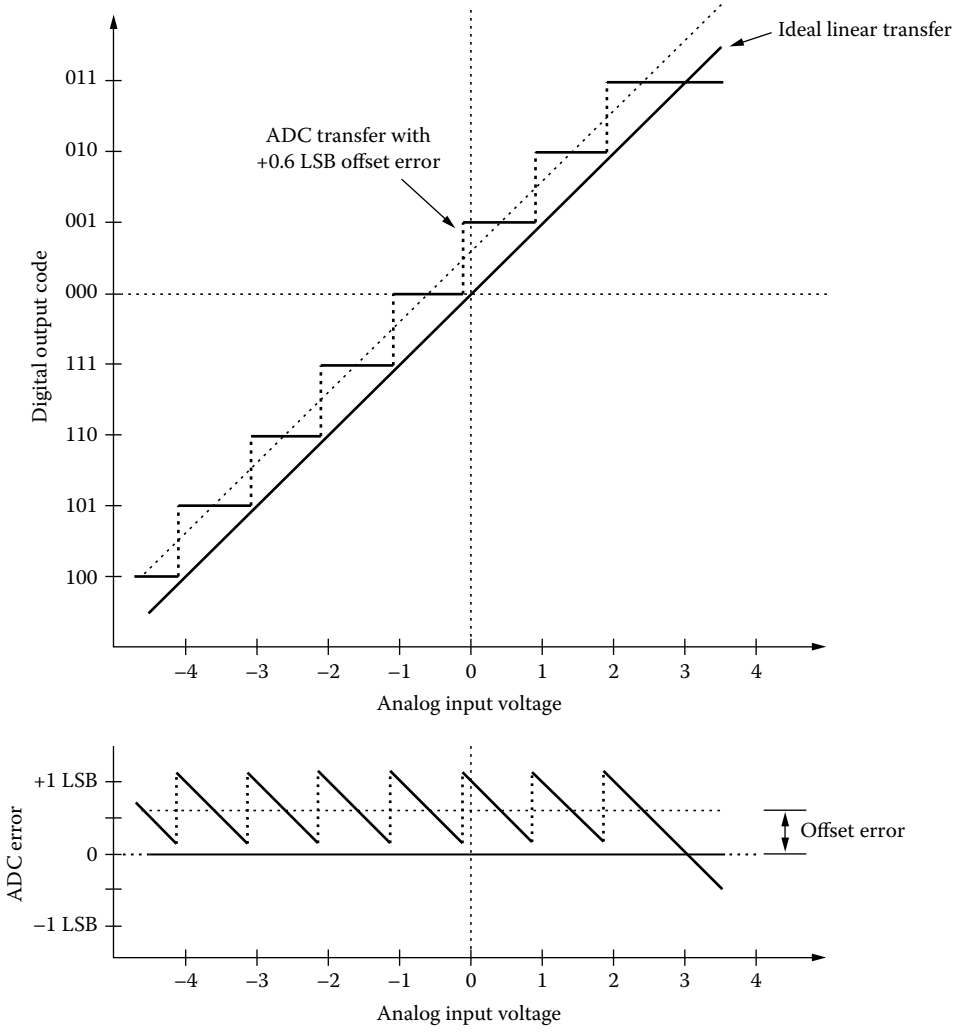

FIGURE 88.3 An ideal 3 bit quantizer, only with +0.6 LSB of offset error.

88.4.4 Nonlinear Errors

Nonlinear errors are much harder to compensate for in either the digital or analog domain, and are best minimized by choosing well-designed, well-specified ADCs. Nonlinearities are characterized in two ways: differential nonlinearity and integral nonlinearity.

DNL measures the irregularity in the code step widths by comparing their widths to the ideal value of 1 LSB. Figure 88.5 illustrates the 3 bit ADC with some irregular code widths. Most of the codes have the proper width of 1 LSB and thus contribute no DNL, but one narrow code has a width of 0.6 LSB, producing a DNL of –0.4 LSB, and one wide code has a width of 1.8 LSB, producing a DNL of +0.8 LSB at that code. This converter would be consistent with a DNL specification of ±0.9 LSB, for example, which guarantees that all code widths are between 0.1 and 1.9 LSB.

It is possible for a code not to appear at all in the transfer function. This happens when the code has a width of 0 LSB, in which case we call it a *missing code*. Its DNL is –1 LSB. If an ADC has a single missing code, the step size at that point in the transfer function is doubled, effectively reducing the local resolution of the ADC by a factor of two. For this reason it is important for an ADC specification to declare that

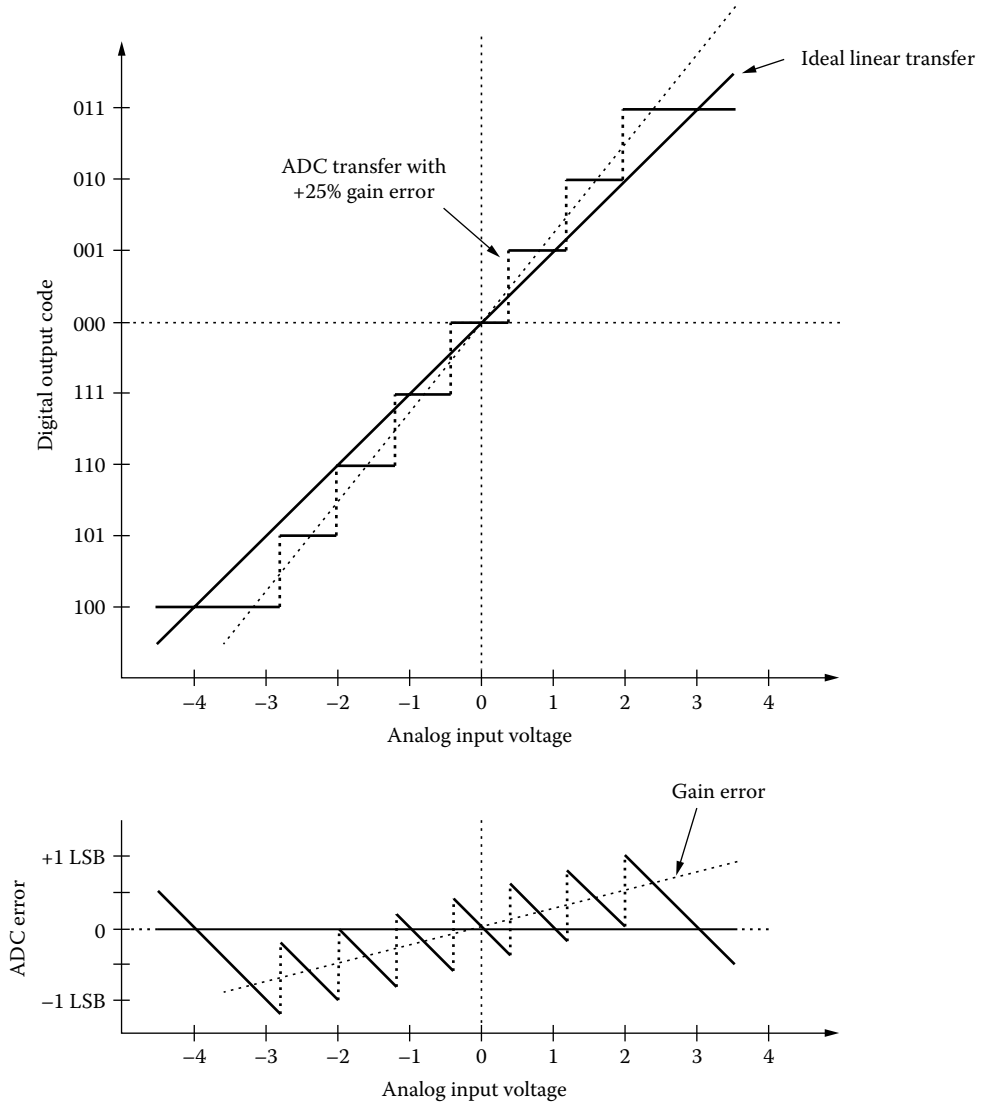

FIGURE 88.4 An ideal 3 bit quantizer, only with a gain of 1.25 instead of 1.00. This represents a +25% gain error.

the ADC has *no missing codes*, guaranteeing that every code has a width greater than 0 LSB. Even if an ADC has missing codes, no code can have a width <0 LSB, so the DNL can never be worse than –1 LSB.

INL measures the deviation of the code transitions from the ideal straight line, providing that the linear errors (offset and gain) have been removed. Figure 88.6 depicts an ADC with an INL error of +0.7 LSB. The offset and gain errors have been calibrated at the end points of the transfer function.

Relative accuracy (*RA*) is a measure of nonlinearity related to INL, but is more useful. It indicates not only how far away from ideal the code transitions are, but also how far any part of the transfer function, including quantization "staircase" error, deviates from ideal (assuming offset and gain errors have been calibrated at the end points). In a noiseless ADC, the worst-case RA always exceeds the worst-cast INL by ±0.5 LSB, as demonstrated in Figure 88.6. In an ADC that has a little inherent noise or has noise (called *dither*) added at the input, the RA actually improves because the addition of noise to the quantizer tends to smooth the *averaged* transfer function. Figure 88.7 shows the average of the digital output data as a function of the input voltage when 0.1 LSB rms of Gaussian random noise is intentionally added to the input.

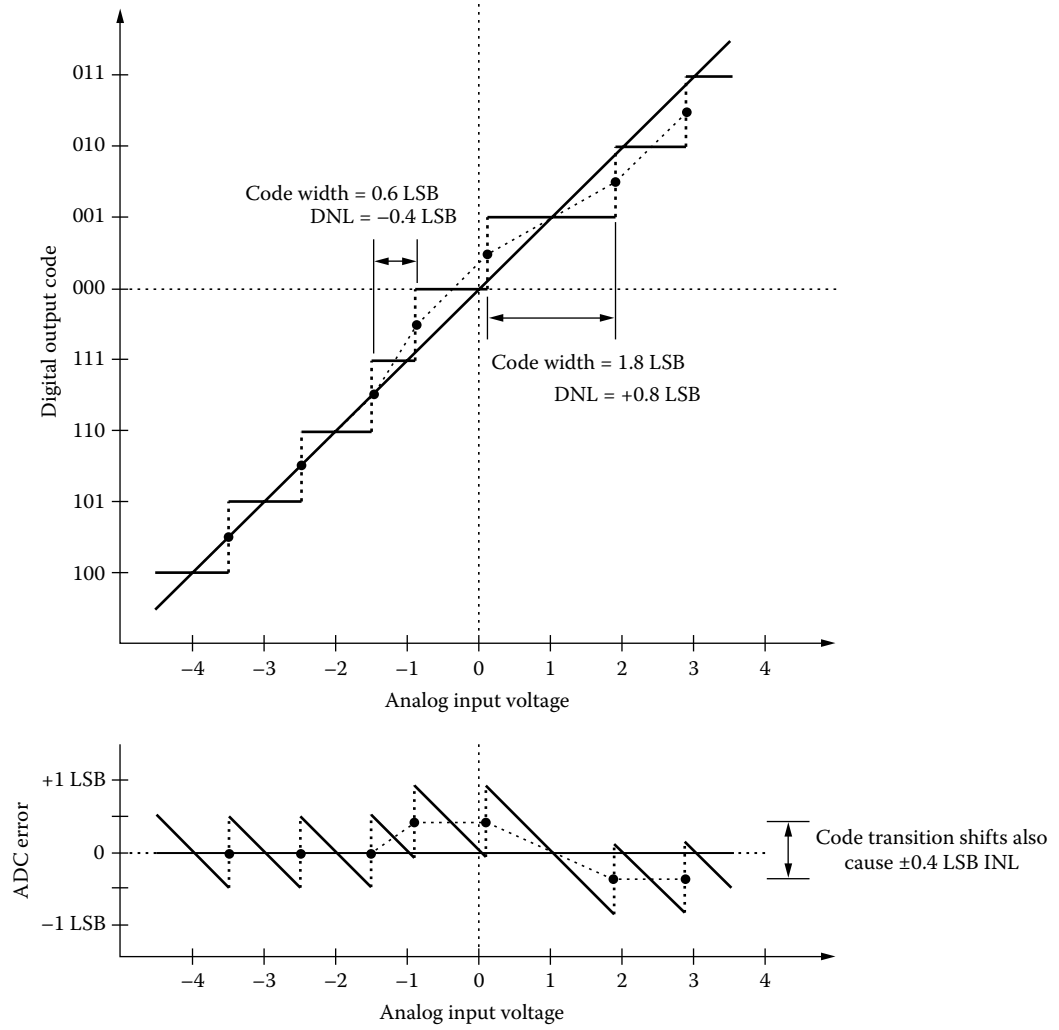

FIGURE 88.5 A 3 bit quantizer with substantial DNL errors. The bottom graph illustrates the resulting INL errors.

The RA improves to ±0.3 LSB from ±0.5 LSB in the noiseless case. If about 0.5 LSB rms of Gaussian noise is added, the quantization staircase becomes nearly straight. This improvement in linearity comes at the expense of the random error in each individual conversion caused by the noise. Adding more noise to the ADC does not improve the average quantization error much more, but it does tend to smooth out local nonlinearities in the averaged transfer function. For a good discussion of noise and dither, see Ref. [4].

88.4.5 Aperture Errors

Aperture errors have to do with the timing of analog-to-digital conversions, particularly of the S/H. *Aperture delay* characterizes the amount of time that lapses from when an ADC (S/H) receives a convert pulse to when the sample is held as a result of the pulse. Although aperture delay (sometimes called *aperture time*) is usually specified as a few nanoseconds for an ADC or S/H by itself, this delay is usually much more than negated by the group delay in any amplifiers that precede the S/H, so that the convert pulse arrives at the S/H quite some time before the analog signal does. For instance, a typical 1 MHz bandwidth amplifier has 160 ns of delay; if the ADC or S/H it was connected to have an aperture delay of 10 ns, the effective aperture delay for the system would be –150 ns.

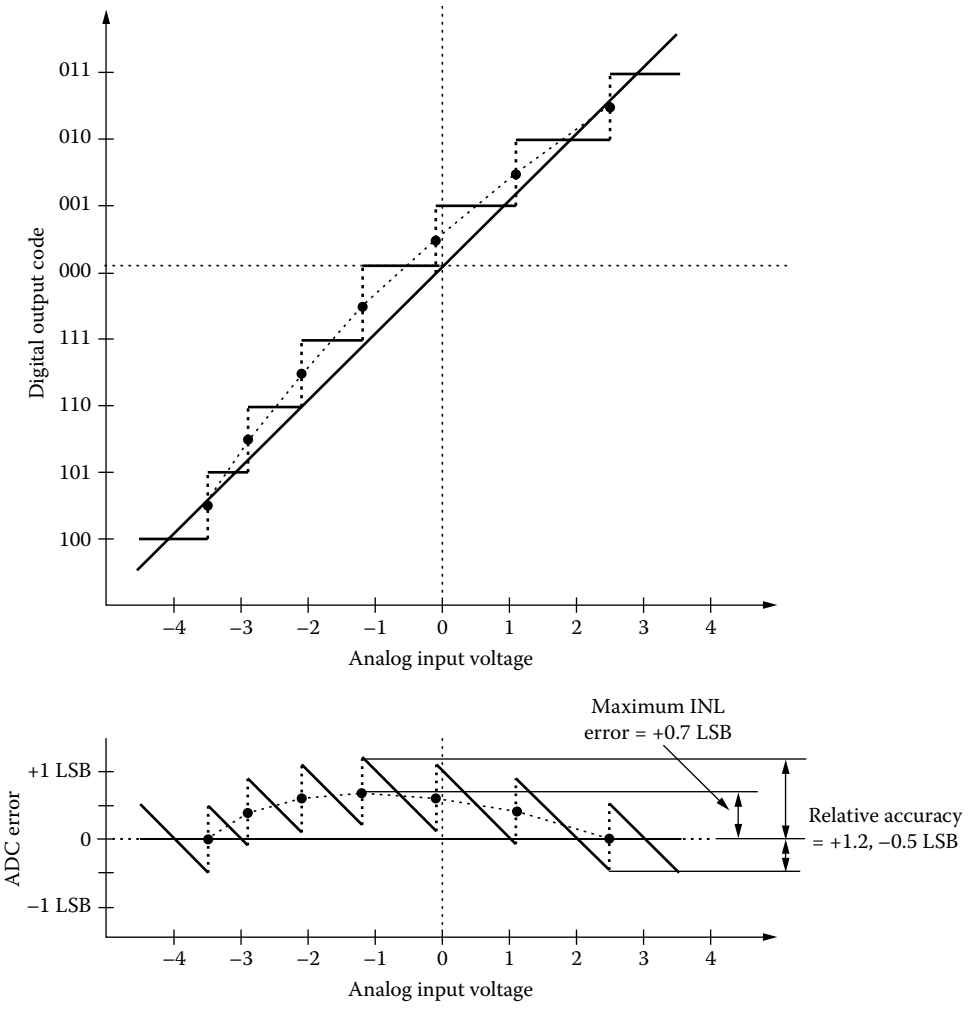

FIGURE 88.6 A 3 bit quantizer with substantial INL errors. Here, the DNL error is still significant, but, for example, a 12 bit converter with 0.7 LSB of INL from a smooth error "bow" like the one above could have negligible DNL because it would have so many more steps over which to accumulate error.

Jitter (or *aperture jitter*) characterizes the irregularity in times at which samples are taken. If the nominal period between samples in an ADC is 1 μs, the actual time may vary from 1 μs by as much as a few hundred picoseconds or even as much as a nanosecond from cycle to cycle. Contributions to these variations can come from the crystal clock source (if included under the jitter specification), digital clock circuitry, or the S/H. Jitter is usually specified in picoseconds peak-to-peak or picoseconds rms.

Jitter interferes with measurements (particularly spectral analysis) by effectively frequency modulating the input signal by the jitter profile. A jittery ADC sampling a pure sine wave would scatter energy from the sine wave all throughout the spectrum, perhaps covering up useful spectral information. In a typical ADC, however, most of the interference from jitter tends to occur at frequencies very close to the main signal.

88.4.6 Noise

Noise, whether inherent in an ADC or introduced intentionally (see dither earlier), limits the resolution of an ADC by adding an interfering waveform to the input signal as the data are converted. Noise comes

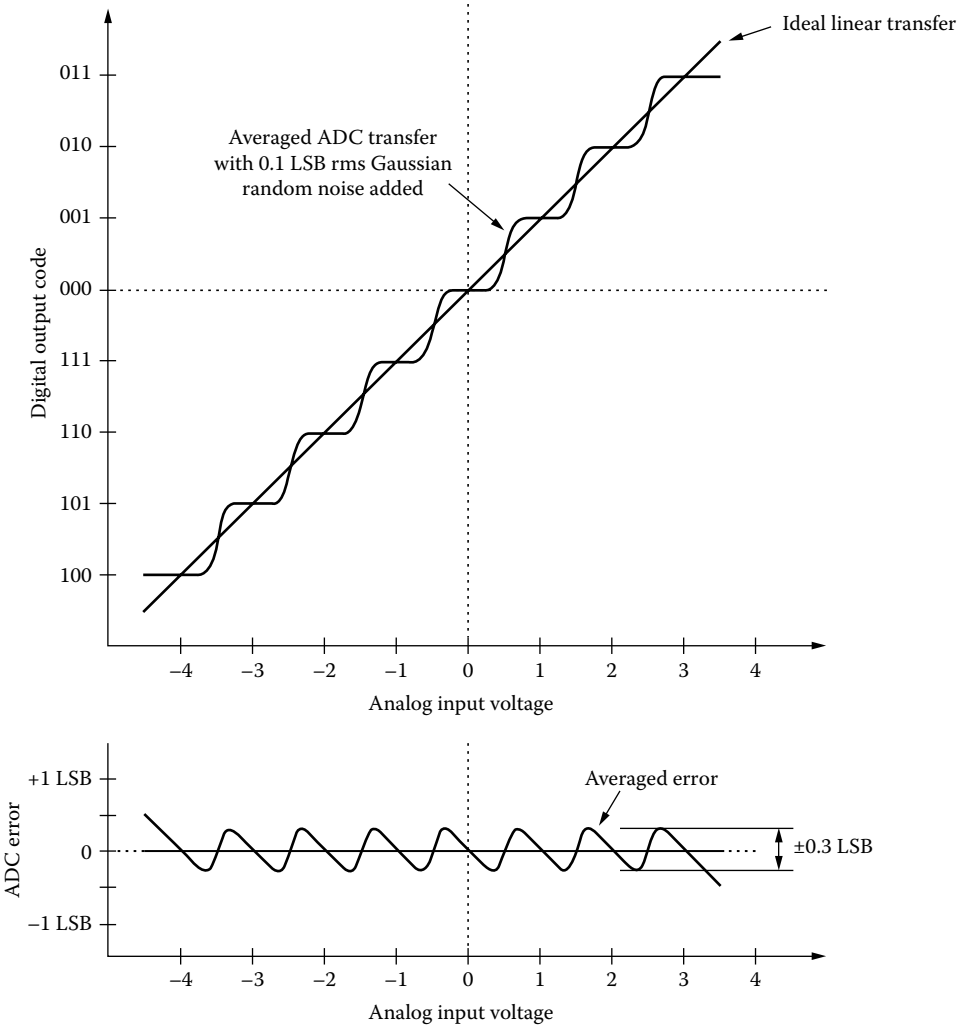

FIGURE 88.7 An ideal 3 bit quantizer with 0.1 LSB rms Gaussian random noise (dither) added at the input. The relative accuracy has improved to ±0.3 LSB rms from the ±0.5 LSB expected from a noiseless quantizer. With the application of 0.5 LSB rms Gaussian noise, the transfer function becomes almost perfectly straight. Larger amounts of dither produce essentially no improvement in linearity.

from many places. The most common kind of noise is *thermal noise*, which is caused by the random nature of electric conduction in resistors and transistors. Thermal noise is worse at higher temperatures and higher resistances. Most other ADC noise is coupled electromagnetically from nearby circuitry, such as clock or logic circuits, or from routing of other input signals. Noise is usually specified in volts rms or peak-to-peak, or LSBs rms or peak-to-peak.

Quantization error (see earlier) can sometimes be thought of as *quantization noise*. Although quantization error is perfectly predictable with respect to the input signal, when a signal is fairly "busy" (i.e., busy enough that consecutive conversions do not tend to repeat data) the quantization error becomes chaotic, and it can be thought of it as another source of random noise, whose statistical distribution is uniform from −0.5 LSB to +0.5 LSB and whose standard deviation is $1/\sqrt{12}$ LSB. This is sometimes the dominant source of noise in spectral analysis applications.

Once noise gets into an ADC, there are ways to process out the noise if it is independent of the signal. Acquisitions of dc signals can be quieted by collecting a number of points and averaging the collection. If the noise is *white random noise*, which has equal energy density at all frequencies, averaging can reduce the amount of noise by the square root of the number of samples averaged. The noise interfering with a repetitive waveform can be quieted by acquiring many waveforms using a level trigger and averaging the collection to produce an average waveform. Most digital oscilloscopes have waveform averaging. Quantization noise, as described earlier, cannot be averaged out unless other random noise is present.

The noise specifications for an ADC are for quiet, low-impedance signals at the input, such as a dead short. To preserve the noise performance of the ADCs, the user must carefully connect signals to the input with tidy cabling that keeps away from sources of electromagnetic noise. For more information on noise sources and treatment and prevention of noise, see Refs. [5,6].

88.4.7 Dynamic Range

The *dynamic range* (DR) of an ADC is the ratio of the largest to the smallest signals the converter can represent. The largest signal is usually taken to be a full-scale sine wave, and the smallest signal is usually taken to be the background noise level of the ADC. It can be expressed simply as a ratio, but it is more common to express it in decibels (dB):

$$\mathrm{DR} = 20\log\left(\frac{\mathrm{S}}{\mathrm{N}}\right) \tag{88.2}$$

where

DR is dynamic range in dB
S is the rms amplitude of the largest signal
N is the rms amplitude of the smallest signal, the noise

The noise must include the quantization noise of the ADC, which for a perfect, noiseless converter is $1/\sqrt{12}$ LSB rms. For an n bit converter, a full-scale sine wave has a peak amplitude of 2^{n-1} LSB, which corresponds to an rms amplitude of $2^{n-1}\sqrt{2}$ LSB, or $2^{n-1.5}$ LSB rms. Hence, a perfect ADC had a DR of

$$\begin{aligned}\mathrm{DR} &= 20\log\left(2^{n-1.5}\times\sqrt{12}\right)\\ &= 20\log(2^n) + 20\log\left(2^{-1.5}\times\sqrt{12}\right)\\ &= (n)[20\log(2)] + 20\log\left(\sqrt{1.5}\right)\\ &\approx 6.0206n + 1.7609.\end{aligned} \tag{88.3}$$

Equation 88.3 can be used to determine the *effective number of bits* (ENOB) of an imperfect ADC. ENOB may take only noise into account, or it may include noise and harmonic distortion products of the input signal. It is computed as

$$\mathrm{ENOB} = \frac{(\mathrm{DR} - 1.7609)}{6.0206} \tag{88.4}$$

For example, a 16 bit ADC with a DR of 92 dB has an ENOB of 14.988 bits.

88.5 Types of ADCs

The fundamental building block of analog-to-digital conversion is the *comparator*. Every type of ADC has at least one comparator in it, and some ADCs have many. The comparator itself is a 1 bit ADC; it has two analog voltage inputs and (usually) one digital output. If the voltage at the positive input is greater than the voltage at the negative input, the output of the comparator is a digital 1. If the voltage at the positive input is less than the voltage at the negative input, the output is a digital 0 (see Figure 88.8).

Another piece that all ADCs have in common is a linearity reference. This is what a comparator in an ADC compares the input signal with in the process of conversion. It directly determines the DNL and INL of the ADC. Examples of linearity references include capacitors (in integrating ADCs) and DACs (found in successive-approximation ADCs).

The third piece that every ADC has is a voltage reference. The reference(s) determine the full-scale input range of the ADC and are usually part of or closely associated with the linearity reference.

88.5.1 Flash

Flash converters are the fastest ADCs, achieving speeds near 1 GS/s and resolutions of 10 bits and below. The flash converter with n bits of resolution has $2^n - 1$ high-speed comparators operating in parallel (see Figure 88.9). A string of resistors between two voltage references supplies a set of uniformly spaced voltages that span the input range, one for each comparator. The input voltage is compared with all of these voltages simultaneously, and the comparator outputs are 1 for all voltages below the input voltage and 0 for all the voltages above the input voltage. The resulting collection of digital outputs from the comparators is called a "thermometer code," because the transition between all 1s and all 0s floats up and down with the input voltage. Fast logic converts the thermometer codes to normal n bit binary numbers.

Because of their simplicity, they are fast, but flash converters are limited to resolutions of 10 bits and below because the number of comparators and resistors goes up exponentially with resolution. Because the string resistor values typically vary only a few percent from each other in practical devices, the differential linearity of the flash ADC is quite good. But the same resistor variations can accumulate error across the input range and cause INL of a few LSBs.

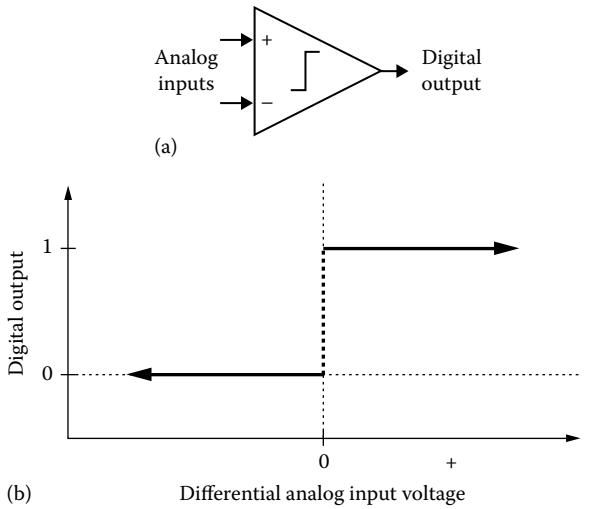

FIGURE 88.8 The comparator is the essential building block of all ADCs. (a) Comparator symbol and (b) comparator input/output transfer function.

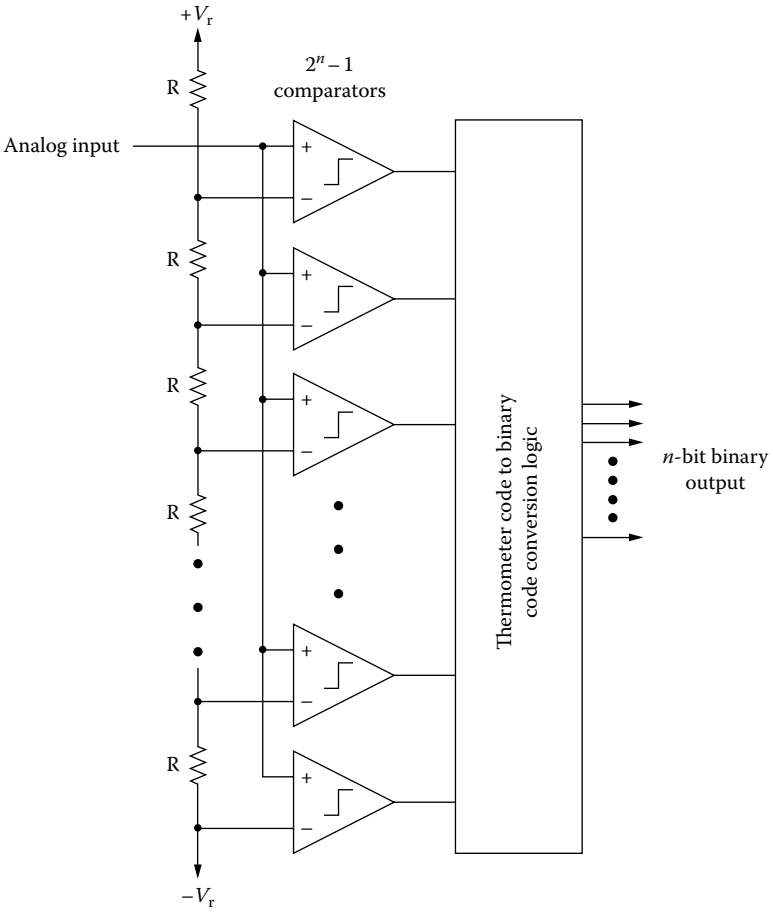

FIGURE 88.9 A flash converter has $2^n - 1$ comparators operating in parallel. It relies on the uniformity of the resistors for linearity.

88.5.2 Successive-Approximation Register

Successive-approximation register (SAR) ADCs are the most common ADCs, having resolutions of 8–16 bits and speeds of 1 MS/s and below. They are generally low in cost, and they typically have very good integral linearity. The *n* bit SAR ADC contains a high-speed *n* bit DAC and comparator in a feedback loop (see Figure 88.10). The SAR sequences the DAC through a series of *n* "guesses," which are compared with the input voltage (Figure 88.11). As the conversion progresses, the register builds the *n* bit binary

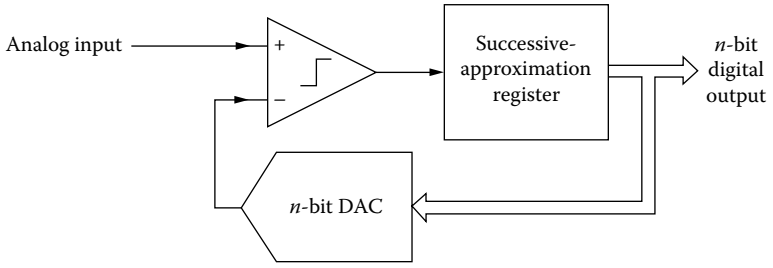

FIGURE 88.10 A successive-approximation converter has only one comparator and relies on an internal, precision DAC for linearity.

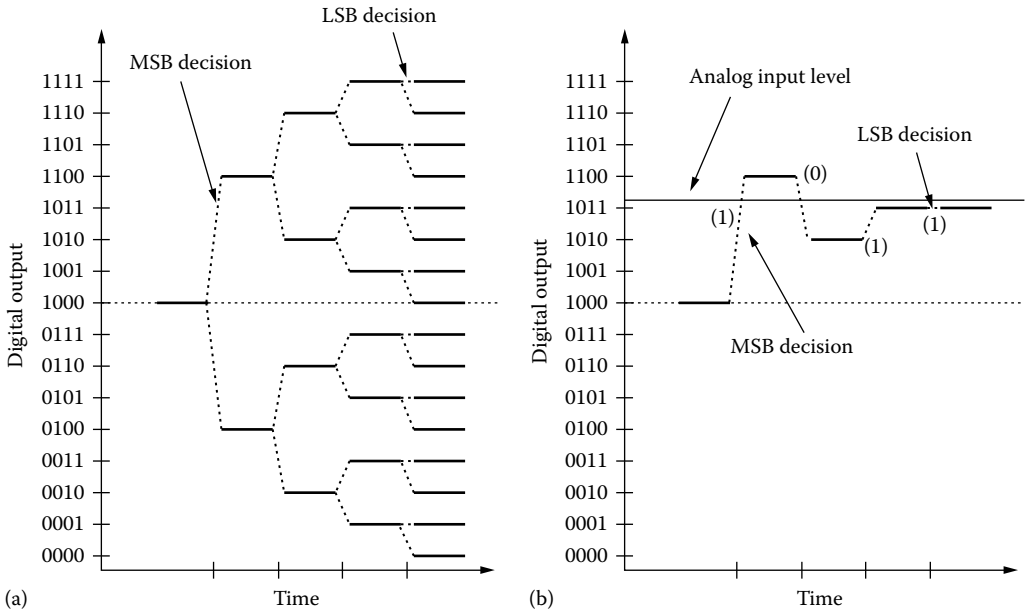

FIGURE 88.11 (a) Decision tree shows all the possible digital "guesses" of a 4 bit successive-approximation converter over time and (b) decision tree for conversion of 4 bit code 1011.

conversion result out of the comparator outputs. By the end of the sequence, the register has converged to the closest DAC value to the input voltage.

The speed of an SAR ADC is limited by the speed of the DAC inside the feedback loop. The DAC must settle n times to within $1/2^{-n}$ of full scale within the conversion time of the ADC. Current SAR technology achieves 12 bit resolution at 1 MS/s and 16 bit resolution at 200 kS/s. Faster conversion at these resolutions requires multistage architectures.

88.5.3 Multistage

To achieve higher sample rates than SAR ADCs at resolutions of 10–16 bits, *multistage* ADCs (sometimes called *subranging* or *multipass* ADCs) use the iterative approach of SAR ADCs but reduce the number of iterations in a conversion. Instead of using just a comparator, the multistage ADC uses low-resolution flash converters (4–8 bits) as building blocks. Figure 88.12 illustrates an example of a 12 bit

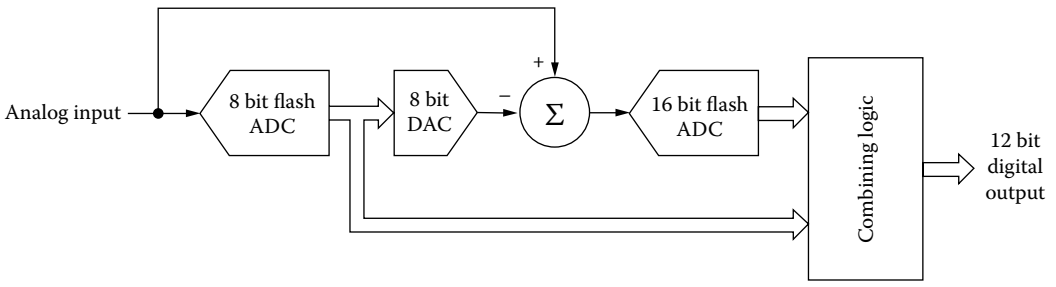

FIGURE 88.12 An example of a 12 bit multistage ADC built out of two flash ADCs and a fast DAC. The 8 bit flash ADC takes a first "guess" at the input signal and the 6 bit flash ADC converts the error in the guess, called the "residue." The 12 bit DAC actually needs to have only 8 bits, but it must be accurate to 12 bits. If the 8 bit flash ADC were perfect, the second flash ADC would only need 4 bits. But since the first flash actually may have some error, the second flash has 2 bits of "overlap."

two-stage ADC built out of two flash ADCs and a fast DAC. The 6 bit flash ADC converts the residual error of the 8 bit flash ADC. The two digital outputs are combined to produce a 12 bit conversion result.

If each flash ADC has a T/H at its input, then each stage can be converting the residual error from the previous stage while the previous stage is converting the next sample. The whole converter then can effectively operate at the sample rate of the slowest stage. Without the extra T/Hs, a new conversion cannot start until the residues have propagated through all the stages. This variation of the multistage ADC is called a *pipelined* ADC.

88.5.4 Integrating

Integrating converters are used for low-speed, high-resolution applications such as voltmeters. They are conceptually simple, consisting of an integrating amplifier, a comparator, a digital counter, and a very stable capacitor for accumulating charge (Figure 88.13). The most common integrating ADC in use is the dual-slope ADC, whose action is illustrated in Figure 88.14. Initially, the capacitor is discharged and so has no voltage across it. At time 0, the input to the integrator is switched to the analog input and the capacitor is allowed to charge for an amount of time, $T1$, which is always the same. Its rate of charging and thus its voltage at $T1$ are proportional to the input voltage. At time $T1$, the input switch flips over to the voltage reference, which has a negative value so that the capacitor will begin to discharge at a rate proportional to the reference. The counter measures how long it takes to discharge the capacitor completely. If the capacitor is of high quality, the ratio of the discharge time

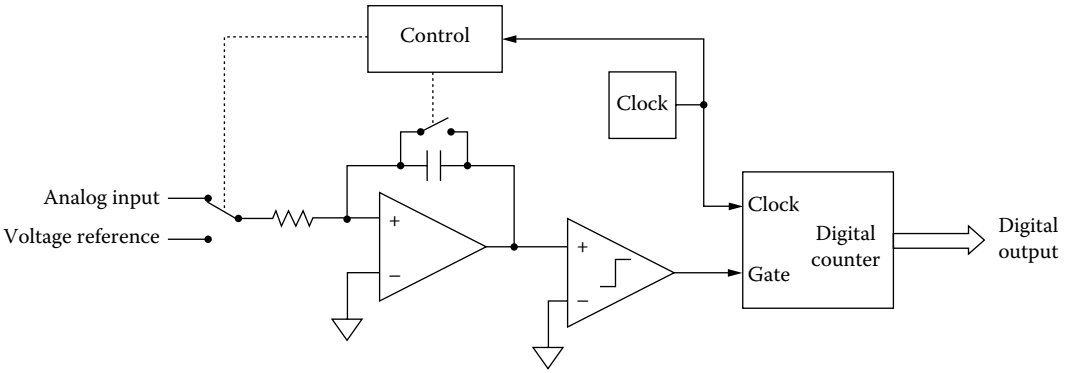

FIGURE 88.13 A dual-slope integrating converter uses a comparator to determine when the capacitor has fully discharged and relies on the capacitor for linearity.

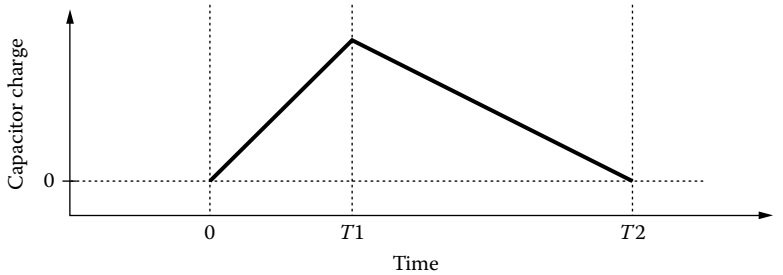

FIGURE 88.14 Charge on the integrating capacitor vs. time. At time 0, the input is switched to analog input and the switch across the capacitor opens. The capacitor integrates charge until fixed time $T1$. The input is then switched to the voltage reference to discharge the capacitor, and the counter begins counting a known clock. The comparator turns off the counter when the capacitor charge reaches 0 again, at time $T2$. The resulting count is proportional to the average input voltage over the time interval 0 to $T1$.

to the charge time is proportional to the ratio of the input voltage to the voltage reference, and so the counter output represents the analog input voltage.

An elaboration of the dual-slope ADC is the *multislope* integrating ADC. It achieves even higher resolution than the dual-slope ADC by discharging the capacitor at several progressively slower rates. At each rate, the counter is able to resolve finer increments of accumulated charge.

An important distinction between integrating converters and other ADCs is the way they sample the input voltage. Integrating converters do not sample the voltage itself; they *average* the voltage over the integration period and *then* they sample the average that is accumulated on the capacitor. This tends to reject noise that conventional sampling cannot, especially periodic noises. Most integrating ADCs operate with an integration period that is a multiple of one ac line period ($\frac{1}{60}$ or $\frac{1}{50}$ s) so that any potential interference from stray electric or magnetic fields caused by the power system is canceled.

Integrating converters are gradually being replaced in the marketplace with low-speed, high-resolution sigma–delta (SD) converters, which see. SD converters are generally more flexible than integrating ADCs, and they are easier to use because they do not require an external charging capacitor. The resolution and speed of the two types are comparable, although integrating converters still have the highest linearity.

88.5.5 Sigma–Delta ADCs

The SD ADC is quickly becoming one of the most popular types of ADC. SD ADCs typically have resolutions of 16–24 bits and sample rates of 100 kS/s down to 10 S/s. Because of their high resolution at 48 kS/s, they are the most common type of converters in modern digital audio equipment. SD ADCs defy intuition by quantizing initially with *very* low resolution (often 1 bit) at very high rates, typically 64× to 128× the eventual sample rate (called *oversampling*). The high-rate, low-resolution quantizer operates inside a feedback loop with an analog low-pass filter and a DAC to force the large amount of otherwise unavoidable quantization error (noise) to frequencies higher than the band of interest. The resulting spectral redistribution of the quantization noise is called *noise shaping*, illustrated in Figure 88.15. The low-resolution digital output of the ADC loop is fed into a digital filter that increases the resolution from the resolution of the ADC loop to the output resolution, reduces the data rate from

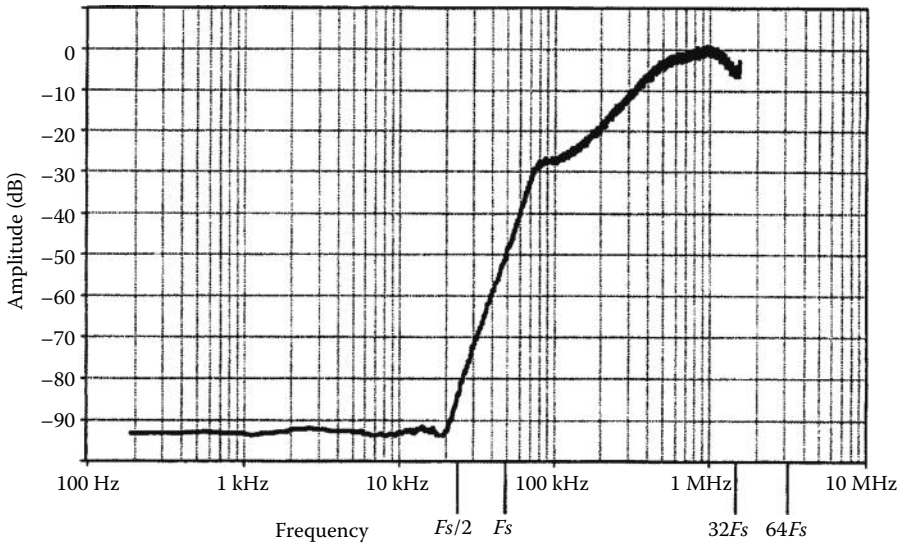

FIGURE 88.15 Spectrum of a 64-time oversampling SD ADC before the digital decimation filter. The modulator loop samples at 3.072 MS/s and the data come out of the filter at 48 kS/s. The filter cuts off sharply at *Fs*/2, or 24 kHz, leaving only the small amount of noise left below 24 kHz.

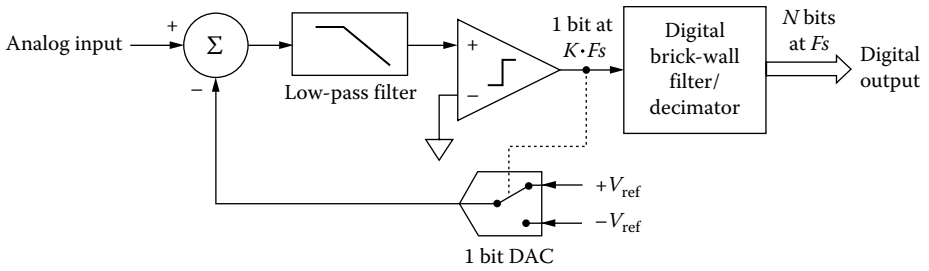

FIGURE 88.16 A SD modulating ADC uses a comparator simply as a 1 bit quantizer. The linearity of a SD ADC is theoretically perfect because the 1 bit DAC can only assume two values, and thus is linear by definition. Modern SD ADCs are made with switched-capacitor circuits which operate at *KFs*, where *Fs* is the output data sample rate and *K* is the oversampling ratio.

the rate of the ADC loop to the output sample rate, and applies a low-pass digital filter, leaving only the signals in the frequency band of interest and a little inherent electronic noise.

Figure 88.16 shows how a 1 bit SD ADC works. The comparator *is* the ADC, and its output is processed digitally, so that no further analog errors can accumulate. The comparator is in a feedback loop with a low-pass filter (typically third to fifth order) and a 1 bit DAC. The 1 bit DAC can take on only one of two values, +full scale and –full scale, so it is perfectly linear. The low-pass filter causes the loop gain to be high at low frequencies (the signal band of interest) and low at high frequencies. Since the error in a feedback loop is low when the gain is high and high when the gain is low, the errors dominate at high frequencies and are low in the band of interest. The result is a 1 bit output whose duty cycle is proportional to the input signal. Together, the elements of the feedback loop are called a *SD modulator*.

Figure 88.17 illustrates the operation of a simple discrete-time (switched-capacitor) SD ADC. In this first-order example, the low-pass filter is just an integrator. The loop tries to force the input to the comparator back to the baseline, and the figure shows how the duty cycle of the resulting digital output reflects input signal. The digital data here have undesirable patterns which tend to repeat, called *limit cycles*. They can appear in the band of interest and interfere with the signal. Higher-order loop filters (third and above) make the bit activity so chaotic that it has no substantial limit cycles.

The chief advantage of a SD converter is that it has a built-in antialias filter, and a darn good one at that. Most SD parts have a *finite-impulse response* (FIR) digital filter, which has an extremely flat frequency response in the passband and an extremely sharp cutoff, properties impossible to implement in analog filters. The ADC still needs an antialias filter to reject signals above one-half the oversampling rate. But this filter is simple to build, since it has to be flat only up to one-half the output sampling rate and has many octaves (all the way to near the oversampling rate) to fall off. The combination of the two filters provides watertight protection from aliases, often 96 dB of attenuation over the entire spectrum.

An important improvement of the 1 bit SD is the multibit SD, wherein the comparator is replaced by a flash converter with as much as 4 bits of resolution. This improves the ENOB of the whole converter by several bits.

88.5.6 Voltage-to-Frequency Converters

Voltage-to-frequency converters (VFCs) are versatile, low-cost circuits that convert analog voltages to periodic waveforms whose frequency is proportional to the analog input voltage. A VFC is conceptually similar to an integrating converter (see earlier) except that the digital counter is missing and is replaced with a short-pulse generator that quickly discharges the capacitor. The voltage reference is not connected intermittently to the input; instead, it appears all the time at the minus input of the comparator

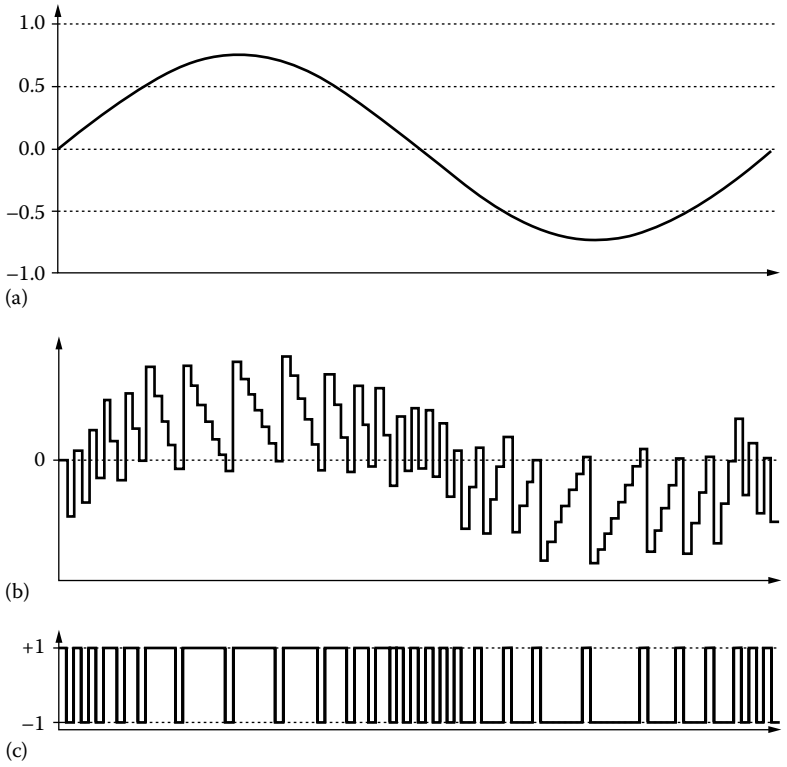

FIGURE 88.17 Behavior of a discrete-time (switched-capacitor) first-order SD modulator, where the low-pass filter is simply an integrator. In each graph, the *x*-axis represents time, and the *y*-axis represents signal level. (a) The input waveform, (b) input to the comparator, and (c) the 1 bit digital comparator output. The duty cycle of this waveform corresponds to the input waveform. The digital filter and decimator recover the original waveform from this 1 bit.

instead of ground. The capacitor charges at a rate proportional to the input voltage, until the voltage is equal to the voltage reference. Then the comparator trips the pulse generator, which quickly discharges the capacitor, and the cycle begins again. The periodic pulse at the comparator output can be used as the digital output.

The advantage of the VFC over conventional ADCs is that the 1 bit output can be transmitted digitally, through isolation transformers, through fiber-optic cable, or through any other isolating, nonisolating, long-distance, or short-distance transmission medium. All that is needed at the receiving end to complete the analog-to-digital conversion is a digital counter, which does not need to be synchronized to the VFC itself. Sometimes, the digital conversion is not needed; a VFC can be used with an isolating transformer and a *frequency-to-voltage converter* (FVC) to create an isolation amplifier. For a good discussion of VFCs, see Ref. [7].

88.6 Instrumentation and Components

88.6.1 Integrated Circuits

Table 88.2 lists several popular high-quality ADCs in integrated circuit form. By no means exhaustive, the list is sampling of a few of the most popular or best-performing chips of each type of ADC. Table 88.3 contains addresses, phone numbers, and Internet sites for the manufacturers in Table 88.2.

TABLE 88.2 ADC-Integrated Circuits

88.6.2 Instrumentation

Plug-in data acquisition cards are becoming increasingly popular as personal computer prices come down and processor performance goes up. These cards typically contain one or more ADCs (with S/H), instrumentation amplifiers with gain and differential input, and multiplexers to switch to different inputs. Some have DACs on-board, and some have digital data and timing functions as well. Once considered low performance and hard to use, data acquisition cards have improved dramatically, equaling and in some cases exceeding capabilities of stand-alone instruments. Most come

with drivers that interface to user-friendly software packages for creating easy-to-use yet custom-built computer instrumentation. Table 88.4 lists a few popular plug-in data acquisition boards and Table 88.5 lists how their manufacturers may be contacted.

89.1 Introduction

Computers are an essential feature of most instrumentation systems because of their ability to supervise the collection of data and allow information to be processed, stored, and displayed. Many modern instruments are capable of providing a remote user with access to measurement information via standard computer networks.

89.2 Computer-Based Instrumentation Systems

The main features of a computer-based instrumentation system are shown in Figure 89.1. The actual implementation of such systems will depend on the application. Many commercially produced instruments such as spectrophotometers or digital storage oscilloscopes are themselves integrated computer-based measurement systems. These "stand-alone" instruments may be fitted with interfaces such as IEEE-488, RS-232, or USB to allow them to be controlled from personal computers (PCs) and also to support the transfer of data to the PC for further processing and display. Alternatively, the instrumentation system may be based around a PC/workstation or an industrial bus system such as a VME or Multibus, allowing the user the ability to customize the computer to suit the application by selecting

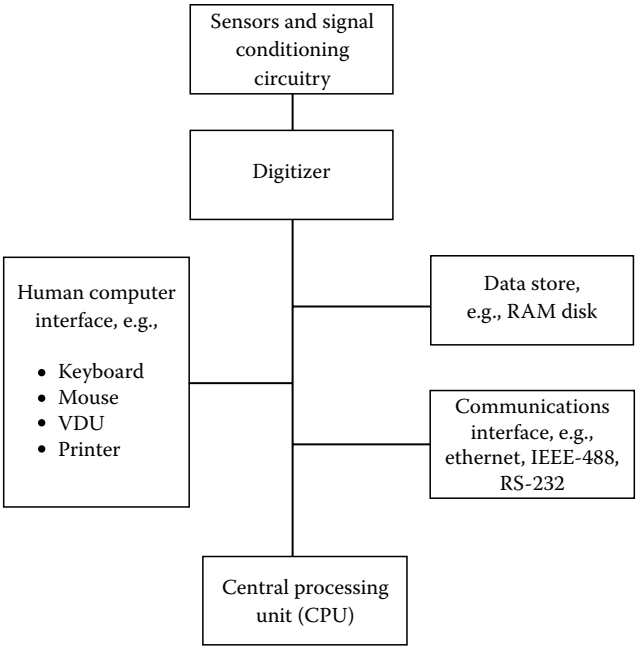

FIGURE 89.1 Elements of a computer-based instrumentation system.

an appropriate set of add-on cards. Recently, the introduction of laptop and notebook PCs fitted with PCMCIA interfaces with input/output capability has provided opportunities for the development of highly portable instrumentation systems.

89.2.1 Single-Board Computer

The simplest form of a computer is based around the single-board computer (SBC) which contains a microprocessor, memory, and interfaces for communicating with other electronic systems. The earliest form of PCs simply comprised an SBC together with a keyboard, display, disk drives, and a power supply unit. Today, the SBC still offers a solution for the addition of limited intelligence to instrumentation systems as well as forming an element of most computer systems, e.g., as the motherboard of a PC.

An overview of a simple SBC is shown in Figure 89.2. The microprocessor, which contains the central processor unit, is responsible for executing the computer program and for controlling the flow of data around the SBC. The random access memory (RAM) acts as a temporary (i.e., volatile) storage area for both program code and data. On the motherboard of a PC, the read-only memory (ROM) is largely used for storing the low-level code used to access the input/output hardware, e.g., the BIOS (basic input–output system). The operating system and applications software are loaded into RAM from the disk unit. In small, dedicated systems such as an oscilloscope the ROM may be used to store the program code to avoid the need for a disk drive. For small production runs or development work, erasable programmable ROM (EPROM) is used as an alternative to ROM, allowing the code to be upgraded without the high cost of commissioning a new ROM chip from the manufacturers.

Data are transferred around the SBC on its data bus, which will be typically 8, 16, or 32 bits wide (corresponding to the number of bits that can be transmitted at the same time). SBCs with 8 bit data buses are less complex and consequently of lower cost than 32 bit systems and may well be the optimum solution for those process control applications which require minimal processing of 8 bit data, e.g., from temperature and position sensors. However, the 32 bit bus width of most modern PCs and workstations is essential to ensure the fast operation of Windows-based applications software.

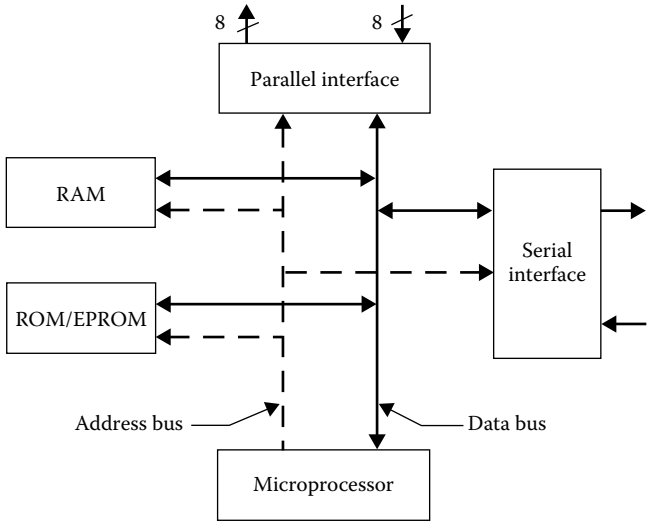

FIGURE 89.2 An overview of a single-board computer.

The address bus is used to identify the destination of the data on the data bus. Data transfer is usually between the microprocessor and the memory or interfaces. However, some SBCs support direct memory access (DMA) which allows data to be transferred directly between interfaces and memory without the need the information to pass through the processor. DMA is inherently faster than program-driven data transfer and is used for moving large blocks of data, e.g., loading programs from disk or the transfer of digitized video images.

SBCs are fitted with interfaces to allow them to communicate with other circuits. Interfaces carry out two main functions. First, they serve to ensure that the signals on the internal buses of the SBC are not affected by the connection of peripheral devices. Second, they ensure that signals can pass into and out of the computer and that appropriate voltage levels and current loading conditions are met. A well-designed interface should also provide adequate electrical protection for the SBC from transients introduced via the external connection. Parallel interfaces allow data to be transferred, usually 8 or 16 bits at a time, and contain registers that act as temporary data stores. Serial interfaces must carry out the conversion of data from the parallel format of the internal SBC data bus to and from the serial format used by the interface standard (e.g., RS-232, RS-422, or USB). Some SBCs may contain additional interfaces to support communication with a VDU, local area network (LAN), or a disk drive. Interfaces can range in complexity from a single parallel interface chip to a LAN controller which may require a significant fraction of the SBC board area.

89.2.2 Computer Bus Architectures

All but the simplest computer systems contain several circuit board cards which plug into a printed circuit board backplane. The cards will include at least one SBC and a number of "add-on" cards providing functions such as interfaces to peripherals (e.g., a LAN, graphics display, disk unit) or additional memory. The actual structure of bus architectures is quite variable but the simple model shown in Figure 89.3 contains the essential features. A group of tracks will carry the data and address information with a second group of tracks being used to control the flow of data and to ensure its reliable transfer. Other tracks are reserved for the signals which provide arbitration between SBC cards to ensure that only one such card has control of the bus at any given moment. There will also be tracks which provide utility functions such as clock signals and the transmission of event or interrupt signals.

The main advantage of bus-based systems is that they help one build a complex computerized system using standard cards. By conforming to agreed standard buses (see Table 89.1 for typical examples), the

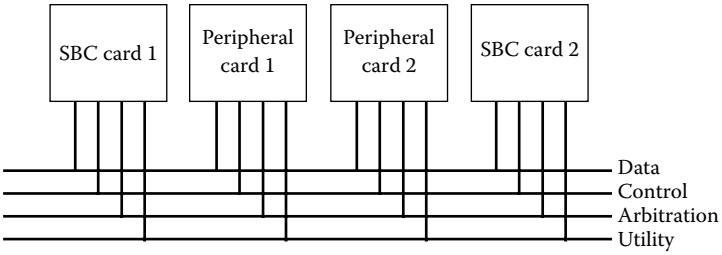

FIGURE 89.3 A simplified model of a computer bus.

TABLE 89.1 Typical Microprocessor Bus Standards

Bus Standard	STE	G96	VME	Multibus II
Data width (bits)	8	8/16	8/16/32	8/16/32
Max address (bytes)	1 M	32 M	4 G	4 G
Synchronous/asynchronous	Async	Async	Async	Sync
Connectors	64 pin	96 pin	96 pin	96 pin + 32 pin

system integrator can minimize problems of incompatibility and keep system costs to a minimum. The complexity of many bus systems is such that a significant fraction of the area of each card is dedicated to providing the logic required to interface to the bus, adding appreciably to the cost. In addition, data transfer between cards, even using DMA, is relatively slow compared with transfers between chips on the same SBC. There is, therefore, a trade-off between integrating functions on a single SBC and a lack of flexibility in customizing the system. An alternative to bus-based systems is to utilize processors such as transputers which are designed to be connected together directly into multiprocessor structures.

Most modern computerized systems adopt some form of distributed intelligence strategy in order to free the central processor unit to run the main application. Graphics controller cards generally employ a dedicated graphics processor able to handle the creation of the basic features such as line drawing or scaling the size of objects. LAN controller cards require intelligence to handle the network protocols and buffer the data flow to and from the network. Disk controller cards relieve the central processor of the need to handle the processes of reading and writing to the disk.

The use of a bus system with more than one SBC allows the designer to dedicate an SBC to the process of data acquisition and temporary data storage in order to ensure that the main SBC can concentrate on data processing and communication with the user. Such a strategy enables the data acquisition SBC to maintain a real-time response to making measurements while allowing the user access to processed data. In most systems, one of the SBCs acts as a system controller, which has ultimate control over the use of the bus and will normally contain the bus arbitration hardware. Only one SBC at a time can obtain the authority of the controller to act as a bus master and initiate data communication. The other cards will be configured as slaves allowing them to respond to requests for information from the master. In some systems, e.g., Multibus II, bus arbitration is distributed throughout the intelligent cards.

89.2.3 Industrial Computers

Many instrumentation systems utilize standard PCs or workstations either fitted with add-on cards or linked to intelligent instruments via standard protocols such as IEEE-488 or RS-232. In many industrial environments, there is a need to provide protection against hazards such as dust, damage by impact or vibration, and unauthorized access. The systems may have to fit more stringent electromagnetic compatibility (EMC) requirements. Industrial or ruggedized versions of desktop computers are available to meet this market. Cardframes designed to accommodate the standard industrial bus systems such as VME and Multibus can be readily customized to meet the demands of the industrial environment and

ruggedized versions of PCs are also available. In designing industrial computers, care must be paid to the specification of adequate power supplies, both to provide sufficient current for the add-on cards and also to provide protection against fluctuations in the mains supply. It may also be necessary in safety critical applications to use an uninterruptable power supply that will guarantee the operation of the system during short failures in the mains supply.

89.2.4 Software

All but the simplest computer systems require an operating system to support the operation of applications software. The operating system will allocate areas of memory for use by the applications programs and provide mechanisms to access system resources such as printers or displays. Some operating systems, such as MS DOS, are single-tasking systems, meaning that they will only support the operation of one program or task at a time. Instrumentation systems which simultaneously take measurements, process data, and allow the user to access information generally require a multitasking operating system, such as OS-9, UNIX, or Windows 95. In such instrumentation systems the applications software may well comprise a single program, but it may generate software processes or tasks each with their own local data and code. The multitasking operating system will allow the actual execution of these tasks to be scheduled and also provide mechanisms for communication of information between tasks and for the synchronization of tasks.

Instrumentation systems are real-time environments, i.e., their operation requires that tasks be carried out within specified time intervals; for example, the capture of data must occur at specified moments. Operating systems adopt a range of strategies for determining the scheduling of software tasks. Round-robin scheduling, for example, provides each task with execution time on a rota basis, with the amount of time being determined by the priority of the task. Operating systems which support preemptive scheduling allow high-priority tasks to become active if a specified event such as trigger signal occurs. The speed at which an operating system can switch from one task to another (i.e., context switch) is an important metric for real-time systems.

The extent to which an operating system can respond to a large number of events is extremely limited, as low-priority tasks will have a poor response time. If an instrumentation system needs to make a large number of measurements and also supports other activities, such as information display, the solution is generally to use a distributed system with dedicated SBCs operating as microcontrollers to capture the data. These microcontrollers will not usually require an operating system and will each operate a single program which will be either downloaded from the master SBC or located in ROM.

Commercial packages (e.g., see Table 89.2) are readily available to support PC/workstation-based instrumentation systems. A typical system will provide a Windows-type environment to control measurements and store, process, and display data and increasingly make use of the virtual instrument concept which allows the user to configure instrumentation systems from an on-screen menu. Most packages will allow stand-alone instruments to be controlled using interface cards supporting standards such as RS-232 or USB. Some packages also support the use of add-on cards for analog-to-digital conversion or a range of control functions such as channel switching and waveform generation; however, their main restriction is the limited range of hardware configurations supported by the software supplier. Each stand-alone instrument and add-on card requires a piece of code called a device driver so that the operating system can access the hardware resources of the card and instrument. Therefore, the development of device drivers requires an intimate knowledge of both the hardware and the operating system.

89.2.5 System Development

The software component of any computerized instrumentation system can form a significant percentage of its total cost. This is especially true of on–off systems which require software to be developed for a specific application, where the cost of the implementation of the software and its maintenance can

considerably exceed the hardware costs. In such circumstances, the ability to reuse existing code and the access to powerful development systems and debugging tools are of crucial importance. Some debug software only provides support for stepping through the operation of code written at the assembly code level. When developing device drivers, for example, access to a source-level debugger which can link the execution of code written in a high-level language to the contents of processor registers is useful.

Many SBCs that are intended for operation as stand-alone microcontrollers, instead of in bus-based systems, are often supported by a high-level language such as C or FORTH and a development environment. A common practice is to utilize a PC to develop the code which can be downloaded via a serial link to the microcontroller. Some debugging support for the execution of the code on the microcontroller is also provided. The development of powerful compact Intel 486 or Pentium microcontroller cards running operating systems such as MS DOS can greatly reduce software development time because of the ready access to PC-based software. The implementation of systems based on dedicated microcontrollers may require the use of a logic analyzer to view data on system buses.

89.3 Computer Buses

89.3.1 VMEbus (IEEE P1014)

The VMEbus [1–3] utilizes a backplane fitted with two 96-pin connectors (called P1 and P2). The P1 connector provides access to all the bus signals with the exception of bits 16–31 of the data bus and bits 24–31 of the address bus, which are provided on the P2 connector. The location of cards in a VME system is important, as slot 1 must contain the system controller and the priority of the SBCs is determined by their proximity to the system controller SBC. As only 32 of the pins on the P2 connector are defined,

the remaining 64 tracks on the P2 backplane may be specified by the user. VME cards may be single height (fitted with a P1 connector only) or double height (fitted with both P1 and P2 connectors). Single-height boards are 100 mm high and 160 mm deep and fit 3U height cardframes. Double-height boards are 233.35 mm high and 160 mm deep and fit 6U height cardframes.

89.3.2 VMEbus Signals

The VMEbus can be described as having four distinct groups of signals.

89.3.2.1 Data Transfer Bus

The Data Transfer Bus (DTB) provides 32 bit data transfer with 32 bit address information using a non-multiplexed asynchronous approach. Transfer is supported by a simple handshake mechanism with the bus master initiating the transfer providing an address strobe (AS) signal to tell the destination card to read the address information. The master also controls two data strobe (DS1 and DS2) lines which in a write operation indicate the presence of valid data on the data bus and in a read operation that the master is ready to receive data from the slave. The slave card uses the data acknowledge signal (DTACK) in a read operation to indicate that it has placed valid data on the bus and in a write operation to confirm that it has read the data. There is clearly a danger that the bus will hang up if the slave does not respond to a request for a data transfer, so in most VME systems a watchdog timer is provided to produce a signal on the bus error (BERR) line if a DTACK signal is not detected within the time-out period.

Revision C of the VME bus specification will support 8, 16, and 32 bit data transfers, whereas revision D supports 64 bit transfers by making use of the address bus to transfer the additional 32 bits. Data may also be transferred in blocks of up to 256 bytes without the need to retransmit the address information. Most SBCs have both master and slave interfaces allowing their memory to be accessed from other SBCs in the system. The VME bus also supports three types of addressing mode, short (16 bits), standard (24 bits), and extended (32 bits), allowing the memory decoding circuitry of cards to be minimized for small systems or for input/output cards. Six address modifier lines (AM0–AM5) are used to indicate the addressing mode and also to give information about the mode of transfer (e.g., block transfer and whether the transfer is in privileged, supervisor, or nonprivileged mode).

89.3.2.2 Arbitration Bus

The arbitration bus provides a mechanism for deciding which master is allowed to gain control of the bus. The arbitration bus provides four bus request lines (BR0–BR3) and four bus grant lines. The SBC in slot 1 of the VME bus acts as a bus controller which provides arbitration using a number of scheduling algorithms. In a simple priority-based algorithm each of the bus request lines is assigned a priority, whereas in a round-robin system access to the bus cycles around the bus request lines. Each of the four bus grant lines is in fact allocated two pins on the P1 connector (see Figure 89.4). The bus grant signal therefore passes through each card (called daisy chaining); thus in Figure 89.4, the signal enters via BG1IN and exits via BG1OUT. This scheme allows a card to intercept the bus grant signal, giving cards nearer the system controller a higher priority. A consequence of daisy chaining is that any unused card slots must be fitted with jumpers between the bus grant pins.

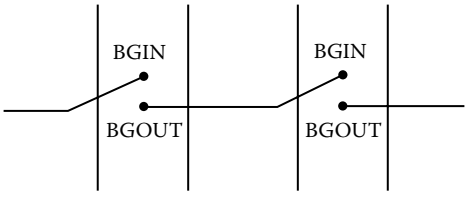

FIGURE 89.4 VMEbus arbitration daisy chain.

89.3.2.3 Priority Interrupt Bus

The priority interrupt bus provides seven interrupt request lines (IRQ1 to IRQ7) with IRQ7 having the highest priority. The interrupt requests may be handled by several SBCs, provided that all interrupts of the same level are handled by the same master. The interrupt acknowledge line is daisy chained through the cards in a similar way to the bus grant lines (the pins are called IACKIN and IACKOUT). Again, any unused card slots must be fitted with jumpers between these pins.

89.3.2.4 Utility Bus

The utility bus provides the power supply tracks, the system reset, a 16 MHz clock, and two system failure lines, SYSFAIL, which allows a card to indicate that it has suffered a failure, and ACFAIL, which is generated by the power supply monitor. Both failure lines are handled by the system controller SBC.

Associated with the VMEbus is VXI (VMEbus extensions for instrumentation). This blends the IEEE 1014 VMEbus standard with the IEEE-488 instrumentation bus using the uncommitted pins on the P2 connector to form the IEEE P1155 standard.

89.3.3 Multibus II (IEEE 1296)

Multibus II [3] is a synchronous bus system which is implemented on a single 96-track backplane. Cards conform to the Eurocard format of 220 × 233.65 mm; however, the bus requires only a single 96-pin DIN 41612-type connector. A second connector may be used to support a local bus or merely provide mechanical stability for a double-height card.

Unlike VME, the Multibus II standard has the following features:

1. A synchronous bus, i.e., data transfer is linked to the bus clock rather than the strobe/acknowledge control lines of the asynchronous VME system
2. A 32 bit multiplexed address and data bus
3. A message-passing strategy as an alternative to interrupt request lines
4. Distributed bus arbitration rather than a central system controller (each card contains a message-passing controller [MPC] chip which participates in implementing the message-passing algorithm)
5. Only intelligent cards (i.e., fitted with microprocessors) that can interface to the main bus; simple input/output (I/O) cards should make use of a local bus (e.g., the iLBX bus) using the second DIN connector

89.3.4 Multibus Signals

Multibus II may be described as having five distinct groups of signals.

89.3.4.1 Central Control

The central services module (CSM) in slot 0 is responsible for the generation of this group of signals. The CSM may be implemented on a dedicated card or incorporated onto a SBC. The CSM produces the 10 MHz bus clock as well as a range of reset signals to support both a cold and warm start as well as recovery from power supply failure.

89.3.4.2 Address/Data

Multibus II supports a 32 bit multiplexed address/data bus (AD0–AD31) with four parity lines (PAR0–PAR3) providing parity information for each data byte. As in all synchronous systems, data are only sampled on an edge of the system clock, a feature that enhances noise immunity.

89.3.4.3 System Control

There are 10 system control lines (SC0–SC9) which provide basic handshake information to assist data transfer, e.g., requester is ready or replier is not ready. In addition, these lines are used to convey information such as data width, data error indication, and whether the bus is in the request or reply phase.

89.3.4.4 Exception Signals

Two exception signals, bus error (BUSERR) and time-out (TIMOUT), are provided. Any card detecting a data integrity problem must report this to all other cards using BUSERR. The CSM generates a TIMOUT when it detects a data communications hang up on the bus.

89.3.4.5 Arbitration Group

The arbitration signals, which determine which card gains control of the bus, consist of a single bus request line (BREQ) and six Bus Arbitration lines (ARB0–ARB5). To request exclusive use of the bus, a card asserts the BREQ line and provides it arbitration ID on ARB0–ARB4. It also uses ARB5 to indicate whether the request has high priority or whether "fairness mode" is acceptable. In this latter mode, the card will not make another request until after all other requesters have used the bus. Each card has the same bus arbitration logic within its MPC chip. If several cards make high-priority requests, the order of access is determined by the numerical value of the arbitration ID.

89.3.5 Message Passing on Multibus II

Multibus II uses message passing to implement block data transfers and interrupt requests. Each MPC chip contains a first-in first-out (FIFO) buffer, which ensures that the full bandwidth of the bus can be utilized by storing data immediately before or after transfer. In "solicited" transfers, the MPCs cooperate by warning each other that a message is to be sent. These messages may be sent as 32 byte packets in a manner that is analogous to the block transfer mechanism in VME. "Unsolicited" packets not expected by the receiving MPC are used to set up a block transfer or to act as the equivalent of interrupt request signals.

89.3.6 System Configuration

Multibus II employs a software configuration approach in which information such as the base memory address and arbitration ID are sent down the bus rather than by the use of jumpers or dip switches. Some information such as card type and serial number are coded on the cards themselves.

89.3.7 Other System Buses for Small-Scale Systems

The G64/G96 and STE standards [3] are examples of buses well suited to small industrial real-time instrumentation and control systems because of their relatively simple and hence lower-cost bus interfaces, compared with VME and Multibus. Both buses support DMA, have multiprocessor bus arbitration, and use single-height Eurocard (100 × 160 mm) cards. Prototyping cards fitted with bus interfaces are readily available and may be used to develop custom-designed I/O cards. Power is supplied on the buses at +5 and ±12 V. In addition, the real-time multitasking operating system OS-9 has been ported onto SBCs which operate with these buses. Development systems that support the use of MS-DOS are also available, thus providing access to a wide range of PC-based software especially for graphics applications.

The G64 bus, which was defined by the Swiss company Gespac in 1979, specifies 64 bus lines which are mapped to rows of a DIN41612 connector. The bus has a 16 bit nonmultiplexed data bus and a 16 bit address bus; 32 bit transfers may be achieved by multiplexing the upper 16 bits of the data bus with the address bus. The G96 standard adds a further 32 bus lines by making use of the third row of a DIN41612 connector to extend the address bus width to 24 bits and provide additional interrupt request lines. The STE bus provides an unmultiplexed 8 bit data and 20 bit address bus using 64-pin DIN41612 connectors.

89.4 PC Buses

There are three main bus standards for PCs—industry standard architecture (ISA), extended ISA (EISA), and the microchannel architecture (MCA). In addition, the Personal Computer Memory Card International Association (PCMCIA) architecture has been developed primarily for use in laptop and notebook computers.

ISA and EISA are pin-compatible and are both synchronous buses with a clock rate of 8 MHz regardless of the clock rate of the main processor, whereas the MCA bus is an asynchronous bus. Slow slave add-on cards can utilize the ISA and EISA buses by using an appropriate number of wait states. The MCA architecture will not be covered in this chapter. Further details of these bus architectures are given in Refs. [4–6].

89.4.1 ISA Bus

The original IBM PC and its clones used the standard PC bus which supported 8 data bus and 20 address bus lines and employed a 62-pin printed circuit card edge connector. When IBM introduced the PC-AT, a second 36-pin connector was added to the motherboard backplane slots to provide a 16 bit data bus and increase the number of address lines to 24. This new bus subsequently became known as the ISA bus and is capable of supporting both cards designed for the original PC bus, and cards with two connectors providing full 16 bit data access. The bus master line allows a card to take over control of the bus; however, this is generally only suited to long-term takeovers. The ISA bus supports 8 and 16 bit DMA transfers allowing efficient transfer of blocks of data, e.g., while loading software from disk into RAM. The ISA bus supports the I/O addressing mode of the Intel 80 × 86 range of processors with an I/O address space of 768 locations in addition to the 256 locations reserved for the motherboard.

89.4.2 EISA Bus

The EISA bus provides full 32 bit data and 32 bit address bus lines. ISA cards can fit into EISA bus connectors; however, cards designed for the EISA standard have bilevel edge connectors, providing double the number of contacts as an ISA card. The presence of a notch in the EISA cards allows them to be inserted farther into the motherboard socket than the ISA cards and thus mates with the additional contacts. The EISA standard increases the maximum ISA data width in DMA transfer to 32 bits and also provides a much-enhanced bus master. The following features of EISA are worthy of note.

89.4.3 Bus Arbitration

All EISA systems have a central arbitration control (CAC) device on the motherboard. The CAC uses a multilevel rotating priority arbitration scheme. The top-priority level rotates around three customers, the DMA controller, the dynamic memory refresh controller, and, alternately, either the main CPU or one of the bus master cards. A device that does not make a request is skipped over in the rotation process. The bus masters take it in turns to gain access to the top-priority level. Whereas ISA supported a single bus request line, the EISA standard provides a dedicated pair of request lines (MREQO to 14) and acknowledges lines (MAKO to 14) for each bus master. (*Note*: Although this allows 15 bus masters to be used, in many systems the chip set which implements the CAC supports bus masters in a limited number of the EISA sockets.) The CAC supports preemption, i.e., it allows a device making a request to capture control from another device if it is next in turn. A bus master card must release the bus within 64 bus clock cycles, whereas a DMA controller has 32 clock cycles to surrender the bus.

89.4.4 Input/Output

The EISA bus provides 768 additional I/O locations for each slot in addition to the 768 ISA I/O locations that may be accessed from any slot. EISA cards contain nonvolatile memory to store configuration information (see later), and a minimum of 340 bytes of the I/O address space of each slot is reserved for this purpose.

89.4.5 System Configuration

The EISA system provides support for automatic system configuration to replace the use of jumpers and dip switches to specify parameters such as the base memory address, interrupt request line number, or DMA channel number used by each add-on card. Information on the product type and manufacturer are stored on each EISA add-on card is read by the CPU during system start-up, making it possible to identify the slots that are fitted with full EISA cards. Manufacturers of both ISA and EISA cards should supply a configuration file containing information on the programmable options that are available. When a system configuration program is run, an optimum configuration of the boards will be determined, and the configuration information written into the I/O space of each EISA card. For ISA cards, the user can be informed of the required jumper settings.

89.4.6 PCMCIA

The PCMCIA architecture was developed by the PCMCIA and the Japan Electronics Industry Development Association for removable add-on cards for laptop and notebook computers. Each PCMCIA socket has its own host bus adapter (HBA), which acts as an interface to the main computer bus. Cards may be plugged into PCMCIA sockets either before or after the computer has been powered up. There are three types of PC card all with the same planar dimensions (54.00 × 85.6 mm) but with differing thicknesses, namely, 3.3 mm for type I, 5.0 mm for type II, and 10.5 mm for type III. Cards and sockets are keyed to prevent them from being inserted the wrong way round. The PCMCIA standard supports cards that operate at several possible voltage levels, i.e., 5.0 V cards, 3.3 V cards, or dual voltage 5.0 V/3.3 V cards.

89.4.7 Configuration

PC cards contain configuration information called the card information structure (CIS) which is stored in nonvolatile memory. Cards may be configured either on system power-up or on insertion of the card into the socket (i.e., plug and play). Configuration is carried out using a form of device driver called an enabler. The enabler may make use of two additional software services called card services and socket services. Socket services, which may be contained in ROM on the PC or loaded from disk during power-up, provide function calls to allow the HBA to be configured to cooperates' computers. Card services, which may be an extension to the operating system or an installable device driver, act as a server for the enabler, which performs as a client. Card services provide a range of functions such as accessing the CIS of the card, requesting system resources required by the card, and telling the enabler that a card has been inserted or removed from the socket. Enablers may be classified as dedicated to one particular card or generic, i.e., designed for a range of cards. Note that early PCMCIA cards were not designed for use with card services.

89.4.8 PCMCIA Socket Interface

The PCMCIA socket comprises a 68-pin connector with 26 address lines providing access to 64 MB of memory space and a 16 bit data bus. Two V_{cc} pins and four ground pins are supplied. The maximum current that can be supplied to the card is 1.0 A with a maximum of 0.5 A from each of the two power supply pins. Release 2.x sockets apply 5.0 V to the V_{cc} pins on power-up and reduce this to 3.3 V if the card has dual-voltage capability. Cards that operate at 3.3 V only are keyed so they cannot fit into this type of socket and only into low-voltage sockets. The supply voltage provided by low-voltage sockets depends on

the logic state of its voltage sense inputs. A PCMCIA socket can be configured either as a *memory-only* socket or as a *memory or I/O socket*. Initially, the socket acts as a memory-only socket but is converted by the enabler to a memory or I/O socket if the card is required to support I/O functions. In this mode, the card can generate an interrupt request via a single IRQ pin and support both 8 and 16 bit I/O data transfers. DMA may be supported but not by Release 2.x systems.

89.4.9 PC/104

The enormous popularity of PC architecture resulted in its use in embedded systems. A need then arose for a more compact implementation of the ISA bus that could accommodate the reduced space and power requirements of embedded applications. The PC/104 specification (1992) was adopted as the base

for an IEEE draft standard called the P996.1 Standard for Compact Embedded PC Modules. The key features of the PC/104 are

- Size reduced to 90 × 96 mm (3.550 × 3.775 in.)
- Self-stacking bus allowing modules to be "piggy-backed" and eliminating backplanes or cardframes
- Rugged 64-contact and 40-contact male and female headers replacing the PC edge connectors (64 + 40 = 104, hence PC/104)
- Lower power consumption (<2 W per module)

PC/104 CPU modules range from a basic 9.6 MHz, 8088 compatible XT with one serial port and a keyboard connector to a 100 MHz, 80486DX4 with four serial ports, parallel port, IDE disk controller, display controller, Ethernet adapter, keyboard port, and up to 64 MB of on-board RAM. Pentium-based systems are also available. Systems can be customized from a wide range of modules, including data acquisition boards, solid-state disk modules, and LAN support, all in the same 3.6 by 3.8 in. stackable format.

The wide availability of software development tools for the PC, the large number of software developers familiar with the PC environment, and the ease of transferring software developed on a conventional PC to the PC/104 make this an increasingly popular format.

Table 89.3 lists some manufacturers and suppliers of bus-based systems and industrial computers.

89.5 Peripherals

Computer peripherals fall conveniently into two categories. The first category may be considered to be internal to the computer system and comprises cards plugged directly into a computer bus slot. The second category comprises instruments external to the computer but controlled by it. These external instruments are usually themselves "intelligent," being controlled by their own CPU, and are linked to the main computer by a serial (RS-232 or USB) line or the IEEE-488 bus (GPIB). Such instruments may normally be operated in a stand-alone mode in response to their front panel controls without the requirement of an external computer.

89.5.1 Internal Cards

Internal cards are available to perform a wide range of functions. Table 89.4 provides a brief list of representative types. Note that both the serial interface and the IEEE-488 adapter required for the control

TABLE 89.4 Typical Internal Peripherals

Card Type	Facilities Offered
Display adapter	Provides video and graphics facilities
Serial communications adapter	Serial communication to a similar device using the RS232, RS422, or RS485 standard
IEEE-488 adapter	Communication with intelligent instruments using the IEEE-488 bus (GPIB)
Digital input/output (I/O)	Individual I/O lines, normally grouped as an 8 bit byte, which may be used to provide logic high and low signals (output) or sense logic high or low signals (input); inputs and outputs may be optically isolated; outputs may drive relays
Counter/timer	Hardware counter timer allowing external pulses to be counted, digital waveforms generated or pulse widths measured; counter/timers are often available as an additional facility on digital I/O cards
Analog input	Converts an analog input voltage to an integer value which may be read by the computer; resolution typically 8, 10, 12, or 16 bits; input voltage range may be fixed or may be user selectable; conversion times vary from several seconds to tens of nanoseconds
Analog output	Produces an analog output voltage proportional to a digital input; resolution typically be 8, 10, 12, or 16 bits

of external "intelligent" peripherals will be fitted as internal cards. Almost all internal peripherals need to be configured before use to set up such parameters as the base address, the interrupts, and/or DMA channels used. This may involve setting jumpers or switches on the card or may be accomplished under software control using a configuration file supplied by the manufacturer. To operate the cards, bytes are written or read from appropriate addresses on the cards by the controlling SBC. The mechanism for doing this is discussed further in the section concerned with software for data acquisition. Further detail on some of the card types is given later.

89.5.2 Display Adapter

While graphics support is normally available as standard on a PC-based system, this is not the case with other bus-based systems such as VME or Multibus. These systems are provided with a serial port that may be connected to a terminal to provide a text-only dialog with the operating system running on the SBC. In such circumstances the choice of display adapter will be determined by the user requirements, taking into account the support for the device provided by any software packages that are to be used. If the user intends to write custom graphics software, it is essential to ensure that a graphics library is available from the vendor providing as a minimum line drawing, arc drawing, and block color fill facilities.

89.5.3 IEEE-488 Adapter

This device provides support for communications across the IEEE-488 bus or GPIB (general-purpose interface bus). The bus itself comprises eight data lines, five interface management lines, and three handshake lines. Transfers are parallel, synchronous, and at rates up to 1.5 MB/s. The IEEE-488 bus and its applications are discussed further in the section on external instruments.

89.5.4 Serial Communications Adapter

This device provides support for serial communications using the RS-232, RS-422, or RS-485 standards. It is used to provide a text-based terminal for systems based on Multibus or VME and to communicate with "intelligent" instruments such as position controllers, multimeters, or storage oscilloscopes fitted with similar interfaces.

Serial adapters convert parallel data to and from a bit stream in which each data byte (5, 7, or 8 bits) is framed by a start bit, an optional parity bit, and one or more stop bits. The bit stream may be sent via a circuit consisting of only two wires at rates of up to 115,200 bits per second (commonly referred to as 115,200 baud). Common bit rates are 300, 600, 1200, 2400, 4800, 9600, 19,200, 28,800, 38,400, 57,600, 115,200 baud. Both the transmitting and receiving adapters must be configured, normally by software, for the same baud rate, number of data bits, stop bits, and parity. Some form of flow control to prevent a receiver from being overloaded with incoming data is essential. This is accomplished either by separate handshake lines (e.g., those denoted by RTS and CTS in the standard) or by software where the receiver sends a special control byte (XOFF) back to the transmitter telling it to stop sending until it receives a second control byte (XON) to reenable it. For historical reasons, the RS-232 standard does not define a bidirectional handshake procedure, and manufacturers have been forced to implement their own schemes which are not always compatible with each other.

Serial communication between devices may be

Full duplex, where either device may transmit or receive data at any time
Half duplex, where both devices are capable of transmission or reception but only one may transmit at any instant

Simplex, where one device is a transmitter, one is a receiver, and data can only flow in a single direction

RS-232, developed by the Electronics Industries Association (EIA), is the oldest standard, originally developed in the early 1960s, to allow mainframe computers to communicate with terminals via modems

and telephone lines. This is the origin of the names of some of the connections (e.g., RI ring indicator, DCD data carrier detect), which have no relevance in the applications considered here. A related problem is that the standard expects that the devices being connected are data terminal equipment (DTE), at one end of the link, and data communication equipment (DCE) at the other. Computers and terminals are DTE, while modems are DCE. The most commonly used revision of the standard, RS-232-C (revisions D and E also exist), was made in 1969 and is still widely used. Serial communication is made using voltage levels in the region of ±12 V, over distances up to 15 m (50 ft) at speeds up to 20,000 baud.

RS-422, also developed by the EIA, is an enhancement of the RS-232 standard. Differential transmitters and receivers are employed which allow one transmitter to drive up to 10 receivers, using a twisted-pair connection for each circuit, at bit rates up to 10 Mbaud at distances up to 12 m (40 ft) or 100 kbaud at distances up to 1200 m (4000 ft). The RTS and CTS lines (defined in the standard) are used for flow control, while the RXD and TXD lines are used to transmit and receive data. Thus, a two-twisted-pair cable is required for duplex connection without hardware handshaking. A four-twisted-pair cable is required if hardware handshaking is used.

RS-485 is based on RS-422 and allows up to 32 driver/receiver pairs to be connected to a common data bus (two-twisted pairs). Clearly, only one device can be allowed to transmit at any one time. The RTS circuit is used to disable the other transmitters connected to the bus if a device is required to transmit data. Handshaking is performed using software.

The serial interfaces on instruments are usually configured as DTE devices. We are faced with the problem of connecting one DTE device (the computer serial interface) to another (the instrument), which is not what the RS-232 standard was designed for. Furthermore, since the standard does not define a bidirectional handshake to control data flow, several incompatible handshaking schemes exist. A comprehensive survey of these is presented in Ref. [7]. A common solution to the DTE to DTE connection problem is the so-called *null modem*, which nothing more than a specially wired cable. Figure 89.5 shows two such connection schemes. One requires the software handshaking procedure and the other implements a bidirectional hardware handshake. The reader should refer to Ref. [7] for details of other schemes and for the definitions of the mnemonics used to label the connections.

Some common problems encountered in practice are

1. The received data are garbage. This is almost always due to the baud rate, parity, and number of stop bits not being the same at both ends of the link.
2. Data initially correct, but parts in the middle are missing. This is probably a handshake problem. The transmitting device is sending data faster than the receiver can process it.
3. No communications at all. Probably a handshake problem where the transmitter does not sense that the receiver is ready.

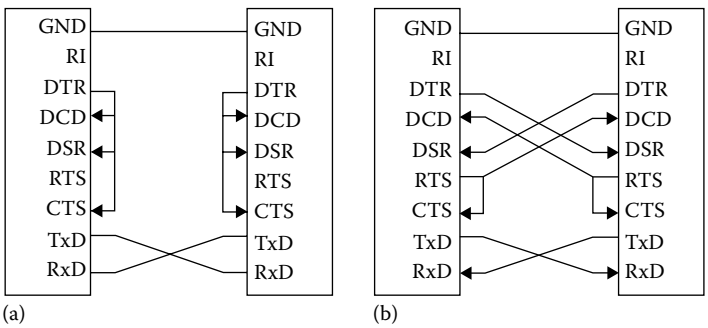

FIGURE 89.5 Two null modems for connecting DTE to DTE. In (a), all handshaking must be in software. The DTR line "fools" the serial interface that it is connected to the handshake lines of another device. Scheme (b) implements a hardware handshake. The DTR–DSR connection shows each device that the other is present. The RTS lines, connected to the DCD of the other device, which it can monitor, are used to control the flow of data in either direction.

89.5.5 Digital Input and Output

These cards provide I/O lines, normally in groups of eight, which may be used to sense or generate digital signals for devices outside the computer. A group of eight input lines is referred to as an (8 bit) input port and a group of eight output lines as an (8 bit) output port. Input and output levels vary from card to card and it is best to consult the appropriate data sheet. Typically, voltages between 2.5 and 5.0 V are considered as high logic levels, whereas voltages between 0.0 and 0.5 are considered as low logic levels. These levels are sometimes referred to loosely as transistor–transistor logic (TTL) levels. Note that the actual logic levels used by the various TTL families differ from these slightly. The "high" and "low" ranges may be slightly different for input and output lines. Output lines often have limited current sourcing and sinking abilities compared with TTL, and it is therefore often necessary to buffer them. It is important that voltages exceeding the maximum rated values do not appear on inputs or outputs (e.g., attempting to switch an inductive load might produce a dangerously high transient voltage at an output); otherwise, the device may be damaged. Where this is likely to be a problem, inputs and outputs should be suitably buffered or even optically isolated, which provides protection up to a few kilovolts. Outputs may also drive appropriately connected relays. I/O cards with these facilities on board are readily available.

As a minimum, I/O card may be expected to support a control register, two I/O ports each with an associated data register, and some handshake lines. Handshake lines may sometimes be used to generate interrupts on the controlling SBC. A byte written to the control register is used to configure the I/O ports, i.e., to determine if they are to behave as input or output ports as well as to select the function, if any, of the handshake lines. It may not be possible to select the direction of optically isolated or buffered ports. Writing a byte to an output port causes a pattern of high and low voltages to appear on the lines reflecting the pattern of zeros and ones in the binary representation of the byte written. Similarly, when a byte is read from an input port, the number read is specified in binary representation by the pattern of high and low logic levels on the input lines. The following example illustrates this.

The Intel 8255 Programmable Peripheral Interface (PPI) is commonly used in digital I/O cards for the PC. Data for this device are readily available [8]. The 8255 provides three ports, denoted by A, B, and C, and a control register. Ports A and B may be designated as an 8 bit input port or an 8 bit output port. Port C may be considered as two independent 4 bit ports, which may be chosen independently as input or output. Port C may also provide handshake functions. There are three modes in which the chip may operate. The simplest case, mode 0, provides basic input and output without automatic handshaking, is used in our example. Note that the 8 bits of an I/O port are conventionally labeled bits 0–7. This is because bit 0 is weighted 2^0, bit 1 weighted 2^1, etc., in the binary representation of the number read from or written to the port.

To configure the PPI to operate in mode 0 with port A as an input port and port B as an output port, the bit pattern 10011001 must be written to the control register. This number is equivalent to 99 in hexadecimal or 153 in decimal. Suppose now that switches connected to port A hold bits 2 and 7 high and the remaining bits low. The resulting binary pattern will be 10000100, which is equivalent to hexadecimal 84 or decimal 132. When port A is read, the number 132 (decimal) will therefore be obtained. To hold the lines connected to bits 2, 3, and 5 of port B high while leaving the remaining lines low, we see that the binary pattern 00101100 must appear at port B. 00101100 binary is equivalent to 2C hexadecimal or 44 decimal. We therefore write the decimal number 44 to port B.

89.5.6 Counter/Timers

These devices typically provide software programmable event counting, pulse, and frequency measurement. As output devices, they may generate a single pulse (one shot) when a programmable number of input pulses have been counted and produce square waves of arbitrary frequency and complex duty cycles. Frequencies generated are normally based on an on-board crystal clock to provide independence

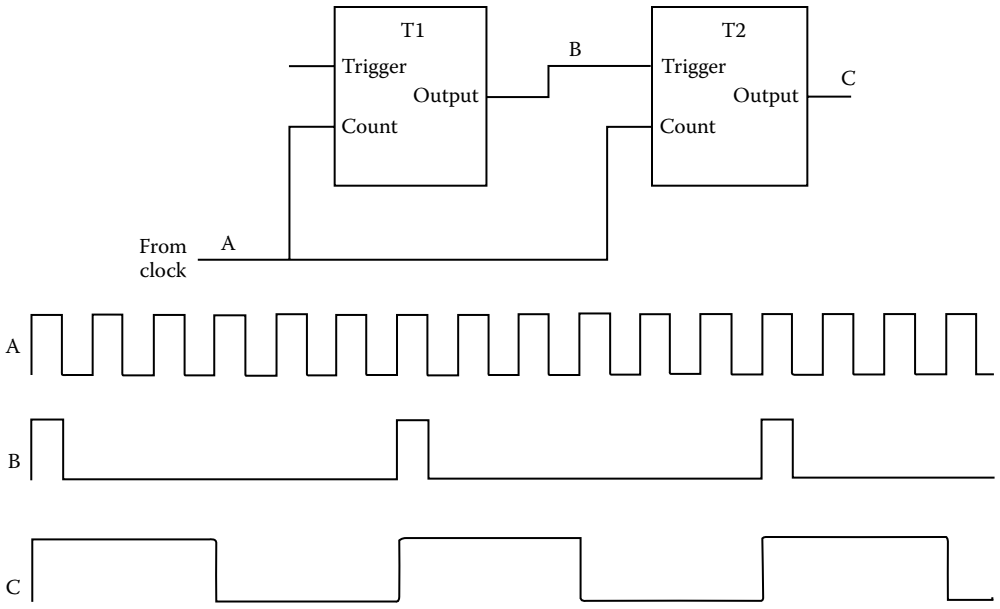

FIGURE 89.6 Using two timers to produce pulse-width modulation under software control. Both timers receive input pulses at a constant frequency from an external clock, as shown at A. Timer T1 operates in continuous mode. The trigger has no effect in this mode. The output of T1 is a single positive-going pulse when it has counted the specified (by software) number of input pulses, as shown at B. Timer T2 operates in one-shot mode. Each time it receives a trigger pulse, its output goes high for a specified (again by software) number of counts, as shown at C. In this way, the frequency of the output at C is controlled by the count specified for T1 and the width of the positive-going part of C is controlled by the count specified for T2.

from the internal clock speed of the computer. Counter/timer cards commonly support at least three independent 16 bit counters.

Common applications include

1. Alarms. The counter is in one-shot mode and generates a single pulse on time-out. This is connected to interrupt the computer and alert the user in the middle of the currently executing task.
2. Watchdog timer. This is used to detect problems, particularly in systems which are intended to operate without operator intervention. It is similar to the Alarm described earlier except that the interrupt is used to reset the computer. In normal operation, this will never occur as all software tasks executing are designed to update the counter constantly so that it never reaches its terminal count. Only if a problem develops, e.g., a software "crash," will the counter time-out and the system be reset.
3. The generation of complex waveforms, e.g., for pulse-width modulation. This application uses two counters in cascade, one (T1) to provide regular pulses at the carrier frequency triggering another (T2), in one-shot mode, to provide the variable duty cycle as shown in Figure 89.6.

89.5.7 Analog Input

An analog input card uses an analog-to-digital converter (ADC) that accepts an input voltage and supplies an integer proportional to that voltage to the computer. Many cards now are produced with on-board signal conditioning circuits that provide for variable gain either by means of switches or under program control. Cards with specialized signal conditioning circuits for common applications such as thermocouple linearization or interfacing to strain gages and other bridge sensors are available. Signal conditioning to protect cards destined to be used in hostile electrical environments is also available.

TABLE 89.5 Common ADC Parameters

Parameter	Description
Resolution	The smallest change in input detectable in the digital output; resolutions are commonly expressed in the number of significant bits in the digital output; hence, 8 bit resolution means 1 part in 256; 10 bit resolution, 1 part in 1024, and 12 bit resolution, 1 part in 4096
Linearity	The extent to which the output deviates from a linear relationship with the input; good devices will be linear to ±1 least-significant bit, i.e., the output value is guaranteed to be within ±1 of an exactly linear conversion
Range	The maximum (and minimum) input voltages; inputs may be unipolar, e.g., 0–5 V or bipolar ±5 V; voltages are specified relative to ground unless the inputs are differential, e.g., those designed for bridge sensors
Conversion speed	The time taken to convert an input voltage into a digital output, typically 1 s–1 μs; may also be quoted as a sample rate
Linearity	The extent to which the conversion is linear, e.g., a linearity of ±1 least-significant bit means that the output value is within ±1 of the ideal linear conversion
Input impedance	The impedance between the input terminal and ground or between differential inputs

Cheaper cards may provide fixed gain and require additional signal conditioning circuits to be provided external to the computer. Many cards also feature multiplexed inputs where one of the several inputs may be selected under program control to be fed to the ADC. Some important parameters to consider in selecting an analog input board are given in Table 89.5.

At rates above a few tens of kilohertz, interrupt-driven data capture is essential to maintain speed. Faster data rates require on-board memory to avoid degrading the performance of the controlling SBC. In this case, DMA may be used to transfer data to main memory and increase performance further.

A timer function is often incorporated to allow samples to be taken at regular intervals independently of what the controlling SBC is doing. An interrupt is generated when the conversion is complete, and an interrupt service routine is then activated to read the result of the conversion into memory. The writing and installation of interrupt service routines is not a trivial task and is best left to those with an intimate knowledge of the operating system running on the SBC. Fortunately, most manufacturers supply software (device drivers) for this purpose. The simpler analog input boards may be driven by writing values directly to registers on them in a similar manner to the example given for digital I/O cards. Manufactures now commonly provide a software library which may be called from a variety of high-level languages to allow the user to access the card in a more intuitive way. This is discussed further in the section on software.

89.5.8 Analog Output

Analog output cards are available as 8, 10, or 12 bit devices. Frequently, a card will support several channels of analog output with provision for delaying the updating of channels so that all can be updated simultaneously. Output voltages may be unipolar or bipolar and current outputs (4–20 mA) are also available. Signal conditioning (buffering) is necessary to drive loads drawing currents of more than a few milliamps. Special care should be taken with inductive loads, e.g., motors to avoid damage to the device by transient voltages. Specially designed position control modules incorporating suitably buffered analog and digital I/O are available for this purpose.

89.5.9 External Peripherals

These are usually "intelligent" devices which can operate via their front panel controls without another computer but are additionally capable of being controlled by a computer. Many common laboratory instruments are available with such facilities, including power supplies, signal generators, storage oscilloscopes, voltmeters, spectrophotometers, and position controllers. A computer can coordinate the

actions of several such instruments to gather then manipulate and display data in a way which enhances the power of the instrumentation system. An almost trivial example is the use of a computer to control a signal generator and a voltmeter in order to generate the frequency response of an amplifier automatically. Such a system has an obvious role in automatic testing rigs.

Two common methods are used to control such devices: a serial link or the IEEE-488 bus. In both cases, the devices are controlled by sending messages consisting of sequences of ASCII characters. Usually the sequences are chosen to have an obvious meaning, as in the example that follows, but this is not always the case—particularly with older devices where user friendliness was often sacrificed as a result of limited memory and processing power. The message sequence

"FREQ10kHz"
"SINE"
"1.0VOLTRMS"

might be used to set a signal generator to produce a 10 kHz sinusoidal signal at 1 V rms. There is little standardization in the form of device messages used although the IEEE standard 488.2 goes some way in this direction. Responses from instruments are sent in the same way, i.e., as ASCII characters so that a voltmeter might respond to a command to make a measurement with the data

"AC2.01mV"

to indicate that it was on an ac voltage range and measured 2.1 mV. Again, there is little standardization in the format of responses. Large blocks of data may be sent in a binary format where possible (8 bit serial links or IEEE-488 bus) to minimize the amount of data to be transferred.

89.5.10 Serial Devices

Serial control of devices is accomplished using links conforming to one of the serial standards (RS-232, RS-422, or RS-485) described elsewhere in this chapter. This is a relatively simple method of control and has the advantage that much of the preliminary testing and debugging of a system can be done using a terminal or a terminal emulator program such as the public domain KERMIT available from Kermit Distribution (Columbia University Academic Information Systems, 612 West 115th Street, New York, NY 10025, Phone: 212-854-3703). The writing of custom software that accesses the serial interface of the controlling computer is relatively easy under common operating systems including DOS, Windows, Windows 95, UNIX, and OS-9 using languages such as C, Pascal, or BASIC. It is increasingly common, particularly for DOS and Windows applications, for manufactures to provide software support for their devices.

Disadvantages of serial transfers are the relative slowness when large amounts of data are transferred, the lack of standardization in device messages, and the limited control facilities available. Advantages are the ease of testing, the simplicity of the controlling software, the relative simplicity of the interconnection scheme, and—for remote instrumentation systems—the fact that with the use of modems data can be transferred over large distances using standard telephone lines or even a radio link.

89.5.11 IEEE-488 Devices

The IEEE standard 488 was developed in the 1970s and rapidly became an industry standard for the interconnection and control of test equipment. This standard was modified slightly in 1987 (IEEE standard 488.1) to allow for the considerable enhancements of IEEE standard 488.2 which was introduced at the same time [9]. The original IEEE standard 488 specifies the electrical characteristics of the bus, the mechanical characteristics of its connectors, and a set of messages to be passed between interfaces.

It does not attempt to provide any syntax or structure for communicating these messages, to specify commonly used commands, or to establish a standard for device-specific messages. These issues are addressed in IEEE standard 488.2.

The bus itself supports synchronous parallel transfers of data using three groups of lines, a bidirectional 8 bit data bus, five interface management lines, and three handshake lines, over distances of up to 20 m and at data transfer rates of up to 1 MB/s.

Devices on the bus are classed as *talkers*, *listeners*, or *controllers*. In general, the computer system is the bus controller which can also talk (send data) or listen (receive data). Most devices are both talkers and listeners, for example, a digital voltmeter will be a listener when receiving instructions to set the voltage range prior to making a measurement but will be a talker when returning the result of the measurement to the controller, which is itself acting as a listener. Each device on the bus must be assigned a unique address which is a number between 0 and 30. This may be done from the front panel of the device or, less conveniently, by setting switches elsewhere on the device.

It is a difficult, time-consuming, and error-prone process to write software to drive an IEEE-488 card. Purchasers of new IEEE-488 interfaces are strongly advised to obtain a device driver from the manufacturer. Such device drivers are now readily available and integrate the card into the filing system of the operating system running on the controlling computer. This allows the interface to be accessed in a natural way from high-level languages running on the controller.

89.6 Software for Instrumentation Systems

The difficulty involved in writing software for instrumentation systems depends largely on the support available from the manufacturers of the subsystems, on the operating system (if any), and on the development tools available. On one extreme, one may be working in a virtual instrument environment, such as that provided by the National Instrument LabVIEW, where software development is entirely graphical and, for small projects at least, is readily undertaken by users with little or no prior experience. On the other extreme, one is faced with the problem of developing software, which is at the very least interrupt-driven and probably multitasking, for a target SBC with no resident operating system; this requires considerable expertise in software design and development together with the availability of development tools such as cross compilers and source-level debuggers.

89.6.1 Virtual Instruments

Figure 89.7 shows a layer model of the software for a generalized instrumentation system. The application layer handles the data acquisition, analysis, and presentation. The instrument drivers provide a mechanism for communicating with the instruments in a standard way without requiring the user to know about the often cryptic data strings which need to be sent. For example, all digital multimeters will need the facility to choose a specific input voltage range. The range coding, resolution, etc. that have to be sent to the multimeter to achieve this will vary from instrument to instrument; however, the instrument driver allows the software writer programming in the application layer to call a procedure such as SetVoltageRange (Voltage Value) and this procedure call is the same for all multimeters. Although some manufacturers use the term slightly differently, the instrument driver is in effect the virtual instrument. Writing *instrument drivers* is a time-consuming but not too difficult task. Instrument drivers for

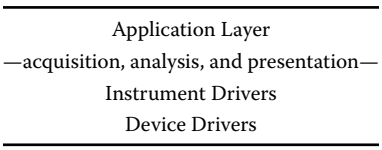

FIGURE 89.7 A layer model for instrumentation systems.

proprietary instrumentation software design packages are readily available from instrument manufacturers. Device drivers integrate the controlling interface (e.g., IEEE-488, RS-232, or internal card) into the operating system of the computer. Writing a *device driver* requires a detailed knowledge of the device hardware and of the computer operating system. This is a difficult task and new interfaces should be purchased with a device driver appropriate for the operating system wherever possible.

A number of development environments which are based on the virtual instrument concept are now available. These free the user from the problems of writing conventional software to control instruments and handle the data produced. Instruments appear to the software developer as "front panels" drawn on the computer screen, complete with familiar buttons, knobs, and displays. Data flow is handled by linking instruments in a block diagram using a mouse in an environment that resembles an ordinary drawing package. The software developer is working only in the application layer.

While the graphical environment allows simple systems to be developed rapidly, experienced programmers may find it restrictive. There are software development systems available that give the programmer access libraries containing instrument drivers, data analysis routines, graphics functions, and data visualization facilities in commonly used high-level languages such as C, Pascal, BASIC, and FORTRAN. Table 89.2 lists representative software packages.

89.6.2 Working Directly with Peripherals

It may occasionally be the case that the cost of software support for a virtual instrument development environment is not justified for a small application. Software must then be written to interface directly with the peripheral. The earlier section on digital input and output explained in principal what was necessary to program a simple interface chip. We now continue this example and show using the language C how this might be achieved.

The method of accessing the registers of peripheral cards depends on the microprocessor involved and may not even be a standard feature of the language being used. Where the peripheral forms part of the same address space as the computer memory, such as in the Motorola 680XX series, pointers can be used to read and write values in the registers. The Intel 80 × 86 series of processors often place peripherals in a separate address space which may not be accessed by pointers. In this case, an extension to the language is required. Borland's Turbo C and C++ provide functions to read and write I/O mapped devices:

unsigned char inportb(int portid)

void outportb(int portid, unsigned char value)

These are used in the code fragment which implements the software for our earlier example. We assume that the 8255 PPI has base address 0 × 1b0 and that the program copies the value read from the input port (port A) directly to the output port (port B), until bit 0 of the input becomes zero:

```
/* define the addresses of the registers for the PPI */
#define BASE 0×1b0
#define PABASE
#define PBBASE+1
#define CONTROLBASE+3
unsigned char xin;/* declare an 8-bit variable */
outportb(CONTROL, 153)/* set port A as input, port B as output */
do
{
          xin = inportb(PA);/* read the input */
          outportb(PB,xin);/* write the output */
}
while(xin & 1);/* loop if bit 0 is still 1 */
```

This fragment also illustrates that high-level languages generally only support input and output of bytes. Masking techniques must be used to access individual bits.

89.6.3 Choice of Operating System

The software development support discussed so far is typically available under DOS, Windows 3.1, Windows 95, Windows NT, and UNIX. When a system is multitasking, it has to meet stringent real-time constraints; however, none of these operating systems is particularly appropriate. DOS does not support multitasking, and the others are not optimized for real-time systems which require speedy context switching and rapid interrupt response. The most fundamental requirement of real-time applications is the ability of the system to respond to external events with very short, bounded, and predictable delays. Table 89.6 lists some important real-time operating systems and kernels.

Real-time operating systems tend not to have the mature and powerful software development support available for conventional operating systems. It is not possible simply to develop the software on a familiar operating system and then transfer the working programs to the target system. Much of the debugging, testing, and system integration will have to be done on the target itself to access the hardware. A common solution is a development system in which a conventional workstation is linked to the target system. Software is developed on the workstation using familiar tools, e.g., a Windows-based editor, support for version control, and a powerful filing system. At any time, code can be cross compiled (i.e., compiled for the processor on the target system) and downloaded to the target. The workstation may then monitor the execution of the software running on the target processor. Features that allow the user to single step through the source code, seen in a workstation window, while viewing the status of key variables in another, are available. It is also possible to set breakpoints and allow the processes to run until one is encountered. Manufacturers of real-time operating systems are often able to provide development support of this type for their product for a variety of workstations.

TABLE 89.6 Some Important Real-Time Operating Systems and Kernels

System	OS/Kernel	Manufacturer

Grounding and Shielding

Daryl Gerke
Kimmel Gerke Associates, Ltd.

William Kimmel
Kimmel Gerke Associates, Ltd.

90.1 Introduction

Electromagnetic compatibility (EMC) is crucial to successful operation of industrial systems. Due to the increased electronic content of most industrial controls, electromagnetic interference (EMI) problems have increased dramatically in recent years. Two keys to EMC success are grounding and shielding. This section will briefly discuss how to implement these two crucial EMC strategies. It will also provide a general introduction to EMI problems in today's industrial electronic systems. The primary emphasis will be on practical insights and ideas gained in dealing with numerous industrial control problems.

90.2 Understanding EMI Problems

Here are three general observations on dealing with EMI problems in industrial electronics:

1. *The industrial environment is harsh*. The primary EMI threats are power disturbances, radio-frequency interference (RFI), and electrostatic discharge (ESD). In addition, analog sensor circuits are often plagued with 50/60 Hz "ground loop" problems. Industrial electronics need more EMC care than most commercial electronics, and even more than many military systems.
2. *Electronics often play a secondary role in electronics systems*. Unlike a computer system, where electronics is the core technology, industrial electronics are often used to support another technology, such as chemical, mechanical, or process function. This leads to EMC challenges when integrating the electronics to nonelectronic technologies.
3. *EMC rules and regulations are finally catching up to industrial electronics*. For many years, industrial electronics were exempt from mandatory EMC rules, so unless there was an actual problem, EMC was often ignored. With the EMC directives of the European Union (EU) now in force, industrial electronics are no longer exempt.

90.2.1 Three Types of EMC Problems

There are three aspects of the EMC problem: *emissions*, *susceptibility* (also known as immunity), and *self-compatibility*. *Emissions* originate within the equipment, and may upset other nearby equipment. On the other hand, external energy may upset equipment, leading to *susceptibility* (or a lack of immunity). Finally, energy internal to the system may interfere with the other internal circuits, resulting in a self-compatibility problem.

Problems with both emissions and susceptibility have led to EMC regulations. Two of the best known are the Federal Communications Commission (FCC) regulations for emissions in the United States, and the EU regulations for both emissions and immunity in Europe. Industrial controls have always been exempt from the FCC regulations, but they are not exempt from the EU regulations which became mandatory in January 1996.

90.2.2 Four Major EMC Threats

Most industrial EMC problems fall into one of four key areas: *emissions*, *power disturbances*, *RFI*, and *electrostatic discharge*. In the past, industrial systems were usually only concerned with power disturbances. Today, all four threats must be considered.

90.2.2.1 Emissions

Emissions refer to electric energy originating within equipment that can interfere with other equipment. The prime concern of this threat is jamming nearby television receivers, which is the basis for the now mandatory EU emissions regulations. Emissions problems between industrial electronic systems, however, are rare. While it is possible to interfere with any other nearby equipment, most industrial electronics generate only minute amounts of conducted and radiated interference, well below upset thresholds for digital or analog circuits.

Emissions are best addressed at the equipment design stage. Strategies include printed circuit board design techniques, high-frequency filtering on power and signal interfaces, shielded cables, and enclosure shielding. Fixes in the field are usually limited to shielded cables or enclosures, add-on filters, and ferrite clamps on cables.

90.2.2.2 Power Disturbances

Power disturbances can take many forms, from short transients to long sags, surges, or complete power outages. The three most serious power threats to industrial controls are transients, voltage sags, and power outages. Stray 50/60 Hz currents can cause also problems with sensitive analog circuits, particularly due to ground loops (to be discussed later). Other power disturbances, like frequency or waveform variations, often have little effect on electronic systems.

Power disturbances are very common in industrial environments. As a result, most industrial systems are pretty robust against this threat, at least at low frequencies. High-frequency threats, such as fast transients or RF on the power lines, can still cause problems. The EU tests simulate these threats with the electrical fast transient (EFT) and injected RF tests.

Most power disturbances are caused by nearby equipment, rather than external sources. (One critical exception is lightning, which can result in some nasty voltage and current surges.) Power disturbances solutions include grounding, power filters, transient protectors, and in extreme cases, uninterruptible power systems (UPS).

90.2.2.3 Radio-Frequency Interference

RFI deals with threats in the RF range. RFI is quite common in industrial environments, and will likely get worse with the proliferation of handheld radios and cellular telephones. It is expected that wireless local area networks (LANs) will also provide some interesting EMI challenges. There have been cases where handheld radios were banned from use due to repeated EMI problems with industrial electronics.

It turns out that the nearby handheld radio is a much bigger threat than a large commercial broadcast station several kilometers away. A key metric is electric field intensity, measured in "volts/meter." This is a function of both transmitter power, and distance from the antenna, and can be quickly predicted by the formula:

$$E\,(\text{V/m}) = 5.5\frac{\sqrt{PA}}{d} \tag{90.1}$$

where

P is the transmitter power in watts
A is the antenna gain
d is the distance from the antenna in meters

For example, the electric field from a 1 W radio with a zero gain antenna at 1 m is about 5 V/m, while the electric field from a 10,000 W broadcast station at 1 km is about 0.5 V/m. Since unprotected equipment can fail in the 0.1–1 V/m range, problems can and do occur. The EU "heavy industrial" limits of 10 V/m are clearly aimed at protecting against the nearby handheld radio.

Solutions to RFI problems include high-frequency filtering on power and signal cables, shielded cables, and shielded enclosures. Analog circuits are particularly vulnerable to RFI, so they often need extra protection. Do not overlook banning radio transmitters in the immediate vicinity. Often, maintaining a 3–10 m distance is enough to solve the problem.

90.2.2.4 Electrostatic Discharge

ESD refers to the sudden discharge that can occur after a gradual buildup of electric charge. ESD is most commonly associated with humans (touching controls or keyboards), but ESD can also be caused by internal arcing due to the movement of paper, plastic, etc. Internal ESD problems are increasing in industrial systems.

Although the static buildup can take a long time (seconds or even minutes), the discharge is almost instantaneous (nanoseconds or less). Furthermore, it is the sudden current, not the voltage that is the culprit. The effect is a bit like having a dam burst—the ESD current is like water running down a mountain, destroying anything in its path. Fortunately, the current surge does not last too long, so the energy levels are not high. They are high enough, however, to damage or upset electronic devices.

The extremely fast discharge results in high frequencies well into the UHF range. At 1 ns, the transient bandwidth is over 300 MHz. As a result, it does not take a "direct ESD hit" to cause a problem. ESD upsets 5–10 m away are not uncommon, due to the intense electromagnetic fields associated with an ESD event. These problems are particularly insidious, since the ESD event may be occurring on a different piece of equipment.

Solutions to ESD problems include transient protection, high-frequency filtering, cable shielding, and enclosure shielding. Grounding is a very important factor in ESD protection, but it must be designed for high frequencies. Since many times ESD causes "reset" problems, extra attention to microprocessor reset circuits is beneficial.

90.2.3 Sources, Paths, and Receptors

A common EMI problem is gathering and organizing data. This is particularly important when troubleshooting EMI in the field. The "source–path–receptor" model is popular. Simply stated, three elements are necessary for any EMI problem:

1. There must be a source of energy.
2. There must be a receptor that is upset by that energy.
3. There must be a coupling path between the source and receptor.

Any interference problem can be broken down into
- Source of interference
- Receptor of interference
- Path coupling the source to the receptor

Sources	Paths	Receptors

FIGURE 90.1 The source–path–receptor model for assessing EMI problems. All three elements must be necessary for an EMI problem to occur.

All three elements must exist at the same time, and if any one is missing, there is no EMI problem. Sometimes one can identify all three, and, other times, one can only guess. While this may seem simple, it is a useful tool to organize EMI information.

Figure 90.1 illustrates this model, giving typical sources, paths, and receptors. Several possible sources have been discussed: emissions from digital circuits, ESD, RFI from communications transmitters, and power disturbances (including lightning). Several different receptors have also been suggested: communications receivers, analog electronics, and digital electronics. Note the two types of paths: radiated and conducted. In both cases, the object is to block unwanted energy from reaching a receptor, which is done with shielding (for the radiated path) and filtering (for the conducted path).

90.3 Grounding

Grounding is probably the most important, yet least understood, aspect of EMI control. Every circuit is connected to some sort of "ground," so every circuit is affected by EMI grounding issues.

90.3.1 What Is a Ground?

A major problem with the subject of grounding is the ambiguity of the term. Our favorite definition is one popular in the EMC community, which says that a *ground is simply a return path for current flow*. These currents can be intended or unintended. The unintended currents are often referred to as "sneak grounds," and can cause many kinds of EMI problems. Finally, a physical connection is not even necessary at higher frequencies, where parasitic capacitance or inductance may form part of a ground path.

90.3.2 Different Types of Grounds

Grounds are used for many reasons, including power, safety, lightning, EMI, and ESD. Although they may share common functions, they may vary widely when it comes to frequencies and current amplitudes. Recognizing these key differences is key to understanding grounding issues.

Table 90.1 shows some frequency and amplitude requirements of several different types of grounds. Note that power and safety grounds must handle high currents, but only at low frequencies. Grounds for EMI and ESD, on the other hand, must often handle high frequencies at relatively low current levels. Lightning grounds must handle extremely high currents, but at moderate frequencies.

TABLE 90.1 A Ground May Work Over Wide Frequency Ranges

Type	Frequency	Typical Current Levels	Typical Duration
Power	50/60 Hz	10–1,000 A	Seconds or minutes
Lightning	300 kHz	100,000 A	Tens of milliseconds
ESD	300 MHz	10–50 A	Tens of nanoseconds
EMI	dc–Daylight	μA–A	Nanoseconds to years

The frequency of transient events is calculated using the formula $f = 1/(\pi t_r)$, where f is the equivalent frequency and t_r is the transient rise/fall time. This relationship can be derived using Fourier analysis. For example, ESD has an equivalent frequency of about 300 MHz based on a typical 1 ns rise time, and lightning has an equivalent frequency of about 300 kHz based on a 1 μs rise time.

Note that out of all these types of grounds only one actually needs an Earth connection—lightning. Other grounds may be connected to Earth by convention or for other safety reasons. For example, power neutrals are connected to Earth in many parts of the world to help provide lightning protection. On the other hand, in many other parts of the world, the power systems do not have Earth connections. When dealing with power grounding, the local safety codes will determine the proper Earth grounding methods.

90.3.3 Ground Impedances

A good ground must have a low enough impedance to minimize voltage drop in the ground system, and must provide the preferred path for current flow. The key to success is maintaining that low impedance over the entire frequency range of interest. We cannot overemphasize this point. Most EMI grounding problems are due to using the wrong approach for a given range.

The impedance of a ground conductor consists of both resistance and inductance ($Z = R + j\omega L$). For frequencies from dc through about 10 kHz, the resistance is the major factor, so heavy-gage wires are often used for low-frequency ground conductors. As the frequency increases, however, the inductance becomes the limiting factor for impedance. As a rule of thumb, the inductance for round wires is in the range of 10 nH/cm.

Table 90.2 gives the resistance, inductance, and inductive reactance for a typical wire sizes used in instrumentation power and signal circuits. It is apparent that at power and audio frequencies (dc to 10 kHz), resistance is the dominant factor in ground impedance. Thus, at low frequencies, look for ways to reduce resistance, typically by using larger wires. At frequencies above the audio range (>10 kHz), inductance becomes the dominant factor in ground impedance. Thus, at higher frequencies, look for

TABLE 90.2 Impedance Parameters for 10 cm Length Wires

Gage	Ω/m	μH/m	Z at 10 kHz	Z at 1 MHz	Z at 100 MHz
10	0.0033	1.01	0.006	0.63	63

28	0.1688	1.40	0.019	0.88	88
30	0.2129	1.43	0.022	0.90	90

TABLE 90.3 Impedance Values for Ground Plane Impedance

	Thickness		
Frequency	0.1 mm	1 mm	10 mm
60 Hz	172 μΩ	17.2 μΩ	1.83 μΩ
1 kHz	172	17.5	11.6
10 kHz	172	33.5	36.9
100 kHz	175	116	116
1 MHz	335	369	369
10 MHz	1.16 mΩ	1.16 mΩ	1.16 mΩ
100 MHz	3.69	3.69	3.69
1000 MHz	11.6	11.6	11.6

ways to reduce the inductance of the ground path. This is accomplished by using ground planes, grids, and straps to lower the inductance.

Table 90.3 gives the impedances for solid ground planes at various frequencies. In this case, the impedances are in "ohms per square," which is a measure of impedance across a diagonal surface. By comparing this with Table 90.2, one can see that at high frequencies (such as 100 MHz) the ground plane impedance may be several orders of magnitude below the impedance of a wire. Furthermore, at high frequencies the thickness is not a factor, since the impedance is limited by the skin effect.

90.3.4 Ground Topologies

Now that we have looked at ground impedance vs. frequency, we are ready to look at ground topologies vs. frequency. The impedance limitations yield two different grounding approaches, dependent on frequency. For low-frequency problems (dc to 10 kHz), single-point grounds are preferred, while at high frequencies (above 10 kHz), multipoint grounds with planes or grids become the preferred approach.

This dichotomy often causes confusion with industrial controls, but this can be minimized by determining the frequency of the EMI threat and then selecting the appropriate grounding approach. In many cases, both approaches may be necessary at the same time, leading to "hybrid" grounds, which use capacitors and inductors to alter the ground topology with frequency.

90.3.4.1 Single-Point Grounds

At low frequencies, one can usually steer current via wires. Since the inductance is low, the limiting factor is the wire resistance itself. Furthermore, capacitive coupling from the ground wires to adjacent wires or surfaces is small, so virtually all the current follows the wiring path.

Figure 90.2 shows a typical industrial grounding scheme. Note what happens if the system is grounded at both ends. Any common noise current in the common ground path is now coupled into the circuit via the "common ground impedance." This results in the severe "ground loop," which will be discussed shortly. A single-point ground eliminates the ground loop, since there is no common impedance across which a common-mode voltage can be generated. Thus, single-point grounding is a very practical way to limit "ground noise" problems with the threat of low-frequency ground currents. This is very typical of 50/60 Hz currents getting into sensitive analog instrumentation circuits.

90.3.4.2 Multipoint Grounds

Unfortunately, as the frequency increases, the inductive reactance of the wires increases. At the same time, parasitic capacitive reactance to adjacent wires or surfaces decreases, and soon it is no longer possible to maintain a true single-point ground, even if the system is wired that way. The only option left

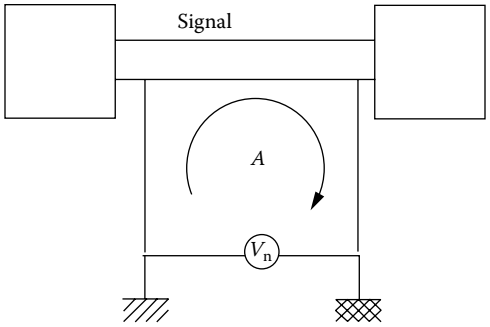

FIGURE 90.2 Typical industrial grounding situations, which also illustrate a ground loop.

is to lower the ground path impedance, and that is accomplished with planes or grids. Furthermore, a single-point connection to a grid or plane is usually not adequate because of transmission line effects, so multipoint grounds (combined with planes/grids) become the preferred approach above 10 kHz.

Ground grids have been used for years in computer facilities, and are seeing increasing use in industrial facilities. The recommended spacing for grids is no more than $\frac{1}{20}$ of a wavelength at the highest frequency of concern. Computer room grids are often spaced about 0.7 m (about 2 ft), which meets this criteria from dc to about 25 MHz. This is very beneficial in addressing ground noise due to lightning and other power transients, which are usually in the 1 MHz range and below. But a 0.7 m grid does not help with VHF/UHF radio problems or ESD. In those cases, solid surfaces may be necessary.

90.3.4.3 Ground Loops

Ground loops are a serious problem for sensitive analog circuits facing low-frequency threats. At high frequencies, ground loops generally do not pose serious threats if proper high-frequency precautions are taken when designing the ground system.

A ground loop exists whenever multiple ground paths exist. Unwanted currents can take unwanted paths, resulting in unwanted noise voltages at unwanted places. The problem is particularly acute with sensitive analog systems, where even a few microvolts can jam intended signals. A classic example is 60 Hz ground currents causing hum in an audio system.

Figure 90.2 shows a typical ground loop problem. Note that there must be the three conditions of any EMI problem: a source, a path, and a victim. In this case, the source can be circulating power currents, the path the common ground impedance, and the victim is often the sensitive analog circuit. With many systems problems, one cannot do anything about either the source or victim, so the solution is with the ground path. As we have already seen, single-point grounding is effective at low frequencies, and ground planes/grids are effective at higher frequencies.

If one cannot change the ground paths, one can still attack the ground loop by "breaking" it in other places. For example, transformers or optical isolators (or even fiber optics) can be used in cable connections, which will block common-mode noise currents while passing intended differential mode signals. Balanced input/output (I/O) circuits can be used to "cancel" the noise through common-mode rejection. All of these are most effective at 50/60 Hz, and become less effective at higher frequencies due to parasitic capacitance.

90.3.5 Grounding Guidelines

By now it should be apparent that there is no magic solution for grounding. Rather, different methods and approaches are necessary for different circuits and operating conditions. Two key parameters are the threat frequency (low vs. high), and the circuit operating levels. Here are some guidelines, but keep in mind that even these may need to be modified for a particular situation.

90.3.5.1 Analog Circuits

Since most analog circuits operate at low frequencies and are subject to low-frequency threats, single-point grounds are preferred. Typical threats are 50/60 Hz power return currents, stray switching power supply currents, and perhaps digital circuit return currents (if separate analog and digital power and grounds are not provided). Low-level analog circuits are the most vulnerable, since the signal levels are small.

Keep in mind that high-frequency threats (such as a VHF radio) to low-frequency circuits may require high-frequency grounding solutions, such as multipoint grounds. Often, this can be accomplished by using small high-frequency capacitors (1000 pF typical) which appear as a short at 100 MHz, yet still appear as a high impedance at 50/60 Hz.

90.3.5.2 Digital Circuits

Most digital circuits today operate at relatively high frequencies, so multipoint grounds and ground planes and grids are preferred. The connections between the circuits and their grounds need to be short, fat, and direct to minimize inductance.

Digital circuits, particularly I/O circuits, are vulnerable to external high-frequency threats like RF and ESD. They are also a key source of high-frequency emissions and internal problems like cross talk. For digital circuits, multilayer boards with internal ground planes are preferred. These ground planes typically are connected to a metallic enclosure through multiple low-inductance connections.

Pay particular attention to where digital and analog circuits meet. A single-point connection is usually preferred to minimize ground loops, but installing a small resistor (1–10 Ω typical) or inductor (1–100 μH typical) at that point is often helpful in providing additional isolation. One may need to experiment with this to determine the optimum solutions.

90.3.5.3 Power Safety Grounding

Entire books have been written about this subject, and rightly so; this is an extremely important safety issue. The key concern here is human safety and prevention of electric shock. In most parts of the world, exposed metal on line-powered equipment must be bonded to a safety grounding conductor. Furthermore, the electric wiring codes (such as the National Electrical Code in the United States) give very specific guidelines on how power grounding must be accomplished.

These guidelines must be followed when wiring any industrial control system, and must never be compromised by "isolated" power grounds or other similar foolishness. *Finally, if there is ever a conflict between EMI and safety grounding, the safety issues must always prevail!*

90.4 Shielding

Many systems today require at least some *shielding* for proper operation or to meet radiated emission or immunity requirements. Many engineers consider shielding purely a mechanical issue, but nothing could be farther from the truth. EMI shielding needs both an electrical and a mechanical understanding of key issues to assure success.

Two of these key issues are selecting the right material and maintaining the shielding integrity over the desired frequency range. While most people worry more about the selection, shield integrity is usually much more important. We will soon see that even very thin metallic coatings can be effective shields, yet even very small holes or penetrations can completely destroy a shield. Like grounding, shielding cannot be left to chance, and must be properly designed and implemented.

90.4.1 How Shielding Works

EMI shielding involves two independent mechanisms: *reflection* and *absorption*. In reflection, an electromagnetic wave bounces off the surface, just like light off a mirror. In absorption, the electromagnetic wave penetrates the material and is absorbed as it passes through, much like heat loss through an insulating wall.

Shielding effectiveness is usually expressed as follows:

$$\text{SE(dB)} = R(\text{dB}) + A(\text{dB}) \tag{90.2}$$

where

SE is the total shielding effectiveness in dB

R and A are the reflection and absorption losses expressed in dB

Reflection is the primary mechanism for high-frequency shielding (emissions, RFI, ESD), while absorption is the key mechanism for low-frequency magnetic field shielding. The actual formulas for calculating reflection and absorption losses are a bit complex, and beyond the scope of this chapter, but several sources are included in the further information section.

90.4.2 Three Types of Fields

It is customary when dealing with shielding to use three types of "fields" to explain shielding. These three fields account for differences in shielding performance due to differences in frequency and circuit impedance levels. They also explain why the same shield can behave differently for different energy sources. These are plane waves, magnetic fields, and electric fields. Figure 90.3 shows typical shielding curves for copper, with references to each type of field.

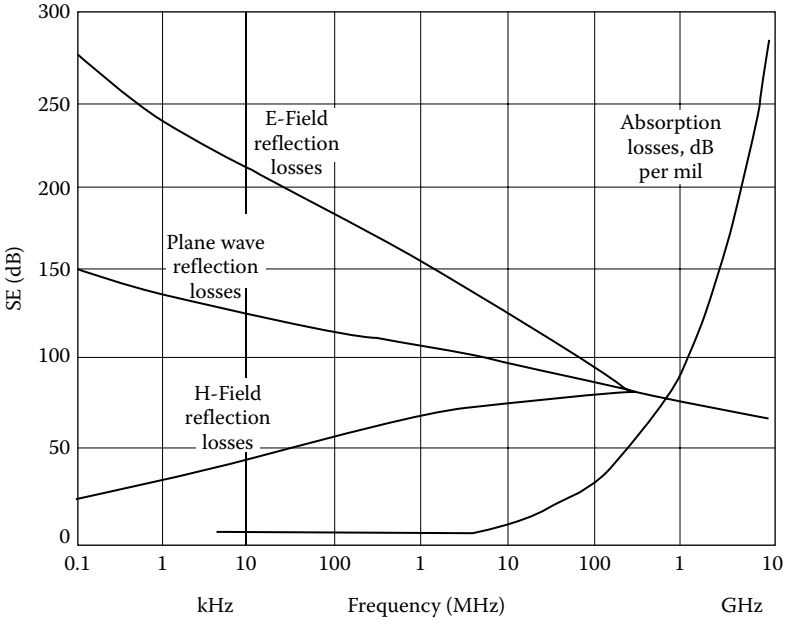

FIGURE 90.3 Typical shielding effectiveness curves for copper. Note two mechanisms (reflection and absorption) and three types of fields (electric, magnetic, and plane wave). Shielding for aluminum is almost the same as for copper.

90.4.2.1 Plane Wave Fields

If one is located greater than about one-sixth wavelength from a point source, the wave impedance (ratio of electric field intensity to magnetic field intensity) is a constant 377 Ω in free space. This field is known as the "far field" or "radiation field," since real energy predominates here and propagates as a "plane wave." Since reflection losses are due to a mismatch between the wave impedance (377 Ω) and a metallic shield surface impedance (typically milliohms or less), shielding effectiveness is usually very high for plane wave sources.

At frequencies 30 MHz and above, once one is more than about 1 m away, one is in the plane wave region. Thus, even very thin shields work well for emissions, ESD, and RFI problems, with reflection as the prime shielding mechanism.

90.4.2.2 Electric and Magnetic Fields

If one is located less than about one-sixth wavelength from the source, then the wave impedance is dependent on the circuit impedance. This region is known as the "near field," since reactive energy predominates here. This region is further divided into "electric" and "magnetic" fields, both dependent on source circuit impedance. For high-impedance sources (electric fields), the reflection losses are still high, but for low-impedance sources (magnetic fields), the impedance can be quite low. In the latter case, the reflection losses can become minimal.

For power line frequencies, the near field almost always predominates. As a result, materials like aluminum or copper have no reflection losses and are virtually transparent to power line magnetic fields. (As a rule, remember that aluminum foil is transparent to 60 Hz magnetic fields.) To solve this problem, permeable materials are needed to boost the electric thickness for a given physical thickness. Steel or high-permeability mu-metals are normally used to absorb (not reflect) the magnetic fields. Even so, it can still be very difficult to shield for low-frequency magnetic fields.

90.4.3 Why Shielding Fails

While material selection is important, other factors must also be considered. For low-frequency/low-impedance threats (power supply or power line magnetic fields), steel or other high-permeability materials are needed. For high-frequency threats, however, even very thin materials like conductive paints provide high levels of shielding. Two problems at high frequencies, however, are shield openings and shield penetrations. Lack of attention to these areas can result in a loss of virtually all shielding effectiveness at high frequencies. Figure 90.4 illustrates these two high-frequency failure modes.

Intuition suggests that any opening in a shield can leak, much like an open window. The surprise is that for electromagnetic leakage it is not the area that is critical, but the longest dimension. For example, a 100 × 1 mm opening is about 10 times leakier than a 10 × 10 mm square hole. And that slot may not even be obvious. It could be a painted seam or a poorly fitting panel or door.

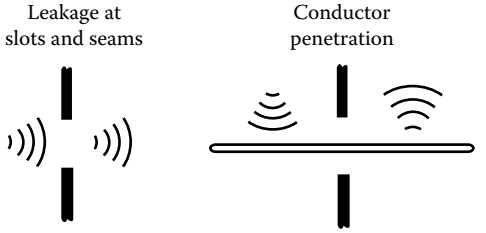

FIGURE 90.4 Two shielding failure modes, due to slots/seams and due to penetration of conductors. In both cases, the critical dimension is $\frac{1}{20}$ wavelength for the highest frequency of concern.

Slots act like small antennas. Because they are antennas, the longer they are, the better they radiate. While a half wavelength is very efficient, as a rule of thumb, we like to limit slots to $\frac{1}{20}$ wavelength or less at the highest frequency of concern. For 100 MHz, this is 15 cm (about 6 in.); at 300 MHz (ESD frequencies), this drops to 5 cm (about 2 in.), and at 1000 MHz, it is only 1.5 cm ($\frac{2}{3}$ in.). And even these dimensions may be too large, as they only assure 20 dB (10-fold) of shielding through the slot. Clearly, even small slots and other openings mean big shielding problems at high frequencies.

The other way to destroy a high-frequency shield is to pass unterminated metal through a shield. Hole dimensions do not matter here, and even a pinhole with an insulated wire passing through can carry large amounts across the shielding barrier. The dimension that does matter is how far the penetration extends on either side of the shield. Once again, the critical distance is $\frac{1}{20}$ wavelength or more.

90.4.4 Shielding Guidelines

Now that we have looked at how shielding works (and fails), let us look at how to design good electromagnetic shields. Most of our focus will be on RF shielding in the 30–1000 MHz range, necessary for emissions, ESD, and RFI.

90.4.4.1 Material Selection

We have already seen that for low-frequency magnetic interference problems, ferrous material like steel or mu-metals are necessary. Most instrumentation problems are either high impedance or high frequency in nature, so most of the time, thin conductive materials will work fine. For high frequencies, however, attention must be given to slots and penetrations.

Many enclosures today are made of plastic. For high-frequency shielding, conductive coatings also work quite well. Popular surface treatments include conductive paints, vacuum deposition, electrodeless plating, and even metal fabrics. Conductive plastics are also available, but they generally do not perform nearly as well as surface treatments for high frequencies.

90.4.4.2 Gasketing and Screening

Large openings, such as ventilation ports or display areas, can be sealed with screening material. Seams or slots can be filled with conductive gaskets. In both cases, the secret is to provide complete and continuous metal-to-metal contact at all junctions. For high-frequency shielding, the connections must be almost watertight. Anything less is asking for problems.

For screening material, the smaller is the openings the higher is the shielding. Window screen spacing is almost as effective as solid materials from dc to 1000 MHz, and even 5 mm (about $\frac{1}{4}$ in.) openings are often acceptable at 1000 MHz. In any case, do not exceed $\frac{1}{20}$ wavelength at the highest frequency of concern.

90.4.4.3 Cable Terminations and Filters

Poor termination of shielded cables can cause big problems at high frequencies. If a shielded cable is not terminated directly at the shielding barrier, a lot of energy leaks, degrading both the cable and the enclosure shield. Pigtail connections, popular for terminating low-frequency cable shields, are particularly bothersome at high frequencies. In fact, this is a leading cause of EMI failures for RFI, emissions, and ESD. As a rule of thumb, pigtail connections should not be used on cable shields at frequencies above about 1 MHz.

Unshielded cables can also cause problems at high frequencies. In those cases, high-frequency filtering is needed directly at the interface to assure that the shield is not degraded at high frequencies. Common solutions are EMI filters on power and signal lines, or ferrite beads on the lines or cables. These must be installed as close to the shield penetration as possible. The best situation is to mount the filter directly in the shield itself, although this is not always necessary for moderate problems.

90.4.4.4 Internal Shields

Finally, do not overlook using internal shield on critical circuits. Radio and television designers have been doing this for years, using selective shields on oscillators, power amplifiers, and the like. A classic example of this approach is the TV tuner, the most sensitive part of a television receiver. It is an inexpensive, yet highly effective shielding strategy.

Defining Terms

Conducted: Energy or interference propagated by a conductor, e.g., power, grounding, or signal interface wiring.

EFT: Electrical fast transient; a high-frequency burst of energy on power wiring.

EMC: Electromagnetic compatibility; the condition wherein electric and electronic equipment operate successfully in close proximity.

EMI: Electromagnetic interference; unwanted electric energy that may impair the function of electronic equipment.

Emissions: Electric energy emanating from an electronic source.

ESD: Electrostatic discharge; the rapid discharge that often follows a buildup of static charge.

EU: European Union; formerly called the European Community.

FCC: Federal Communications Commission (US government).

Ground: A return path for current.

Radiated: Energy or interference is propagated by electromagnetic radiation through space.

RFI: Radio-frequency interference; an older term for EMI, now normally used to describe interference caused by a nearby radio transmitter.

Shield: A metallic enclosure used to reduce electric or magnetic field levels.

Susceptibility: Vulnerability of electronic equipment to external sources of interference; often used interchangeably with immunity.

Further Information

Amplifiers and Signal Conditioners

Ramón Pallás-Areny
Universitat Politècnica de Catalunya

91.1 Introduction

Signals from sensors do not usually have suitable characteristics for display, recording, transmission, or further processing. For example, they may lack the amplitude, power, level, or bandwidth required, or they may carry superimposed interference that masks the desired information. Further, implementing other functions such as amplitude demodulation, linearization, and temperature compensation before digitizing signals can sometimes be cost effective.

Signal conditioners, including amplifiers, adapt sensor signals to the requirements of the receiver (circuit or equipment) to which they are to be connected. The functions to be performed by the signal conditioner derive from the nature and properties of both the signal and the receiver. Commonly, the receiver requires a single-ended, low-frequency ("dc") voltage with low-output impedance and amplitude range close to its power supply voltage(s). A typical receiver here is an analog-to-digital converter (ADC). Sampling ADCs are preceded by a sample-and-hold amplifier that keeps constant the voltage during its digitization. Integrating ADCs obtain the average of the input voltage during the integration time.

Signals from sensors can be analog or digital. Digital signals come from position encoders, electromechanical or magnetic switches, or oscillator-based sensors connected to frequency counters or time-to-digital converters. The amplitude for digital signals must be compatible with logic levels for the digital receiver, and their edges must be fast enough to prevent any false triggering. Slow edges can be accelerated by a Schmitt trigger. Small digital voltages can be amplified and large voltages can be attenuated by *logic-level translators*. Alternatively, large voltages can be attenuated by a voltage divider.

Analog sensors are either self-generating or modulating. *Self-generating sensors* yield a voltage (thermocouples, photovoltaic, and electrochemical sensors) or current (piezo- and pyroelectric sensors) whose bandwidth equals that of the measurand. *Modulating sensors* yield a variation in resistance, capacitance, self-inductance or mutual inductance, or other electrical quantities. Modulating sensors need to be powered by an excitation voltage or current in order to provide an output voltage or current. Some sensors based on electromagnetic effects such as the Hall effect or based on semiconductor junctions (*p-n* junction temperature sensors, photodiodes) need to be biased to yield an output voltage or current. Impedance variation–based sensors are normally placed in voltage dividers, or in either Wheatstone bridges (resistive sensors) or ac bridges (resistive and reactance-variation sensors). The bandwidth for signals from modulating sensors equals that of the measurand in dc-excited or biased sensors, and is twice that of the measurand in ac-excited sensors (sidebands about the carrier excitation frequency). Capacitive and inductive sensors require an ac excitation, whose frequency must be at least 10 times higher than the maximal frequency variation of the measurand in order to simplify the filtering of undesired harmonics in the demodulator. Pallas-Areny and Webster [1] give the equivalent circuit for different sensors and analyze their electronic interface.

Current signals can be converted into voltage signals by inserting a series resistor into the circuit, or using other current-to-voltage converters described in Section 91.6. Alternatively, current input ADCs, such as the DDC series from Texas Instruments, can directly digitize low-level currents. Henceforth, we will refer to voltage signals to analyze transformations to be performed by signal conditioners.

91.2 Dynamic Range

The *dynamic range* for a measurand is the quotient between the measurement range and the desired resolution. The dynamic range for the input or output of any signal-processing stage can be defined as the quotient between the corresponding voltage range and the resolution, often determined by noise. Any stage for processing the signal from a sensor must have a dynamic range equal to or larger than that of the measurand. For example, to measure a temperature from 0 °C to 100 °C with 0.1 °C resolution, we need a dynamic range of at least (100 − 0)/0.1 = 1000 (60 dB). Hence, a 10 bit ADC should be appropriate to digitize the signal because $2^{10} = 1024$ (>1000). Let us assume we have a 10 bit ADC whose input range is 0–10 V; its resolution will be 10 V/1024 = 9.8 mV. If the sensor sensitivity is 10 mV/°C and we connect it to the ADC, the 9.8 mV resolution for the ADC will result in a 9.8 mV/(10 mV/°C) = 0.98 °C resolution! In spite of having the suitable dynamic range, we do not achieve the desired resolution in temperature because the output range of our sensor (0–1 V) does not match the input range for the ADC (0–10 V).

The basic function of voltage amplifiers is to amplify the input signal so that the output voltage extends across the input range of the subsequent stage. Further, the voltage levels of the amplified and further processed signal must match the input voltage levels of the ADC; otherwise, the voltage level must be shifted, even if the voltage ranges match. In the earlier example, an amplifier with a gain of 10 V would match the sensor output range to the ADC input range of 10 V and the 0 V sensor output at 0°C to the 0 V ADC input. In addition, the signal source should not be disturbed when connecting the amplifier, the output of the amplifier should depend only on the input signal, and the output noise should be smaller than the equivalent input noise of the stage that follows the amplifier. To fulfill these requirements, the amplifier must be selected according to the characteristics of the input signal. Amplifiers improve the sensitivity and resolution of the system with respect to that of the ADC, but because they amplify both the signal and the noise that comes with the signal, they do not improve the dynamic range

of the signal. Filters that reduce noise without modifying the information-carrying signal improve the dynamic range. Whenever a sampling ADC is used, an *antialiasing filter* must be used to reduce noise amplitude above the *Nyquist frequency* (half the sampling frequency) to less than the voltage resolution of the ADC. Integrating ADCs do not need antialiasing filters as the converter itself behaves as a low-pass filter, rather than behaving as a multiplier as sampling ADCs do.

Alternatively, instead of using an amplifier in front of the ADC, an ADC can be selected whose resolution matches the desired resolution for the measurand. In the example given earlier, 0.1°C resolution implies 1 mV change at the sensor output and the ADC should have N bits such that $10\ V/2^N = 1$ mV. That is, $N = 14$. The output voltage levels of the sensor must be within the input voltage levels of the ADC. Then, the four most significant bits of the ADC will not change and the 10 least significant bits will change when the temperature changes from 0 °C to 100 °C. In general, we can either use an N bit ADC preceded by an amplifier with gain G, or use an ADC with N bits and use algorithm for a gain G and no analog amplifier.

91.3 Signal Classification

Signals can be classified according to their amplitude, the relationship between their source terminals and ground (signal ground—also termed circuit common—chassis ground, earth [safety] ground), their bandwidth, and the value of their output impedance. Signals lower than around 100 mV are considered to be low level and need either amplification or an ADC whose voltage resolution is equal or better than the desired resolution for the signal. Signals larger than 100 mV may also need amplification depending on the input range of the receiver.

91.3.1 Single-Ended and Differential Signals

A *single-ended signal* source has one of its two output terminals at 0 V (signal ground). For example, Figure 91.1a shows a voltage divider whose terminal L remains at the power supply reference voltage (circuit common or signal ground terminal) regardless of the sensor resistance, as shown in Figure 91.1b. If terminal L is at (earth) ground potential (grounded power supply in Figure 91.1a), then the signal is single-ended and grounded. If terminal L is completely isolated from ground (for example, if the power supply is a battery), then the signal is single-ended and floating. If terminal L is at some voltage with respect to earth ground, then the signal is single-ended and driven-off ground. The voltage at terminal H will be the sum of the signal plus the off-ground voltage. Therefore, the off-ground voltage is common to H and L; hence, it is called the *common-mode voltage* and carries no information. For example, a thermocouple yields a voltage that depends on its temperature; a thermocouple bonded to a power transistor yields a signal whose amplitude depends on the temperature of the transistor case, riding on a common-mode voltage equal to the case voltage. Common-mode voltages can also arise because of a limited isolation of signal ground with respect to earth ground, that is, a finite impedance between circuit common and earth ground.

A *differential signal* source has two output terminals whose voltages change simultaneously by the same magnitude but in opposite directions with respect to the common (signal ground) terminal, hence the alternative name *push–pull signal*. The Wheatstone bridge in Figure 91.1c provides a differential signal. Its equivalent circuit (Figure 91.1d) shows that there is a differential voltage ($v_d = v_H - v_L$) proportional to x and a common-mode voltage ($v_c = (v_H + v_L)/2 = V_r/2$) that does not carry any information about x. Further, the two output impedances are balanced. We thus have a balanced differential signal with a superimposed common-mode voltage. Were the output impedances different, the signal would be unbalanced. If the bridge power supply is grounded, then the differential signal will be grounded; otherwise, it will be floating. When the differential signal is very small as compared with the common-mode voltage, in order to simplify circuit analysis it is common to use the equivalent circuit in Figure 91.1e, where v_H and v_L are not longer symmetrical with respect to v_c. Other measurement signals, such as impedances

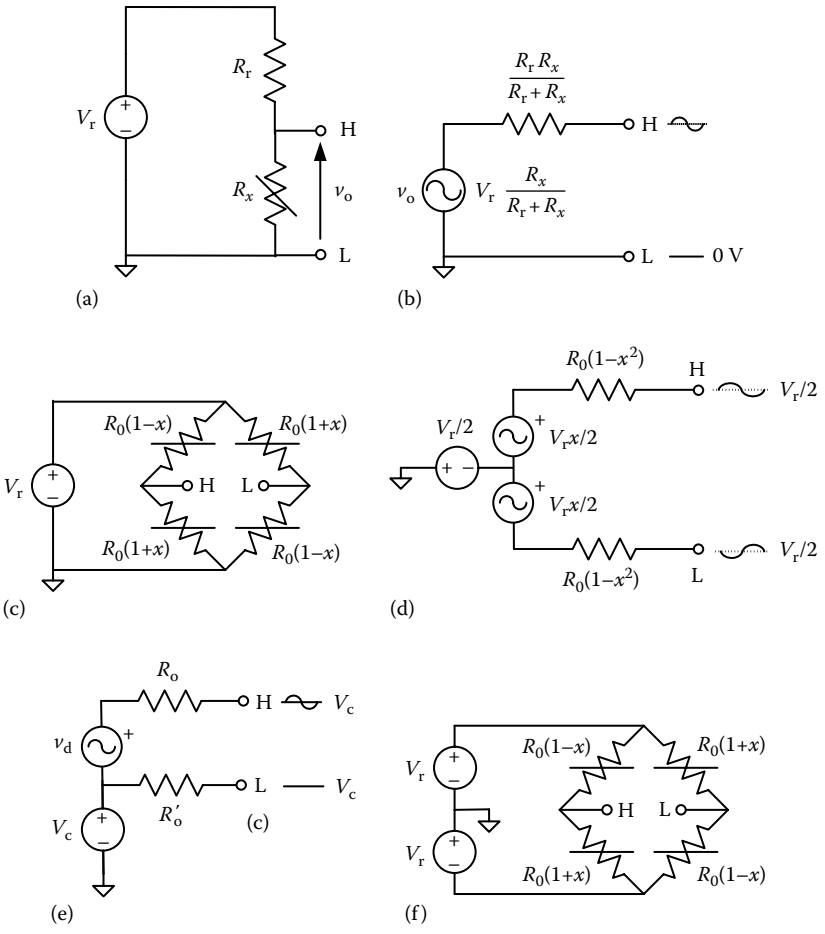

FIGURE 91.1 Classes of signals according to their source terminals. A voltage divider (a) provides a single-ended signal (b) where terminal L is at a constant voltage. A Wheatstone bridge with four sensors (c) provides a balanced differential signal which is the difference between two voltages v_H and v_L having the same amplitude but opposite signs and riding on a common-mode voltage v_c and the equivalent circuit of the Wheatstone bridge is shown in (d). For differential signals much smaller than the common-mode voltage, the equivalent circuit in (e) is used. A Wheatstone bridge with four sensors supplied by a split power source (f) yields a differential voltage with zero common-mode voltage. In all cases, if circuit common (signal ground) is (earth) grounded, the signal (single-ended or differential) will be grounded; if the reference point is floating, the signal will also be floating.

measured with the four-wire (or four-lead) method, can also be modeled by the equivalent circuit in Figure 91.1e, where v_c can be an ac voltage; because in this case v_H and v_L do not change in a push–pull fashion, the signal is termed *pseudodifferential*. Some differential signals (grounded or floating) have a zero common-mode voltage, for example, the output of a full-sensor Wheatstone bridge supplied by a split voltage (Figure 91.1f). Note that the output signal in voltage dividers and Wheatstone bridges depends on the excitation voltage V_r (or current); therefore, that excitation, the same as bias voltages or currents applied to sensors, must be stable with time and temperature. If the same V_r is used as voltage reference in the ADC, its actual value and stability are irrelevant; therefore, the power supply voltage can be used instead, provided it is not too noisy. Reference [5] analyzes several circuits able to obtain a stable voltage or current from a voltage reference IC.

Signal conditioning must ensure the compatibility between sensor signals and receivers (amplifiers), which will depend on the relationship between input terminals and ground. For example, a differential

and grounded signal is incompatible with an amplifier having only two input terminals, one of which is grounded. Hence, amplifiers must also be described according to their input topology.

91.3.2 Narrowband and Broadband Signals

A *narrowband signal* has a very small frequency range relative to its central frequency, defined as the geometric mean of its minimal and maximal frequency components ($f_c^2 = f_{min} \times f_{max}$), that is, $f_{max} - f_{min} < f_c$. Narrowband signals can be dc, or static, resulting in very low frequencies, such as those from a thermocouple or a weighing scale, or ac, such as those from an ac-driven modulating sensor, in which case the exciting frequency (carrier) becomes the central frequency.

Broadband signals, such as those from sound and vibration sensors, have a large frequency range relative to their central frequency $f_{max} - f_{min} > f_c$. Therefore, the value of the central frequency is crucial to determine whether a signal is narrowband or broadband; a signal ranging from 1 Hz to 10 kHz is a broadband instrumentation signal, but two 10 kHz sidebands around 1 MHz are considered to be a narrowband signal. Signal conditioning of ac narrowband signals is easier because the conditioner performance only needs to be guaranteed within a narrow band around the carrier frequency.

91.3.3 Low- and High-Output Impedance Signals

The output impedance of signals determines the requirements of the input impedance of the signal conditioner. Figure 91.2a shows a voltage signal connected to a device whose input impedance is Z_d. The voltage detected will be

$$v_d = v_s \frac{Z_d}{Z_d + Z_s} \tag{91.1}$$

Therefore, the voltage detected will equal the signal voltage only when $Z_d \gg Z_s$; otherwise $v_d \neq v_s$ and there will be a *loading effect*, also called *voltage-divider effect*. Furthermore, it may happen that a low Z_d disturbs the sensor (the signal source), changing the value of v_s and rendering the measurement useless or, worse still, damaging the sensor. Qualitatively, Z_d/Z_s should be large enough for the ADC not to detect that Z_d is finite, that is, the difference between v_s and v_d should be less than the resolution of the ADC (1 LSB). This requires $|Z_d + Z_s| > 2^N|Z_s|$.

At low frequencies, it is relatively easy to achieve large input impedances even for high-output impedance signals, such as those from piezoelectric sensors. At high frequencies, however, stray input capacitances make it more difficult. For narrowband signals this is not a problem, unless v_s were disturbed, because the value for Z_s and Z_d will be almost constant and any attenuation because of a loading effect can be compensated for later. However, if the impedance seen by broadband signals is frequency-dependent, then each frequency signal undergoes different attenuations which are impossible to compensate for.

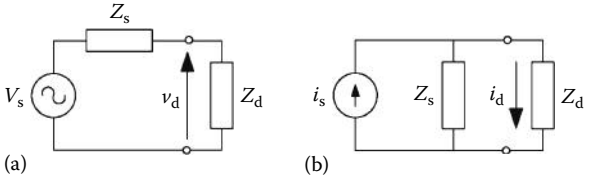

FIGURE 91.2 Equivalent circuit for a voltage signal connected to a voltage detector (a) and for a current signal connected to a current detector (b). We require $Z_d \gg Z_s$ in (a) to limit the voltage-loading effect, and $Z_d \ll Z_s$ in b) to limit the current shunting effect.

It is better to model signals with very high-output impedance as current sources (Figure 91.2b). The current through the detector will be

$$i_d = i_s \frac{Z_s}{Z_d + Z_s} \tag{91.2}$$

In order for $i_d = i_s$, it is required that $Z_d \ll Z_s$, which is easier to achieve than $Z_d \gg Z_s$. If Z_d is not low enough, then there is a *shunting effect*. Qualitatively, Z_d/Z_s should be small enough for the ADC not to detect that Z_d is nonzero.

91.4 General Amplifier Parameters

A *voltage amplifier* produces an output voltage which is a proportional reproduction of the voltage difference at its input terminals, regardless of any common-mode voltage and without loading the voltage source. Figure 91.3a shows the equivalent circuit for a general (differential) amplifier. If one input terminal is connected to one output terminal as in Figure 91.3b, the amplifier is single-ended; if this common terminal is (earth) grounded, the amplifier is single-ended and grounded; if the common terminal is isolated from ground, the amplifier is single-ended and floating. In any case, the output power comes from the power supply, and the input signal only controls the shape of the output signal, whose amplitude is determined by the *amplifier gain*, defined as

$$G(f) = \frac{V_o(f)}{V_d(f)} \tag{91.3}$$

The ideal amplifier would have any required gain for all signal frequencies. A practical amplifier has a *gain-bandwidth trade-off*, which implies that the larger the gain, the lower is the frequency where the gain starts to roll off; even for unity gain, at high frequency the gain decreases because of parasitic capacitances. In order to reduce noise and reject interference, it is common to add reactive components to reduce the gain for out-of-band frequencies further. If the gain decreases by $n \times 10$ when the frequency increases by 10, we say that the gain (downward) slope is $20n$ dB/decade. The corner (or –3 dB) frequency f_0 for the amplifier is that for which the voltage gain is 70% of that in the bandpass. (*Note*: 20 log 0.7 = –3 dB.)

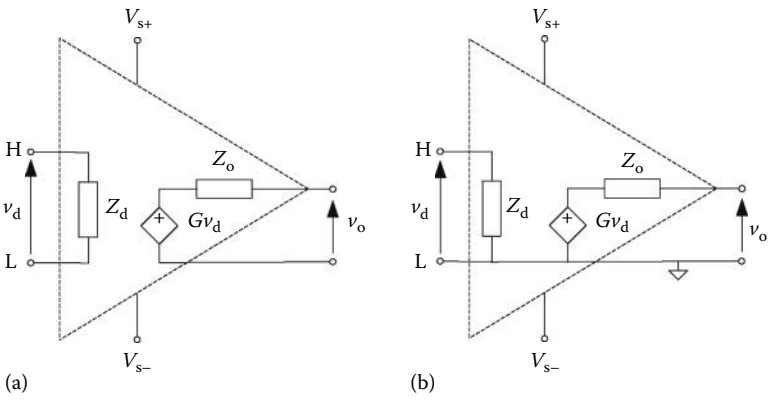

FIGURE 91.3 General amplifier with differential (a) or single-ended (b) input. The input voltage controls the amplitude of the output voltage, whose power comes from the power supply.

The *gain error* at f_0 is then 30%, which may be too large for some measurement applications. If a maximal error ε is accepted at a given frequency f_ε, then the corner frequency for the amplifier should be

$$f_0 = \frac{f_\varepsilon(1-\varepsilon)}{\sqrt{2\varepsilon-\varepsilon^2}} \approx \frac{f_\varepsilon}{\sqrt{2\varepsilon}} \tag{91.4}$$

For example, $\varepsilon = 0.01$ requires $f_0 = 7f_\varepsilon$, $\varepsilon = 0.001$ requires $f_0 = 22.4f_\varepsilon$. A broadband signal with frequency components larger than f_ε would undergo amplitude distortion. A narrowband signal centered on a frequency larger than f_ε would be amplified by a gain lower than expected, but if the actual gain is measured, the gain error can later be corrected.

Whenever the gain decreases, the output signal is delayed with respect to the output. In the aforementioned amplifier, an input sine wave of frequency f_0 will result in an output sine wave delayed by 45° (and with relative attenuation 30% as compared with a sine wave of frequency $f \ll f_0$). Complex waveforms that include frequency components close to f_0 would undergo shape (or phase) distortion. In order for a waveform to be faithfully reproduced at the output, the phase delay should be either zero or proportional to the frequency (linear phase shift). This last requirement is difficult to meet. Hence, for broadband signals it is common to design amplifiers whose bandwidth is larger than the maximal input frequency, even though this means that more amplifier noise will add to the amplified signal. (Power spectral density for amplifier noise has a white component plus an $1/f$ component at frequencies below 1 kHz for common models.) Narrowband signals undergo a delay which can be measured and corrected.

An ideal voltage amplifier would have infinite *input impedance*. Then no input current would flow when connecting the signal (Figure 91.2a), and no energy would be taken from the signal source, which would remain undisturbed. A practical voltage amplifier, however, will have a finite, yet large, input impedance at low frequencies, decreasing at larger frequencies because of stray input capacitances. If sensors are connected to conditioners by coaxial cables with grounded shields, then the capacitance to ground can be very large (from 70 to 100 pF/m, depending on the diameter of the cable). This capacitance can be reduced by using driven shields (or guards). If twisted pairs are used instead, the capacitance between wires is only about 5–8 pF/m, but there is an increased risk of capacitive interference; this interference, however, can be rejected by a balanced differential signal-to-amplifier connection.

Signal conditioners wired to remote sensors or working in environments where voltage or current surges are common, such as in automotive vehicles, or when there is risk of an electrostatic discharge (ESD), must be protected by *limiting* both *voltage* and *input currents*. Current can be limited by inserting a power resistor (e.g., 100 Ω–1 kΩ, 1 W), a polymeric positive temperature coefficient (PPTC) resistor, or a fuse between each signal source lead and conditioner input terminal; PPTC devices are resettable which is an advantage with respect to fuses that must be replaced when blown out. Current limiters increase the voltage-loading effect because they are connected in series to the internal impedance of the signal source.

Input voltages can be limited by connecting reverse-biased diodes, zeners, metal oxide varistors (MOV), gas-discharge devices, or other surge-suppression nonlinear devices, from each input line to dc power supply lines or to ground, depending on the particular protecting device. Voltage limiters reduce the conditioner input impedance because they are connected in parallel to it. Some devices, such as PolyZen® from Tyco Electronics, incorporate a Zener diode for voltage clamping and a PPTC resistor that responds to either diode heating or overcurrent events by transitioning from a low to high resistance state. Fault detection circuits intended to detect broken wires also add resistors from the conditioner input terminal to the supply voltages, which also limits their input resistance.

The ideal amplifier would also have zero *output impedance*. This would imply no loading effect because of possible finite input impedance for the following stage, low-output noise, and unlimited output power. Practical amplifiers can indeed have a low-output impedance and low noise, but their output power is very limited. Common signal amplifiers provide at best about 40 mA output current and sometimes only 10 mA, or even 1 mA in low-power amplifiers. The power gain, however, is quite noticeable, as input

currents can be in the picoampere range (10^{-12} A) and input voltages in the millivolt range (10^{-3} V); a 10 V, 10 mA output would mean a power gain of 10^{14}! Yet the output power available is very small (100 mW). Power amplifiers are quite the opposite; they have a relatively small power gain but provide a high-power output. For both signal and power amplifiers, output power comes from the power supply, not from the input signal, and maximal and minimal input and output voltage levels are determined by power supply voltages. The headroom between power supply voltages and maximal and minimal input and output voltages can be from 2 to 3 V in devices built with bipolar technologies, to a few millivolts in the so-called *rail-to-rail input* (RRI), *rail-to-rail output* (RRO), or *rail-to-rail input and output* (RRIO) amplifiers.

Some sensor signals do not require amplification but only *impedance transformation*, for example, to match their output impedance to that of a low-impedance ADC. Amplifiers for impedance transformation (or matching) and $G = 1$ are called *voltage buffers*.

91.5 Instrumentation Amplifiers

For instrumentation signals, the so-called *instrumentation amplifier* (IA, *ins amp*) offers performance closest to the ideal amplifier, at a moderate cost (from about $1.00 up). Figure 91.4a shows the symbol for the IA and Figure 91.4b its input/output relationship; ideally this is a straight line with slope G and passing through the point (0,0), but actually it is an off-zero, seemingly straight line, whose slope is somewhat different from G. The output voltage is

$$v_o = v_a + (V_{os} + V_b + v_r + v_n)G + V_{ref} \tag{91.5}$$

where

- v_a depends on the input voltage v_d, the second term includes offset, drift, noise, and interference-rejection errors
- G is the designed gain, set by an external resistor or a single connection between IC pins
- V_{ref} is the reference voltage, commonly 0 V (but not necessarily, thus allowing output level shifting)

Equation 91.5 describes a worst-case situation where absolute values for error sources are added. In practice, error sources will seldom achieve their worse value simultaneously. Nevertheless, if systematic effects are not calibrated out, the accuracy will seldom suit a 10 bit ADC. Calibration improves accuracy to about 14 bit for very low-frequency signals and 12 bit for ac signals.

Figure 91.5 shows a circuit model for *error analysis* when a practical IA is connected to a signal source (assumed to be differential for completeness). Impedance from each input terminal to ground (Z_c) and between input terminals (Z_d) are all finite. Furthermore, if the input terminals are both connected to (signal) ground, v_o is not zero and depends on G; this is modeled by V_{os}. If the input terminals are grounded through resistors, then v_o also depends on the value of these resistors; this is modeled by current sources

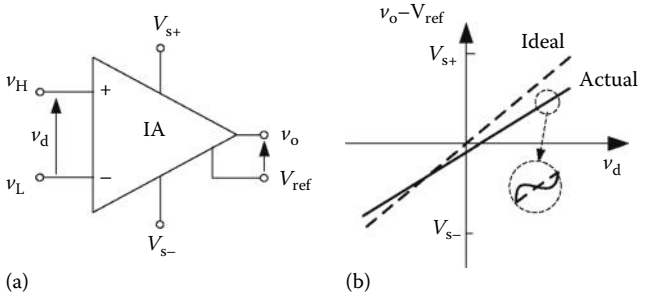

FIGURE 91.4 Instrumentation amplifier. (a) Symbol and (b) ideal and actual input/output relationship. The ideal response is a straight line through the point (0,0) and slope G, the gain.

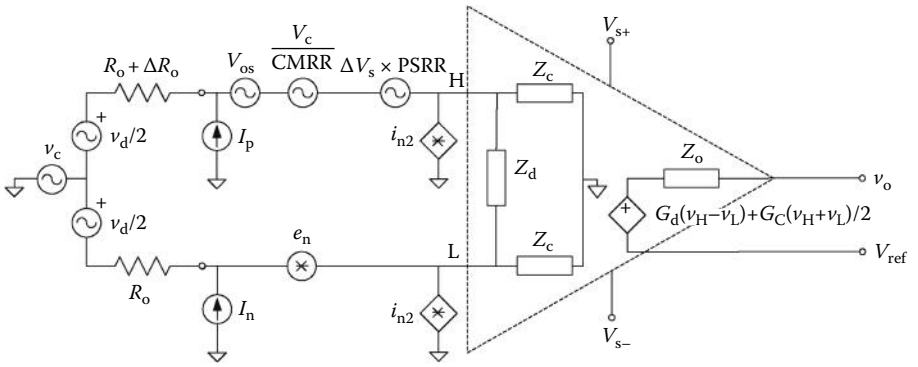

FIGURE 91.5 A circuit model for a practical instrumentation amplifier including major error sources.

I_p and I_n, which represent input bias or leakage currents. These currents need a return path, and therefore a third lead is required that connects the signal source to the amplifier, or to a common ground in the circuit. Neither V_{os} nor I_p nor I_n are constant; rather, they change with temperature and time: slow changes (<0.01 Hz) are called drifts and fast changes are described as noise (hence the noise sources e_n, i_{n1}, and i_{n2} in Figure 91.5). Common specifications for instrumentation amplifiers are defined in Ref. [2].

If a voltage v_c is simultaneously applied to both inputs, then v_o depends on v_c and its frequency. The *common-mode gain* is

$$G_c(f) = \frac{v_o(f)\big|_{v_d=0}}{v_c(f)} \tag{91.6}$$

v_c will be acceptable as long as $v_c \times G_c < 1$ LSB. In order to describe the output voltage due to v_c as an input error voltage, we must divide the corresponding v_o (when $v_d = 0$) by G (the normal or differential-mode gain, $G = G_d$). The *common-mode rejection ratio* (CMRR) is defined as

$$\text{CMRR} = \frac{G_d(f)}{G_c(f)} \tag{91.7}$$

and is usually expressed in decibels ($\{\text{CMRR}\}_{dB} = 20 \log \text{CMRR}$). Note that CMRR is not a gain but a quotient of gains, and it that it will depend on the frequency of the common-mode signal, not on that of the (differential-mode) signal. The input error voltage will be

$$\frac{v_o\big|_{v_c}}{G_d} = \frac{G_c v_c}{G_d} = \frac{v_c}{\text{CMRR}} \tag{91.8}$$

In the aforementioned analysis, we have assumed $Z_c \gg R_o$; otherwise, if there were any unbalance (such as ΔR_o for the source impedance in Figure 91.5), v_c at the voltage source would result in a differential-mode voltage at the amplifier input,

$$v_d\big|_{v_c} = v_c\left(\frac{R_o + \Delta R_o}{Z_c + R_o + \Delta R_o} - \frac{R_o}{Z_c + R_o}\right) = v_c \frac{z_c \Delta R_o}{(Z_c + R_o + \Delta R_o)(Z_c + R_o)} \approx v_c \frac{\Delta R_o}{Z_c} \tag{91.9}$$

which would be amplified by G_d. Then, the *effective CMRR* would be

$$\frac{1}{\text{CMRR}_e} = \frac{\Delta R_o}{Z_c} + \frac{1}{\text{CMRR}} \tag{91.10}$$

where CMRR is that of the IA alone, expressed as a fraction, not in decibels. A large $CMRR_e$ requires large common-mode input impedances Z_c relative to the signal source imbalance ΔR_o. Often, the CMRR for the amplifier is specified for $\Delta R_o = 1\ k\Omega$, which means that if the actual imbalance is smaller, the effective CMRR will be better than that specified. Stray capacitances from input terminals to ground will decrease Z_c, therefore reducing $CMRR_e$.

The ideal amplifier is unaffected by power supply fluctuations. The practical amplifier shows output fluctuations when supply voltages change. For slow changes ΔV_S, the equivalent input error can be expressed as a change in input offset voltages in terms of the *power supply rejection ratio* (PSRR):

$$\text{PSRR} = \frac{\Delta V_{os}}{\Delta V_S} \tag{91.11}$$

The terms in Equation 91.5 can be detailed as follows. Because of gain errors, we have

$$v_a = v_d\left(G + e_G + \frac{\Delta G}{\Delta T} \times \Delta T + e_{NLG}\right) \tag{91.12}$$

where

G is the differential gain designed (assumed to be constant in the bandpass for v_d)
e_G is its absolute error
$\Delta G/\Delta T$ is its thermal drift
ΔT is the difference between the actual temperature and that at which the gain G is specified
e_{NLG} is the nonlinearity gain error, which describes the extent to which the input/output relationship deviates from a straight line (insert in Figure 91.4b)

The actual (working) temperature T_J is calculated by adding to the current ambient temperature T_A the temperature rise produced by the power P_D dissipated in the device. This rise depends on the thermal resistance θ_{JA} for the case

$$T_J = T_A + P_D \times \theta_{JA} \tag{91.13}$$

where P_D can be calculated from the respective voltage and current supplies

$$P_D = |V_{S+}||I_{S+}| + |V_{S-}||I_{S-}| \tag{91.14}$$

The terms for the equivalent *input offset error* will be

$$V_{os} = V_{os}(T_a) + \frac{\Delta V_{os}}{\Delta T} \times (T_J - T_a) \tag{91.15}$$

$$V_b = (I_p - I_n)\ R_o + I_p \Delta R_o = I_{os} R_o + I_b \Delta R_o \tag{91.16}$$

where

T_a is the ambient temperature in data sheets
$I_{os} = I_p - I_n$ is the offset current
$I_b = (I_p + I_n)/2$

and all input currents must be calculated at the actual temperature,

$$I = I(T_a) + \frac{\Delta I}{\Delta T} \times (T_J - T_a) \tag{91.17}$$

Temperature must be corrected because offset voltage and current specifications for instrumentation amplifiers are measured shortly after turning the device on, hence before it warms up.

Error contributions from finite *interference rejection* are

$$v_r = \frac{v_c}{\text{CMRR}_e} + \Delta V_S \times \text{PSRR} \tag{91.18}$$

where

the CMRR_e must be that at the frequency for v_c

the PSRR must be that for the frequency of the ripple ΔV_S

It is assumed that both frequencies fall inside the bandpass for the signal of interest v_d.

The equivalent *input voltage noise* is

$$v_n = \sqrt{e_n^2 B_e + i_{n1}^2 R_o^2 B_{i1} + i_{n2}^2 R_o^2 B_{i2}} \tag{91.19}$$

where

e_n^2 is the voltage noise power spectral density of the IA

i_{n1}^2 and i_{n2}^2 are the current noise power spectral densities for each input of the IA (normally $i_{n1}^2 = i_{n2}^2$, and to simplify they are assumed to be uncorrelated, even though they are not)

B_e, B_{i1}, and B_{i2} are the respective noise equivalent bandwidths of each noise source

In Figure 91.5, the transfer function for each noise source is the same as that of the signal v_d, but this is not always the case, for example, when signals are ac-coupled to the IA using a high-pass filter. If the signal bandwidth is determined as $f_H - f_L$ by sharp filters, then

$$B_e = f_H - f_L + f_{ce} \ln \frac{f_H}{f_L} \tag{91.20}$$

$$B_{i1} = B_{i2} = f_H - f_L + f_{ci} \ln \frac{f_H}{f_L} \tag{91.21}$$

where f_{ce} and f_{ci} are, respectively, the frequencies where the value of voltage and current noise power spectral densities is twice their value at high frequency, also known as corner or –3 dB frequencies.

Another noise specification method for instrumentation amplifiers states the peak-to-peak noise at a given low-frequency band (f_A to f_B), usually 0.1–10 Hz, and the noise spectral density at a frequency at which it is already constant, normally 1 or 10 kHz. In these cases, if the contribution from noise currents is negligible, the equivalent input voltage noise can be calculated from

$$v_n = \sqrt{v_{nL}^2 + v_{nH}^2} \tag{91.22}$$

where v_{nL} and v_{nH} are, respectively, the voltage noise in the low-frequency and high-frequency bands expressed in the same units (peak-to-peak or rms voltages). To convert rms voltages into

peak-to-peak values, multiply by 6.6. If the signal bandwidth is from f_L to f_H, and $f_L = f_A$ and $f_H > f_B$, then Equation 91.22 can be written

$$v_n = \sqrt{v_{nL}^2 + (6.6e_n)^2(f_H - f_B)} \tag{91.23}$$

where

v_{nL} is the specified peak-to-peak value
e_n is the rms voltage noise as specified in data books

Equation 91.23 results in a peak-to-peak calculated noise that is somewhat lower than the real noise, because noise spectral density is not constant from f_B up to f_H. However, it is a simple approach providing an useful estimate.

For signal sources with high-output resistors, thermal and excess noise from resistors must be included. For first- and second-order filters, noise bandwidth is slightly larger than signal bandwidth. Motchenbacher and Connelly [3] show how to calculate noise bandwidth, resistor noise, and noise transfer functions when different from signal transfer functions.

Low-noise design always seeks the minimal bandwidth required for the signal. When amplifying low-frequency signals, if a large capacitor C_i is connected across the input terminals in Figure 91.5, then noise and interference having a frequency larger than $f_0 = 1/(2\pi 2R_oC_i)$ ($f_0 \ll f_s$) will be attenuated. As for low-frequency noise, minimal signal bandwidth does not necessarily ensure minimal noise. Hence, ac coupling, for example to cancel out offset, must consider that the noise bandwidth for input noise currents is not the same as the signal bandwidth.

Another possible source of error for any IA, not included in Equation 91.5, is the *slew rate limit* of its output stage. Because of the limited current available inside the IA, the voltage at the output terminal cannot change faster than a specified value SR. Then, if the maximal amplitude A of an output sine wave of frequency f exceeds

$$A = \frac{SR}{2\pi f} \tag{91.24}$$

the waveform will be distorted near zero crossings.

Table 91.1 lists some basic specifications for IC instrumentation amplifiers whose gain G can be set by an external resistor or a single connection.

91.5.1 Instrumentation Amplifiers Built from Discrete Parts

Instrumentation amplifiers can be built from discrete parts by using operational amplifiers (op amps) and a few resistors. By so doing, the amplifier bandwidth can be better tailored to the signal bandwidth, and some shortcomings of IC instrumentation amplifiers can be overcome, such as limited high-frequency gain or slew rate. An *op amp* is basically a differential voltage amplifier whose gain A_d is very large (from 10^5 to 10^7) at dc and rolls off (20 dB/decade) from frequencies of about 1 to 100 Hz, becoming 1 at frequencies from 1 to 10 MHz for common models (Figure 91.6a), and whose input impedances are so high (up to $10^{12}\ \Omega||1$ pF) that input currents are almost negligible. Op amps can also be modeled by the circuit in Figure 91.5, and their symbol is that in Figure 91.4a, either deleting IA or replacing it by OA. However, because of their large gain, op amps cannot be used directly as amplifiers; a mere 1 mV dc input voltage would saturate any op-amp output. Furthermore, op-amp gain changes from unit to unit, even for the same model, and for a given unit it changes with time, temperature, and supply voltages.

Note: All parameter values are maximum, unless otherwise stated (typ, typical; min, minimum; n.a., not applicable; n.s., not specified). Measurement conditions are similar; consult manufacturers' data books for further detail.

[a] For the INA110, the gain nonlinearity error is specified as percentage of the full-scale output.

[b] Input current drift for the INA110KP approximately doubles for every 10 °C increase, from 25 °C (10 pA-typ) to 125 °C (10 nA-typ).

[c] The PSRR for the INA110 is specified as an input offset ±(10 + 180/G) μV/V maximum.

Nevertheless, external negative feedback around op amps yields a variety of analog circuits with excellent performance, thus rendering op amps very flexible. They are also cheaper than instrumentation amplifiers as they cost below $0.20 for packages with four units with modest performance. But when the cost for external feedback components and their connections and overall reliability are also considered, the optimal solution depends on the situation.

Figure 91.6b shows an amplifier built from an op amp with external feedback. If input currents are neglected, the current through R_2 will flow through R_1 and we have

$$v_d = v_i - v_o \frac{R_1}{R_1 + R_2} \tag{91.25}$$

$$v_o = A_d v_d \tag{91.26}$$

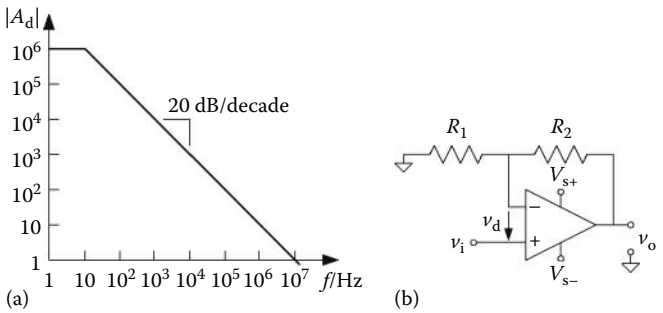

FIGURE 91.6 (a) Open-loop gain for an op amp and (b) voltage amplifier based on an op amp with external feedback.

Therefore,

$$\frac{v_o}{v_i} = \frac{A_d\left(1+\dfrac{R_2}{R_1}\right)}{A_d+1+\dfrac{R_2}{R_1}} = \frac{G_i}{1+\dfrac{G_i}{A_d}} \tag{91.27}$$

where $G_i = 1 + R_2/R_1$ is the ideal gain for the amplifier. If G_i/A_d is small enough (G_i small, A_d large), the gain does not depend on A_d but only on external components. At high frequencies, however, A_d becomes smaller and, from Equation 91.7, $v_o < G_j v_i$ so that the bandwidth for the amplifier will reduce for large gains. Franco [4] analyzes different op-amp circuits useful for signal conditioning.

Figure 91.7 shows an IA built from three op amps in two stages. The input stage is a fully differential amplifier and the output stage is a *difference amplifier* converting a differential voltage into a single-ended output voltage. Difference amplifiers (op amp and matched resistors) are available in IC form from several manufactures (Analog Devices, National Semiconductor, Texas Instruments). The gain equation for the complete IA is

$$G = \left(1+2\frac{R_2}{R_1}\right)\frac{R_4}{R_3} \tag{91.28}$$

Pallas-Areny and Webster [5] have analyzed matching conditions in order to achieve a high CMRR. Resistors R_2 do not need to be matched but the input op amps must. Resistors R_3 and R_4 need to be closely matched, hence the interest on an IC difference amplifier. If R_1 can be selected from a resistor network, for example by analog switches, we have a *programmable-gain amplifier* (PGA); *digitally controlled potentiometers*, available from several manufactures, include such an array of resistors and analog switches.

The *three-op-amp IA* has a symmetrical structure making it easy to design and test. Instrumentation amplifiers based on an IC difference amplifier do not need any user trim for high CMRR. The circuit in Figure 91.8 is an IA that lacks these advantages but uses only two op amps. Its gain equation is

$$G = 1+\frac{R_2}{R_1}+\frac{2R_2}{R_G} \tag{91.29}$$

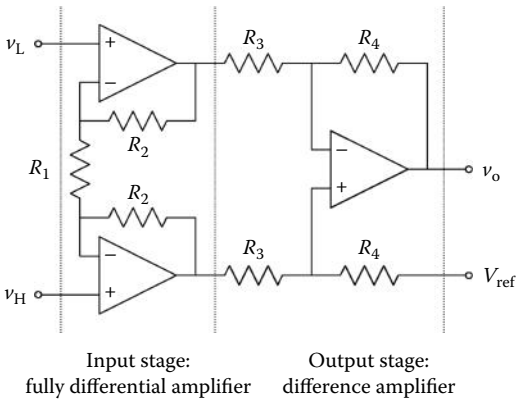

FIGURE 91.7 Instrumentation amplifier built from three op amps. The two input op amps, and R_3 and R_4 must be matched. IC difference amplifiers include an op amp and matched R_3 and R_4. This amplifier can be replaced by a LT1167 amplifier.

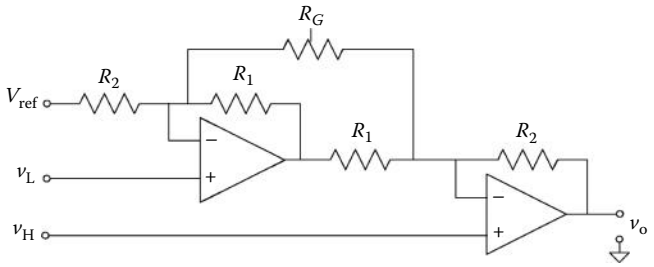

FIGURE 91.8 Instrumentation amplifier built from two op amps. R_1 and R_2 must be matched.

R_1 and R_2 must be matched and R_G should be comparable to R_2. Noise in instrumentation amplifiers built from discrete op amps may exceed that from integrated IAs because noise from separate op amps will be uncorrelated.

91.5.2 Composite Instrumentation Amplifiers

Instrumentation amplifiers have a gain limited to about 10,000, at low frequencies, and a bandwidth around 4 MHz for a gain of 10. Moreover, their inputs must be either dc-coupled or, if ac-coupled with input series capacitors, there must be a path for bias currents; if that path is a resistor from each input to ground, then the common-mode input impedance Z_c decreases and interference from the common-mode voltage increases.

Bandwidth can be increased by cascade connection of two or more amplifiers. However, if the additional gain is provided by a single-ended amplifier after the IA, then the overall CMRR is that of the IA, which is small at high frequencies. The circuit in Figure 91.9a is a broadband IA with large CMRR because the CMRR for the second stage is multiplied by the differential gain for the first stage, which can be very high if implemented by broadband op amps. The overall gain is

$$G = G_1 G_2 = \left(1 + \frac{2R_b}{R_a}\right) G_{IA} \tag{91.30}$$

The input stage can also be used as fully differential amplifier for differential-input ADCs.

An IA can be *ac-coupled* by feeding back its dc output to the reference terminal as shown in Figure 91.9b. The high-pass corner frequency is $f_0 = 1/(2\pi R_0 C_0)$. However, the dc level of the input signal will be amplified by the gain of the IA's first stage, whose output can saturate. Alternatively, a passive fully

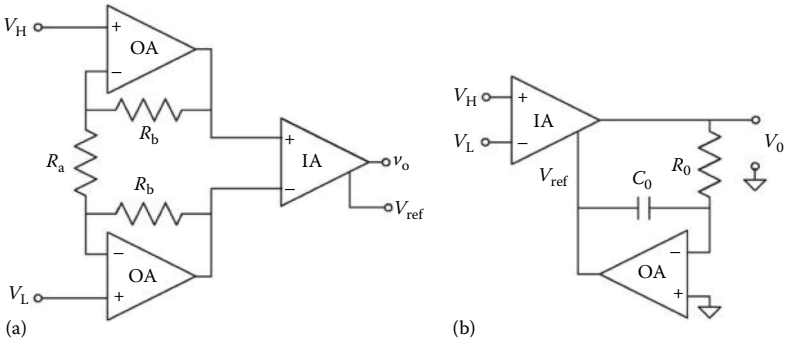

FIGURE 91.9 Composite instrumentation amplifiers. (a) Broadband IA with large CMRR built by preceding an IA by a fully differential amplifier and (b) the ac-coupled IA; the maximal dc level of the input voltage is limited by the gain of the input stage.

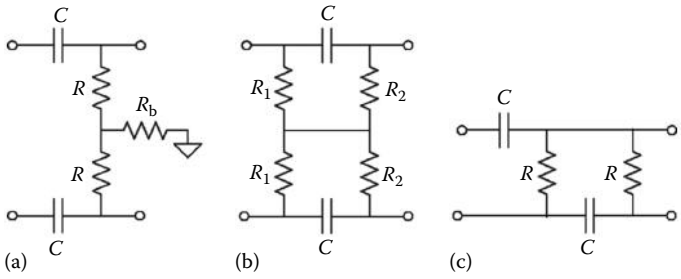

FIGURE 91.10 Fully differential ac-coupling networks, with first-order response (a) and (b), and second-order response (c).

differential high-pass filter can be placed in front of the IA, either in Figure 91.9b or in Figure 91.9a, which has a higher input impedance than that in Figure 91.9b. Figure 91.10 shows three alternative ac-coupling networks that do not need any component matching to achieve a large CMRR. Networks (a) and (b) are first-order filters, whereas network (c) is a second-order filter. R_b in circuit (a) and resistors R_1 in network (b) provide a means to bias the IA correctly; R_b reduces the CMRR, and R_1 limits the input impedance. Networks (b) and (c) yield the best CMRR because they have no connections to signal ground. Network (b) has the longer transient response to differential signals (damping ratio $\zeta = 1.5$), whereas the transient response of network (a) to common-mode input signals depends on component tolerance. Reference [6] compares the performance of each network when the limited input common-mode input impedance and input bias currents of the ensuing differential amplifier are considered.

91.6 Single-Ended Signal Conditioners

Single-ended floating signals can be connected to amplifiers with single-ended grounded input. Single-ended grounded signals can be connected to *single-ended amplifiers* provided the difference in ground potentials from signal to amplifier is not too large. Otherwise, a differential amplifier must be connected between signal terminals; thus, the voltage drop between (signal and amplifier) ground potentials becomes a common-mode voltage to the amplifier.

91.6.1 Inverting and Noninverting Voltage Amplifiers

Figure 91.11a shows a simple single-ended inverting amplifier based on an IA. However, op amps are normally better suited than IAs for single-ended amplifiers and signal conditioners that must perform functions additional or alternative to voltage amplification, such as filtering or integration. Figure 91.11b shows an op amp–based *inverting amplifier* whose gain is $G = -R_2/R_1$, and whose input impedance is R_1,

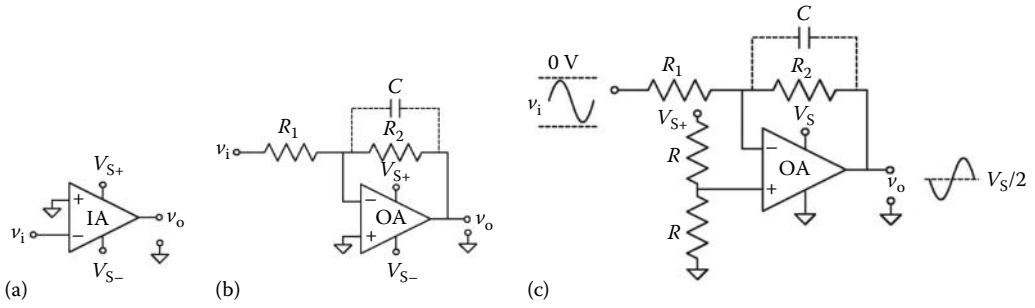

FIGURE 91.11 Single-ended inverting voltage amplifiers based on (a) an IA, (b) an op amp with split power supply, and (c) an op amp with a single power supply.

much smaller than that of the inverting amplifier built from an IA (Figure 91.11a). The capacitor on the dashed line (10 pF or larger) prevents gain peaking and oscillation. Signals with frequency larger than $f_c = 1/(2\pi R_2 C)$ are attenuated at a rate of 20 dB/decade; attenuation at f_c is 3 dB. If a capacitor C replaces R_2, input voltages are integrated and inverted. If C replaces R_1, instead, input voltages are differentiated and inverted. If the op amp is supplied by a single power source V_S instead of a split power source (V_{S+}, V_{S-}), the noninverting input must be biased to $V_S/2$, as shown in Figure 91.11c; the output voltage v_o can swing from about 0 V to about V_S, and will be close to $V_S/2$ when $v_i = 0$ V. For $v_i > 0$ V, the output will saturate. The same can be said for the inverting amplifier in Figure 91.11a if the IA is supplied between V_S and 0 V.

The circuit in Figure 91.6b is an op amp–based *noninverting amplifier* whose gain is $G = 1 + R_2/R_1$ and whose input impedance is close to the common-mode input impedance of the op amp, hence very large. By adding capacitors, undesired low- or high-frequency signals can be attenuated. For example, the amplifier in Figure 91.12a has $G = 1$ for dc signals, very low-frequency signals relative to $f_1 = 1/(2\pi R_1 C_1)$ (offset and drift included), and very high-frequency signals relative to $f_2 = 1/(2\pi R_2 C_2)$. The asymptotic gain in the passband is $G = 1 + R_2/R_1$; if f_2 is not at least 10 times larger than f_1, the actual gain will deviate from G by >10%. If the op amp is supplied by a single power source V_S, negative input voltages will saturate the output, and input voltages whose average value is relatively far from $V_S/2$ can result in a distorted output. Alternatively, if a single power supply is available, ac signals can be amplified with the circuit in Figure 91.12b. A noninverting amplifier can also be built from an IA as shown in Figure 91.12c; however, low-pass filtering must be then performed in later stages. The circuit in Figure 91.12d calculates the average for n voltages and amplifies it by $1 + R_2/R_1$. The difference between two voltages can be obtained from the difference amplifier in Figure 91.7 (output stage).

Op amps (and IAs) must be carefully selected according to the application. For dc circuits, *autozero op amps* (and autozero IAs) and *chopper-stabilized op amps* offer the best performance, with offset

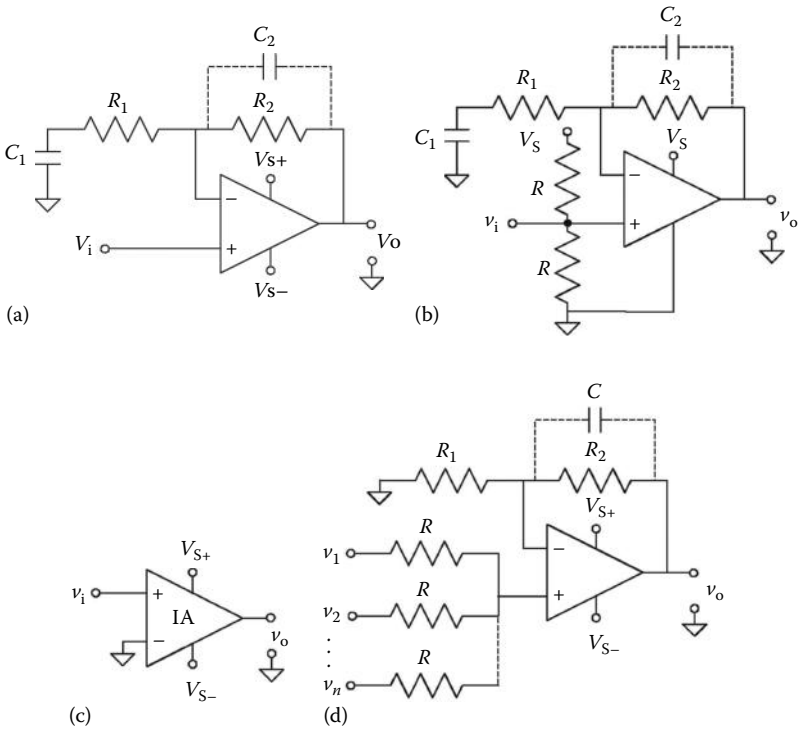

FIGURE 91.12 Single-ended noninverting amplifiers: ac amplifier based on (a) an op amp with split supply or (b) single supply, (c) dc amplifier based on an IA, and (d) voltage average amplifier.

voltages as low as 1–10 μV and temperature drifts below 0.1 μV/°C. For low-impedance signals, op amps with bipolar input transistors are better because of their lower offset voltage and voltage noise. For high-impedance signals, op amps with FET input transistors (J-FET or CMOS) offer lower input currents than bipolar amplifiers at room temperature, but they have larger drift and voltage noise, and their bias (input leakage) currents almost double each 10°C. Bipolar op amps offer wide power supply rails (+15 V/–15 V, +12 V/–12 V), whereas power supply rails for CMOS op amps seldom exceed +5 V/–5 V, yet these offer low-power consumption and there are low-supply voltage models, from 5 to 1.8 V. Manufacturers provide interactive selection guides in their websites that identify their most appropriate models for a set of user-defined values for some parameters.

91.6.2 Transimpedance Amplifiers

Current signals in instrumentation come from current-output sensors, such as photodiodes and some *p-n* junction–based temperature sensors (AD590 and the like), and also from 4 to 20 mA current loops used for signal transmission. Current can be sensed by inserting a resistor R in the current loop and measuring the drop in voltage across R using a single-ended or a differential voltage amplifier, depending on whether one of the resistor terminals is grounded or not. However, small currents may need $R = 100$ MΩ or even larger resistor values, which result in a measurement circuit with a large equivalent resistance, hence susceptible to capacitive interference as any small current coupled to the circuit will produce a large drop in voltage that can saturate it. A grounded shield enclosing the circuit reduces interference but at the cost of a large capacitance from the signal line to ground, which will reduce signal bandwidth. A transimpedance amplifier (Figure 91.13a) improves the bandwidth by placing the sensing resistor in the feedback loop of an op amp, whose input bias current must be negligible compared to the sensor current if this one includes low-frequency components. Stray capacitance from the sensor terminal to ground has a minor effect on bandwidth as the voltage at the inverting terminal is very close to signal ground; that stray capacitance, however, can induce oscillations, which can be prevented by shunting R with a capacitor C, in the range of picofarads. C will ultimately limit the signal bandwidth, but not that much as sensor and cable capacitance because these can be in the order of tens of nanofarads. In any case, the maximal "gain" I will be limited by the op-amp open-loop gain. Graeme [7] provides a thorough analysis of amplifiers for photodiodes.

91.6.3 Charge Amplifiers/Converters

Sensors whose equivalent circuit is a voltage source with an internal capacitive impedance are prone to interference the same as current-output sensors. That is the case for piezoelectric sensors and sensors based on a variation of capacitance. Measuring the voltage without incurring in an unacceptable voltage-loading effect requires an amplifier with very large input impedance. This is feasible at low

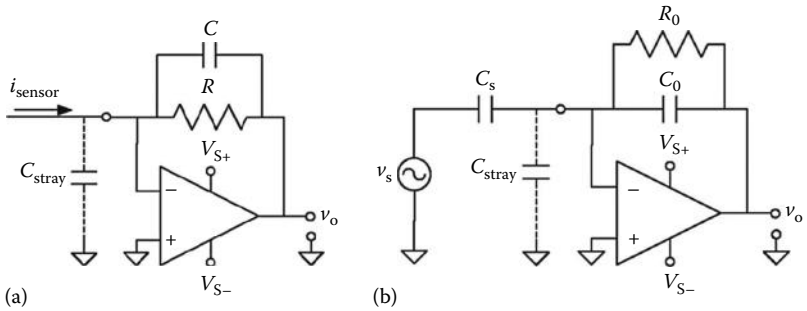

FIGURE 91.13 (a) Transimpedance amplifier to convert current to voltage and (b) charge amplifier/converter to convert charge to voltage.

frequencies, as a noninverting amplifier can provide it, but it is hard to achieve at medium to high frequencies because of stray capacitances to ground. The charge amplifier in Figure 91.13b is an alternative to voltage amplifiers: the sensor voltage yields a current through its internal capacitance C_s, and this current is converted into a voltage by flowing through C_0. The output voltage will be $v_o = -v_s C_s/C_0$, and its internal impedance will be very small as it corresponds to the op-amp output with negative feedback. Because there is no charge amplification but a charge transfer from C_s to C_0, this circuit is also called *charge converter*: it converts the charge across the sensor into a low-impedance voltage (v_o). R_0 provides a path for op-amp bias currents; it limits the (–3 dB) low-frequency response to $f_0 = 1/(2\pi R_0 C_0)$ and contributes to the output offset voltage ($I_b R_0$), albeit this offset can be canceled by high-pass coupling the output voltage to the next signal-processing stage.

91.6.4 Current Integrators

A current connected to the input of a charge amplifier will charge C_0 until the output voltage reaches the limits of the output signal range for the op amp, close to the power supply rails in the best case. The input–output relation if the integration time τ is short enough to not reach those limits will be

$$v_o(t) = -\frac{1}{C_0}\int_{t_1}^{t_1+\tau} i_i(t)dt \tag{91.31}$$

To obtain the response in the frequency domain, we assume $i_i(t) = I \sin\omega t$ to obtain

$$V_o(\omega) = -\frac{1}{C_0}\int_{t_1}^{t_1+\tau} I\sin\omega t\, dt = -\frac{I\omega}{C_0} 2\sin\left(\omega t_1 + \frac{\omega\tau}{2}\right)\sin\frac{\omega\tau}{2} \tag{91.32}$$

The absolute value of this voltage will be maximal when $\omega t_1 + \omega\tau/2 = \pi/2$. Then,

$$V_o(f) = \frac{I\tau}{C_0}\frac{\sin\pi f\tau}{\pi f\tau} = V_o(0)\frac{\sin\pi f\tau}{\pi f\tau} \tag{91.33}$$

where $V_o(0)$ is the dc amplitude response. Integration, it turns out, attenuates high-frequency signals, and those signals whose frequency is such that $f\tau$ is an integer, that is, multiple of the reciprocal of the integration time. The ability to discriminate signals of interest from those added to them is described by the *series* (or *normal*) *mode rejection ratio* (SMRR, NMRR), and is usually expressed in decibels. In the present case, if the signals of interest are those that remain constant during $\tau (f\tau \to 0)$,

$$\text{SMRR} = 20\log\frac{V_o(0)}{V_o(f_c)} = 20\log\frac{\pi f\tau}{\sin\pi f\tau} \tag{91.34}$$

which is represented in Figure 91.14a. Integrating ADCs have this same comblike response, which is used to reduce power-line interference.

Figure 91.14b shows the simplified equivalent circuit of an IC integrator; opening switch S1 stops the integration time and closing switch S2 resets the integration capacitor before starting to integrate the input current again. The ACF2101 and IVC102 are switched integrators that use this approach, the same as the DDC112, a dual input ADC that digitizes low-level currents by first converting them to voltage; current integration is continuous as each input uses two integrators: while one is being digitized, the other is integrating.

Table 91.2 lists some parameters for several different op amps. Some manufacturers provide selection guides which suggest the most appropriate model for a set of *r*-defined values for some parameters.

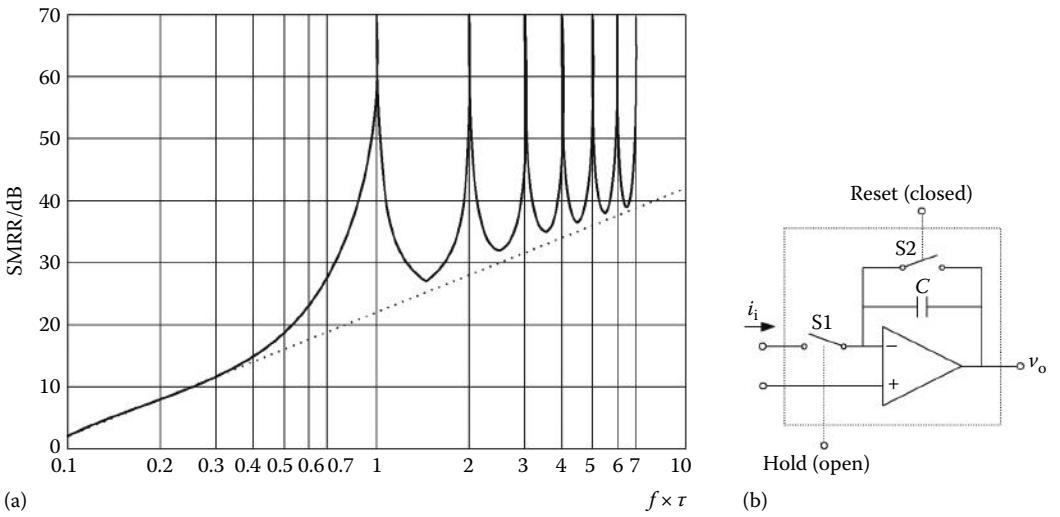

FIGURE 91.14 (a) Series-mode rejection ratio (SMRR) for an integrator: interference rejection is maximal for frequencies multiple of the reciprocal of the period of integration; (b) simplified schematic for a switching IC current integrator.

91.7 Carrier Amplifiers

A *carrier amplifier* is a conditioner for extremely narrowband ac signals from ac-driven sensors. A carrier amplifier is made of a sine wave oscillator, to excite the sensor (either directly as in LVDTs, or placed in a voltage divider or sensor bridge, as in sensors based in a variable capacitance, inductance, or resistance), an ac voltage amplifier for the sensor output, a synchronous demodulator, and a low-pass filter (Figure 91.15). The AD598, AD698, and NE5520/1 are carrier amplifiers in IC form intended for (but not limited to) LVDTs driven at a frequency from 2 to 20 kHz.

Carrier amplifiers make it possible to recover the amplitude and phase of the modulating signal after amplifying the output modulated waveform from the bridge or voltage divider. This is useful first because ac amplifiers are not affected by offset, drift, or low-frequency noise, and therefore the bridge or voltage-divider output can easily be amplified. Second, the *phase-sensitive demodulator* yields not only the amplitude but also the sign of the measurand. If the measurement range includes positive and negative values for the measurand, phase detection is essential.

A further advantage of carrier amplifiers is their extremely narrow frequency response, determined by the output low-pass filter. In the demodulator, the product of the modulated carrier of frequency f_c by the reference signal, also of frequency f_c, results in a baseband component and components at nf_c ($n \geq 2$). The output low-pass filter rejects components other than the baseband. If the corner frequency for this filter is f_0, then the passband for the system is $f_c \pm f_0$. Therefore, any interference of frequency f_i added to the modulated signal will be rejected if falling outside that passband. The SMRR when the output low-pass filter is Butterworth with order n is

$$\text{SMRR} = 20\log\frac{|v_o(f_c)|}{|v_o(f_i)|} = 20\log\sqrt{1+\left(\frac{f_c - f_i}{f_0}\right)^{2n}} \approx 20n\log\frac{|f_c - f_i|}{f_0} \tag{91.35}$$

A power-line interference superimposed on a 10 kHz carrier will undergo an 80 dB attenuation if the output low-pass filter is first order and has $f_0 = 1$ Hz. The same interference superimposed on the baseband signal would be attenuated by only 35 dB.

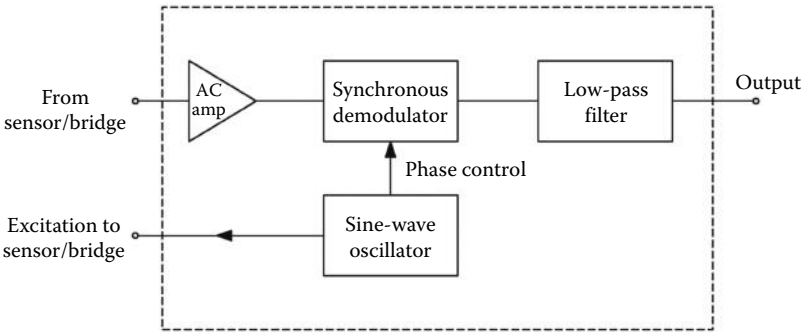

FIGURE 91.15 Elements for a carrier amplifier.

Carrier amplifiers can be built from a precision sine wave oscillator, and a demodulator (plus the output low-pass filter). The AD630 is an IC demodulator based on switched amplifiers. Alternatively, amplitude demodulation can be performed in the digital domain [8].

91.8 Lock-In Amplifiers

A *lock-in amplifier* is based on the same principle as a carrier amplifier, but instead of driving the sensor, here the carrier signal drives the experiment, so that the measurand is frequency translated. Lock-in amplifiers are manufactured as equipment intended for recovering signals immersed in high (asynchronous) noise. These amplifiers provide a range of driving frequencies and bandwidths for the output filter. Some models are vectorial because they make it possible to recover the in-phase and quadrature (90° out-of-phase) components of the incoming signal, by using two demodulators whose reference signals are delayed by 90°. Still other models use bandpass filters for the modulated signal and two demodulating stages. Meade [9] analyzes the fundamentals and specifications of analog lock-in amplifiers. Signal recovery (a division of Ametek, Inc.) offers, upon registration in its website, several application notes about analog and digital lock-in amplifiers.

91.9 Isolation Amplifiers

The maximal common-mode voltage withstood by common amplifiers is smaller than their supply voltage range and seldom exceeds 10 V. Exceptions are some difference amplifiers that integrate an input voltage divider and whose common-mode range is up to ±200 V. Signals with large off-ground voltages, for example, in voltage dividers or sensor bridges, or differences in ground potentials between signals and amplifiers exceeding the input common-mode range, result in permanent amplifier damage or destruction, and a safety risk, in spite of an exceptional CMRR: a 100 V common-mode 60 Hz voltage at the input of a common IA having a 120 dB CMRR at power-line frequency does not result in a $100\ V/10^6 = 100\ \mu V$ output, but a burned-out IA.

Figure 91.16a shows a signal source grounded at a point 1 far from the amplifier ground (point 2). Both ends of the signal loop have paths to ground, and the difference in voltage between grounds $v_i = v_2 - v_1$ forces a current into a signal line (and back to ground) that not only distorts the true measurement because of the drop in voltage across the nonnegligible lead impedance, but also can destroy the amplifier. Avoiding the *ground loop* by "lifting" one of the two ground connections would solve the problem but electrical safety codes mandate local earth ground connections. The solution is to break the ground loop to prevent voltage between grounds from forcing any large current through the signal circuit and at the same time to provide an information link between the signal source and the amplifier receiver. Figure 91.16b shows a solution: the signal source and the amplifier have separated (isolated) power supplies and the signal is coupled to the amplifier through a transformer acting as an isolation barrier for v_i;

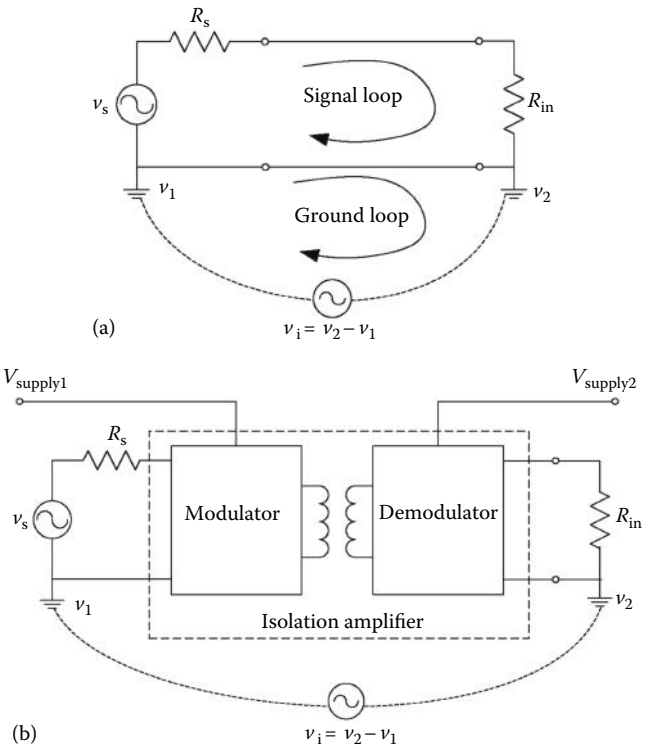

FIGURE 91.16 (a) A large difference in ground potentials damages amplifiers. (b) An isolation amplifier breaks the ground loop thus preventing large currents caused by the difference in ground potentials from flowing through the circuit.

the only current forced by v_i will be that allowed by the stray capacitance between the transformer's primary and secondary windings. Other isolation barriers are optocouplers, series capacitors, and magnetoresistors. Those barriers impose a large series impedance (isolation impedance, Z_i) but do not usually have a good low-frequency response, hence the need to modulate and then demodulate the signal to be transferred through Z_i. The subsystem made of the modulator and demodulator, plus sometimes an input and an output amplifier and a dc–dc converter for the separate power supply, is called an *isolation amplifier*. The ability to reject the voltage difference across the barrier (isolation-mode voltage, v_i) is described by the *isolation mode rejection ratio* (IMRR), expressed in decibels:

$$\text{IMRR} = 20 \log \frac{\text{Isolation-mode voltage}}{\text{Output voltage}} \tag{91.36}$$

Ground isolation also protects people and equipment from contact with high voltage because Z_i limits the maximal current. Some commercial isolation amplifiers are the AD20x series, and AD210/5 (Analog Devices), the ISO121/2/4 (Texas Instruments), and the HCPL-7850 and 5962-9755701 (Avago Technologies). Sometimes, it is more cost-effective to isolate digital rather than analog signals because digital isolators are far less expensive than isolation amplifiers. This means to postpone isolation after A-to-D conversion and implies a larger isolated power supply for the circuits previous to the isolation barrier.

Table 91.3 summarizes the compatibility between signal sources and amplifiers. When grounded, amplifiers and signals are assumed to be grounded at different physical points. Floating signals can be connected to any amplifier, provided other requirements are fulfilled; for example, if a single-ended

TABLE 91.3 Compatibility between Signal Sources and Conditioners

Conditioner → / Input signal source ↓					Incompatible unless grounds are very close	Compatible if CMRR is large	Compatible	Compatible
	Compatible	Compatible	Compatible	Compatible
	Incompatible unless grounds are very close	Compatible if CMRR is large	Compatible for large Z_i	Compatible

	Incompatible	Compatible	Compatible for large Z_i	Compatible
	Compatible	Compatible	Compatible	Compatible
	Incompatible	Compatible if CMRR is large	Compatible for large Z_i	Compatible

Note: When grounded, signals sources and amplifiers are assumed to be grounded at different points. Isolation impedance is assumed to be very high for floating signal sources but finite (Z_i) for conditioners. Single-ended signals are considered to be compatible with isolated differential conditioners because resistors can be included to bias the conditioner correctly.

floating signal is connected to a differential amplifier, a bias resistor must be connected from each amplifier input to ground because ground currents cannot flow to ground through the floating (isolated) signal ground. Conversely, isolation amplifiers can be connected to any signal, but a bias path must be provided if the signal source does not provide it.

91.10 Analog Linearization

Nonlinearity in instrumentation can result from the measurement principle, from the sensor, or from sensor conditioning. In pressure-drop flowmeters, for example, the drop in pressure measured is proportional to the square of the flow velocity; hence, flow velocity can be obtained by taking the square root of the pressure signal. Calculations are better performed using digital processors. Many sensors are linear only in a restricted measurand range; others are essentially nonlinear (NTC thermistors, LDR); still others are linear in some ranges but nonlinear in other ranges of interest (thermocouples). Linearization techniques for particular sensors are described in the respective chapters.

Nonlinearity attributable to sensor conditioning is common, for example, when resistive (linear) sensors are placed in voltage dividers or sensor bridges. The Wheatstone bridge in Figure 91.17a, for example, includes a (single) linear sensor but yields a nonlinear output voltage:

$$v_s = V_r\left(\frac{1+x}{2+x} - \frac{1}{2}\right) = \frac{V_r x}{2(2+x)} \tag{91.37}$$

The nonlinearity arises from the dependence of the current through the sensor on its resistance, because the bridge is supplied at a constant voltage. The circuit in Figure 91.17b provides a solution based on 1 op amp which forces a constant current V_r/R_0 through the sensor. The bridge output voltage is

$$v_s = \frac{V_r - v_a}{2} + v_a = \frac{V_r + v_a}{2} = V_r\frac{x}{2} \tag{91.38}$$

In addition, v_s is single-ended whereas in Figure 91.17a it was differential. The op amp must have a good dc performance and the output will need further amplification.

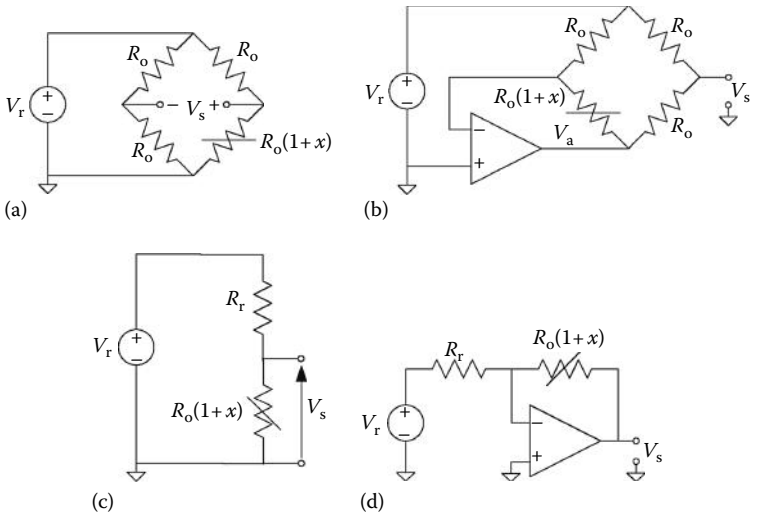

FIGURE 91.17 (a) A Wheatstone bridge with a single sensor yields a nonlinear output voltage; (b) by adding an op amp which forces a constant current through the sensor, the output voltage is linearized; (c) a voltage divider with a single linear sensor also yields a nonlinear output voltage; and (d) forcing a constant current through the sensor linearizes the output voltage.

The same applies to voltage dividers. Figure 91.17c shows a voltage divider with a single linear sensor, and whose output voltage is

$$v_s = V_r \frac{R_0(1+x)}{R_r + R_0(1+x)} = V_r \frac{1+x}{R_r/R_0 + 1 + x} \tag{91.39}$$

If $R_r/R_0 + 1 \gg x$, the output will be approximately linear, at the cost of a reduced sensitivity (which would require $R_r = R_0$). Forcing a constant current through the sensor, as shown in Figure 91.17d, would yield a linear output for any R_r and x.

If the sensor in Figure 91.17a and c was nonlinear, the nonlinearity of the Wheatstone bridge and voltage divider can be used in some cases to linearize the output voltage, to some extent. For example, if the sensor has a concave-upward calibration curve (such as NTC and PTC thermistors) and its values for x_1, x_2, and x_3, with $x_1 - x_2 = x_2 - x_3$, are R_{x1}, R_{x2}, and R_{x3}, in a voltage divider we only need to select

$$R_r = \frac{R_{x2}(R_{x1} + R_{x3}) - 2R_{x1}R_{x3}}{R_{x1} + R_{x3} - 2R_{x2}} \tag{91.40}$$

to obtain a linearized output voltage. In the sensor bridge in Figure 91.17a, we would replace R_0 in the same branch than the sensor by R_r. Additional circuits for bridge output linearization, as well as further signal conditioning and sensor lead compensation can be found in Ref. [1,10].

91.11 Time- and Frequency-Based Sensor Conditioners

Because ADCs digitize voltages rather than currents, most sensor signal conditioning is oriented toward obtaining voltages that are processed to suit ADC requirements relative to voltage range and levels, and input impedance. However, indirect ADCs such as dual- and triple-slope models internally convert voltage to time, and count time to obtain a digital output. These are low-speed ADCs that suit many low-frequency measurements. It follows that converting the measurand to time instead of voltage can save components and footprint in printed circuit boards (PCBs). Modulating sensors placed in a relaxation oscillator can readily yield an analog output with information encoded in a time parameter (oscillation period, pulse with, duty cycle) instead of an amplitude parameter (voltage or current). Some IC sensors for acceleration (ADXL202), temperature (TMP04, MAX6676), and light (TSL237, S9705) offer such an output, and are commonly designed digital sensors; actually, they must be considered *quasi-digital sensors* because their output is not a digital code but a two-level voltage that can yield a digital code by using a time counter. No ADC is required, hence no amplification, no level shifting, no demodulation, no ac-to-dc conversion, no antialiasing filtering.

Further on, microcontroller units (MCU) can easily implement by their I/O ports the switching actions involved in relaxation oscillators and can also count time. Figure 91.18 describes the working principle for an RC network; the MCU is assumed to have a Schmitt trigger (ST) input, otherwise an external STs should be used. First, the capacitor is charged by placing a high-output voltage (V_{OH}) in port 1 while port 2 is kept in a high-impedance state (Figure 91.18a). Afterward, port 1 (ST input) is placed at a high-impedance state, while port 2 is set to the low-output voltage (V_{OL}), which makes C to discharge through R_x (Figure 91.18b). The voltage across C during discharge will be

$$v_c(t) = V_0 + (V_{OH} - V_0)e^{-t/\tau} \tag{91.41}$$

where

V_0 is the initial voltage across C when it was charged

$\tau = R_xC$

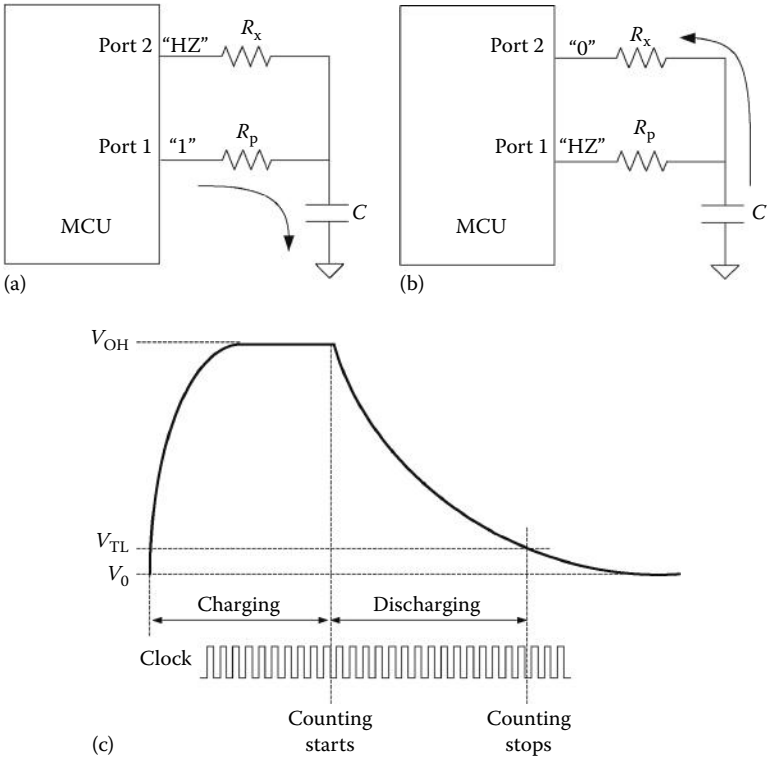

FIGURE 91.18 A microcontroller can (a) charge a capacitor and (b) then discharge it through a sensor R_x to obtain (c) a number of counts proportional to R_x, hence a digital output.

The discharging time until the low threshold (V_{TL}) is detected by the ST circuit in port 1 is

$$T_x = R_x C \ln \frac{V_{OH} - V_0}{V_{TL} - V_0} \tag{91.42}$$

hence proportional to R_x and C. If R_x is the sensor, to obtain an output that neither depends on C nor on V_0, V_{OH}, and V_{TL}, which are internal MCU parameters that depend on temperature and power supply, the charging–discharging procedure can be repeated through a known reference resistor R_r connected between C and an additional output port. The ratio between discharging times will be proportional to R_x/R_r. Better yet, a two-point calibration based on two known resistors can compensate for both multiplicative factors (such as those in Equation 91.42) and additive factors such as internal port resistance. Figure 91.19a shows the circuit to implement that calibration; R_{c1} and R_{c2} are known, stable resistors, and R_p limits the current surge when charging C. The sensor resistance can be obtained from

$$R_x = \frac{T_x - T_1}{T_2 - T_1}(R_{c2} - R_{c1}) + R_{c1} \tag{91.43}$$

This calibration is easier to implement than calibrations based on known voltages because stable resistors of any (standard) value are easier to obtain than stable voltages other than 0 V and voltages close to the full-scale range of ADCs.

The resolution and accuracy that can be achieved with this method is limited by several factors [11]. First of all, the resolution is not that of the time counter available because here there is no equivalent to

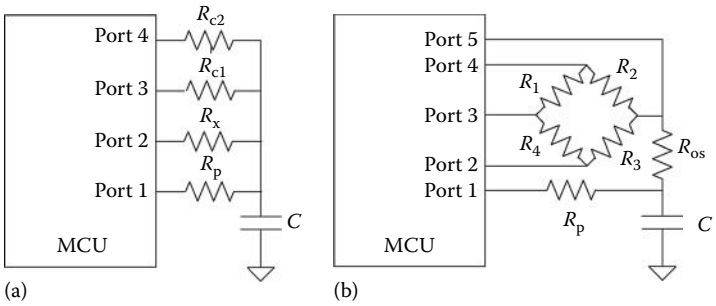

FIGURE 91.19 By successively charging a capacitor and discharging it through different resistors and performing basic calculations with the respective discharging times, additive and multiplicative effects can be corrected for (a) a single resistive sensor and (b) a Wheatstone bridge including one, two, or four sensors.

the "range matching" performed by amplifiers. Instead, if the time counts corresponding to the maximal and minimal sensor values are T_{max} and T_{min}, the resolution in bits is

$$M = \text{lb}\frac{T_{max} - T_{min}}{T_{clock}} = \text{lb}\left((x_{max} - x_{min})\frac{\tau}{T_{clock}} \right) \tag{91.44}$$

where in the last step the sensor has been assumed to be linear. The resolution improves with a higher clock frequency, the same as in any timing process, and also with a large τ, albeit at the cost of a longer measurement time, hence a reduced bandwidth for the measurand.

The accuracy is mostly determined by trigger noise that introduces uncertainty in the measured times, particularly in the time to stop counting. This noise can be inherent to the input voltage $v_c(t)$ (that across capacitor C), or be superimposed on the voltage threshold V_{TL}. Because V_{TL} is derived from the MCU supply voltage, to reduce this trigger noise the power supply voltage for the MCU must be bypassed by a large capacitor connected to ground, and the internal MCU activity, which involves switching, hence voltage transients, suspended during the discharging time. The equivalent number of bits (ENOB) is [11]

$$\text{ENOB} = \frac{R_{max} - R_{min}}{R_{max}} \frac{(V_{TL} - V_0)\ln\dfrac{V_{OH} - V_0}{V_{TL} - V_0}}{\sqrt{12}\sqrt{E_{ns}^2 + E_{ni}^2}} \tag{91.45}$$

where

E_{ns} is voltage noise in the capacitor decaying voltage
E_{ni} is the voltage noise in V_{TL}

Overall, a 10–12 bit ENOB can be obtained for single measurements of a 1000 Ω sensor that last 2–3 ms, which can be improved by about 2 bits by averaging 10 measurements, which obviously take 10 times longer.

This performance is useful enough to consider the same approach for sensor bridges. Figure 91.19b shows a sensor bridge connected to a MCU but not in the usual method for voltage measurements with two input and two output terminals. Instead, there is one terminal connected to C, through R_{os}, and three terminals each connected to ports 2, 3 and 4. First, C is charged through R_p and then it is discharged through port 2 by placing it at the low-output voltage, while ports 3, 4, and 5 are in high-impedance state. Then C is charged again and the discharging procedure repeated through ports 3, 4, and 5. Therefore, we will have three discharging times (T_2, T_3, T_4) related to sensor bridge resistances, and one discharging time T_5 that will depend on R_{os} plus the internal resistance of port 5. These times

can be combined to obtain a linear estimate x^* of the sensor fractional resistance change x, regardless of the number of sensors in the bridge [12]. For example, if there is a single sensor $R_3 = R_0(1 + x)$, we can use

$$x^* = \frac{2(T_2 - T_4)}{T_3 + T_4 - T_2 - T_5} \tag{91.46}$$

For a full-sensor bridge with $R_1 = R_3 = R_0(1 + x)$ and $R_2 = R_4 = R_0(1 - x)$, we can use

$$x^* = \frac{T_2 - T_4}{T_3 - T_5} \tag{91.47}$$

T_5 is used to reduce the effect of internal resistances of MCU ports.

Capacitive sensors can be measured in a similar way by interchanging resistors and capacitors in the circuits above, but stray capacitances to ground and between MCU pins can reduce the performance for low-capacitance sensors.

A resistive, capacitive, or inductive sensor that replaces a similar component in a harmonic oscillator (Wien bridge, Colpitts, Hartley) will make the oscillation frequency to depend on the measurand. Whenever that frequency is higher than that of the clock available to measure it, it is faster to measure frequency than period, for a given resolution. Counting events (oscillation cycles) is equivalent to analog integration, hence the frequency response is as shown in Figure 91.14a. The high SMRR at specific frequencies is of particular interest to reduce power-line interference. To extend this capability to voltage- or current-output sensors, there are IC voltage- (and current-) to-frequency converters that offer an output frequency of up to about 3 MHz for a 2.5 V full-scale input.

91.12 Special-Purpose and Programmable Signal Conditioners

Industrial sensors were a response to the need for process control, particularly to produce aircraft fuel during World War II. Harsh environmental conditions in process control forced the remote placement of signal conditioners in control rooms, so that sensors and conditioners were separate electronic units. Progress in electronics involved a better knowledge of silicon properties, including its electrical response to temperature, light, magnetic fields, and stress (pressure), and this lead to sensors with integrated electronics, such as photointerrupters. Sensors were increasingly used in buildings, machinery, cars, and consumer products, which meant large markets that paid for the cost of developing microelectromechanical sensors (MEMS) based on mechanical properties of silicon and for specific signal conditioning circuits, sometimes cofabricated with MEMS, able to withstand, for example, the special environmental conditions in automotive applications. Further, many functions in signal conditioning apply to all sensors, the main difference being in degree, that is, for example, how much offset or gain needs to be applied; this flexibility is offered by programmable circuits, whose lowest-cost units are microcontrollers.

Overall, in addition to general-purpose integrated circuits that can be used to build any signal conditioning circuit on a multichip System on Board (SoB), there are (a) sensors that integrate the signal conditioner and use external components for further signal processing; (b) sensors that integrate analog and digital signal processing; (c) analog signal conditioners aimed as specific sensors, such as thermocouples, LVDTs, inductive sensors, and ultrasound-based sensors; (d) ADCs with analog front ends for a particular group of sensors that share a common operating principle, e.g., resistive or capacitive sensors, or low-level dc or ac voltages coming from sensors; and (e) microcontrollers with additional nonvolatile memory and data-acquisition capabilities that can be almost directly connected to a variety of sensors. Some of these ICs are the core of electronic modules intended for industrial applications based on rail-mounted systems or modular units for rack-mounted instruments. Table 91.4 lists some signal conditioners in IC form intended for specific sensors or sensor groups and their respective functions.

MLX90323	4–20 mA current loop output for bridge or differential sensors	Melexis
XTR101/5/6/8	4–20 mA two-wire transmitter	Texas Instruments
XTR110/1/2/4/5/6/7	4–20 mA current loop transmitter	Texas Instruments
RCV420	4–20 mA current loop receiver	Texas Instruments
XTR300	Voltage/current-output driver	Texas Instruments
ADE7878	Polyphase energy metering IC	Analog Devices
TLE2425/6	Virtual ground	Texas Instruments

The decision whether to design a signal conditioner from parts or use a model from Table 91.4 is a matter of cost, reliability, and availability. As a practical matter, whereas many general purpose and some specific op amps are pin-to-pin compatible or at least functionally equivalent, most other ICs are not compatible neither there are any second sources for them. This can be a major risk as integrated circuits can be discontinued and no replacement offered.

Defining Terms

Carrier amplifier: Voltage amplifier for narrowband ac signals, that includes in addition a sine wave oscillator, a synchronous demodulator, and a low-pass filter.

Common-mode rejection ratio (CMRR): The gain for a differential voltage divided by the gain for a common-mode voltage in a differential amplifier. It is usually expressed in decibels.

Common-mode voltage: The average of the voltages at the input terminals of a differential amplifier.

Differential amplifier: Circuit or device that amplifies the difference in voltage between two terminals, none of which is grounded.

Dynamic range: The measurement range for a quantity divided by the desired resolution.

Instrumentation amplifier: Differential amplifier with large input impedance and low offset and gain errors.

Isolation amplifier: Voltage amplifier whose ground terminal for input voltages is independent from the ground terminal for the output voltage (i.e., there is a large—isolation—impedance between both ground terminals).

Isolation Mode Rejection Ratio (IMRR): The amplitude of the voltage across the isolation impedance divided by the amplitude of the output voltage that produces.

Series (Normal) Mode Rejection Ratio (SMRR, NMRR): The gain of a circuit to signals of a frequency of interest divided by the gain at other frequencies.

Signal conditioner: Circuit or device that adapts a sensor signal to an ensuing circuit, such as an ADC.

Voltage buffer: Voltage amplifier whose gain is 1, or close to 1, and whose input impedance is very large while its output impedance is very small.

Data Acquisition Systems

Edward McConnell
National Instruments

92.1 Introduction

The fundamental task of a *data acquisition system* is the measurement or generation of real-world physical signals. Before a physical signal can be measured by a computer-based system, a sensor or transducer is used to convert the physical signal into an electrical signal, such as voltage or current. Often only a plug-in data acquisition (DAQ) board is considered the data acquisition system; however, a board is only one of the components in the system. A complete DAQ system consists of sensors, signal conditioning, interface hardware, and software. Unlike stand-alone instruments, signals often cannot be directly connected to the DAQ board. The signals may need to be conditioned by some signal-conditioning accessory before they are converted to digital information by the plug-in DAQ board. Software controls the data acquisition system—acquiring the raw data, analyzing the data, and presenting the results. The components are shown in Figure 92.1.

92.2 Signals

Signals are physical events whose magnitude or time variation contains information. DAQ systems measure various aspects of a signal in order to monitor and control the physical events. Users of DAQ systems need to know the relation of the signal to the physical event and what information is available in the signal. Generally, information is conveyed by a signal through one or more of the following signal parameters: state, rate, level, shape, or frequency content. The physical characteristics of the measured signals and the related information help determine the design of a DAQ system.

All signals are, fundamentally, analog, time-varying signals. For the purpose of discussing the methods of signal measurement using a plug-in DAQ board, a given signal should be classified as one of five

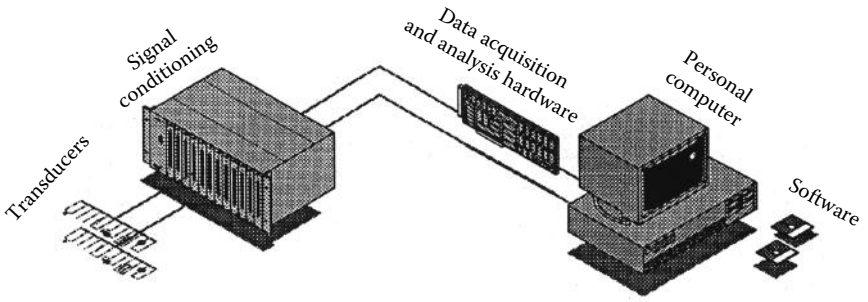

FIGURE 92.1 Components of a DAQ system.

signal types. Because the method of signal measurement is determined by the way the signal conveys the needed information, a classification based on this criterion is useful in understanding the fundamental building blocks of a DAQ system.

As shown in Figure 92.2, any signal can generally be classified as analog or digital. A digital, or binary, signal has only two possible discrete levels of interest—a high (on) level and a low (off) level. The two digital signal types are on–off signals and pulse train signals. An analog signal, on the other hand, contains information in the continuous variation of the signal with time. Analog signals are described in the time or frequency domains depending upon the information of interest. A dc-type signal is a low-frequency signal, and if the phase information of a signal is presented with the frequency information, then there is no difference between the time or frequency domain representations. The category to which a signal belongs depends on the characteristic of the signal to be measured. The five types of signals can be closely paralleled with the five basic types of signal information—state, rate, level, shape, and frequency content.

Basic understanding of the signal representing the physical event being measured and controlled assists in the selection of the appropriate DAQ system.

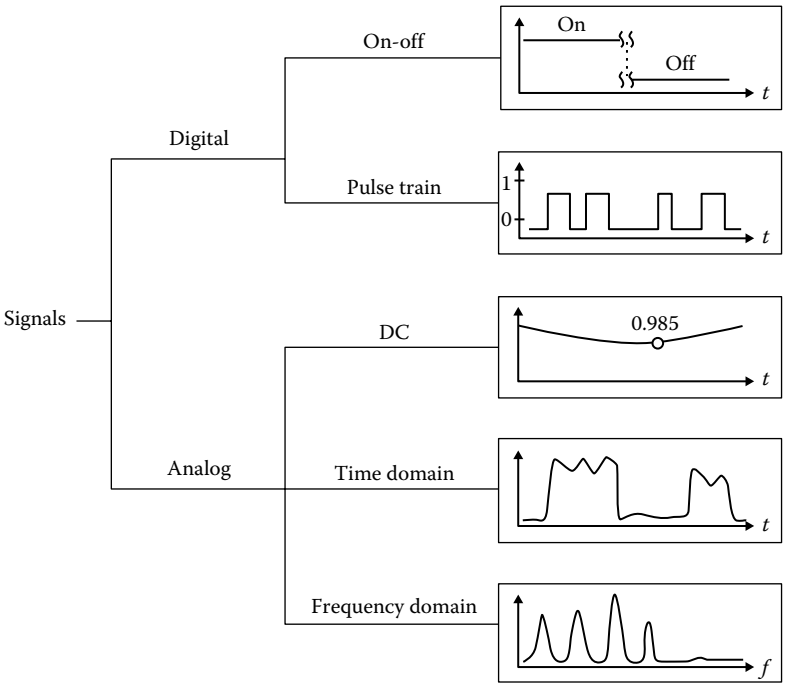

FIGURE 92.2 Classes of analog and digital signals.

92.3 Plug-In DAQ Boards

The fundamental component of a DAQ system is the plug-in DAQ board. These boards plug directly into a slot in a PC and are available with analog, digital, and timing inputs and outputs (I/O). The most versatile of the plug-in DAQ boards is the multifunction I/O board. As the name implies, this board typically contains various combinations of analog-to-digital converters (ADCs), digital-to-analog converters (DACs), digital I/O lines, and counters/timers. ADCs and DACs measure and generate analog voltage signals, respectively. The digital I/O lines sense and control digital signals. Counters/timers measure pulse rates, widths, delays, and generate timing signals. These many features make the multifunction DAQ board useful for a wide range of applications.

Multifunction boards are commonly used to measure analog signals. This is done by the ADC, which converts the analog voltage level into a digital number that the computer can interpret. The analog multiplexer (MUX), the instrumentation amplifier, the sample-and-hold (S/H) circuitry, and the ADC compose the analog input section of a multifunction board (see Figure 92.3).

Typically, multifunction DAQ boards have one ADC. Multiplexing is a common technique for measuring multiple channels (generally 16 single-ended or 8 differentials) with a single ADC. The analog MUX switches between channels and passes the signal to the instrumentation amplifier and the S/H circuitry. The MUX architecture is the most common approach taken with plug-in DAQ boards. While plug-in boards typically include up to only 16 single-ended or 8 differential inputs, the number of analog input channels can be further expanded with external MUX accessories.

Instrumentation amplifiers typically provide a differential input and selectable gain by jumpers or software. The differential input rejects small common-mode voltages. The gain is often software programmable. In addition, many DAQ boards also include the capability to change the amplifier gain while scanning channels at high rates. Therefore, one can easily monitor signals with different ranges of amplitudes. The output of the amplifier is sampled, or held at a constant voltage, by the S/H device at measurement time so that voltage does not change during digitization.

The ADC transforms the analog signal into a digital value which is ultimately sent to computer memory. There are several important parameters of A/D conversion. The fundamental parameter of an ADC is the number of bits. The number of bits of an A/D determines the range of values for the binary output of the ADC conversion. For example, many ADCs are of 12 bits, so a voltage within the input range of the ADC will produce a binary value that has one of $2^{12} = 4096$ different values. The more bits an ADC has, the higher the resolution of the measurement. The resolution determines the smallest amount of change that can be detected by the ADC. Resolution is expressed as the number of digits of a voltmeter or dynamic range in decibels, rather than with bits. Table 92.1 shows the relation among bits, number of digits, and dynamic range in decibels.

The resolution of the A/D conversion is also determined by the input range of the ADC and the gain. DAQ boards usually include an instrumentation amplifier that amplifies the analog signal by

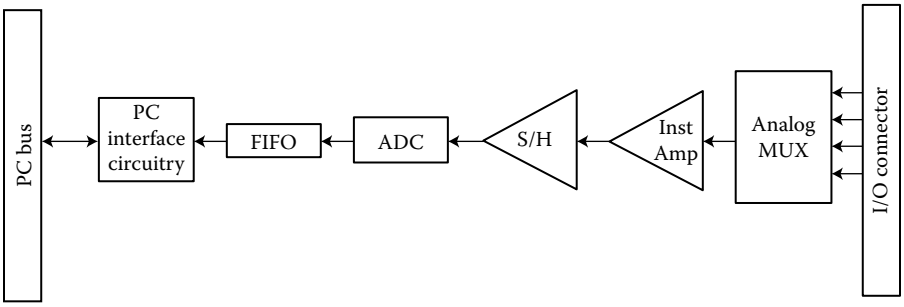

FIGURE 92.3 Analog input section of a plug-in DAQ board. FIFO, first-in first-out buffer; S/H, sample and hold; Inst Amp, instrumentation amplifier; MUX, analog multiplexer.

TABLE 92.1 Relation among Bits, Number of Digits, and Dynamic Range (dB)

Bits	Digits	dB
20	6.0	120
16	4.5	96
12	3.5	72
8	2.5	48

a gain factor prior to the conversion. This gain amplifies low-level signals so that more accurate measurements can be made.

Together, the input range of the ADC, the gain, and the number of bits of the board determine the minimum resolution of the measurement. For example, suppose a low-level ±30 mV signal is acquired using a 12 bit ADC that has a ±5 V input range. If the system includes an amplifier with a gain of 100, the resulting resolution of the measurement will be range/(gain × 2 bits) = resolution, or 10 V/(100 × 2^{12}) = 0.0244 mV.

Finally, an important parameter of digitization is the rate at which A/D conversions are made, referred to as the sampling rate. The A/D system must be able to sample the input signal fast enough to measure the important waveform attributes accurately. In order to meet this criterion, the ADC must be able to convert the analog signal to digital form quickly enough.

When scanning multiple channels with a multiplexing DAQ system, other factors can affect the throughput of the system. Specifically, the instrumentation amplifier must be able to settle to the needed accuracy before the A/D conversion occurs. With multiplexed signals, multiple signals are being switched into one instrumentation amplifier. Most amplifiers, especially when amplifying the signals with larger gains, will not be able to settle to the full accuracy of the ADC when scanning channels at high rates. To avoid this situation, consult the specified settling times of the DAQ board for the gains and sampling rates required by the application.

92.4 Types of ADCs

Different DAQ boards use different types of ADCs to digitize the signal. The most popular type of ADC on plug-in DAQ boards is the successive approximation ADC, because it offers high speed and high resolution at a modest cost.

Subranging (also called half-flash) ADCs offer very high-speed conversion with sampling speeds up to several million samples per second.

The state-of-the-art technology in ADCs is sigma–delta modulating ADCs. These ADCs sample at high rates, are able to achieve high resolution, and offer the best linearity of all ADCs.

Integrating and flash ADCs are mature technologies still used on DAQ boards today. Integrating ADCs are able to digitize with high resolution but must sacrifice sampling speed to obtain it. Flash ADCs are able to achieve the highest sampling rate (gigahertz) but are available only with low resolution. The different types of ADCs are summarized in Table 92.2.

92.5 Analog Input Architecture

With a typical DAQ board, the multiplexer switches among analog input channels. The analog signal on the channel selected by the multiplexer then passes to the programmable gain instrumentation amplifier (PGIA), which amplifies the signal. After the signal is amplified, the S/H keeps the analog signal constant so that the ADC can determine the digital representation of the analog signal. A good DAQ board will then place the digital signal in a first-in first-out (FIFO) buffer, so that no data will be lost if the sample cannot transfer immediately over the PC I/O channel to computer memory.

TABLE 92.2 Types of ADCs

Type of ADC	Advantages	Features
Successive approximation	High resolution	1.25 MS/s sampling rate
	High speed	12 bit resolution
	Easily multiplexed	200 kS/s sampling rate
		16 bit resolution
Subranging	Higher speed	1 MHz sampling rate
		12 bit resolution
Sigma–delta	High resolution	48 kHz sampling rate
	Excellent linearity	16 bit resolution
	Built-in antialiasing	
	State-of-the-art technology	
Integrated	High resolution	15 kHz sampling rate
	Good noise rejection	
	Mature technology	
Flash	Highest speed	125 MHz sampling rate
	Mature technology	

Having a FIFO becomes especially important when the board is run under operating systems that have large interrupt latencies, such as Microsoft Windows.

92.5.1 Basic Analog Specifications

Almost every DAQ board data sheet specifies the number of channels, the maximum sampling rate, the resolution, and the input range and gain.

The number of channels, which is determined by the multiplexer, is usually specified in two forms—differential and single-ended. Differential inputs are inputs that have different reference points for each channel, none of which is grounded by the board. Differential inputs are the best way to connect signals to the DAQ board because they provide the best noise immunity.

Single-ended inputs are inputs that are referenced to a common ground point. Because single-ended inputs are referenced to a common ground, they are not as good as differential inputs for rejecting noise. They do have a larger number of channels, however. Single-ended inputs are used when the input signals are high level (greater than 1 V), the leads from the signal source to the analog input hardware are short (less than 5 m), and all input signals share a common reference.

Some boards have pseudo-differential inputs which have all inputs referenced to the same common—like single-ended inputs—but the common is not referenced to ground. These boards have the benefit of a large number of input channels, like single-ended inputs, and the ability to remove some common-mode noise, especially if the common-mode noise is consistent across all channels. Differential inputs are still preferable to pseudo-differential, however, because differential is more immune to magnetic noise.

Sampling rate determines how fast the analog signal is converted to a digital signal. When measuring ac signals, sample must be at least twice faster than the highest frequency of the input signal. Even when measuring dc signals, the oversample and average the data increase the accuracy of the signal by reducing the effects of noise.

If the physical event consists of multiple dc-class signals, a DAQ board with interval scanning should be used. With interval scanning, all channels are scanned at one sample interval (usually the fastest rate of the board), with a second interval (usually slow) determining the time before repeating the scan. Interval scanning gives the effects of simultaneously sampling for slowly varying signals without requiring the additional cost of input circuitry for true simultaneous sampling.

Resolution is the number of bits that are used to represent the analog signal. The higher the resolution, the higher the number of divisions the input range is broken into, and therefore the smaller the possible detectable voltage. Unfortunately, some DAQ specifications are misleading when they specify the resolution associated with the DAQ board. Many DAQ board specifications state the resolution of the ADC without stating the linearities and noise, and therefore do not give the information needed to determine the resolution of the entire board. Resolution of the ADC, combined with the settling time, *integral nonlinearity* (INL), *differential nonlinearity* (DNL), and noise will give an understanding of the accuracy of the board.

Input range and gain determine the level of signal that should be connected to the board. Usually, the range and gain are specified separately, so the two must be combined to determine the actual signal input range as

$$\text{Signal input range} = \frac{\text{range}}{\text{gain}}$$

For example, a board using an input range of ±10 V with a gain of 2 will have a signal input range of ±5 V. The closer the signal input range is to the range of the signal, the more accurate the readings from the DAQ board will be. If the signals have different input ranges, use a DAQ board with the feature of different gains per channel.

92.6 Data Acquisition Software

The software is often the most critical component of the DAQ system. Users of DAQ systems usually program the hardware in one of two ways—through register programming or through high-level device drivers.

92.6.1 Board Register–Level Programming

The first option is not to use vendor-supplied software and program the DAQ board at the hardware level. DAQ boards are typically register-based; that is, they include a number of digital registers that control the operation of the board. The developer may use any standard programming language, such as C, C++, or Visual BASIC, to write series of binary codes to the DAQ board to control its operation. Although this method affords the highest level of flexibility, it is also the most difficult and time-consuming, especially for the inexperienced programmer. The programmer must know the details of programming all hardware, including the board, the PC interrupt controller, the DMA controller, and PC memory.

92.6.2 Driver Software

Driver software typically consists of a library of function calls usable from a standard programming language. These function calls provide a high-level interface to control the standard functions of the plug-in board. For example, a function called SCAN_OP may configure, initiate, and complete a multiple-channel scanning DAQ operation of a predetermined number of points. The function call would include parameters to indicate the channels to be scanned, the amplifier gains to be used, the sampling rate, and the total number of data points to be collected. The driver responds to this one function call by programming the plug-in board, the DMA controller, the interrupt controller, and CPU to scan the channels as requested.

92.6.3 What Is Digital Sampling?

Every DAQ system has the task of gathering information about analog signals. To do this, the system captures a series of instantaneous "snapshots" or samples of the signal at definite time intervals. Each sample contains information about the signal at a specific instant. Knowing the exact time of each conversion and the value of the sample, one can reconstruct, analyze, and display the digitized waveform.

92.6.4 Real-Time Sampling Techniques

In real-time sampling, the DAQ board digitizes consecutive samples along the signal (Figure 92.4). According to the *Nyquist sampling theorem*, the ADC must sample at least twice the rate of the maximum frequency component in that signal to prevent aliasing. *Aliasing* is a false lower-frequency component that appears in sampled data acquired at too low a sampling rate. The frequency at one-half the sampling frequency is referred to as the Nyquist frequency. Theoretically, it is possible to recover information about those signals with frequencies at or below the Nyquist frequency. Frequencies above the Nyquist frequency will alias to appear between dc and the Nyquist frequency.

For example, assume the sampling frequency, f_s, is 100 Hz. Also assume the input signal to be sampled contains the following frequencies—25, 70, 160, and 510 Hz. Figure 92.5 shows a spectral representation of the input signal.

The mathematics of sampling theory show us that a sampled signal is shifted in the frequency domain by an amount equal to integer multiples of the sampling frequency, f_s. Figure 92.6 shows the spectral content of the input signal after sampling. Frequencies below 50 Hz, the Nyquist frequency ($f_s/2$), appear correctly. However, frequencies above the Nyquist appear as aliases below the Nyquist frequency. For example, F1 appears correctly; however, F2, F3, and F4 have aliases at 30, 40, and 10 Hz, respectively.

The resulting frequency of aliased signals can be calculated with the following formula:

Apparent (Alias) Frequency = ABS (Closest Integer Multiple of Sampling Frequency – Input Frequency)

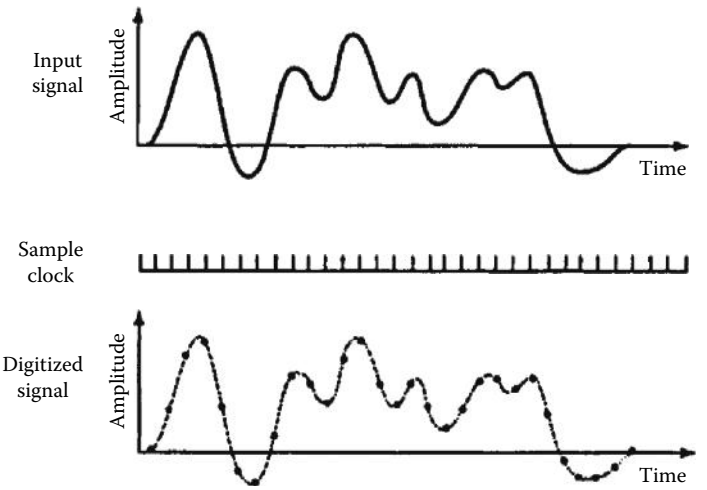

FIGURE 92.4 Consecutive discrete samples recreate the input signal.

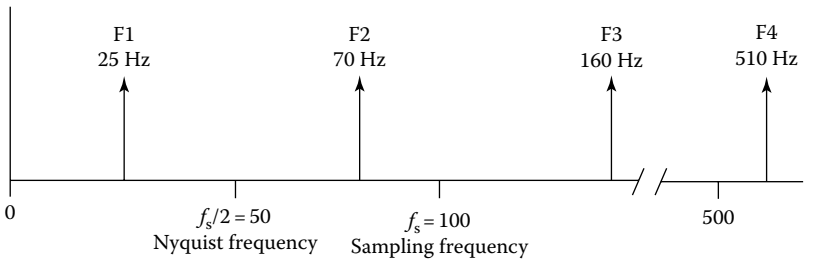

FIGURE 92.5 Spectral of signal with multiple frequencies.

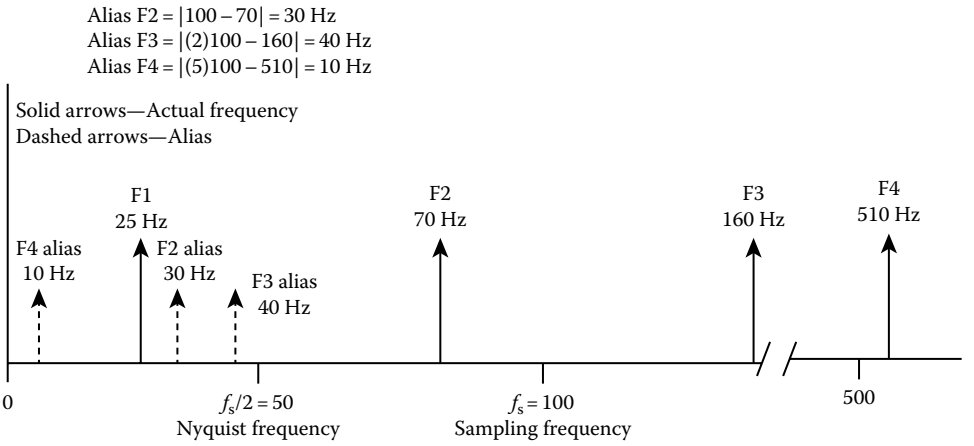

FIGURE 92.6 Spectral of signal with multiple frequencies after sampling at f_s = 100 Hz.

For the example of Figures 92.5 and 92.6:

$$\text{Alias F2} = |100 - 70| = 30 \text{ Hz}$$

$$\text{Alias F3} = |(2)100 - 160| = 40 \text{ Hz}$$

$$\text{Alias F4} = |(5)100 - 510| = 10 \text{ Hz}$$

92.6.5 Preventing Aliasing

Aliasing can be prevented by using filters on the front end of the DAQ system. These antialiasing filters are set to cut off any frequencies above the Nyquist frequency (half the sampling rate). The perfect filter would reject all frequencies above the Nyquist; however, because perfect filters exist only in textbooks, one must compromise between sampling rate and selecting filters. In many applications, one- or two-pole passive filters are satisfactory. The rule of thumb is to oversample (5–10 times) and use these antialiasing filters when frequency information is crucial.

Alternatively, active antialiasing filters with programmable cutoff frequencies and very sharp attenuation of frequencies above the cutoff can be used. Because these filters exhibit a very steep roll-off, the DAQ system can sample at two to three times the filter cutoff frequency. Figure 92.7 shows a transfer function of a high-quality antialiasing filter.

The computer uses digital values to recreate or to analyze the waveform. Because the signal could be anything between each sample, the DAQ board may be unaware of any changes in the signal between samples. There are several sampling methods optimized for the different classes of data; they include software polling, external sampling, continuous scanning, multirate scanning, simultaneous sampling, interval scanning, and seamless changing of the sample rate.

92.6.6 Software Polling

A software loop polls a timing signal and starts the A/D conversion via a software command when the edge of the timing signal is detected. The timing signal may originate from the internal clock of the computer or from a clock on the DAQ board. Software polling is useful in simple, low-speed applications, such as temperature measurements.

The software loop must be fast enough to detect the timing signal and trigger a conversion. Otherwise, a window of uncertainty, also known as jitter, will exist between two successive samples. Within the window of uncertainty, the input waveform could change enough to reduce the accuracy of the ADC drastically.

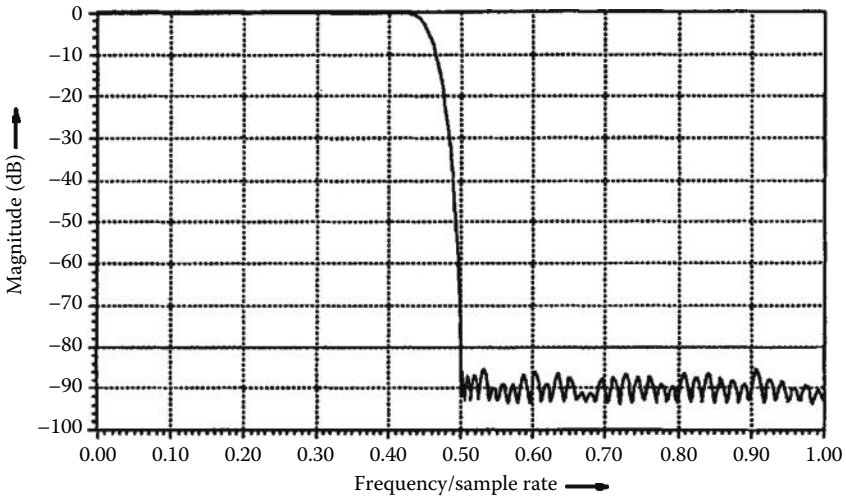

FIGURE 92.7 Magnitude portion of transfer function of an antialiasing filter.

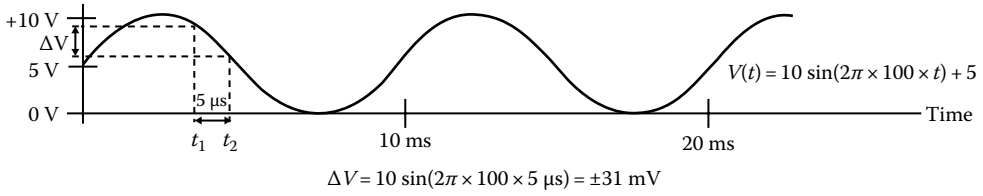

FIGURE 92.8 Jitter reduces the effective accuracy of the DAQ board.

Supposing that a 100 Hz, 10 V full-scale sine wave is digitized (Figure 92.8); if the polling loop takes 5 ms to detect the timing signal and to trigger a conversion, then the voltage of the input sine wave will change as much as 31 mV [$\Delta V = 10 \sin(2\pi \times 100 \times 5 \times 10^{-6})$]. For a 12 bit ADC operating over an input range of 10 V and a gain of 1, one least significant bit (LSB) of error represents 2.44 mV:

$$\left(\frac{\text{Input range}}{\text{gain} \times 2^n}\right) = \left(\frac{10\text{ V}}{1 \times 2^{12}}\right) = 2.44\text{ mV}$$

But because the voltage error due to jitter is 31 mV, the accuracy error is 13 LSB:

$$\left(\frac{31\text{ mV}}{2.44\text{ mV}}\right)$$

This represents uncertainty in the last 4 bits of a 12 bit ADC. Thus, the effective accuracy of the system is no longer 12 bits but rather 8 bits.

92.6.7 External Sampling

Some DAQ applications must perform a conversion based on another physical event that triggers the data conversion. The event could be a pulse from an optical encoder measuring the rotation of a cylinder. A sample would be taken every time the encoder generates a pulse corresponding to n degrees of rotation. External triggering is advantageous when trying to measure signals whose occurrence is relative to another physical phenomenon.

92.7 Scanning

92.7.1 Continuous Scanning

When a DAQ board acquires data, several components on the board convert the analog signal to a digital value. These components include the analog MUX, the instrumentation amplifier, the S/H circuitry, and the ADC. When acquiring data from several input channels, the analog MUX connects each signal to the ADC at a constant rate. This method, known as continuous scanning, is significantly less expensive than having a separate amplifier and ADC for each input channel.

Continuous scanning is advantageous because it eliminates jitter and is easy to implement. However, it is not possible to sample multiple channels simultaneously. Because the MUX switches between channels, a time skew occurs between any two successive channel samples. Continuous scanning is appropriate for applications where the time relationship between each sampled point is unimportant or where the skew is relatively negligible compared with the speed of the channel scan.

If samples from two signals are used to generate a third value, then continuous scanning can lead to significant errors if the time skew is large. In Figure 92.9, two channels are continuously sampled and added together to produce a third value. Because the two sine waves are 90° out of phase, the sum of the signals should always be zero. Because of the skew time between the samples, an erroneous sawtooth signal will result.

92.7.2 Multirate Scanning

Multirate scanning, a method of scanning multiple channels at different rates, is a special form of continuous scanning. Applications that digitize multiple signals with a variety of frequencies use multirate scanning to minimize the amount of buffer space needed to store the sampled signals. Channel-independent ADCs are used to implement hardware multirate scanning; however, this method is extremely expensive. Instead of multiple ADCs, only one ADC is used. A channel/gain configuration register stores the scan rate per channel and software divides down the scan clock based on the per-channel scan rate. Software-controlled multirate scanning works by sampling each input channel at a rate that is a fraction of the specified scan rate.

Suppose the system scans channels 0 through 3 at 10 kS/s, channel 4 at 5 kS/s, and channels 5 through 7 at 1 kS/s. A base scan rate of 10 kS/s should be used. Channels 0 through 3 are acquired at the base scan rate. Software and hardware divide the base scan rate by 2 to sample channel 4 at 5 kS/s, and by 10 to sample channels 5 through 7 at 1 kS/s.

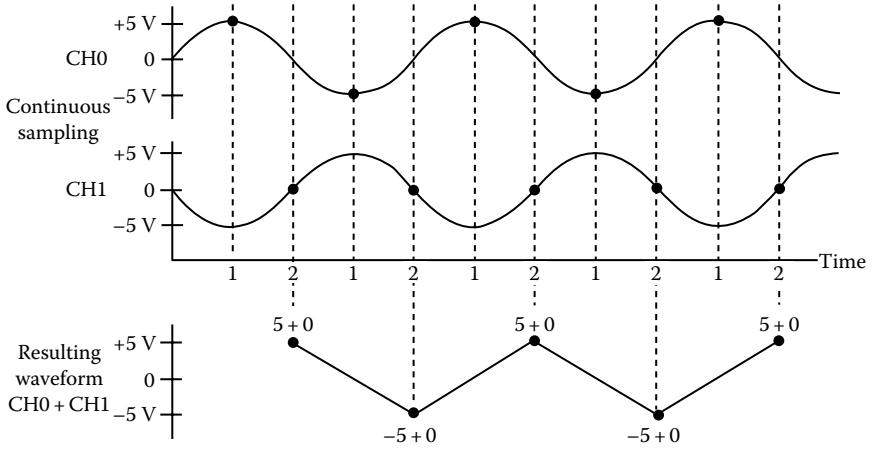

FIGURE 92.9 If the channel skew is large compared with the signal, then erroneous conclusions may result.

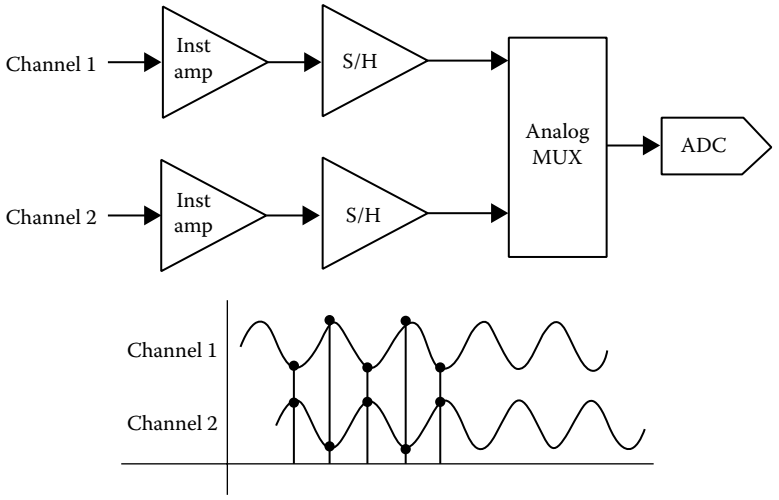

FIGURE 92.10 Block diagram of DAQ components used to sample multiple channels simultaneously.

92.7.3 Simultaneous Sampling

For applications where the time relationship between the input signals is important, such as phase analysis of ac signals, simultaneous sampling must be used. DAQ boards capable of simultaneous sampling typically use independent instrumentation amplifiers and S/H circuitry for each input channel, along with an analog MUX, which routes the input signals to the ADC for conversion (as shown in Figure 92.10).

To demonstrate the need for a simultaneous-sampling DAQ board, consider a system consisting of four 50 kHz input signals sampled at 200 kS/s. If the DAQ board uses continuous scanning, the skew between each channel is 5 μs (IS/200 kS/s) which represents a 270° [(15 μs/20 μs) × 360°] shift in phase between the first channel and fourth channel. Alternatively, with a simultaneous-sampling board with a maximum 5 ns interchannel time offset, the phase shift is only 0.09° [(5 μs/20 μs) × 360°]. This phenomenon is illustrated in Figure 92.11.

92.7.4 Interval Scanning

For low-frequency signals, interval scanning creates the effect of simultaneous sampling, yet maintains the cost benefits of a continuous-scanning system. This method scans the input channels at one rate and uses a second rate to control when the next scan begins. If the input channels are scanned at the fastest rate of the ADC, the effect of simultaneously sampling the channels is created. Interval scanning is

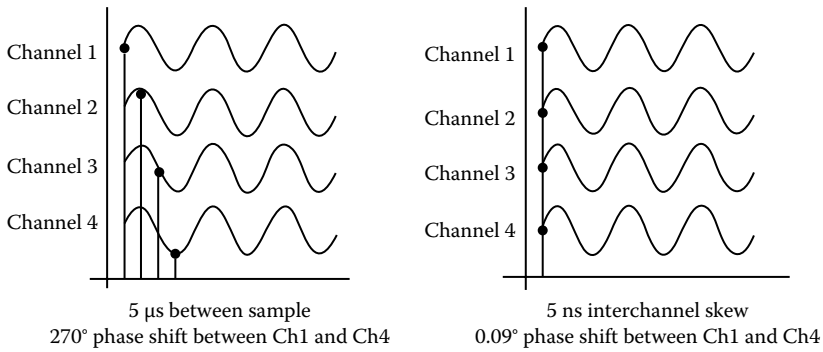

FIGURE 92.11 Comparison of continuous scanning and simultaneous sampling.

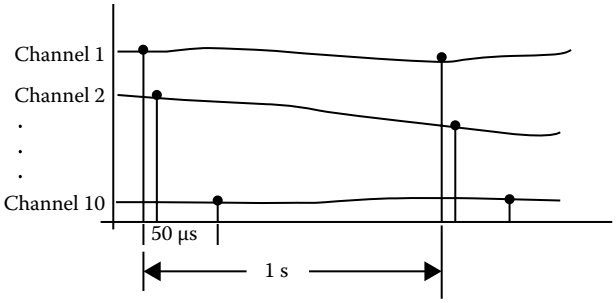

FIGURE 92.12 Interval scanning—all 10 channels are scanned within 45 μs; this is insignificant relative to the overall acquisition rate of 1 S/s.

appropriate for slow-moving signals, such as temperature and pressure. Interval scanning results in a jitter-free sample rate and minimal skew time between channel samples. For example, consider a DAQ system with 10 temperature signals. By using interval scanning, a DAQ board can be set up to scan all channels with an interchannel delay of 5 μs, and then repeat the scan every second. This method creates the effect of simultaneously sampling 10 channels at 1 S/s, as shown in Figure 92.12.

To illustrate the difference between continuous and interval scanning, consider an application that monitors the torque and RPMs of an automobile engine and computes the engine horsepower. Two signals, proportional to torque and RPM, are easily sampled by a DAQ board at a rate of 1000 S/s. The values are multiplied together to determine the horsepower as a function of time.

A continuously scanning DAQ board must sample at an aggregate rate of 2000 S/s. The time between which the torque signal is sampled and the RPM signal is sampled will always be 0.5 ms (1/2000). If either signals change within 0.5 ms, then the calculated horsepower is incorrect. But using interval scanning at a rate of 1000 S/s, the DAQ board samples the torque signal every 1 ms, and the RPM signal is sampled as quickly as possible after the torque is sampled. If a 5 μs interchannel delay exists between the torque and RPM samples, then the time skew is reduced by 99% [(0.5 ms − 5 μs)/0.5 ms], and the chance of an incorrect calculation is reduced.

92.8 Factors Influencing the Accuracy of Measurements

How does one determine if a plug-in DAQ will deliver the required measurement results? With a sophisticated measuring device like a plug-in DAQ board, significantly different accuracies can be obtained depending on the type of board used. For example, one can purchase DAQ products on the market today with 16 bit ADCs and get <12 bits of useful data, or one can purchase a product with a 16 bit ADC and actually get 16 bits of useful data. This difference in accuracies causes confusion in the PC industry where everyone is used to switching out PCs, video cards, printers, and so on, and experiencing similar results between equipment.

The most important thing to do is to scrutinize more specifications than the resolution of the ADC that is used on the DAQ board. For dc-class measurements, one should at least consider the settling time of the instrumentation amplifier, DNL, *relative accuracy*, INL, and noise. If the manufacturer of the board under consideration does not supply these specifications in the data sheets, ask the vendor to provide them or run tests to determine these specifications.

Defining Terms

Alias: A false lower-frequency component that appears in sampled data acquired at too low a sampling rate.

Asynchronous: (1) Hardware—a property of an event that occurs at an arbitrary time, without synchronization to a reference clock. (2) Software—a property of a function that begins an operation and returns prior to the completion or termination of the operation.

Conversion time: The time required, in an analog input or output system, from the moment a channel is interrogated (such as with a read instruction) to the moment that accurate data are available.

DAQ (data acquisition): (1) Collecting and measuring electric signals from sensors, transducers, and test probes or fixtures and inputting them to a computer for processing. (2) Collecting and measuring the same kind of electric signals with ADC and/or DIO boards plugged into a PC, and possibly generating control signals with DAC and/or DIO boards in the same PC.

DNL (differential nonlinearity): A measure in LSB of the worst-case deviation of code widths from their ideal value of 1 LSB.

INL (integral nonlinearity): A measure in LSB of the worst-case deviation from the ideal A/D or D/A transfer characteristic of the analog I/O circuitry.

Nyquist sampling theorem: A law of sampling theory stating that if a continuous bandwidth-limited signal contains no frequency components higher than half the frequency at which it is sampled, then the original signal can be recovered without distortion.

Relative accuracy: A measure in LSB of the accuracy of an ADC. It includes all nonlinearity and quantization errors. It does not include offset and gain errors of the circuitry feeding the ADC.

93.1 An Introduction to Plasma-Driven Flat Panel Displays

93.1.1 Development History and Present Status

Plasma-driven flat panel display pixels were invented by Bitzer and Slottow at the University of Illinois in 1966 [1–3]. Figure 93.1 shows one of the inventors' early designs and demonstrates its simplicity. Parallel sets of thin conducting wires are deposited on two glass substrates which are then mounted with the conductor sets perpendicular to one another as shown in the Figure 93.1. A spacer, in this case a perforated glass dielectric, is used to maintain a gap separation of about 100 μm between the glass plates. The gap region then is filled with an inert gas, typically at a pressure of half an atmosphere. Individual pixels formed by the intersection of two conductor wires are aligned with the perforations. Pixels are illuminated by applying a voltage between two intersecting wires sufficient to initiate gas breakdown. Over the years, this basic pixel design has undergone a multitude of refinements and improvements, but the fundamental concept is still widely used.

Throughout the 1980s, plasma display products on the market were monochrome and operated with neon-based gases, directly producing within the discharge volume the red–orange (585–640 nm) visible photons that are characteristic of the quantum energy level structure of the neon atom. Dot matrix displays of the type shown in Figure 93.2 were widely used [3,4]. Early work by Owens—Illinois led to improvements in glass-sealing and spacer supports [5,6], and work by IBM led to improved understanding and control of the discharge [7–15]. These advances ultimately paved the way for manufacture of large-area, high-resolution monochrome displays. The largest area plasma display panels ever

manufactured were produced by Photonics Imaging. These monochrome displays had a 1 m diagonal dimension and contained over 2 million pixels with a pixel pitch of 20 pixels/cm (50 lines/in.) [4].

Advances in lithography, patterning, and phosphors have enabled continued improvement of plasma display performance and resolution. Today, many of companies offer full-color plasma flat panel displays. Table 93.1 presents a summary list compiled by the National Research Institute of display panel specifications for some of the major companies investing in plasma flat panel manufacturing [16]. According to Stanford Research, Inc., sales for plasma display panels in 1995 totaled $230 million, but projected sales for 2002 are $4.1 billion [17]. NEC projects a more aggressive market growth reaching $2.0 billion by the year 2000 and $7.0 billion by 2002 [17]. The production capacities listed in Table 93.1 represent investments committed to manufacturing as of January 1997. As these production facilities come online, color plasma flat panel display production will grow to nearly 40,000 units per month by the end of 1998, and to over 100,000 units per month by early in 2000. In 1993, Fujitsu was the first to market a high-information-content full-color plasma flat panel display, a 21 in. diagonal, ac-driven system with a 640 × 480 pixel array [17,18]. Two examples of more recent market entries are shown in Figures 93.3 and 93.4. The first example is the NHK full color, 102 cm (40 in.) diagonal, high definition

TABLE 93.1 Plasma Flat Panel Display Specifications and Manufacturer's Business Plans

	Product Specification			Efficiency Specification				Plan			
Company	Inch	Aspect	Pixels	Luminescence (cd/m^2)	Contrast	lm/W	Power (W)	Factory	Capital Cost ($M)	Product Ability (unit/month)	Target Region
Fujitsu	42	16:9	852 × 480	300	70:1	0.7	350 (set) 300 (panel)	Miyazaki	20	10,000	Europe (Philips), Japan

television (HDTV) [19–22]. The system comprises 1,075,000 full-color pixels (1344 × 800) with a pixel pitch of 0.65 mm in both horizontal and vertical directions (15.4 pixels/cm). This pulsed, dc-driven display has a peak luminance of 93 cd/m^2 with a contrast ratio of 80 to 1, and produces 256 gray levels. The display has an overall thickness of only 8 cm and weighs only 8 kg. The dimensions of the display panel itself are 87.5 × 52.0 cm with a width of only 6 mm. Shown in Figure 93.4 is the 76 cm (30 in.) diagonal,

full-color ac plasma display manufactured by Photonics Imaging [23,24]. The display contains an array of 1024 × 768 full-color pixels. At 16.8 pixels/cm (pixel pitch = 0.59 mm), this is the highest resolution full-color, plasma display manufactured to date. This unit has 64 gray levels per color channel and an average area (white) luminance greater than 103 cd/m^2 (30 fL).

93.1.2 DC and AC Plasma Pixels

As indicated earlier, plasma display pixels can be designed for either ac or dc operation. Figure 93.5 shows schematic diagrams for the simplest dc and ac pixel designs. In either case, sets of parallel conductor wires are deposited on glass substrates. In most cases, display costs are kept low by utilizing ordinary soda-lime float glass. The two glass plates are then mounted with a separation of about 100 μm and with the conductor wire sets perpendicular to one another. The gap region between the glass plates is filled with an inert gas, which discharges and illuminates the pixels when sufficient voltage is applied across two intersecting wires.

For dc pixels, shown in Figure 93.5a, the working gas is in direct contact with the electrodes. Electrons produced within the discharge volume flow rapidly to the anode, while ions produced flow more slowly toward the cathode. At 53.3 kPa (400 torr), a gap gap of 100 μm and an applied voltage of 200 V, the electron and ion transit times across the gap are roughly 0.2 and 20 ns, respectively. Once breakdown is initiated, the electrical resistance of the discharge is negligible. Consequently, dc operation requires that external resistors in series with each pixel be included in the circuit in order to limit the current amplitude. Often, dc pixels are operated in pulsed discharge mode with frequency modulation used to define the pixel brightness. For ac or dc pixels, a base firing frequency of 50 kHz

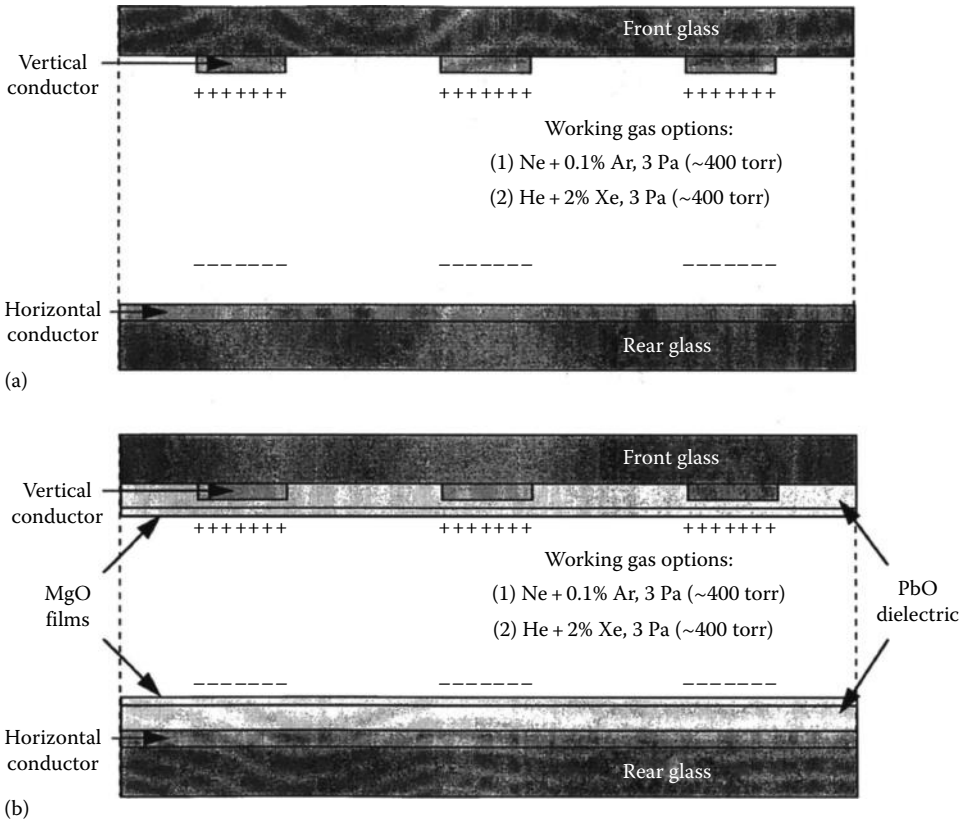

FIGURE 93.5 Schematic diagrams of (a) dc- and (b) ac-opposed electrode plasma pixels.

is typical. This frequency is too fast for the human eye to detect any *on–off* flicker, but allows sufficient flexibility for intensity and refresh control. In reviewing the literature on plasma displays, it is easy to confuse dc and ac pixels since dc pixels are often operated in pulsed mode and with electrode polarity reversal which distributes sputter damage over both electrode surfaces. The dc pixels are readily identified by conducting electrodes in direct contact with the discharge gas and the inclusion of a current-limiting resistor in the circuit for each pixel. While polarity reversal is optional for dc pixel operation, it is inherently required for ac pixel operation as discussed later. Drive electronics, current limiting, gray scale, and other aspects of both dc and ac pixel operation are discussed in greater detail in subsequent sections.

Figure 93.5b shows a schematic representation of an ac plasma pixel configuration. One can see that the differences between ac and dc pixel geometry are slight; however, the resulting operational differences are significant. In the ac pixel, the conductor wires are covered with a dielectric film. Typically, lead oxide (PbO), which has a dielectric constant of about 15, is deposited at a film thickness of about 25 μm. Most ac pixels are made with a thin-film (50–200 nm) magnesium oxide (MgO) dielectric coating covering the PbO and in contact with the working gas. This dual material dielectric film serves two principal functions: charge storage and secondary electron emission.

The exact voltage required for gas breakdown depends upon the gap width, the gas pressure, the gas composition, and MgO surface conditioning. For the pixel parameters shown in Figure 93.5b, an externally applied voltage of about 120–180 V is required to initiate a discharge. In the ac pixel, once the discharge is initiated, electrons and ions flow toward the anode and cathode, respectively, as in the dc pixel. However, in the ac case, charge carriers are unable to reach the conductor wires and instead collect as a surface charge on the dielectric coating. The electric field within the gas gap is always the sum of that produced by the externally applied voltage and that produced by the surface charge. During pixel firing, if the externally applied voltage is held constant for only a few microseconds, the net electric field within the gas gap very quickly decreases (~100–200 ns). The gap potential drop, produced by the surface charge, shields out the one produced by the externally applied voltage. Eventually, the gap electric field is insufficient to sustain the discharge and the pixel turns *off*. Thus, each ac pixel is inherently self-current-limiting and, unlike the dc pixel, requires no external resistance in series with it. At the start of the next ac half cycle, the externally applied voltage is reversed. When this occurs, the voltage across the gas gap is the sum of the external voltage and the voltage produced by the surface charge established during the previous discharge. If a sufficient surface charge is present, a new discharge pulse can be initiated by application of an external voltage, by which it would be insufficient to break down the gas. Within the new discharge, charge carriers flow quickly to reverse the polarity of the surface charge concentrations. Once again, the field within the gap is diminished and the discharge turns *off*. Storage of surface charge makes ac pixels easily controllable and provides them with their inherent memory properties. The presence or absence of surface charge determines whether or not a given pixel will discharge at the onset of the next ac half cycle of the externally applied voltage. The details of how these discharge dynamics are used to write, erase, and sustain each pixel are discussed in subsequent sections, along with drive mechanisms for gray scale and for pixel array refresh.

93.1.3 General Attributes of Plasma Displays

Plasma-driven flat panel displays offer a number of advantages over competing display technologies. The highly nonlinear electrical behavior of each pixel, with inherent memory properties, can be used to advantage in design of the drive electronics required to refresh and to update the pixel array of the display. The simplicity of the pixel design makes large-area manufacturing problems, such as alignment and film thickness uniformity, somewhat more manageable. Relative to color active matrix liquid crystal displays (AMLCDs) which use a thin-film transistor (TFT) to control each pixel, less-complicated manufacturing and less-complicated drive electronics give plasma flat

panel displays advantage for large-area applications. On the other hand, plasma displays require more robust drive electronics with voltages of 100–275 V. Plasma displays are also not well suited for portable applications since power consumption is high relative to other display technologies, but not restrictive for office or domestic use. The 76 cm (30 in.) diagonal color display manufactured by Photonics Imaging shown in Figure 93.4 has a peak power consumption of only 300 W [23]. At high power levels, plasma-driven flat panel displays are bright enough to be readable in sunlight. The displays are also easily adjusted to a low-ambient-light condition by discharge amplitude or frequency modulation.

Plasma flat panel displays are well suited for large-area (0.5–5 m) applications such as videoconferencing, large meeting room displays, outdoor displays, and simulators requiring large viewing areas. Thin, high-resolution, large-area, color plasma displays are also very attractive for desktop workstation or personal computer applications requiring high-resolution graphics. Note, too, that plasma flat panel displays have very large viewing angles, greater than 160° in many designs [22–24]. For displays using metal electrodes, one often finds that the best viewing angle is slightly off normal since the front electrode wire blocks out a portion of the pixel emission. This occurs both for monochrome pixels producing visible emissions within the discharge and for color plasma displays where the viewer sees visible red, green, and blue (RGB) emissions from vacuum ultraviolet (VUV) photon-stimulated phosphors. Some manufactures have investigated use of transparent electrodes, such as indium–tin oxide (ITO), but there is a trade-off with power consumption since the conductivity of ITO is less than that of metal electrodes [18]. In contemporary designs, the metal conductor width is thin (~20 μm) and its opacity does not present a major problem.

For color pixels, the discharge gas mixture is modified to produce emissions in the VUV. In all other respects, the operational principals of the plasma discharge by the pixel are identical for color and for monochrome displays. Ideally in color plasma displays, no visible emissions are produced within the discharge itself and VUV-photostimulated luminous phosphors are used to produce the required RGB visible light. The ac color pixel design concept shown in Figure 93.6 is that utilized by Fujitsu [18]. Long, straight barrier structures, each about 100 μm tall, are constructed parallel to and between each of the vertically oriented conductor wires on the rear glass plate. The sidewalls of these barriers are alternately coated with RGB-photostimulated phosphors. Note that the Fujitsu panel employs a three-electrode, ac-driven surface discharge pixel design which is slightly more complicated than the opposed electrode ac design shown in Figure 93.5b. This chapter will return to surface discharge configurations and other aspects of color pixel design and operation after reviewing fundamentals of the discharge physics and electrical behavior governing pixel operation.

93.2 Fundamentals of Plasma Pixel Operation

93.2.1 Atomic Physics Processes

Although simplistic in design, the plasma display pixel is a rich environment for study of basic atomic physics, electron collisional processes, photon production and transport, and plasma–surface interactions. The coupling of these processes for a neon–argon monochrome pixel discharge was nicely summarized in the diagram from Weber which is reproduced here as Figure 93.7 [4]. The reader interested in additional information on fundamental discharge physics is directed to one of the excellent textbooks in this field [25–27].

The physical processes governing of the behavior of the pixel discharge are closely coupled and form a closed-loop system. The discussion begins by assuming that a seed electron is resident within the gas gap and is subjected to an electric field which results from application of an externally applied voltage to the two conductors forming that pixel. Some of the gas and surface processes for production of the seed electrons will become evident as the discussion progresses. In order to ensure reliable discharge initiation, seed particles, which are either electrons or electron-producing photons or metastable atoms, are often provided by a controlled source which may be external to the pixel being fired. Some display panels include electrodes for production of seed particles at the edges of the panel outside the field of view or hidden behind opaque conductor wires. Other display panels use well-controlled temporal

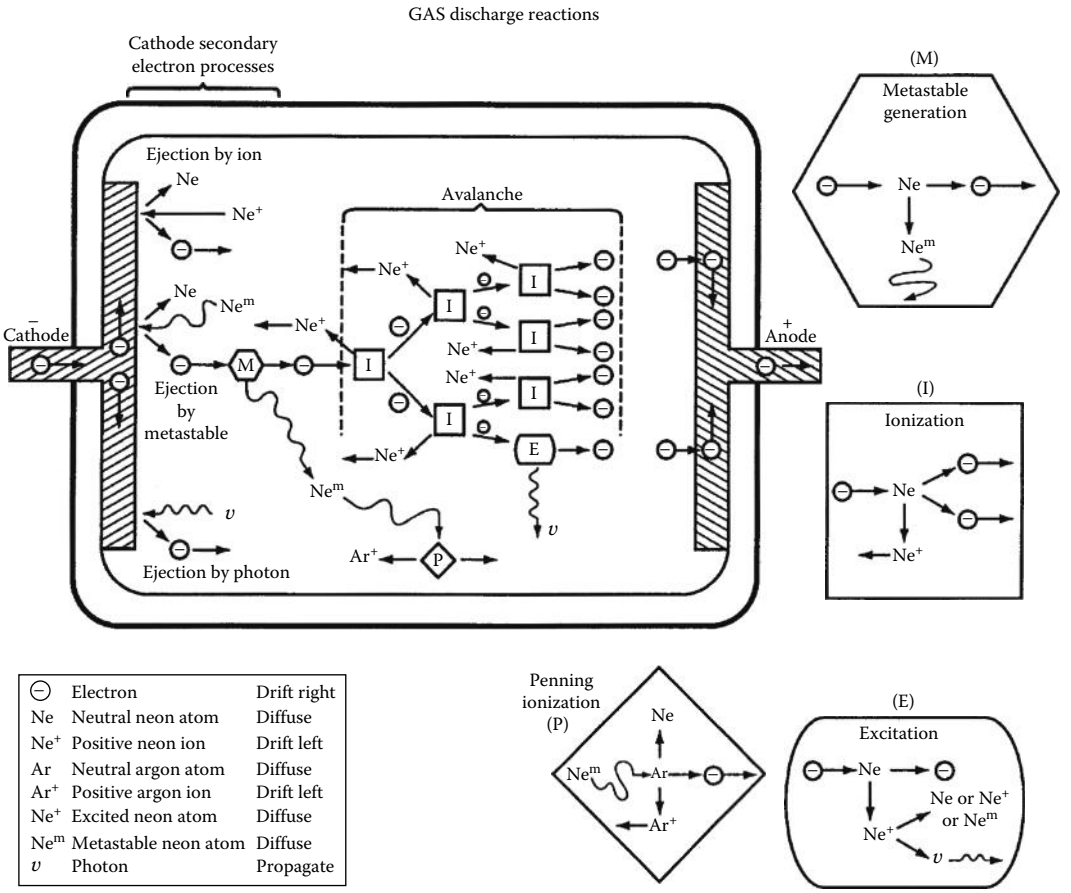

FIGURE 93.7 Collisional and surface interactions in a gas discharge. (From Weber, L.F., *Flat Panel Displays and CRTs*, Tannas, L.E., Jr., Ed., Van Nostrand Reinhold, New York, 1985. With permission.)

sequencing to ensure that the nearest-neighbor pixels provide seed particles for one another [4,19,28]. Pixel-addressing sequences are discussed further later in this chapter.

The transport of electrons or ions across the gas gap is a balance between field acceleration and collisional energy loss. In the example of Figure 93.7, the gas is mostly neon (98%–99.9%) and field-accelerated electrons will predominantly collide with Ne atoms. The quantum energy level diagram for excitation of the Ne atom is shown schematically in Figure 93.7 [29]. Note that the lowest-lying excited state is 16.6 eV above the ground state, while the ionization energy is 21.6 eV. This means that electrons with energies <16.6 eV can only experience elastic collisions with the Ne atoms. When an electron is field-accelerated to energy in excess of 16.6 eV, inelastic collisions which transfer energy from the incident electron to one of the outer-shell electrons in the Ne atom can take place. Incident electrons with kinetic energies in excess of 21.6 eV can drive ionization reactions:

$$\mathrm{Ne} + \mathrm{e}^- \rightarrow \mathrm{Ne}^+ + 2\mathrm{e}^- \tag{93.1}$$

Excitation and ionization collisions transfer energy from the electron population to the neutral atoms in the gas. At the same time, the electron population available to ionize the Ne further is increased with every ionizing event. The result is the discharge avalanche schematically shown in Figure 93.9, which manifests itself experimentally as a rapid increase in electric current flowing in the pixel gas gap. In dc panels, an external resistor of about $R = 500\ \mathrm{k}\Omega$ is placed in series with each pixel. The amplitude of the externally applied voltage provided by the driving electronics, V_a, is held constant and the total voltage across the gas gap, $V_g = V_a - IR$, decreases as the circuit current, I, increases. Very quickly, a steady-state dc current in the gas gap and in the circuit is established. Brightness and gray scale are controlled by frequency modulation of the pulsed dc pixel firing using a base frequency of about 50 kHz. In ac pixel discharges, electrons and ions are driven by the applied field to the dielectric-covered anode and cathode, respectively. The buildup of charge on the dielectric surfaces shields the gap region from the field produced by the externally applied voltage. Eventually, the electric field in the gap drops below a level sufficient to sustain the discharge and the pixel turns *off*.

For electron energies greater than 16.6 eV, collisions with Ne atoms can excite outer-shell electrons in the atom to one of the numerous excited energy states shown in Figure 93.7:

$$\mathrm{Ne} + \mathrm{e}^- \rightarrow \mathrm{Ne}^{\mathrm{ex}} + \mathrm{e}^- \tag{93.2a}$$

$$\mathrm{Ne}^{\mathrm{ex}} \rightarrow \mathrm{Ne}^* + h\nu \tag{93.2b}$$

Most of these excited states have short lifetimes ranging from fractions to tens of nanoseconds [30] and quickly decay to lower-lying atomic quantum states accompanied by the emission of a characteristic photon, indicated in Equation 93.2 by $h\nu$, the product of Planck's constant times the photon frequency. As can be seen in Figure 93.8, the characteristic red–orange Ne gas emissions result from electron transitions within the atom from higher-energy 2p quantum states to lower-lying 1s energy levels [30,31]. Two of the four 1s energy levels radiate to ground-emitting VUV photons with wavelengths of 74.4 and 73.6 nm. Due to quantum mechanical exclusion principles, electron decay from the other two 1s levels is more complex and depends upon fine details of the electronic wave function and upon very small perturbing interactions [31]. Consequently, decay lifetimes for these so-called metastable states are measured in seconds, which is very long relative to other dynamic physical processes governing pixel discharge behavior, such as charge or neutral particle transport. An Ne atom with an electron trapped in one of these metastable levels harbors 16.6 eV of latent energy. The metastable atom, Ne*, is unable to dissipate its stored energy in collisions with ground-state Ne atoms, yet readily liberates its energy whenever a lower-lying energy configuration can be accessed. The principal channels in this system to lower-energy configurations are Ne* collisions with Ar or Ne* incidence onto pixel interior surfaces.

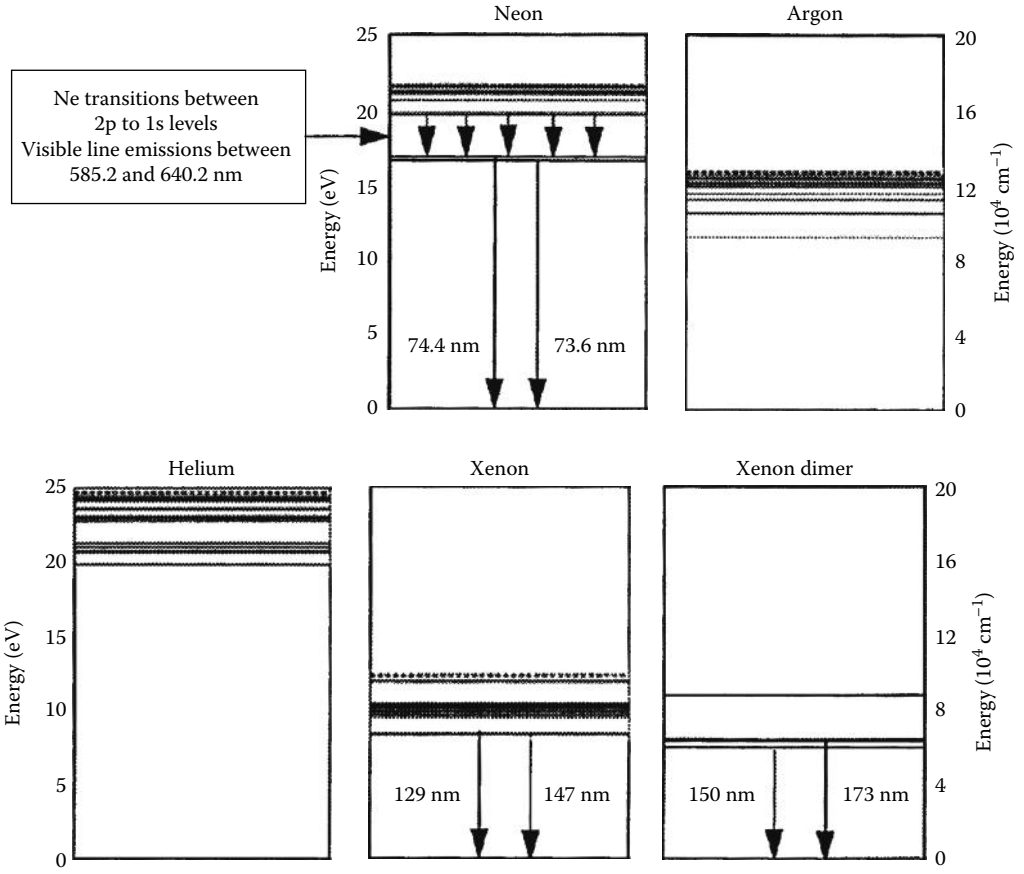

FIGURE 93.8 Quantum energy level diagrams for He, Ne, Ar, Xe, and the Xe^{2*} dimer.

Figure 93.8 shows simplified energy level diagrams for several inert gases. The relative positioning of the allowable energy levels provides insight into the energy exchange that occurs in collisional coupling. The ionization energy of the Ar atom is 15.8 eV and lies 0.8 eV below the metastable-state Ne*. Consequently, the Ne* has sufficient stored energy to ionize the Ar atom:

$$Ne^* + Ar \rightarrow Ne + Ar^+ + e^- \tag{93.3}$$

Ionizing reactions of this type are called Penning reactions, and gas mixtures that rely on metastable states of the majority gas constituent (Ne) for ionization of the minority gas constituent (Ar) are referred to as Penning gas mixtures [25,26,32]. Figure 93.9 shows the efficiency with which charge pairs are produced through ionization within Ne/Ar Penning gases containing various fractions of Ar. The curves show that for any given pressure, ion pair production per volt applied is optimal at low Ar gas fractions (0%–10%) except for very large values of E/P, greater than 75 V/m/Pa (100 V/cm/torr), where E is the electric field strength and P is the gas pressure. Penning gas mixtures have been studied for many years. Figure 93.9 shows the original data on Ne/Ar gas breakdown published by Kruithof and Penning in 1937 [32]. An extensive volume of literature has been published on inert gas Penning processes since then, and the interested reader is referred to the excellent texts which have recently been rereleased through the American Vacuum Society and MIT Press [25,26].

Plasma display pixels usually operate at pressures near 53.3 kPa (400 torr) in order to achieve sufficient photon production and brightness. Typical pixel fields are roughly 100 MV/m. Consequently,

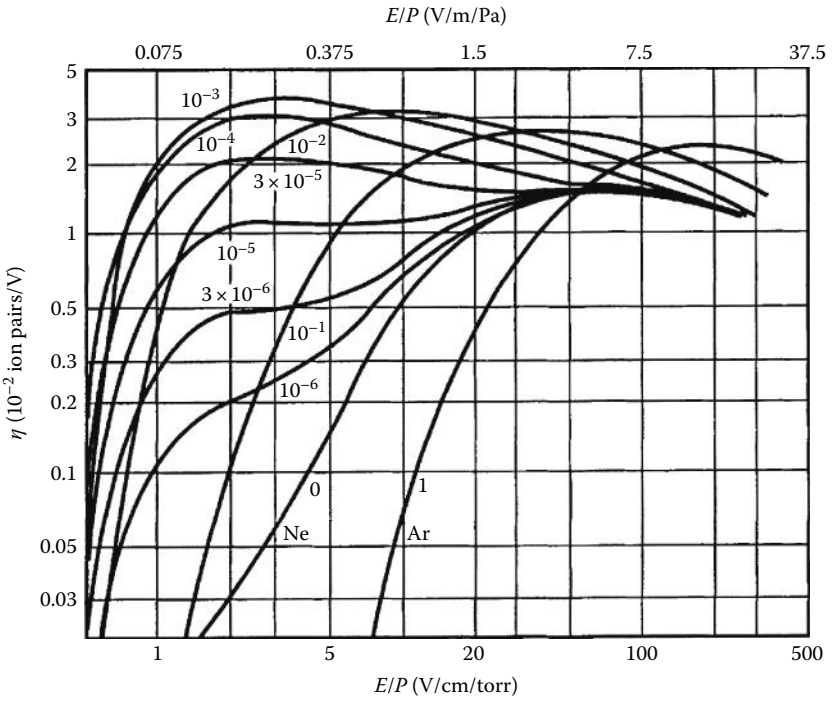

FIGURE 93.9 Ionizing collisions plotted vs. electric field strength divided by pressure. The numbers on each curve indicate the ratio of the Ar partial pressure to the total gas pressure. (From Brown, S., *Basic Data of Plasma Physics—The Fundamental Data on Electrical Discharges in Gas*, American Institute of Physics Press, New York, 1993. With permission.)

plasma pixels operate with *E/P* values near 18.8 V/m/Pa (25 V/cm/torr). Both charge pair production and luminous efficiency are then optimized with Ar gas fractions between 0.1% and 10%, depending upon the specifics of the pixel gas pressure, gap width, and driving voltage. For a given applied voltage, the product of the gas pressure (P) and the gas gap dimension (d) provides a measure of the balance between electron acceleration by the electric field and electron energy loss due to collisions with the background gas. Paschen curves, which plot the gas breakdown voltage vs. the Pd product, for several inert gas mixtures are shown in Figure 93.10 [26,33,34]. In each case, minimum voltage for breakdown occurs at a value of the Pd product which is dependent upon the ionization levels, collisionality, and energy channels within the gas. For example, in Ne atomic excitation and ionization processes dominate, while in air much of the energy absorbed by the gas goes into nonionizing molecular vibration, rotation, and dissociation. For fixed pressure, the Paschen curves show that increased gap dimension lowers the electric field strength per volt applied and a large voltage is required for breakdown. On the other hand, if d is reduced for a given pressure, the electric field strength can be large, but electrons transit the gap without initiating a sufficient number of collisions to drive the type of discharge avalanche shown in Figure 93.7. If the gas gap, d, is held fixed while pressure is varied, the shapes of the Paschen curves are again explained by electron acceleration and collisional processes. For high pressures, the mean free paths between electron collisions with the background gas atoms are short and electrons are unable to accelerate to energies sufficient to initiate ionization unless the electric field is especially strong. At low pressures, the electrons may be accelerated by the field to energies sufficient to initiate ionization, but few collisions with the background gas occur and, again, the avalanche is difficult to initiate. Penning processes are especially efficient at driving ionization. Introduction of 0.1% Ar into the neon gas lowers the minimum breakdown voltage from the value near 250 V, shown in Figure 93.10, to about 150 V. The minimum breakdown voltage occurs at a Pd product of 40 Pa m (30 torr cm) for this gas mixture.

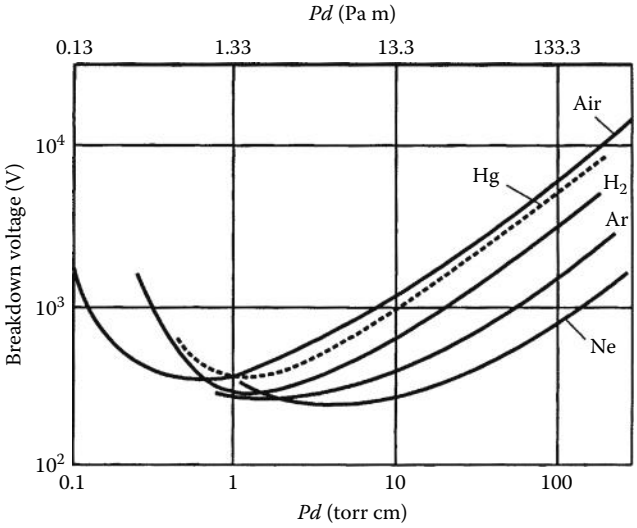

FIGURE 93.10 Breakdown voltage as a function of pressure—gas gap length product for various gases. (From Brown, S., *Basic Data of Plasma Physics—The Fundamental Data on Electrical Discharges in Gas*, American Institute of Physics Press, New York, 1993. With permission.)

93.2.2 Discharge Physics for Plasma Pixels

Within any discharge, electrons move very quickly, while the more massive ions move relatively slowly in comparison. In charge-neutral plasma that is subjected to an externally applied electric field, the mobile electrons quickly respond to the applied field and rush toward the anode. The inertia-laden ions, in a much slower fashion, begin their motion toward the cathode. Very quickly, a local charge imbalance is established as the electrons reach the anode faster than the rate of arrival of ions at the cathode. Poisson's equation

$$\nabla \cdot E(x) = 4\pi\rho(x) = 4\pi e(n_i(x) - n_e(x)) \tag{93.4}$$

shows that a local electric field is established in response to the net positive charge density, $\rho(x)$, in the plasma region. Here, $n_i(x)$ and $n_e(x)$ are the spatial profiles of the ion and electron densities, respectively, and e is the electron charge. The field established retards the rate at which electrons flow out of any volume within the plasma column and forces them to follow the net ion motion. The ion drift motion is correspondingly accelerated, but this acceleration is smaller by a factor proportional to the mass ratio of the electron to the ion. The net ion/electron motion is called ambipolar flow and is described in detail in many basic plasma physics texts [25–27].

In steady-state dc plasma pixel discharges, the amplitude of the current flowing in the circuit and in the gas gap is defined by the value of the applied voltage and the resistor in series with the pixel. Steady-state operation dictates that charge buildup within the gap region cannot occur. The rate at which charge particle pairs arrive at the electrodes must equal their rate of production due to ionization. At the same time, the rates at which ions and electrons leave the plasma volume, arriving at the cathode and anode, respectively, must be equal. Equilibrium is sustained by establishment of the spatial potential profile within the gas gap shown in Figure 93.11a. Due to the high electron mobility, the plasma is extremely efficient in shielding out externally applied electric fields. As a result, the potential profile is flat across the gas gap of a pixel sustaining a fully developed discharge. The entire potential drop is localized in a small zone called the sheath adjacent to each electrode. The spatial extent of the sheath is

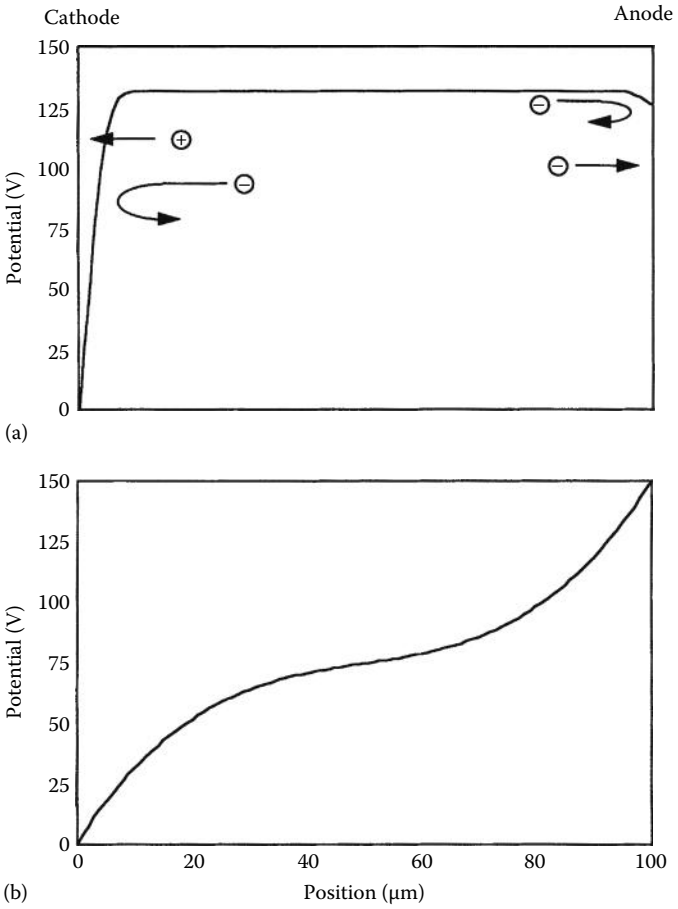

FIGURE 93.11 Potential profiles in the pixel gap region for (a) high-electron-density and (b) low-electron-density discharges.

determined by the effectiveness of the electron population in shielding out the electric fields produced by the electrode potentials. The Debye length

$$\lambda_D = \sqrt{\frac{kT_e}{4\pi e^2 n_e(x)}} \tag{93.5}$$

provides a measure of the shielding distance. The expression for λ_D implies that the sheath thickness increases with increasing electron temperature, T_e, and decreases as the electron density, n_e, increases. For fully developed plasma pixel discharges, the product of Boltzmann's constant and the electron temperature, kT_e, is at most a few electron volts, and n_e is of order $10^{16}/m^3$. Thus, the sheath thickness is roughly 5 μm. The potential within the plasma region adjusts, V_p, within the discharge volume rises to a value just above that of the applied voltage at the anode. Consequently, only the most energetic electrons can overcome the potential barrier at the anode which adjusts to a potential such that the rate of electron loss at the anode equals the rate of ion loss at the cathode. For ac plasma pixels, a similar potential profile is established, but changes dynamically as the pixel pulse evolves. Charge pairs incident upon the anode and cathode in ac pixels are trapped there by the dielectric film covering the conductor wires. Consequently, the potential at the discharge boundary is diminished as surface charge collects at each electrode, as shown in Figure 93.11b. Ultimately, the discharge terminates as the electric field produced

by the surface charge cancels that produced by the externally applied voltage. As the density of charge carriers is reduced near the termination of an ac pixel discharge pulse, the effectiveness of the electrons to shield out electric fields within the gap is diminished. In this situation, the sheath potential drop is small but the sheath region occupies a large fraction of the gap [35,36].

93.2.3 Plasma Surface Interactions

93.2.3.1 Ion-Induced Secondary Electron Emission

Ions arriving at the cathode sheath are accelerated by the sheath potential drop. Incident ions strike the cathode with kinetic energies equal to the plasma potential, V_p, which is just over 200 V in the example shown in Figure 93.12. Ions incident on the cathode quickly capture an electron, additionally depositing on the cathode surface energy equal to the recombination or ionization energy for that atom. Energy deposition on the cathode surface drives two important processes for plasma pixels—ion-induced secondary electron emission and sputtering. The first process significantly enhances the luminous efficiency of plasma pixels. The second shortens their operational lifetime as is discussed in subsequent sections.

Ion-induced secondary electron emission occurs when ion energy deposition on the surface results in electron ejection. Secondary electrons are exceptionally effective at driving discharge ionization since they gain large amounts of kinetic energy as they are accelerated across the cathode sheath and because they have ample opportunities for ionizing collisions as they traverse the entire width of the gas gap. The secondary electron emission coefficient, γ, is defined as the number of electrons ejected per incident ion [25,26]. As one would expect, γ varies with incident ion energy and with cathode material. Most ac plasma display panels take advantage of the strong secondary electron emission of MgO, which is also a good insulating material as required for surface charge storage in ac operation. Measurement of the MgO γ-value is difficult, especially for low-energy ion incidence (<500 eV), and is complicated by charge buildup on the samples during the measurements [37]. Most often, relative values of secondary electron yields for different materials are deduced from discharge intensity measurements [11,12,38–41].

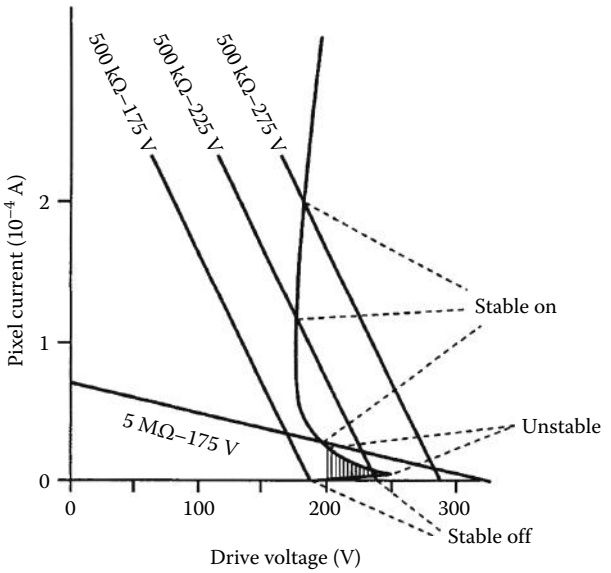

FIGURE 93.12 A representative current–voltage characteristic for gas breakdown. Load lines representative of plasma pixel operation are also shown. (From Weber, L.F., *Flat Panel Displays and CRTs*, Tannas, L.E., Jr., Ed., Van Nostrand Reinhold, New York, 1985. With permission.)

Chou directly measured the ion-induced secondary electron emission coefficient for MgO using a pulsed ion beam with sample surface neutralization between pulses. For ion incidence at 200 eV, he found $\gamma = 0.45$ and $\gamma = 0.05$ for Ne^+ and Ar^+, respectively [38]. Note, too, that photons and metastable atoms incident on the electrode surfaces are also capable of initiating secondary electron emission, as shown in Figure 93.7. Since neither photons nor metastables are influenced by the electric fields within the gas gap, they propagate isotropically throughout the gas volume and are often utilized as seed particles.

93.2.3.2 Sputtering

Ions accelerated across the sheath deposit energy on the cathode surface. This often initiates sputtering, whereby an atom within the cathode material is ejected from the surface. Sputtering processes erode the cathode surface and degrade pixel performance. Contamination of the discharge by sputtered surface impurities can lead to reduction in luminous efficiency due to visible emissions from the contaminant atoms or molecules which compromise the color purity of the pixel. Unwanted surface coatings from redeposited materials can also degrade the electrical characteristics of the pixel or, in color applications, shield the phosphors from VUV photons, and further degrading luminous efficiency. For argon ion, Ar^+, bombardment of MgO surfaces at 2 keV, the measured sputtering yield is slightly greater than one ejected atom per incident ion [42]. Data on sputtering yields at lower-energy ion incidence are difficult to obtain. Because yields are small, large incident ion currents are required to obtain measurable signals and sample charging is once again a problem. In spite of the lack of detailed data on low-energy MgO sputtering, manufactures of ac plasma panels have been able to demonstrate display lifetimes well in excess of 10,000 h [18,23]. Schone et al. [43] have demonstrated that Rutherford backscattering of high-energy (2.8 MeV) α-particle can be used to measure the thickness of MgO film on a PbO substrate. The film thickness accuracy obtained was ±1.5 nm. Because the technique requires a large (and expensive) particle accelerator, this technique is a very nice research tool but is ill suited for any fabrication line measurements.

93.3 Pixel Electrical Properties

93.3.1 Electrical Properties of DC Pixels

Figure 93.5 shows schematic diagrams and circuit models for dc and ac pixels. In the dc case, the pixel gas gap functions electrically as a variable impedance resistor. Prior to gas breakdown, the resistance is large and the pixel represents an open-circuit element. Once breakdown is initiated, the plasma is an excellent conductor and offers only modest resistance, R_P, to current flow. Since $R \gg R_P$, the circuit equation simplifies to

$$V_a = I(R + R_P) \approx IR \tag{93.6}$$

and the circuit current, I, is defined by the amplitude of the applied voltage and the size of the circuit series resistor, R. The externally applied voltage, V_a, is typically a 50 kHz square wave with a fast voltage rise time (~50 ns). The dc driving voltages range from 175 to 275 V and a typical value for the series resistor is $R = 500$ kΩ. Pixel currents then range from 0.35 to 0.55 mA. Note that without a large resistance in series with the pixel, the current is limited by some physical failures such as melting of the pixel electrodes.

Figure 93.12 shows the characteristic I–V behavior of a dc pixel which has a breakdown voltage of 250 V [4]. Only a very small current due to a few stray charge carriers flows across the gas gap as the voltage increases from 0 to 250 V and the pixel remains in the *off* state. At the breakdown voltage, the situation is dynamic with the current growing rapidly and the voltage across the gas gap dropping as a result. The steady-state operating point achieved is identified by the intersection of the load line, $V_a = IR$, with the discharge I–V characteristic as shown in Figure 93.12. For an applied voltage of 175 V the pixel is

always *off*, while for $V_a = 275$ V the pixel is always *on*. For a line resistance of 500 kΩ, the bimodal operation and memory of the dc pixel at $V = 225$ V is evident in the figure. If an applied voltage of 225 V is approached from the low-voltage direction, the pixel remains *off*. If, on the other hand, a large voltage is applied and subsequently lowered to $V_a = 225$ V, then the pixel will be in an *on* state. Note that the region where the 225 V/500 kΩ load-line intersects the negative resistance portion of the *I–V* characteristic is unstable. The pixel discharge will quickly transition to either the stable *on* or stable *off* operating point. As a practical matter, one should note that the negative resistance region of the *I–V* characteristic curve cannot be experimentally measured in a pixel circuit operating with a 500 kΩ series resistance. Instead, as shown in the figure, a much larger series resistor, $R = 5$ MΩ, provides a load line with slope small enough to produce stable operation in the negative resistance regime.

93.3.2 Electrical Properties of AC Pixels

The physical design of an opposed electrode ac pixel is shown in Figure 93.5b. Electrically, the pixel functions as a breakdown capacitor and is described by the circuit equation:

$$V_a(t) = I(t)R + \frac{1}{C}\int_0^t I(t')dt' = I(t)R + \frac{Q(t)}{C} \tag{93.7}$$

where

V_a is the externally applied voltage
I is the circuit current
C is the pixel capacitance
Q is the charge collected

For ac pixels the line resistance, R, is minimized in order to minimize power consumption and Equation 93.7 simplifies to

$$V_a(t) = \frac{1}{C}\int_0^t I(t')dt' = \frac{Q(t)}{C} \tag{93.8}$$

The capacitance for each pixel is the series summation of the capacitance for each dielectric film and for the gas gap:

$$\frac{1}{C} = \frac{1}{C_{PbO}} + \frac{1}{C_{MgO}} + \frac{1}{C_{gas}} \tag{93.9}$$

In each case,

$$C_i = \frac{e_i A}{d_i} \tag{93.10}$$

where

i is the material index
Surface area, A, is roughly equal to the square of the conductor wire width

As shown in Figure 93.5b, an ac pixel is typically constructed with a PbO film of thickness $d = 25$ μm, while the thin-film MgO has thickness $d = 50$–200 nm. The lead oxide has a dielectric constant of

roughly $\varepsilon_{PbO} = 15\varepsilon_0$, while that for MgO is $\varepsilon_{MgO} = 6\varepsilon_0$ with exact values dependent upon the film purity and microstructure [34]. Note that the MgO contribution to the total capacitance is negligible and that this material is incorporated into the design because of its excellent secondary electron emission properties. Prior to gas breakdown, the capacitance of the pixel is attributed largely to the gas gap. For 20 μm thick conductor wires, the capacitance of a pixel gas gap prior to breakdown is about 500 pF. The time derivative of Equation 93.8 gives the circuit current:

$$I(t) = C\frac{dV(t)}{dt} \tag{93.11}$$

This charge displacement current appears as the initial large amplitude current peak in Figure 93.13, which shows the temporal current response of a 45 × 45 ac pixel array to a single pulse within a 50 kHz square wave applied voltage pulse train. The electrical measurement shown was made using a simple induction loop probe to measure the current and a high impedance voltage probe (1 MΩ, 3 pF) to monitor the applied voltage. The signals were captured using a high-speed (300 MHz) oscilloscope.

If the applied voltage amplitude is below the gas breakdown threshold, only the capacitor charging displacement current, defined by Equation 93.11, is observed as shown in Figure 93.13a. If the voltage for gas breakdown is exceeded, a second current pulse due to the plasma discharge current within the gas gap is observed in the circuit (Figure 93.13b). The plasma pulse is accompanied, of course, by strong

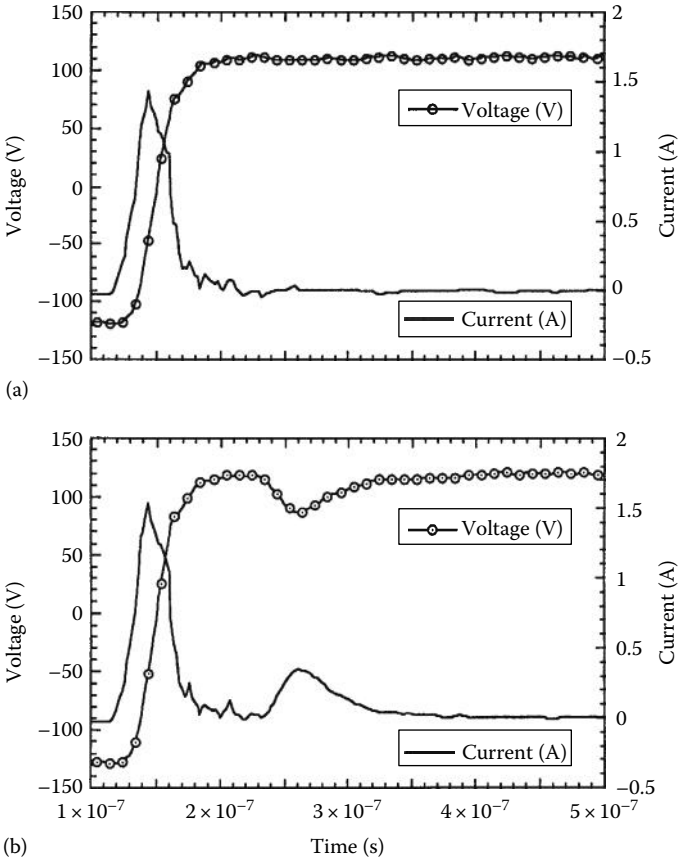

FIGURE 93.13 Voltage and current traces for a 45 × 45 array of ac plasma pixels in the (a) *on* and (b) *off* states. Drive voltage amplitudes were 117 and 127 V, respectively.

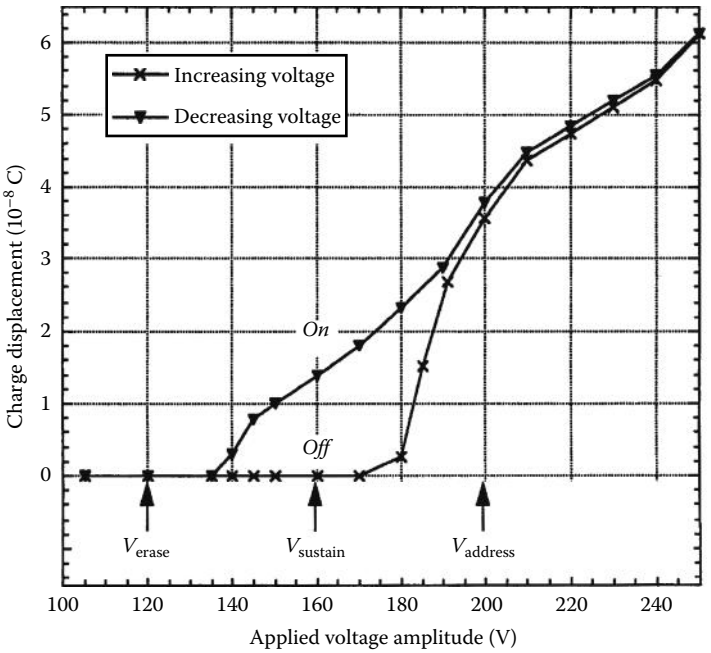

FIGURE 93.14 Discharge charge displacement for operation of a 45 × 45 array of ac-opposed electrode pixels with an He–Xe (2%) gas mixture at 53.3 kPa (400 torr).

photon emission from the gas gap region. The total charge displacement in the discharge pulse as a function of amplitude of the square wave–applied voltage is plotted in Figure 93.14 for a helium–xenon (2%) Penning gas mixture [44]. The hysteresis or inherent memory property of the ac pixel is apparent. As the applied voltage amplitude is increased from 0 to 180 V, no measurable current flows across the pixel gas gap. When no surface charge is present below 180 V, the electric field within the gap region is insufficient to drive the electron collisions into the avalanche regime. For any voltage amplitude in excess of 180 V, a gas discharge is initiated and the pixel turns *on*. If a pixel is subjected to a single voltage pulse with amplitude <135 V, the pixel turns *off* even if a surface charge is present.

In ac pixels, charge pairs produced during one discharge pulse collect on the surfaces of the dielectric films at the boundaries of the gas gap and are available to assist formation of the next discharge pulse in the sequence. In a fully developed ac pixel discharge, the surface charge accumulation on the dielectric film produces an electric field within the gas gap, which cancels the gap field produced by the externally applied voltage. This is shown in Figure 93.15, which is a composite representation of experimental current measurements and computational model predictions of the surface charge accumulation producing the surface or wall voltage [35,45]. When the polarity of the applied voltage is reversed, the potential drop due to the surface charge and that due to the applied voltage suddenly are additive as shown in the figure. The gas gap is momentarily subjected to an intense electric field which results from a potential drop roughly equal to twice the applied voltage. The presence or absence of surface charge results in the bimodal current–voltage behavior is shown in Figure 93.14.

Addressing of ac pixels is easily accomplished by taking advantage of the inherent memory of the pixel that results from this bimodal *I–V* behavior. For the pixel electrical properties shown in Figure 93.14, each pixel would be continuously supplied with an ac square wave–applied voltage pulse train with an amplitude of 160 V, called the sustain voltage, $V_{sustain}$. If the pixel is initially in an *off* state, it will remain so indefinitely since no surface charge is available to enhance the field produced by the sustain voltage. To turn the pixel *on*, a single high-amplitude voltage pulse, called an address (or write) pulse is delivered across the pixel electrodes. In this example, an address pulse of 200 V

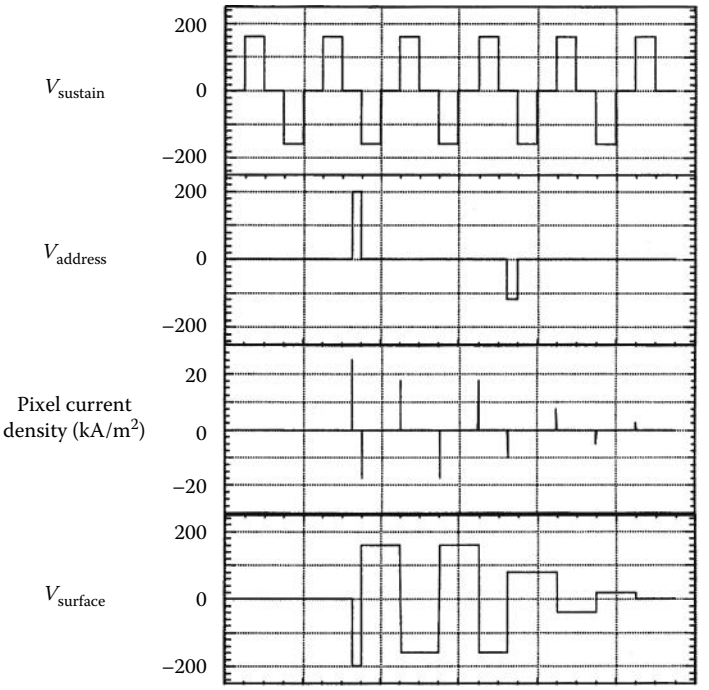

FIGURE 93.15 Sustain and address voltage waveforms for ac-driven plasma pixels. The amplitude of the pixel current density and wall voltage resulting from the surface charge buildup provide a measure of the discharge intensity.

initiates a discharge whose charge pairs collect on the internal dielectric surfaces of the pixel. The self-limiting nature of the ac pixel is such that the surface charge concentration produced for a fully developed pixel discharge completely shields the gap region from the externally applied field. When the next sustain polarity reversal occurs, the pixel gas gap experiences a voltage equal to the sum of the sustain voltage (160 V) plus the voltage due to the surface charge produced by the previous pulse, $V_{surface} = 200$ V in this case. The new gap voltage of 360 V is more than sufficient to initiate a second discharge and to establish a new surface charge whose polarity is opposite that of the preceding pulse. Once again, the surface charge adjusts to produce a voltage exactly canceling the field of the applied voltage. For this pulse, $V_{wall} = 160$ V, and the next sustain voltage polarity reversal subjects the gap to a potential difference of $V_{gap} = V_{sustain} + V_{address} = 160\ \text{V} + 160\ \text{V} = 320$ V, which is again sufficient to initiate a new discharge pulse. Consequently, the pixel remains in the *on* state until action is taken to eliminate or diminish the surface charge buildup accompanying each discharge. This is accomplished by application of a single low-voltage pulse called an erase pulse with amplitude $V_{erase} = 120$ V for the example shown in Figures 93.14 and 93.15. Application of the erase pulse produces a potential drop across the gas gap of $V_{gap} = V_{applied} + V_{surface} = V_{erase} + V_{surface} = 120\ \text{V} + 160\ \text{V} = 280$ V. The erase pulse produces a discharge of lower intensity which is insufficient to reestablish a reversed polarity surface charge. Consequently, the erase discharge diminishes the concentration of the surface charge so that no discharge is initiated during the next pulse in the sustained applied voltage train. Ideally, the erase pulse drives the surface charge concentration identically to zero, but this rarely occurs in practice and is not essential for ac pixel operation, as can be seen in Figure 93.15. Very low-intensity discharges with negligible photon production drive the pixel to its ideal *off* state within a few ac cycles. Fortunately, these minor deviations from the ideal *off* condition have little effect on subsequent write pulses for frequency-modulated ac operation, and therefore do not affect the timing of pixel addressing and refresh which is covered in the next section.

93.4 Display Priming, Addressing, Refresh, and Gray Scale

Pixel priming is necessary to provide the initial source of electrons, or the priming current, required to initiate a discharge avalanche. Metastable atoms or photons can also be used as priming particles since these produce electrons via ionization of the background gas. Pilot cell priming and self-priming are two options used in currently available commercial products. In pilot cell priming, a separate cell which generates electrons is located near the pixel to be addressed. Pilot cells are often located on the periphery of the display outside the viewing area, yet can produce seed electrons throughout the display. In self-priming, an auxiliary discharge created within each pixel provides the priming electron source for the main pixel discharge. These priming discharges are often hidden from view by positioning them behind opaque conductor wires. Introducing a trace amount of radioactive Kr^{85} into the gas mixture provides a passive priming option. The ionizing radiation from Kr^{85} generates priming electrons uniformly throughout the display interior. Because the required Kr concentration is low and because the β-radiation produced cannot penetrate the glass enclosure of the display, the radiation exposure risk to the display user is negligible. However, display manufacture using radioactive seeding involves potential health hazards associated with radioactive material handling. Consequently, this seeding approach, while very effective, is not at present employed in commercial products.

A simplistic scanning scheme for pixel illumination is shown in Figure 93.2, reproduced here from Ref. [4]. The scan switches on one axis open and close sequentially in a repetitive fashion, while the data switches on the other axis determine if the pixel is fired on a given scan. This simplistic refresh and data update method fails to take advantage of the discharge properties or inherent memory functions available with plasma pixels. High-resolution dynamic displays utilizing this address scheme would not be cost-competitive since display drivers constitute a significant portion of the total cost of plasma displays. Driver circuit costs also increase with required output voltage. Thus, it is desirable to design plasma displays with operating voltages as low as possible and which require the fewest number of driver chips. Designers strive then to maximize the number of pixels driven by a single chip.

For nonmemory dc pixels, one option for reducing the number of external drive switches required is to sweep the firing of priming discharges repetitively across each pixel row, such as in the self-scan circuitry developed by Burroughs [46,47]. More recently, NHK has developed a pulse memory drive scheme for its 102 cm (40 in.) diagonal dc HDTV plasma display, which is being widely used [48]. Sustain operation at high frequency is used to take advantage of residual charge pairs and metastable atoms present in the pixel gas volume as result of the preceding discharge [49]. In this fashion, each pixel is self-seeding, with seed particle populations dependent upon the time elapsed since the termination of the preceding discharge. The high-frequency operation is fast enough to take advantage of the short duration memory characteristic of the dc pixel. As the sustain voltage pulse train is applied to the electrode of a pixel, it will remain in the *on* or *off* state indefinitely until an address or erase pulse is supplied. In the NHK scheme, an auxiliary anode is used to assist in the *address* access operations. Figure 93.16a shows the block diagram of such as system, while Figure 93.16b shows the time sequences for the scheme [48]. Note that the pulses are dc and that *on*-state pulses have larger gap voltages than erase pulses. The timing sequence is critical to address a pixel selectively within the matrix. Implementation of this scheme requires (1) display anode drivers, (2) auxiliary anode drivers, (3) cathode drivers, and (4) and interfaces to decode the HDTV signals provided to the drivers.

For ac displays with memory, drivers need to provide (1) *address* (or *write*) pulses, (2) *sustain* pulses, and (3) *erase* pulses. A complex refresh scan signal is not required since a continuously supplied sustain signal, coupled with the ac pixels inherent memory, trivially maintains each pixel in either an *on* or *off* state. Pixels respond to address, sustain, and erase pulses as described in the preceding section. Similar to dc pixel dynamic control discussed earlier, ac pixel addressing requires well-timed application of voltage waveforms to the rows and columns of the display matrix so that the proper voltage appears across

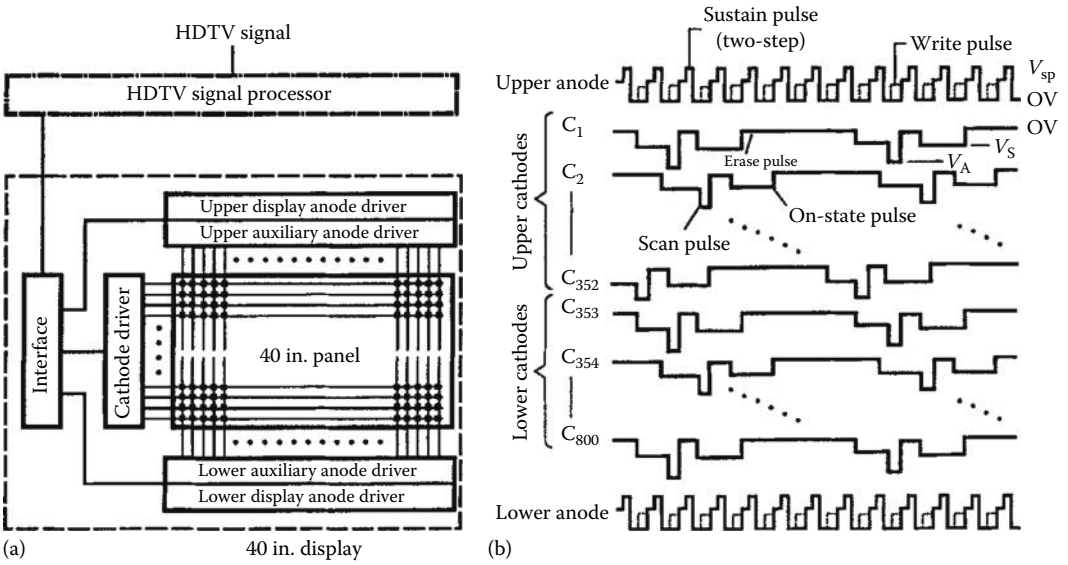

FIGURE 93.16 Pulsed memory operation of the NHK dc plasma display: (a) block diagram of the driver system and pixel array and (b) temporal sequences for pulsed memory operation. (From Yamamoto, T. et al., *SID '93 Symposium Digest*, 165–168, 1993. With permission.)

the electrodes for the pixel of interest without modifying the state of adjacent pixels. A more detailed discussion of ac pixel addressing can be found in Refs. [4,47].

Gray scale is achieved for dc or ac plasma displays either by modulation of the discharge current or by duty cycle modulation with fixed current. Modulating the applied voltage amplitude to vary the discharge current is not widely used because of practical limitations in effectively controlling the nonlinear response of the discharge current. However, duty cycle modulation is a viable technique both for pulse memory–driven dc displays and for ac memory displays. In either case, duty cycle modulation requires complex circuit design for the well-timed delivery of *on* and *off* pulses. Gray scale is achieved by varying the time a pixel is *on* compared with *off* during each refresh cycle. In 50 kHz operation, a sustain half cycle is 10 μs. VUV photon emission occurs usually in <1 μs. For color displays, the visible light emission persists much longer, with the fastest phosphors having 10% persistence times of about 5 μs. More typical phosphors have 10% persistence times in the 5–10 ms range [50]. If the image is updated every 40 ms, corresponding to a refresh rate of 25 images per second, then a 1/8 level brightness is achieved by having the pixel *on* for 5 ms and *off* for 35 ms during that refresh cycle. The time *on* is interspersed throughout the 40 ms refresh period by appropriate timing circuit design. For example, the NHK 102 cm (40 in.) display has a 2^8 or 256 levels of gray scale per color, providing a total of 16 million (256^3) color-scale levels [48].

93.5 Color Plasma Flat Panel Displays

93.5.1 Color Pixel Structures

In color plasma display panels, photoluminescent phosphors provide the primary RGB optical emissions required for full-color image display. In this case, visible emissions from the discharge itself must be suppressed in order to avoid color contamination. A common approach is to utilize xenon as the minority species constituent in the Penning gas mixture of the panel. The structure and phosphor layout of the 102 cm (40 in.) diagonal color dc plasma display available from NHK is shown in Figure 93.17, while that of the Fujitsu 53 cm (21 in.) diagonal ac color display is shown in Figure 93.6. Each uses

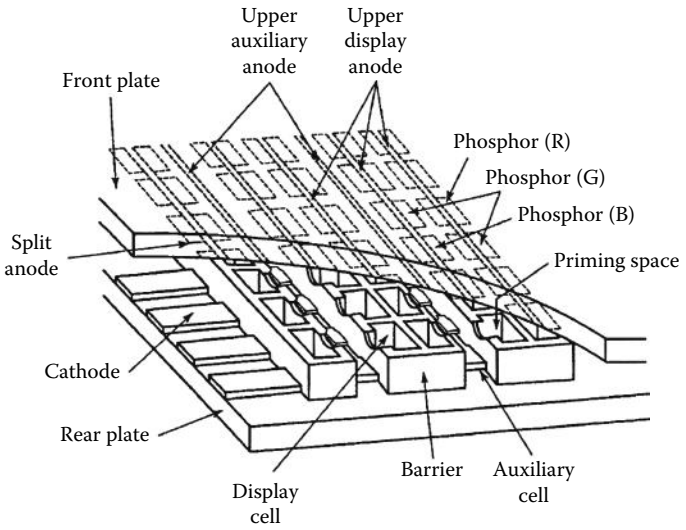

FIGURE 93.17 Structure of the 40 in. color display manufactured by NHK. (From Yamamoto, T. et al., *SID '93 Symposium Digest*, 165–168, 1993. With permission.)

screen printing and hard mask or abrasive-resistant lithographic processes for conductor wire deposition, barrier structure definition, and phosphor deposition [51]. In the NHK design, the fourth section within the honeycomb color pixel structure houses a redundant green phosphor subpixel to compensate for the lower photoluminance of green phosphors relative to that of either red or blue phosphors. In a similar honeycomb dc color pixel structure, Panasonic instead incorporates a series resistor in this fourth subpixel position [20]. Printing the series resistor for each pixel on the display glass substrate complicates panel manufacturing but simplifies design requirements for the drive electronics. In the Fujitsu, the opposed electrode ac color pixel structure shown in Figure 93.6, barrier or separation rib structures running between and parallel to each conductor wire are fabricated on the rear glass substrate. The barrier rib heights are typically 100–150 μm. The ac barrier rib structures and dc pixel honeycomb lattice structures are usually composed of the same PbO thick-film dielectric used to cover the conductor wires.

93.5.2 VUV Photon Production and Utilization for Color Plasma

93.5.2.1 Flat Panel Displays

Color plasma display gas mixtures utilizing xenon as the minority species are optimized for production of VUV emissions which are used to excite RGB photoluminescent phosphors. Both neon–xenon and helium–xenon combinations are popular. The ionization energy of xenon at 12.3 eV lies below the lowest excited atomic states of either neon or helium, as shown in Figure 93.8. Consequently, electrons accelerated by electric fields within the pixel volume preferentially impart their kinetic energy to the xenon atoms. In addition, the excited states of He or Ne produced readily transfer stored energy to the xenon atoms through ionizing Penning collision processes. Consequently, the red–orange visible emissions typical of Ne discharges are suppressed as Xe concentration is increased. Fujitsu utilizes an Ne–10% Xe working gas in its color display [18], while Photonics Imaging prefers to use He-based background gas in its panel [23] where suppression of unwanted optical emissions from the discharge can be accomplished at somewhat lower xenon concentrations.

The tendency of xenon to fill its outermost electronic shell results in the formation of the xenon dimer molecule, Xe_2^*, whose energy states are also shown in Figure 93.8 [52,53]. Radiative dissociation of the dimer produces photons with wavelengths near 173 and 150 nm. Figure 93.18 shows how

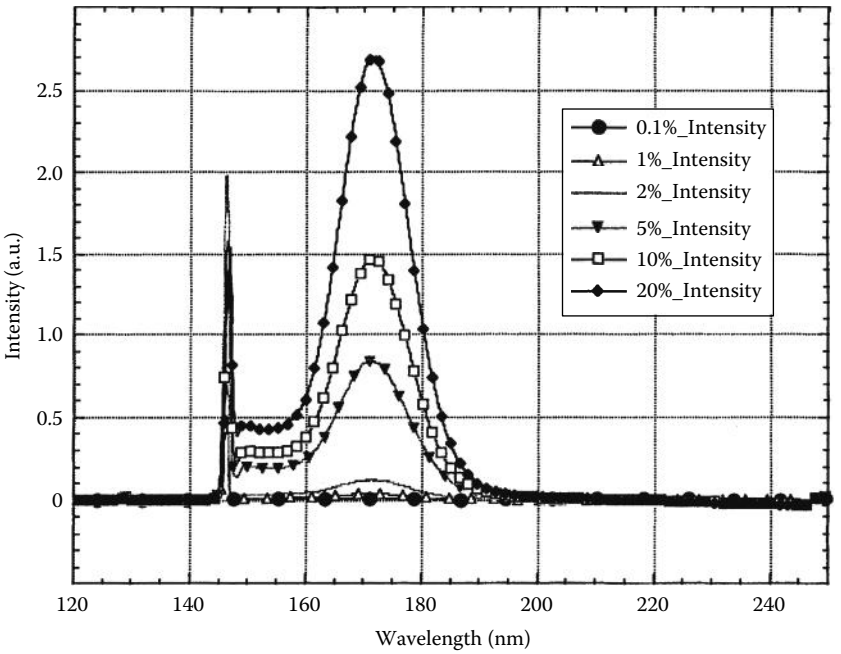

FIGURE 93.18 VUV emission spectra from opposed electrode ac plasma pixel discharges in He/Xe gas mixtures. Each spectrum was collected near the minimum sustain (or first *on*) voltage for that gas mixture, which ranged from 150 V for 0.1% Xe to 350 V for 20% Xe.

the dimer emissions dominate the VUV spectra from He–Xe gas pixel discharges as the fraction of Xe is increased. Since VUV photons are completely absorbed by glass, the spectra shown in the figure were measured by mounting opposed electrode pixels inside of a vacuum chamber filled with the gas mix of interest. The boundaries of the panel glass were not sealed which then allowed on-edge viewing of the pixel discharges with a McPherson 0.2 m monochromator operating in conjunction with a Princeton Instrument CCD optical multichannel analyzer [45]. The background gas mix was varied to obtain the various Xe concentrations in He shown while maintaining a total gas pressure of 53.3 kPa (400 torr). At low Xe concentrations, photons from the atomic Xe $1s^4$ and $1s^5$ states dominate the emission spectra producing lines at 147 nm and, with much less intensity, at 129 nm. The Tachibana laser-induced spectroscopic measurements show the spatial and temporal evolution of the $1s^4$ Xe atomic state in He/Xe plasma display discharges [54]. Both of these atomic lines experience significant resonant absorption and reemission. Thus, the measured line intensities are strong functions of photon path length traveled and of Xe partial pressure in the background gas [55]. For the emission spectra shown in Figure 93.18, the lithium fluoride (LiF) entrance window to the evacuated spectrometer chamber was positioned between 100 and 150 nm from the nearest pixel discharges, which is roughly the location of the phosphors relative to the discharge in an opposed electrode ac color display panel, for example, see Figure 93.5.

Recall that the optimal charge pair production per volt applied in Penning gas discharges occurs at minority species concentrations as low as 0.1% (see Figure 93.9). However, color plasma pixels must optimize usable photon production per watt while maintaining stringent color purity requirements. Consequently, color plasma pixels typically operate with xenon concentrations ranging between 2% and 10%. Figure 93.18 shows that increased xenon concentration results in significant dimer formation and radiative emission from dimer dissociation. Since the dimer dissociation is a three-body process involving a photon and two xenon atoms, the momentum and energy conservation equations do not demand unique solutions. Consequently, emission lines produced cover a broad spectral range spanning several

tens of nanometers. Increased dimer emission is accompanied by the suppression of xenon atomic emission as energy within the atomic manifolds continues to flow toward the lowest available atomic levels (see Figure 93.8). Note, too, that the dimer emission lines are not subject to resonant absorption. Therefore, the measured intensities shown reflect dimer emission from all pixels rows within the line of site of the spectrometer (four for the data of Figure 93.18). In contrast, due to the strong resonance absorption of the atomic lines, >90% of the measured intensity of the 147 nm line is produced in the pixel row adjacent to the spectrometer window [45,55]. Care must be taken to account for these large variations in photon mean free paths when analyzing emission data.

93.5.2.2 Phosphor Excitation and Emission for Color Plasma Flat Panels

A variety of photoluminous phosphors are commercially available. Efficiencies for conversion of VUV photons to visible emissions have a complex dependence on excitation photon wavelength as can be seen in Figure 93.19, which shows quantum conversion efficiencies relative to a sodium salicylate standard for some of the available green phosphors [50]. Conversion efficiencies for red, blue, and other green phosphors can be found in Refs. [56,57]. Table 93.2 provides the compositions of some selected commercially available phosphors and lists their relative quantum efficiencies for the principal emission lines of xenon discharges. Note that quantum efficiencies listed are relative values and that phosphors that convert 8.4 eV photons to visible photons near 2.3 eV have absolute efficiencies of only 27%. In principle, it is possible to produce two or more visible photons from a single high-energy photon, but to date no such phosphors have been developed [58]. Table 93.2 also lists the chromaticity diagram coordinates which provide a measure of the color purity of the visible RGB emission spectra produced. The chromaticity diagram can be found in many references including Ref. [59]. Another consideration in the plasma display phosphor selection is persistence. Most of the phosphors listed in Table 93.2 require

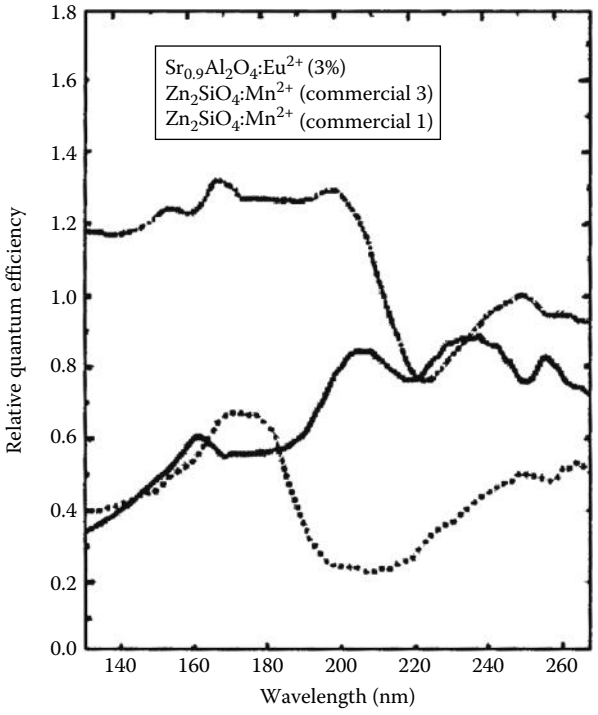

FIGURE 93.19 Relative quantum efficiencies of a Tb-activated lanthanum phosphate compared to that of yttrium and gadolinium phosphate prepared by Sarnoff Research Center. (From Yocum, N. et al., *J. SID*, 4/3, 169, 1996. With permission.)

5–13 ms for the emission intensity to decay to 10% of maximum value. For ac pixel operation at 50 kHz, each sustain voltage half cycle lasts only 10 μs while the discharge produces VUV emissions for only a small fraction of that time. Efforts are continuing for development of phosphors with faster response times. For example, Eu^{2+} green phosphors with 10% decay times of only 5–10 μs and with good quantum efficiencies near 173 nm have been developed [50].

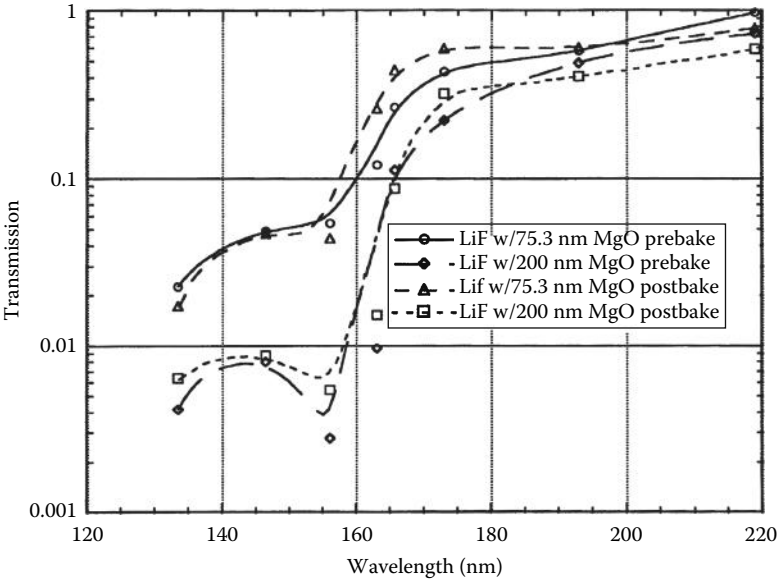

FIGURE 93.20 Photon transmission through MgO films before and after bake-out to remove water vapor.

93.5.2.3 Color Plasma Display Lifetime Considerations

Phosphors for plasma flat panel displays must be tolerant of the harsh environment produced by the pixel discharge. Photoluminous phosphor degradation mechanisms are at present not well understood. Contamination of the discharge by phosphor materials is a serious concern. Discharge modeling indicates that damage results principally from the accumulated fluence of photon and metastable bombardment, although fringe electric fields and prolonged surface charge accumulations could also result in ion bombardment [36]. Most ac plasma displays take advantage of MgO for enhancement of the discharge intensity by coating dielectric surfaces above the electrodes with an additional thin film of MgO. For ease of fabrication, the MgO is most often deposited using electron beam evaporation as one of the final manufacturing steps before glass seal and gas fill. If no mask is used, the MgO can also cover the phosphors. While providing the phosphors with a protective coating, the MgO film also attenuates the intensity of the VUV photon flux available to excite the phosphors. Figure 93.20 shows VUV photon transmission as a function of wavelength through MgO films [45,60]. The measurements show that the primary atomic Xe emission lines at 129 and 147 nm are nearly 95% attenuated by an MgO film only 75 nm thick. In contrast, the dimer emission lines centered near 173 nm are much less attenuated with transmission factors of 30%–50%, respectively, for MgO films of 200 and 75 nm. Consequently, ac plasma display designers must often achieve a balance among discharge enhancement due to MgO secondary electron emission, discharge degradation due to MgO photon absorption, and fabrication complexity associated with MgO deposition, which impacts the final cost of the display. Additionally, the designer must consider the aging or brightness degradation with time of the display, which is influenced in part by the rate of MgO sputter erosion discussed briefly later.

93.6 Inspection and Metrology

Plasma display panel manufacturing uses some process steps typically found in semiconductor device manufacturing. Although the feature sizes are much larger than those required in semiconductor manufacturing, the dimensions over which feature integrity must be assured are also much larger. Confirmation that a display manufacturing process is under control or rapid quantitative characterization of the deviation from acceptable process limits is essential to producing high-quality displays with

TABLE 93.3 Equipment for Noncontact Profiling and Chemical Characterization of Thin Films

	CyberOptics Point Range Sensor	Zygo NewView 200	Leitz FTM400
Physical principle	Laser triangulation	Scanning white light interferometry	Laser interferometry
Maximum thickness/step height	150 μm (high-resolution head)	100 μm (standard) (to 5 mm with z-drive)	70 μm
Vertical resolution	0.38 μm	100 pm	150 pm or 0.5%
Spatial resolution	>0.5 μm	0.22 μm	0.5 μm
Spot diameter/FOV	5.1 μm	140 × 110 μm	20 μm
Scan rate	10 points/s	2 or 4 μm/s	75 mm/s max.

Maximum sample weight	Based on table	4.5 kg	4.5 kg (including holder)
Elemental detection	NA	NA	NA

high yield. Information on a variety of length scales is required. Blanket deposition of materials onto substrates should be uniform; large deviations in thickness of the deposited material from one point on the substrate to a widely separated point should be avoided. Similarly, roughness of the deposited layers must be kept within defined limits. Finally, chemical compositions of the deposited layers and their spatial homogeneity need to be measured and controlled.

The three commercial profile measuring devices, the CyberOptics, Zygo, and Leitz units, are based on laser or white light triangulation or interferometry (see Table 93.3) [61–63]. These machines are well suited for determining the profile of metallization after patterning. They do not appear to be useful for measuring the thickness of opaque layers and cannot, for example, measure the thickness of the blanket metallization before patterning. The CyberOptics unit is in wide use in the electronic packaging industry because of the low noise in its signal. Improvements in vertical resolution would increase its value for display manufacturing process control. The Zygo instrument has better vertical resolution, but has no real scanning capability. The Leitz unit is designed specifically for metrology of unfinished liquid crystal display components, and is presumably optimized for that application. Both the CyberOptics and Zygo units have a variety of heads with differing resolutions and fields of view. However, the vertical distance over which the interference can take place in the Zygo unit is very limited, so it may not be suitable for measuring features with large vertical dimensions.

Depending on system requirements, a useful laser metrology system can be purchased for as little as $20,000. Full-featured systems can easily cost $100,000. The bulk of the cost is, however, in the precision transport tables used for moving samples in a precisely controlled manner beneath stationary measurement heads. Since precision transport tables meeting the needs of the metrology equipment may already be part of the display production process or would require only minor upgrades to be brought in line with requirements, the cost to bring the metrology capability online may be much smaller than the figures mentioned earlier. Since laser head costs are low, it may also be desirable to use multiple fixed heads to speed up inspection and metrology.

Listed in Table 93.4 are the characteristics of two advanced measurement techniques for noncontact profiling and chemical analysis. To the authors' knowledge, systems of this type are not yet commercially available. They are being utilized, however, by researchers at Sandia National Laboratories and show promise for commercial usage. In β-backscattering measurements, the energy spectra of the backscattered β-particles provide an accurate measure of the elemental composition of a surface. This technique has been used to measure the thin-film thickness of trace-deposited metals on large-area surfaces (several square meters) in tokamaks [64]. With a depth resolution of about 100 pm, β-backscatter could serve as the physical basis for a high-sensitivity surface-profiling device. X-ray fluorescence measurements, routinely performed in air, can give information on film thickness and composition, and performance parameters for this technique are also listed in Table 93.4.

TABLE 93.4 Advanced Techniques for Noncontact Profiling/Chemical Characterization of Thin Films

Physical Principle	β-Backscatter	X-Ray Microfluorescence
Maximum thickness/step height	A few mm	50 μm
Vertical resolution	About 0.1 nm	0.1 μm
Spatial resolution	Depends on pinhole size	50 μm–2 mm
Spot diameter/FOV	Depends on pinhole size	100 μm
Scan rate	<1 min/measurement	1 spot/min
Maximum sample size	No restriction	24 cm × 21.5 cm
Maximum sample weight	No restriction	4.5 kg
Elemental detection	NA	<10–300 ppm

Vacuum must be used when studying light elements like carbon, a potential undesired product of phosphor binder burnout, because the x-rays produced are "soft." Although x-ray fluorescence equipment may have good lateral resolution, a larger spot size may prove useful when more averaged information such as film thickness is needed. Finally, eddy current measurements may provide a fast and reliable method for determining the thickness of the opaque, blanket metallization before patterning. This technique should be capable of providing 10% thickness measurement accuracy for conductor layers as thin as 1 μm.

Many of the devices for quantitative characterization of the thickness and chemistry of the deposited layers suffer from the fact that they have a rather limited field of view. Characterization techniques are needed that will allow rapid identification of visual defects in the blanket-deposited layers and in the patterned layers produced from them. Visual inspection equipment is available for defect identification in liquid crystal displays. Manufacturers include Minato Electronics, Advantest, ADS, Photon Dynamics, and Teradyne. All use CCD devices and special algorithms for the identification of line and area defects. The defects found during high-volume plasma display manufacturing may be sufficiently similar in appearance to those found in liquid crystal display manufacturing that this equipment will prove useful with appropriate adjustments. These devices, however, are expensive.

Although researchers and equipment manufacturers believe that the equipment and techniques described earlier will be suitable for online process control during plasma display manufacturing, all agree that more development is required. Real parts will need to be characterized extensively on specific commercial equipment in production environments before conclusions can be drawn about the suitability of the equipment and techniques for the intended application. This is particularly true for more difficult measurements like that of the thickness of dielectric above conductor lines. It is clear that there is no single instrument that will meet all film and feature dimensional measurement requirements and those for chemical characterization. A number of instruments will be needed to measure confidently the parameters needed for inspection, and characterize and control the manufacturing processes for plasma displays.

Electroluminescent Displays

William A. Barrow
Planar Systems, Inc.

94.1 Introduction

Electroluminescence (EL) is the nonthermal generation of light resulting from the application of an electric field to a substance. The light-emitting substance is generally a luminescent crystal. Most commercially available monochrome EL displays utilize ZnS:Mn as the luminescent material. EL displays have become very important in certain display markets. These include medical instrumentation, industrial control equipment, portable instrumentation, and military vehicles. The attributes of EL displays that make them attractive in these types of applications are mechanical ruggedness, relative insensitivity to ambient temperature, rapid display response, essentially unlimited viewing angle, compactness, and lightweight.

There are four types of EL devices: ac thin film, ac powder, dc thin film, and dc powder. The ac thin-film display is by far the dominant device type. Some liquid crystal displays use ac powder EL for backlights. There is currently little or no commercial application of dc EL devices, either thin

film or powder [1]. The focus here is on ac thin-film EL (ACTFEL) devices. While there are no widely established standard measurement techniques for the other EL device types, measurements similar to those described herein for ACTFEL devices could be applied with appropriate modifications to the other methods of device excitation.

94.2 Device Structure and Operation

A schematic, cross-sectional representation of the basic ACTFEL device structure [2] is shown in Figure 94.1. The supporting substrate is usually made of very low sodium glass. If a suitable ion barrier layer is deposited between the substrate and lower electrode of the EL device, soda-lime glass can be used. The lower electrode, usually a transparent conductor such as indium tin oxide (ITO), is deposited next. The ITO is usually between 350 and 120 nm in thickness, providing sheet resistance in the range of 5–15 Ω/square. On top of the ITO electrode a lower insulator is deposited. This layer is typically SiON or aluminum titanium oxide (ATO). The thickness is normally around 200 nm. The phosphor layer, typically ZnS:Mn, is deposited between the lower insulator and a similar upper insulator. The phosphor thickness is typically in the range 200–1000 nm thickness, depending on the application. The upper electrode, typically aluminum, is deposited on top of the upper insulator. The aluminum is generally 100–200 nm thick.

A matrix-addressed monochrome display is created by dividing the upper and lower electrodes into orthogonal arrays of electrode stripes. The EL device is then excited locally by applying a voltage between a pair of crossing electrodes, causing an electric field to exist between them, which excite the phosphor. A color display can be created by dividing the phosphor into stripes of red-, green- and blue-emitting phosphors which are aligned with one of the sets of electrode stripes [3,4]. This is shown schematically in Figure 94.2. Color displays can also be created by using an unpatterned phosphor which emits a broad spectrum including red, green, and blue and filtering the emission using either a patterned color filter which is aligned with the electrode stripes or a frame sequential color filter.

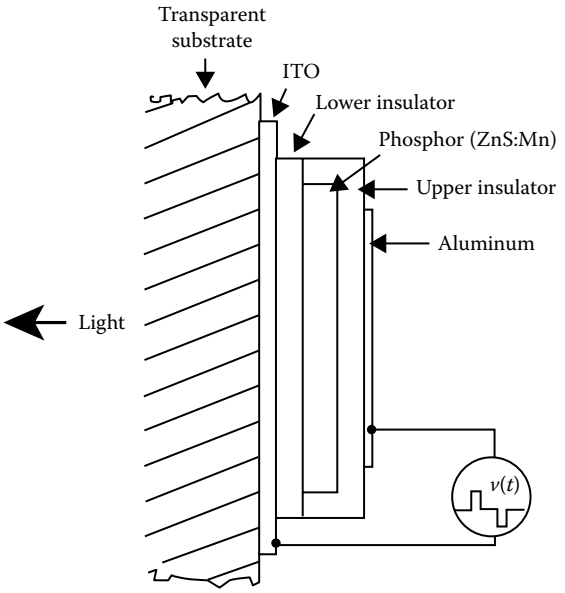

FIGURE 94.1 Schematic, cross-sectional diagram of the basic ACTFEL device structure.

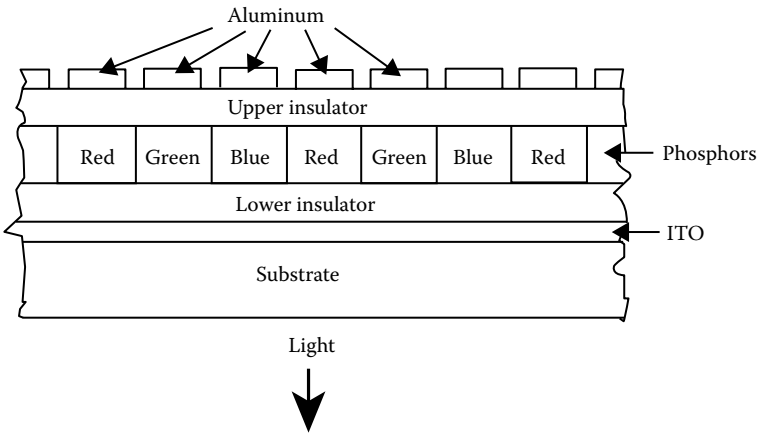

FIGURE 94.2 Schematic, cross-sectional diagram of a color ACTFEL device with the red, green, and blue primary colors produced by patterned color phosphor stripes. The color phosphor stripes are end on in this view.

94.3 Device Fabrication

94.3.1 Thin-Film Deposition Methods

A wide variety of deposition techniques are used by various manufacturers and researchers in the fabrication of ACTFEL devices. The electrode materials ITO and aluminum are usually deposited by physical vapor deposition (PVD) techniques. ITO is almost universally deposited by dc magnetron sputtering from either a conductive ITO target or a metal alloy target [5]. Optimum ITO conductivity is obtained by postdeposition annealing in a very low oxygen environment. Al is deposited either by dc magnetron sputtering from an Al metal target or by electron beam evaporation of Al metal. The insulator and phosphor layers are deposited by chemical vapor deposition (CVD) as well as PVD. Phosphor layers have been deposited by thermal as well as e-beam evaporation, sputtering, metal–organic CVD (MOCVD), and atomic layer epitaxy (ALE). Insulator layers have been deposited by e-beam evaporation, radio frequency (RF) sputtering, plasma-enhanced CVD (PECVD), and ALE.

94.3.2 Thin-Film Patterning Methods

Patterning of the electrodes is generally accomplished either through etching or liftoff, although some early workers patterned the upper aluminum electrodes by evaporating through a shadow mask. Aluminum is easily etched wet or dry. There are commercially available wet etches for Al. Dry etching of Al can be carried out using standard chlorine chemistries, e.g., Cl_2/BCl_3. Al can also be patterned by evaporating onto a reversed photoresist pattern and lifting off excess metal. ITO can be etched wet or dry. ITO wet etches generally consist of mixtures of HCl and HNO_3. ITO can be dry-etched in HI or HBr. Patterning of the phosphor layers is more problematic. Phosphor etches exist for most ACTFEL phosphor materials, but they are generally proprietary. Thin-film phosphors are difficult to etch because they are usually water-sensitive, and some color phosphors contain heavy metals which are difficult to volatilize in a dry-etch process.

94.4 Device Operation

94.4.1 Luminescence Mechanisms

As the device structure shown in Figure 94.1 indicates, ACTFEL devices are capacitively coupled. Since only displacement current can flow across the insulator layers, the drive signal must be an alternating polarity waveform. A typical alternating polarity, trapezoidal waveform is shown in Figure 94.3.

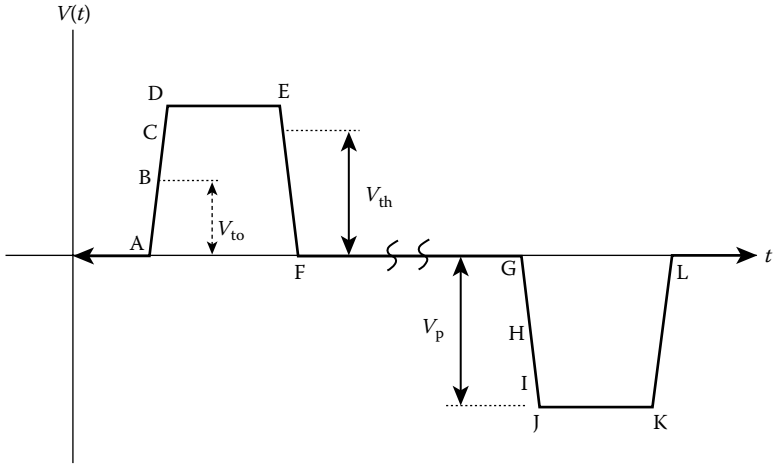

FIGURE 94.3 Typical alternating polarity, pulse drive waveform. Letters A–L mark points on the drive waveform which are referenced later in Figures 94.5 and 94.6. The pulse width would generally be about 30 μs and the frequency would be between 60 and 500 Hz for a passive matrix-addressed display.

If the peak voltage, V_P, in Figure 94.3 is larger than the *threshold voltage* of the device, V_{th}, then, when the positive pulse of the waveform is applied between the Al and ITO electrodes of the device structure shown in Figure 94.1, the energy band diagram of the ACTFEL device will be as shown in Figure 94.4. Electrons, which are the majority carriers in ACTFEL devices, tunnel out of the interface states on the left and into the conduction band. Once in the conduction band the electrons are accelerated by the large electric field, which is ~1 MV/cm = 100 kV/mm. The conduction electrons drift across the ZnS:Mn layer until they impact excite an Mn^{2+} center, transferring some energy to one of its electrons and causing it to undergo a transition to an excited state. The conduction electron may undergo additional collisions,

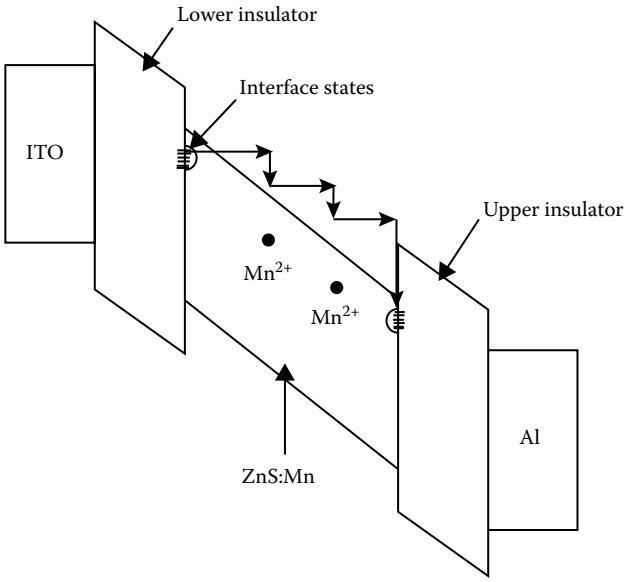

FIGURE 94.4 Energy band diagram of an ACTFEL device during the peak of the applied voltage pulse. Electrons tunnel out of insulator/phosphor interface states into the conduction band, are swept across the phosphor layer, and impact exciting emission centers as they go until they are finally thermalized and trapped at the opposite interface.

eventually reaching the right interface and getting trapped in interface states there until the next voltage pulse, which is of the opposite polarity. This pulse causes the electrons to tunnel out and drift back across the ZnS:Mn layer, transferring energy to Mn^{2+} centers along the way, until eventually they are trapped again at the left interface. This transfer of charge back and forth between the interface states continues as long as the alternating polarity drive signal with peak amplitude above the threshold voltage of the device continues to be applied. Light emission occurs when the Mn^{2+} centers, which have been impact excited by the hot electrons, relax [6–8]. The light emission thus results from transitions of the electrons within the Mn^{2+} centers, rather than electron–hole pair recombination near a *p-n* junction as occurs in a light-emitting diode (LED).

94.4.2 Description of Charge Flow

If the external charge, *Q*, flowing into the ACTFEL device is plotted vs. the externally applied voltage, *V*, the resulting curve is called a *QV* loop [9,10]. If the amplitude of the applied voltage pulses is less than the threshold voltage of the device, the *QV* loop is simply a straight line with slope equal to the total capacitance of the insulator/phosphor/insulator stack. If the amplitude of the applied voltage pulses is greater than the threshold voltage of the device, the *QV* loop opens up. *QV* loops below and above threshold are shown in Figure 94.5. Above threshold, power is dissipated in the ACTFEL device. The area encompassed by the *QV* loop is equal to the energy delivered to the device per period of the drive waveform.

The *QV* loop is measured directly. A theoretical extension of the *QV* loop that is sometimes used by researchers studying the physics of ACTFEL devices is a plot of the actual charge flow across the phosphor layer, Q_p, vs. the electric field across the phosphor layer, F_p. The quantities required for a plot of Q_pF_p can be calculated from the *QV* data if the thicknesses and dielectric constants of the insulator layers and phosphor layer are known. The actual charge flow across the phosphor is calculated by subtracting the reactive charge from the total charge. The field in the phosphor layer is calculated by adding the externally applied field to the internal *polarization field* due to the actual flow of charges across the phosphor layer. A Q_pF_p loop

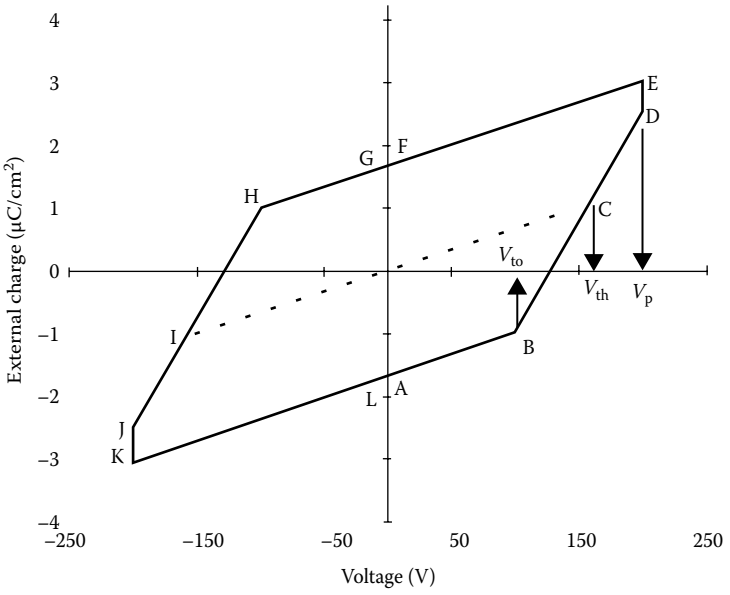

FIGURE 94.5 Idealized *QV* loop with no charge leakage from interface states between drive pulses. Letters A–L mark points on the *QV* loop which are coincident in time with the points labeled A–L on the drive waveform in Figure 94.3. The dashed line is the *QV* loop for the case just below threshold. The solid line is the open loop above threshold. The area of the *QV* loop represents the energy dissipated by the device per cycle of the drive waveform.

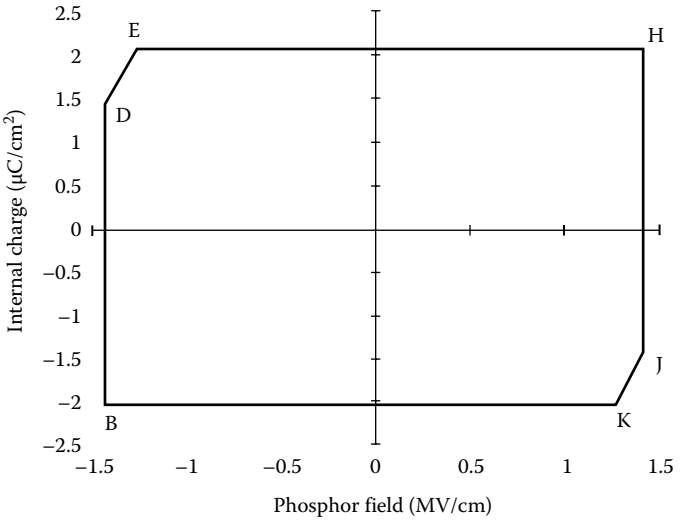

FIGURE 94.6 Q_pF_p loop corresponding to the above threshold *QV* loop in Figure 94.5. This loop represents the charge flow across the phosphor layer as a function of the electric field across the phosphor layer.

corresponding to the above threshold *QV* loop of Figure 94.5 is shown in Figure 94.6. The Q_pF_p loop is useful because it expresses the internal electrical characteristics of the phosphor layer during device operation.

94.4.3 Device Excitation

Whether the device under test is a test dot or a matrix display, the drive waveform must be ac-coupled. Passively addressed matrix displays are scanned one row at a time. Data are loaded into the column drivers for a single row of pixels and the selected pixels in the row are all turned on simultaneously. The row pulse brings the voltage across each pixel in the row to a level just below threshold. The columns of selected pixels are then pulsed to bring the voltage across selected pixels to a level above threshold and the pixels are turned on. During the following frame, the voltage polarities across the pixels are reversed. Each individual pixel is subjected to a drive signal similar to that shown in Figure 94.3. To activate a pixel fully requires the voltage to be held above V_{th} for 10–20 μs. Since each row must be scanned in sequence, a typical display with ~500 rows requires at least 5 ms to scan one frame. The maximum frame rate is thus ~200 Hz. Displays that are addressed by an active matrix of transistors are not scanned a line at a time as passively addressed displays are, but instead are bulk driven. They have one unpatterned common electrode, usually an upper layer of ITO, to which an ac drive signal is applied. Each pixel is connected to ground through a transistor which drops a portion of the applied drive voltage when the pixel is not selected. In this type of display, the drive waveform can be any ac signal of the appropriate voltage. Sine, trapezoid, and triangle waveforms have been used. An active matrix display can be driven with a frame rate higher than a passive matrix-addressed display by a factor equal to the number of rows in the display, since row-at-a-time scanning is not required. Since a light pulse is emitted for each voltage pulse, the average luminance is proportional to the frame rate, resulting in much higher luminance capability for active matrix-addressed displays.

94.5 Standard Measurements

Measurable quantities of interest include luminance, luminous efficiency, emission spectrum, latent image, and defects. The luminance of an ACTFEL display is a function of the peak voltage and frequency of the drive waveform, the intrinsic efficiency of the insulator/phosphor/insulator stack, and

the operating history (aging). The efficiency is a function of the drive waveform shape and frequency as well as various device parameters. The emission spectrum is primarily determined by the phosphor host material and activators, although it is also affected by deposition and anneal conditions and in some cases by the drive voltage and frequency. *Latent image* is the burning in of a permanent image of a fixed pattern which is displayed for long periods. It can appear as a faint dark image superimposed on a bright background or as a faint bright image superimposed on a dark background. Formation of latent image is affected primarily by drive waveform symmetry and device processing parameters. Display defects include pixel, line, and mura defects.

94.6 Time-Resolved Measurements

Measurements of luminance, efficiency, and emission spectra as introduced so far involve time-averaged light emission. There are two fairly common time-resolved measurements of ACTFEL light emission: light emission decay time and time-resolved light emission spectroscopy. The *light emission decay time*, τ, is the time it takes for the light emission from one excitation pulse to fall to $1/e$ times its initial value. The measurement of τ is started just after the trailing edge of the excitation pulse. This is necessary in order that the measured value of τ not be affected by the continuing excitation of additional emission centers, so that it represents the intrinsic relaxation time of the emission center. In devices with evaporated ZnS:Mn phosphor, τ is a strong function of the Mn concentration. It can thus be used as an analytical technique to determine the Mn concentration. Time-resolved spectroscopy is the measurement of the emission spectrum occurring during specific portions of the excitation and emission process. An example of the application of this technique is the study of the separate light pulses emitted during the leading and trailing edges of the excitation pulse with the blue-emitting phosphor SrS:Ce. Both of these techniques are frequently used to help elucidate the excitation and emission mechanisms in ACTFEL phosphors.

94.7 Test Dot Characterization

94.7.1 Luminance and Efficiency

A schematic representation of a measurement system for collecting luminance and efficiency vs. voltage data on a test dot is shown in Figure 94.7. An arbitrary waveform generator provides a drive signal with the waveshape, frequency, and peak voltage determined by a control computer. The waveform generator output signal is amplified from ±5 to ±300 V range. A photometer, also under computer control, measures the luminance, L, of the test dot. An oscilloscope measures the voltage across the test dot and the voltage across the sense resistor. The current is calculated by dividing the voltage across the sense resistor by its resistance. The control computer can thus adjust the peak voltage up and down and collect the luminance data, as well as the waveforms representing the voltage across the test dot and the current through it. The energy dissipated, E_p, during each drive pulse is calculated as

$$E_p = \int_D I(t) \times V(t)\, dt \tag{94.1}$$

where

$I(t)$ and $V(t)$ are the current and voltage waveforms, respectively
D is the duration of either the positive or negative drive pulse

This integration can be carried out by most oscilloscopes or the $I(t)$ and $V(t)$ data can be transferred to the control computer for the calculation, although this approach is generally slower. The average energy dissipated per period of the drive waveform, E, is the average of E_p for a positive pulse and

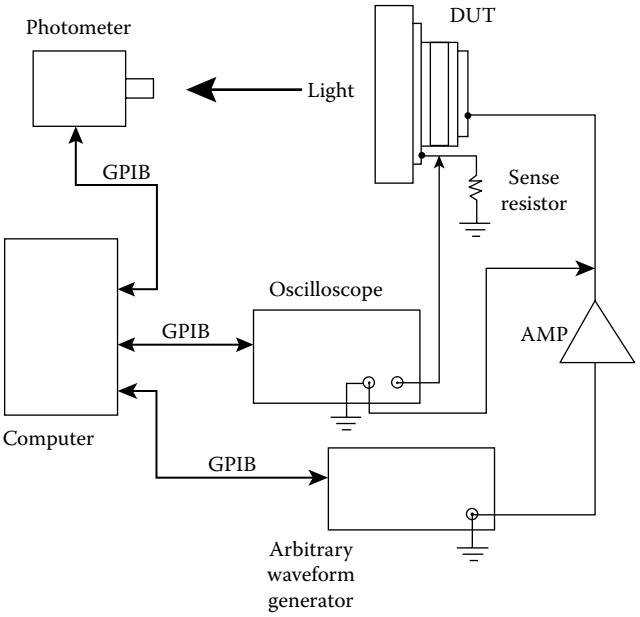

FIGURE 94.7 Schematic diagram of a system for measuring luminance and efficiency as functions of the peak drive voltage. The voltage waveform, $V(t)$, is measured by the oscilloscope at the Al electrode of the device under test. The current waveform, $I(t)$, is measured by the oscilloscope as the voltage across the sense resistor divided by its resistance. The luminance is measured by the photometer.

a negative pulse. The average power dissipated, P, can be calculated by multiplying E by the frequency of the drive waveform. The efficiency, η, is calculated as follows:

$$\eta = \frac{\pi LA}{P} \tag{94.2}$$

where

L is the luminance in cd/m^2
A is the area of the test dot in m^2
P is the average power in watts

Values of L and η are collected for peak voltages ranging from 10 V below threshold to 40 or 50 V above threshold. Plots of L and η vs. peak voltage for a typical device are shown in Figure 94.8.

94.7.2 Charge Flow and Electric Field

The QV loop is measured using a circuit identical to that in Figure 94.7, except that the sense resistor is replaced by a sense capacitor and the photometer is not used. The sense capacitor value is chosen to be much larger than the capacitance of the ACTFEL device so that the voltage dropped by the sense capacitor is small. Since the sense capacitor and the ACTFEL device are in series, the charges stored on them are equal. The charge, Q, on the ACTFEL device is thus

$$Q = C_S V_S \tag{94.3}$$

where

C_S is the capacitance of the sense capacitor
V_S is the voltage appearing across it

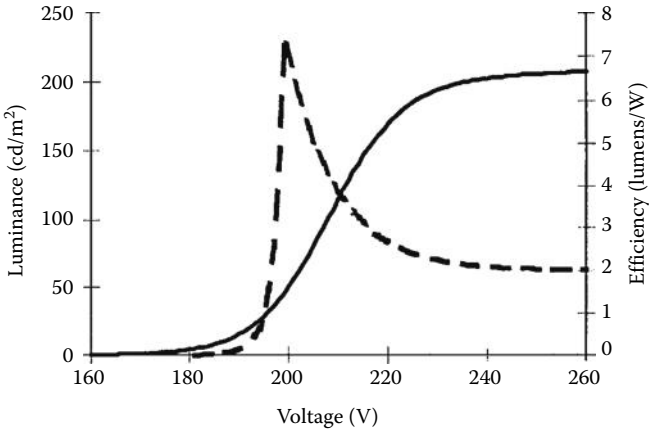

FIGURE 94.8 Plots of luminance and efficiency as functions of peak drive voltage. The solid line is the luminance and the dashed line is the efficiency.

When $Q(t)$ is plotted vs. $v(t)$, the QV loop results. In the idealized QV loop shown in Figure 94.5, V_{th} (C) is the threshold voltage, V_{to} (B) is the turn-on voltage, and V_p (D, E) is the peak voltage of the drive waveform. Threshold voltage is the voltage at which the first knee in the LV curve occurs. If C_T is the total capacitance of the device below threshold, this is also the voltage at which the line $Q = C_T V$ intersects the open, above threshold QV loop (C). In practice, it is sometimes defined as the voltage at which a certain luminance value occurs at a given frequency, e.g., the voltage at which the luminance is 1 cd/m^2 at 60 Hz. V_{to} is the voltage at which the slope of the QV loop changes from C_T to C_I, where C_I is the capacitance of the insulator layers.

Since a differential element of energy delivered to the ACTFEL device is $dE = V(t)dQ$, then

$$E = \int V(t)\,dQ \tag{94.4}$$

The energy delivered per period of the drive waveform is thus equal to the area encompassed by the QV loop. The power dissipated is just the energy per period multiplied by the frequency. In practice, the area of the QV loop is measured by numerical integration. The calculation can be carried out on the oscilloscope if it has analysis capabilities or the data can be transferred to the control computer for integration.

Generation of the Q_pF_p loop does not require any electrical measurements other than those required for the QV loop. Q_p is the charge separation across the phosphor layer and F_p is the electric field across the phosphor layer. If the thicknesses and dielectric constants of the insulator and phosphor layers are known, Q_p and F_p can be calculated from the values of $Q(t)$ and $V(t)$ on the QV loop. This is accomplished by applying the following equations [11,12]:

$$Q_p(t) = \frac{C_i + C_p}{C_i} Q(t) - C_p V(t) \tag{94.5}$$

and

$$F_p(t) = \frac{1}{d_p}\left(\frac{Q(t)}{C_i} - V(t)\right) \tag{94.6}$$

where

C_i is the capacitance of the insulators
C_p is the capacitance of the phosphor layer
d_p is the thickness of the phosphor layer

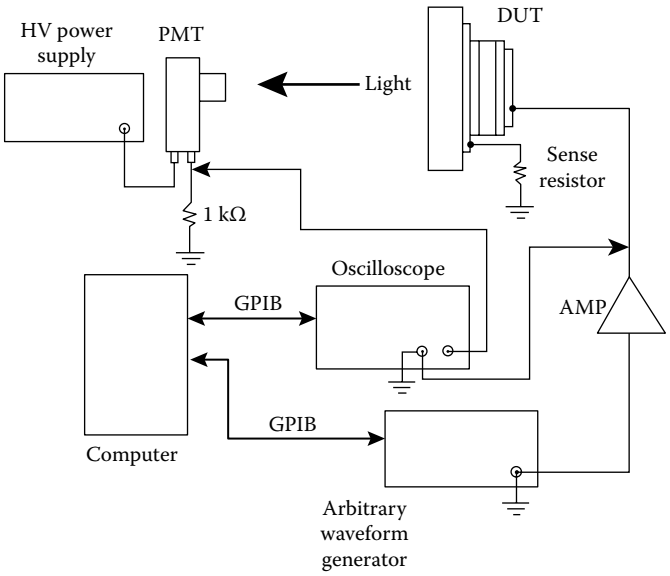

FIGURE 94.9 Apparatus for measuring the luminescent decay time of the ACTFEL phosphor. The light signal is measured by the oscilloscope across the sense resistor on the output of the PMT. The oscilloscope is triggered on the drive pulse.

94.7.3 Time-Resolved Measurements

The apparatus for measuring τ is shown in Figure 94.9. A photomultiplier tube (PMT) is used to detect the light emission as a function of time. The drive system is set to provide relatively narrow drive pulses, typically 10 μs pulse width, at relatively low frequency, typically 60 Hz. This approach works well for phosphors with relatively long decay times, on the order of 100 μs to a few milliseconds. This is the case for many common ACTFEL phosphors such as ZnS:Mn and ZnS:Tb. Phosphors such as SrS:Ce, however, have very fast decay times and cannot be measured in this manner. In such cases, the photoluminescent decay time must be measured using a pulsed laser to excite the phosphor and appropriately low RC response time of the light detection system.

The general setup for measuring time-resolved emission spectra from ACTFEL devices is shown schematically in Figure 94.10. The oscilloscope is triggered on the drive waveform and the signal integration period is set to the region of interest. A boxcar integrator can also be used to integrate the light signal during the desired time window. The monochrometer wavelength is scanned and the emission spectrum is collected for the selected portion of the emission process.

94.7.4 Aging

ACTFEL devices tend to stabilize after a few tens of hours of burn-in, but can exhibit complex aging behavior during the burn-in process. The luminance vs. voltage curves for ZnS:Mn devices in which the phosphor layer is deposited by evaporation, for example, tend to shift to slightly higher voltage during burn-in [2]. Luminance vs. voltage curves for devices in which the ZnS:Mn is deposited by ALE tend to shift to slightly lower voltage [13]. Aging data are collected by measuring luminance vs. voltage at selected time intervals during aging. The measurement is carried out as described earlier for luminance vs. voltage measurements. The aging is done by continuously operating the device at a fixed voltage or at a fixed voltage above threshold. The aging process can be accelerated by operating the device at higher frequency.

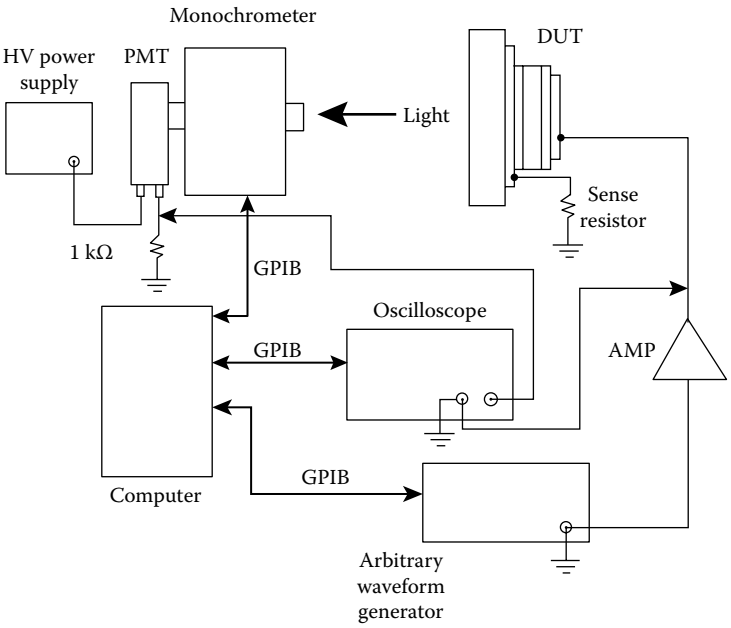

FIGURE 94.10 System for measuring the time-resolved emission spectrum of an ACTFEL device. The oscilloscope is set to integrate the light signal from the PMT during a selected time window. The monochrometer wavelength is scanned over the entire spectral range and the emission intensity data are collected from the oscilloscope.

94.8 Characterization of Matrix-Addressed Displays

The characterization of matrix-addressed displays differs from characterization of test dots because less control of the drive waveform is readily available. The row and column drivers do not provide great flexibility, although some control can be exercised by varying the composite drive waveform and the control signals to the driver chips. These types of modifications, however, require detailed knowledge of the addressing and control electronics involved and are best left to the original display manufacturer. Measurements, which are more accessible and of more general interest, involve characterization of the luminance, chromaticity, uniformity, display life, latent image, and defects. For these measurements, the display under test is controlled by a computer through a standard video output or a custom video display interface provided with the display. The display operating voltage and frequency are fixed. The display is placed in a dark room or enclosure. Luminance is measured with a photometer. Chromaticity is measured with a spectrophotometer or a photometer equipped with tristimulus filters. Uniformity can be measured by mounting either the display or the photometer/spectrophotometer on a translation system and collecting data at points in a regular array of locations throughout the display surface. Display life is characterized by operating the display in a full-on pattern, cycling through checkerboard patterns, etc., and making luminance measurements at exponentially increasing time intervals. Latent image is formed by displaying small blocks in various fixed locations and various fixed gray levels (if available) continuously for long periods. It is characterized by setting the entire screen to each gray level available and measuring the luminance in the locations which had blocks displayed during aging as well as unaged areas nearby. Latent image is the percent luminance difference between aged blocks and nearby unaged areas. Latent image is typically measured after aging the block pattern for 1000 h. Defects are classified into pixel, line, and mura defects. They are characterized by visual inspection with the aid of an eye loupe or by an automated flat panel inspection system.

94.9 Excitation and Measurement Equipment

94.9.1 Excitation of Test Dots

Test dots can be excited by any signal source that provides bipolar pulses up to a peak voltage of 300 V and sufficient current sourcing and sinking capability to charge and discharge the device capacitance. Bipolar pulse drivers with sufficient voltage and current output can be built with commercially available components. A hybrid circuit op amp, produced by Apex Microtechnology, provides sufficient voltage output and frequency response. A current boosting stage can be added to the output if the DUT capacitance is too large to drive directly. This amplifier approach is very flexible since any waveform that can be generated by the arbitrary waveform generator can be used. There are also some commercial amplifiers available that are effective for driving test dots for some measurements. They tend to have limited bandwidth and must be used with caution in situations in which the measurement is sensitive to the exact shape of the drive pulse. This would be the case, for example, in *QV* measurements and often in efficiency measurements.

94.9.2 Excitation of Matrix-Addressed Displays

Excitation of matrix-addressed displays is straightforward since the drive electronics are integrated with the display. Generally, only a standard ac power outlet and a computer with an appropriate video card are required. Test patterns for measurement can be created using simple computer programs.

94.10 Measurement Instruments

94.10.1 Measurement of Drive Voltage and Current

Digital oscilloscopes are used for all of the electrical measurements described in this chapter. Suitable instruments are available from several manufacturers, including Tektronix and Hewlett-Packard. A bandwidth of 100 MHz is more than sufficient. Waveform analysis capabilities are very helpful but not absolutely necessary. RS 232 or IEEE 488 interfaces are required for computer control and data transfer.

94.10.2 Measurement of Emitted Light

Several types of instruments are used for measuring light emission from ACTFEL displays. Photometers are used for luminance measurements. Spectrophotometers are used for measuring the emission spectrum and with suitable software can also provide luminance measurements. Time-resolved measurements are accomplished by using PMTs or photodiode detectors. Table 94.1 lists

some examples of photometers, spectroradiometers, photomultipliers, and photodiodes along with the names of the companies that manufacture them. A relatively new development for characterizing the light emission characteristics of flat panel displays, including ACTFEL displays, is the flat panel inspection system. This is a large measurement system comprising a CCD camera detector, light-tight enclosure, control computer, image processor, and specialized software. This type of system images an entire flat panel display on the CCD camera and measures luminance, chromaticity, and various defects by analyzing the image. These systems are intended for high-throughput manufacturing environments and cost several hundred thousand dollars. An example of this type of system is also included in Table 94.1. Contact information for the companies listed in Table 94.1 is provided in Table 94.2.

Defining Terms

Electroluminescence: The nonthermal generation of light resulting from the application of an electric field to a substance, usually a luminescent crystal.

Latent image: The ghost image of a previously displayed pattern which can sometimes be seen in a full field on an electronic display screen.

Light emission decay time: The time it takes for the light emission from one excitation pulse to fall to $1/e$ times its initial value.

Polarization charge: The charge trapped at the phosphor/insulator interface following the application of a drive pulse.

Polarization field: The field across the phosphor layer resulting from the polarization charge.

***Q_pF_p* loop:** The closed curve which results from plotting the internal charge flow across the phosphor layer (Q_p) vs. the electric field across the phosphor layer (F_p).

***QV* loop:** The closed curve which results from plotting the external charge (Q) flowing into a TFEL device vs. the externally applied voltage (V).

Threshold voltage: The voltage amplitude of the drive waveform above which current flows across the phosphor layer and light is emitted from a TFEL device.

Turn-on voltage: The voltage corresponding to the first knee in the *QV* loop of a TFEL device. This is the voltage at which charge begins to flow across the phosphor layer. This voltage is generally less than the threshold voltage because the internal field across the phosphor layer is enhanced by the polarization field once the polarization charge has built up in the steady state.

Light-Emitting Diode Displays

Mohammad A. Karim
The University of Tennessee, Knoxville

95.1 Introduction

A light-emitting diode (LED) display manifests itself as a flat panel display that uses LEDs to display video. An LED is a particular solid-state *p-n* junction diode that gives out light upon the application of a bias voltage. The luminescence process in this case is electroluminescence, which is associated with emission wavelengths in the visible and infrared regions of the spectrum. When a forward bias is applied to the *p-n* junction diode, carriers are injected into the depletion region in large numbers. Because of their physical proximity, the electron–hole pairs undergo a recombination that is associated with the emission of energy. Depending on the semiconductor band-gap characteristics, this emitted energy can be in the form of heat (as phonons) or light (as photons).

95.2 LED Bandgaps

The solution of the Schrödinger equation for a typical crystal reveals the existence of Brillouin zones. A plot between the energy E of an electron in a solid and its wave vector $\mathbf{k}$ represents the allowed energy bands. It may be noted that the lattice structure affects the motion of an electron when k is close to $n\pi/l$ (where n is any integer and l is the crystal periodicity) and the effect of this constraint is to introduce an energy band gap between the allowed energy bands. Figure 95.1a shows portions of two E vs. k curves for neighboring energy bands within the regions $k = \pi/l$ and $k = -\pi/l$ (also known as the reduced zone).

While the upper band of Figure 95.1 represents the energy of conduction band electrons, the curvature of the lower band can be associated with electrons having negative effective mass. The concept of negative effective mass can readily be identified with the concept of holes in the valence band. While the majority of the electrons are identified with the minima of the upper E–k curve, the majority of the holes are identified with the maxima of the lower E–k curve. The minimum value of the conduction band and the maximum value of the valence band in Figure 95.1a both have identical k values. A semiconductor having such a characteristic is said to have a direct band gap, and the associated recombination in such a semiconductor is referred to as direct.

The *direct recombination* of an electron–hole pair always results in the emission of a photon. In a direct band-gap semiconductor, the emitted photon is not associated with any change in momentum

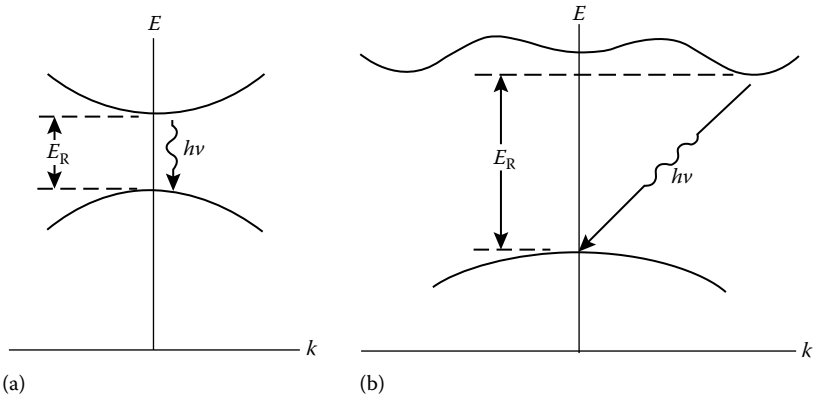

FIGURE 95.1 *E* vs. *k* for semiconductors having (a) a direct band gap and (b) an indirect band gap.

(given by $hk/2\pi$) since $\Delta k = 0$. However, for some semiconducting materials, the *E* vs. *k* curve may be somewhat different, as shown in Figure 95.1b. While the minimum conduction band energy can have a nonzero *k*, the maximum valence band energy can have $k = 0$. The electron–hole recombination in such a semiconductor is referred to as indirect.

An *indirect recombination* process involves a momentum adjustment. Most of the emission energy is thus expended in the form of heat (as phonons). Very little energy is left for the purpose of photon emission, which in most cases is a very slow process. Furthermore, since both photons and phonons are involved in this energy exchange, such transitions are less likely to occur. The interband recombination rate is basically given by

$$\frac{dn}{dt} = B_r np \tag{95.1}$$

where B_r is a recombination-dependent constant which for a direct band-gap semiconductor is $\sim 10^6$ times larger than that for an indirect band-gap semiconductor. For direct recombination, B_r value ranges from 0.46×10^{-10} to 7.2×10^{-10} cm^3/s.

All semiconductor crystal lattices are alike, being dissimilar only in terms of their band characteristics. Si and Ge both have indirect band transitions, whereas GaAs, for example, is a semiconductor that has a direct band transition. Thus, while Si and Ge are preferred for fabrication of transistors and integrated circuits, GaAs is preferred for the fabrication of LEDs.

95.3 LED Wavelengths

The direct recombination (when *k* = constant) results in a photon emission whose wavelength (in micrometers) is given by

$$\lambda = \frac{hc}{E_g} = \frac{1.24}{E_g}\,(\text{eV}) \tag{95.2}$$

where E_g is the band-gap energy. The LEDs under proper forward-biased conditions can operate in the ultraviolet, visible, and infrared regions. For the visible region, however, the spectral luminous efficiency curves of Figure 95.2, which account for the fact that the visual response to any emission is a function of wavelength, should be of concern. It is unfortunate that there is not a single-element semiconductor suitable for fabrication of LEDs, but there are many binary and ternary compounds that can be used for fabrication of LEDs. Table 95.1 lists some of these binary semiconductor materials. The ternary semiconductors include GaAlAs, $CdGeP_2$, and $ZnGeP_2$ for infrared region operation, $CuGaS_2$ and $AgInS_2$ for visible region

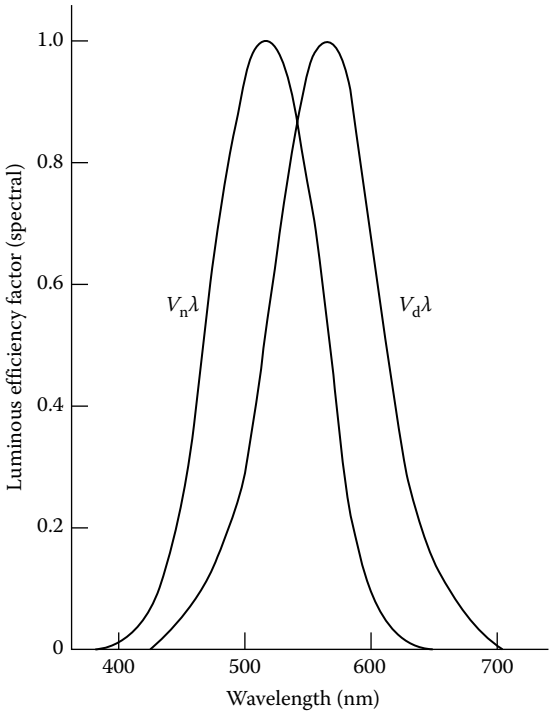

FIGURE 95.2 Spectral luminous efficiency curves. The photopic curve $V_d\lambda$ corresponds to the daylight-adapted case while the scotopic curve $V_n\lambda$ corresponds to the night-adapted case. FIGURE 95.3 Band-gap energy vs. x in $GaAs_{1-x}P_x$. (From Casey, H.J., Jr. and Parish, M.B., eds., *Heterostructure Lasers*, Academic Press, New York, 1978. With permission.)

operation, and $CuAlS_2$ for ultraviolet region operation. Ternary semiconductors are used because their energy gaps can be tuned to a desired emission wavelength by picking appropriate composition.

Of the ternary compounds, gallium arsenide–phosphide (written as $GaAs_{1-x}P_x$) is an example that is basically a combination of two binary semiconductors, namely, GaAs and GaP. The corresponding band-gap energy of the semiconductor can be varied by changing the value of x. For example, when $x = 0$, $E_g = 1.43$ eV. E_g increases with increasing x until $x = 0.44$ and $E_g = 1.977$ eV, as shown in Figure 95.3. However for $x \geq 0.45$, the band gap is indirect. The most common composition of $GaAs_{1-x}P_x$ used in LEDs has $x = 0.4$ and $E_g \cong 1.3$ eV. This band-gap energy corresponds to an emission of red light. Calculators and watches often use this particular composition of $GaAs_{1-x}P_x$.

Interestingly, the indirect band gap of $GaAs_{1-x}P_x$ (with $1 \geq x \geq 0.45$) can be used to output light ranging from yellow through green provided the semiconductor is doped with impurities such as nitrogen. The dopants introduced in the semiconductor replace phosphorus atoms which, in turn, introduce electron trap levels very near the conduction band. For example, $x = 0.5$, the doping of nitrogen increases the LED efficiency from 0.01% to 1%, as shown in Figure 95.4. It must be noted, however, that nitrogen doping shifts the peak emission wavelength toward the red. The shift is comparatively larger at and around $x = 0.05$ than $x = 1.0$. The energy emission in nitrogen-doped $GaAS_{1-x}P_x$ devices is a function of both x and the nitrogen concentration.

Nitrogen is a different type of impurity from those commonly encountered in extrinsic semiconductors. Nitrogen, like arsenic and phosphorus, has five valence electrons, but it introduces no net charge

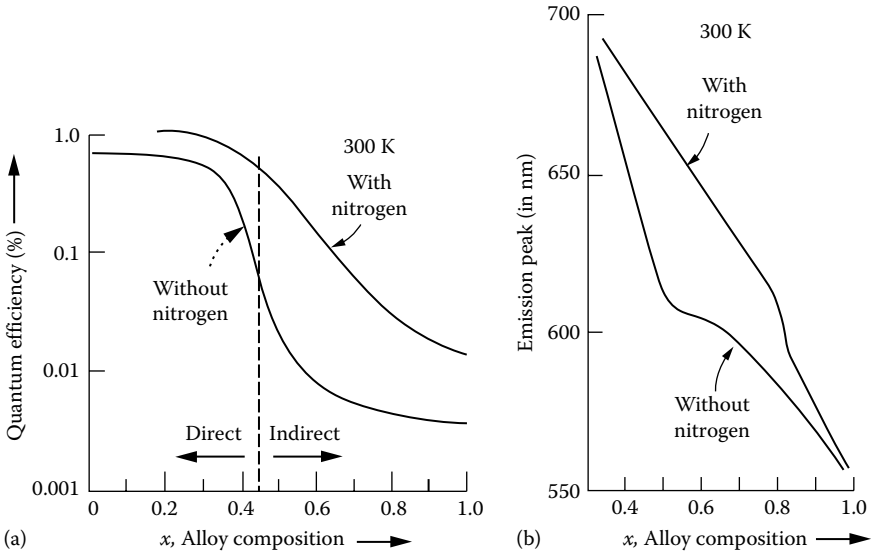

FIGURE 95.4 The effects of nitrogen doping in $GaAS_{1-x}P_x$: (a) quantum efficiency vs. x and (b) peak emission wavelength vs. x.

carriers in the lattice. It provides active radiative recombination centers in the indirect band-gap materials. For an electron, a recombination center is an empty state in the band gap into which an electron falls and, then, thereafter, falls into the valence band by recombining with a hole. For example, while a GaP LED emits green light (2.23 eV), a nitrogen-doped GaP LED emits yellowish green light (2.19 eV), and a heavily nitrogen-doped GaP LED emits yellow light (2.1 eV).

The injected excess carriers in a semiconductor may recombine either radiatively or nonradiatively. Whereas nonradiative recombination generates phonons, radiative recombination produces photons. Consequently, the internal quantum efficiency η, defined as the ratio of the radiative recombination rate R_r to the total recombination rate, is given by

$$\eta = \frac{R_r}{(R_r + R_{nr})} \tag{95.3}$$

where R_{nr} is the nonradiative recombination rate. However, the injected excess carrier densities return to their value exponentially as

$$\Delta p = \Delta n = \Delta n_o e^{-t/\tau} \tag{95.4}$$

where

τ is the carrier lifetime

Δn_o is the excess electron density at equilibrium

Since $\Delta n/R_r$ and $\Delta n/R_{nr}$ are, respectively, equivalent to the radiative recombination lifetime τ_r and the nonradiative recombination lifetime τ_{nr}, we can obtain the effective minority carrier bulk recombination time τ as

$$\left(\frac{1}{\tau}\right) = \left(\frac{1}{\tau_r}\right) + \left(\frac{1}{\tau_{nr}}\right) \tag{95.5}$$

such that $\eta = \tau/\tau_r$. The reason that a fast recombination time is crucial is that the longer the carrier remains in an excited state, the larger the probability that it will give out energy nonradiatively. In order for the internal quantum efficiency to be high, the radiative lifetime τ_r needs to be small. For indirect band-gap semiconductors, $\tau_r \gg \tau_{nr}$ so that very little light is generated, and for direct band-gap semiconductors, τ_r increases with temperature so that the internal quantum efficiency deteriorates with the temperature.

95.4 LED Response Time

As long as the LEDs are used as display devices, it is not too important to have fast response characteristics. However, LEDs are also used for the purpose of optical communications, and for those applications it is appropriate to study their time response characteristics. For example, an LED can be used in conjunction with a photodetector for transmitting optical information between two points. The LED light output can be modulated to convey optical information by varying the diode current. Most often, the transmission of optical signals is facilitated by introducing an optical fiber between the LED and the photodetector.

There can be two different types of capacitances in diodes that can influence the behavior of the minority carriers. One of these is the *junction capacitance*, which is caused by the variation of majority charge in the depletion layer. While it is inversely proportional to the square root of bias voltage in the case of an abrupt junction, it is inversely proportional to the cube root of bias voltage in the case of a linearly graded junction. The second type of capacitance, known as the *diffusion capacitance*, is caused by the minority carriers.

Consider an LED that is forward biased with a dc voltage. Consider further that the bias is perturbed by a small sinusoidal signal. When the bias is withdrawn or reduced, charge begins to diffuse from the junction as a result of recombination until an equilibrium condition is achieved. Consequently, as a response to the signal voltage, the minority carrier distribution contributes to a signal current.

Consider a one-dimensional *p*-type semiconducting material of cross-sectional area *A* whose excess minority carrier density is given by

$$\frac{\delta \Delta n_p}{\delta t} = \frac{D_n \delta^2 \Delta n_p}{\delta x^2} - \frac{\Delta n_p}{\tau} \tag{95.6}$$

As a direct consequence of the applied sinusoidal signal, the excess electron distribution fluctuates about its dc value. In fact, we may assume excess minority carrier density to have a time-varying component as described by

$$\Delta n_p(x,t) = \langle \Delta n_p(x) \rangle + n'_p(x) e^{j\omega t} \tag{95.7}$$

where $\langle \Delta n_p(x) \rangle$ is a time-invariant quantity. By introducing Equation 95.7 into Equation 95.6, we get two separate differential equations:

$$\frac{\delta^2}{\delta x^2}(\langle \Delta n_p(x) \rangle) = \frac{\langle \Delta n_p(x) \rangle}{(L_n)^2} \tag{95.8a}$$

and

$$\frac{\delta^2}{\delta x^2}[\Delta n'_p(x)] = \frac{\Delta n'_p(x)}{[L_n^*]^2} \tag{95.8b}$$

where

$$L_n^* = \frac{L_n}{(1+j\omega\tau)^{1/2}} \tag{95.9a}$$

and

$$L_n = (D_n\tau)^{1/2} \tag{95.9b}$$

The dc solution of Equation 95.8a is well known. Again, the form of Equation 95.8b is similar to that of Equation 95.8a and, therefore, its solution is given by

$$\Delta n_p'(x) = \Delta n_p'(0)e^{-x/L} \tag{95.10}$$

Since the frequency-dependent current $I(\omega)$ is simply a product of eAD_n and the concentration gradient, we find that

$$\begin{aligned} I(\omega) &= \left| \frac{eAD_n dn_p'(x)}{dx} \right|_{x=0} \\ &= \frac{I(0)}{(1+\omega^2\tau^2)^{1/2}} \end{aligned} \tag{95.11}$$

where $I(0)$ is the intensity emitted at zero modulation frequency. We can determine the admittance next by dividing the current by the perturbing voltage. The real part of the admittance, in this case, will be equivalent to the diode conductance, whereas its imaginary part will correspond to the diffusion capacitive susceptance.

The modulation response as given by Equation 95.11 is, however, limited by the carrier recombination time. Often an LED is characterized by its modulation bandwidth, which is defined as the frequency band over which signal power (proportional to $I^2(\omega)$) is half of that at $\omega = 0$. Using Equation 95.11, the 3 dB modulation bandwidth is given by

$$\Delta\omega \approx \frac{1}{\tau_r} \tag{95.12}$$

where the bulk lifetime has been approximated by the radiative lifetime. Sometimes the 3 dB bandwidth of the LED is given by $I(\omega) = \frac{1}{2}I(0)$, but this simplification contributes to an erroneous increase in the bandwidth by a factor of 1.732.

Under conditions of thermal equilibrium, the recombination rate is proportional to the product of initial carrier concentrations, n_o and p_o. Then, under nonequilibrium conditions, additional carriers $\Delta n = \Delta p$ are injected into the material. Consequently, the recombination rate of injected excess carrier densities is given by initial carrier concentrations and injected carrier densities as

$$\begin{aligned} R_{\Delta r} &= [B_r(n_o + \Delta n)(p_o + \Delta p) - B_r n_o p_o] \\ &= B_r(n_o + p_o + \Delta n)\Delta n \end{aligned} \tag{95.13}$$

where B_r is the same constant introduced in Equation 95.1. For p-type GaAs, for example, $B_r = 1.7 \times 10^{-10}$ cm^3/s when $p_o = 2.4 \times 10^{18}$ holes/cm^3. Equation 95.13 is used to define the radiative carrier recombination lifetime by

$$\tau_r = \frac{\Delta n}{R_{\Delta r}} = [B_r(n_o + p_o + \Delta n)]^{-1} \tag{95.14}$$

In the steady-state condition, the excess carrier density can be calculated in terms of the active region width d by

$$\Delta n = \frac{J\tau_r}{ed} \tag{95.15}$$

where J is the injection current density.
The radiative recombination lifetime is found by solving Equation 95.14 after having eliminated Δn from it using Equation 95.15:

$$\tau_r = \frac{\left[\left\{(n_o + p_o)^2 + (4J/B_r ed)\right\}^{1/2} - (n_o + p_o)\right]}{(2J/ed)} \tag{95.16}$$

Thus, while for the low carrier injection (i.e., $n_o + p_o \gg \Delta n$), Equation 95.16 reduces to

$$\tau_r \approx [B_r(n_o + p_o)]^{1/2} \tag{95.17a}$$

for the high carrier injection (i.e., $n_o + p_o \ll \Delta n$), it reduces to

$$\tau_r \approx \left(\frac{ed}{JB_r}\right)^{1/2} \tag{95.17b}$$

Equation 95.17a indicates that in highly doped semiconductors, τ_r is small. But the doping process has its own problem, since in many of the binary LED compounds higher doping may introduce nonradiative traps just below the conduction band, thus nullifying Equation 95.12. In comparison to Equation 95.17a, Equation 95.17b provides a better alternative whereby τ_r can be reduced by decreasing the active region width or by increasing the current density. For the case of p-type GaAs, the radiative lifetimes vary between 2.6 and 0.35 ns, respectively, when p_o varies between 1.0×10^{18} and 1.5×10^{19} holes/cm^3.

Usually, LEDs are operated at low current (≈10 mA) and low voltages (≈1.5 V), and they can be switched on and off in the order of 10 ns. In addition, because of their small sizes, they can be reasonably treated as point sources. It is, therefore, not surprising that they are highly preferred over other light sources for applications in fiber-optic data links.

95.5 LED Designs

Two particular LED designs are popular: *surface emitters* and *edge emitters*. They are shown in Figure 95.5. In the former, the direction of major emission is normal to the plane of the active region, whereas in the latter the direction of major emission is in the plane of the active region. The emission pattern of the surface emitters is very much isotropic, whereas that of the edge emitters is highly directional.

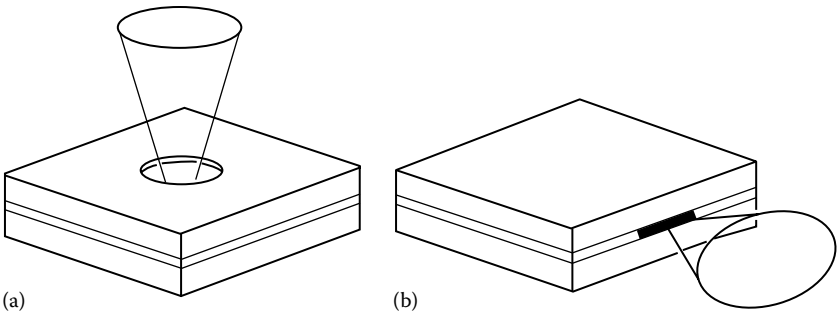

FIGURE 95.5 LED type: (a) surface emitter and (b) edge emitter.

As the LED light originating from a medium of refractive index n_1 goes to another medium of refractive index $n_2 (n_2 < n_1)$, only a portion of incident light is transmitted. In particular, the portion of the emitted light corresponds to only that which originates from within a cone of semiapex angle θ_c, such that

$$\theta_c = \sin^{-1}\left(\frac{n_2}{n_1}\right) \tag{95.18}$$

In the case of an LED, n_1 corresponds to the refractive index of the LED medium and n_2 corresponds to that of air (or vacuum). Light originating from *beyond* angle θ_c undergoes a total internal reflection. However, the light directed from *within* the cone of the semiapex angle θ_c will be subjected to Fresnels loss. Thus, the overall transmittance T is given by

$$T = 1 - \left\{\frac{(n_1 - n_2)}{(n_1 + n_2)}\right\}^2 \tag{95.19}$$

Accordingly, the total electrical-to-optical conversion efficiency in LEDs is given by

$$\begin{aligned}
\eta_{\text{LED}} &= T\left[\frac{(\text{solid angle within the cone})}{(4\pi)}\right] \\
&= \left(\frac{T}{2}\right)(1 - \cos\theta_c) \\
&= \left(\frac{T}{4}\right)\sin^2\theta_c \\
&= \left(\frac{T}{4}\right)\left(\frac{n_2}{n_1}\right)^2\left[1 - \left\{\frac{(n_1 - n_2)}{(n_1 + n_2)}\right\}^2\right]
\end{aligned} \tag{95.20}$$

Only two schemes increase the electrical-to-optical conversion efficiency in an LED. The first technique involves guaranteeing that most of the incident rays strike the glass-to-air interface at angles less than θ_c. It is accomplished by making the semiconductor–air interface hemispherical. The second method involves schemes whereby the LED is encapsulated in an almost transparent medium of high refractive index. The latter means is comparatively less expensive. If a glass of refractive index 1.5 is used for encapsulation, the LED efficiency can be increased by a factor of 3. Two of the possible encapsulation arrangements and the corresponding radiation patterns are illustrated in Figure 95.6.

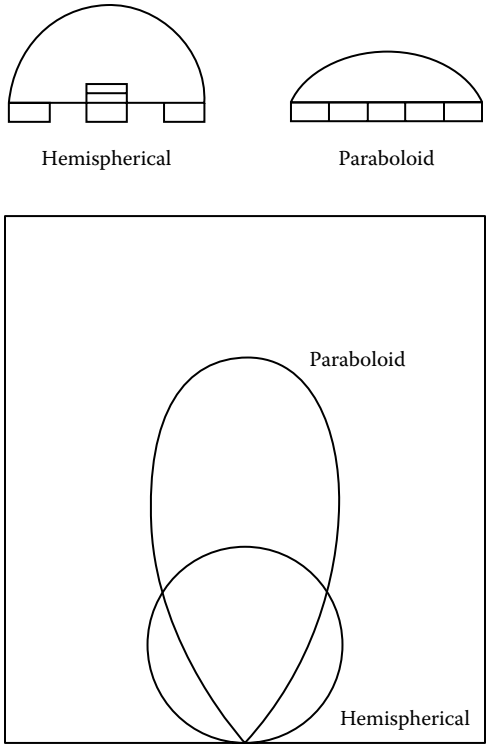

FIGURE 95.6 LED encapsulation geometries and their radiation patterns.

LEDs are often used in conjunction with a phototransistor to function as an optocoupler. The optocouplers are used in circumstances when it is desirable to have a transmission of signals between electrically isolated circuits. They are used to achieve noise separation by eliminating the necessity of having a common ground between the two systems. Depending on the type of coupling material, these miniature devices can provide both noise isolation as well as high voltage isolation. Figure 95.7 shows a typical case

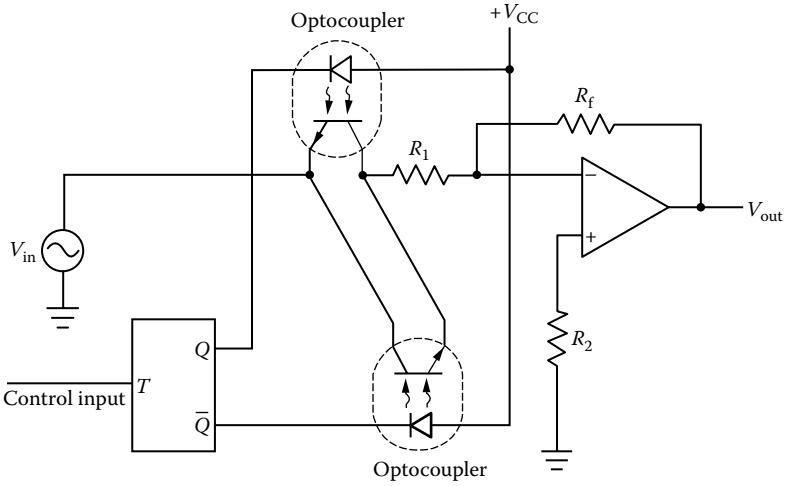

FIGURE 95.7 A chopping circuit with an amplifier.

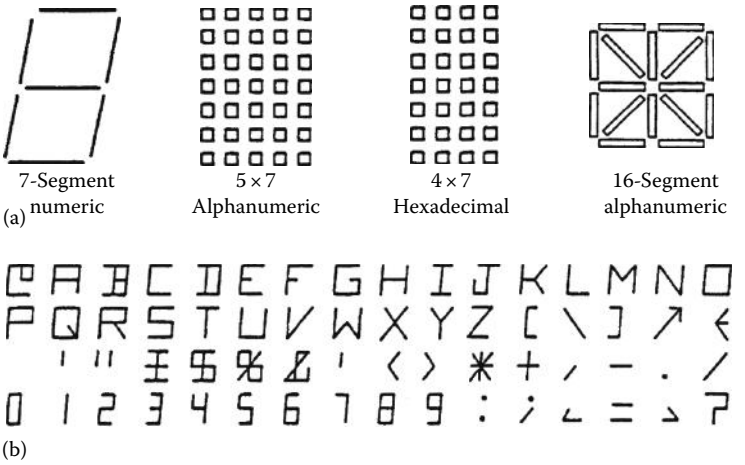

FIGURE 95.8 (a) LED display formats and (b) displayed alphanumeric characters using 16-segment displays.

where two optocouplers are used to attain a chopper circuit. The two optocouplers chop either the positive or the negative portion of the input signals with a frequency of one half that of the control signal that is introduced at the *T* flip-flop. The operational amplifier provides an amplified version of the chopped output waveform. In comparison, a chopper circuit that uses simple bipolar transistors produces noise spikes in the output because of its inherent capacitive coupling.

The visible LEDs are best known for their uses in displays and indicator lamps. In applications where more than a single source of light is required, an LED array can be utilized. An LED array is a device consisting of a row of discrete LEDs connected together within or without a common reflector cavity. Figure 95.8a shows different LED arrangements for displaying hexadecimal numeric and alphanumeric characters, whereas Figure 95.8b shows, for example, the possible alphanumeric characters using 16-segment displays. In digital systems, the binary codes equivalent to these characters are usually decoded and, consequently, a specific combination of LED segments are turned on to display the desired alphanumeric character.

The dot matrix display provides the most desirable display font. It gives more flexibility in shaping characters and has a lower probability of being misinterpreted in case of a display failure. However, these displays involve a large number of wires and increased circuit complexity. LED displays, in general, have an excellent viewing angle, high resonance speed (≈10 ns), long life, and superior interface capability with electronics with almost no duty cycle limitation. LEDs with blue emission are not available commercially. When compared with passive displays, LED displays consume more power and involve complicated wiring with at least one wire per display element.

An alternative version of the LED displays can be realized using organic LED (OLED) that relies instead on carbon-based semiconductors. OLEDs create white by combining red, green, and blue semiconductor films—either stacked on top of each other or arranged in the form of alternating stripes. In OLED, the electroluminescent emissive layer of the diode is an organic compound in either crystalline form or polymers. OLEDs can provide for thin displays with a low driving voltage, wide viewing angle, and high contrast and color gamut.

96.1 Introduction

The heart of recording technology is for the process of information storage and retrieval. In addition to its obvious importance in different branches of science and engineering, it has become indispensable to our daily life. When we make a bank transaction, reserve an airplane ticket, use a credit card, watch a movie from a video tape, or listen to music from a CD, we are using the technology of recording. The general requirements for recording are information integrity, fast access, and low cost. Among the different techniques, the most popularly used ones are magnetic and optical recording.

Typical recording equipment consists of a read/write head, a medium, a coding/decoding system, a data access system, and some auxiliary mechanical and electronic components. The head and medium are for data storage and retrieval purposes, and the coding/decoding system is for data error correction. The data access system changes the relative position between the head and the medium, usually with a servo mechanism for data track following and a spinning mechanism for on-track moving. While the data access system and the auxiliary components are important to recording equipment, they are not considered essential in this chapter to the understanding of recording technology, and will not be covered. Interested readers are referred to Ref. [1].

96.2 Magnetic Recording

At present, magnetic recording technology dominates the recording industry. It is used in the forms of hard disk, floppy disk, removable disk, and tape with either digital or analog mode. In its simplest form, it consists of a magnetic head and a magnetic medium, as shown in Figure 96.1. The head is made of a piece of magnetic material in a ring shape (core), with a small gap facing the medium and a coil away from the medium. The head records (writes) and reproduces (reads) information, while the medium stores the information. The recording process is based on the phenomenon that an electric current i generating a magnetic flux ϕ as described by Ampere's law. The flux ϕ leaks out of the head core at the gap,

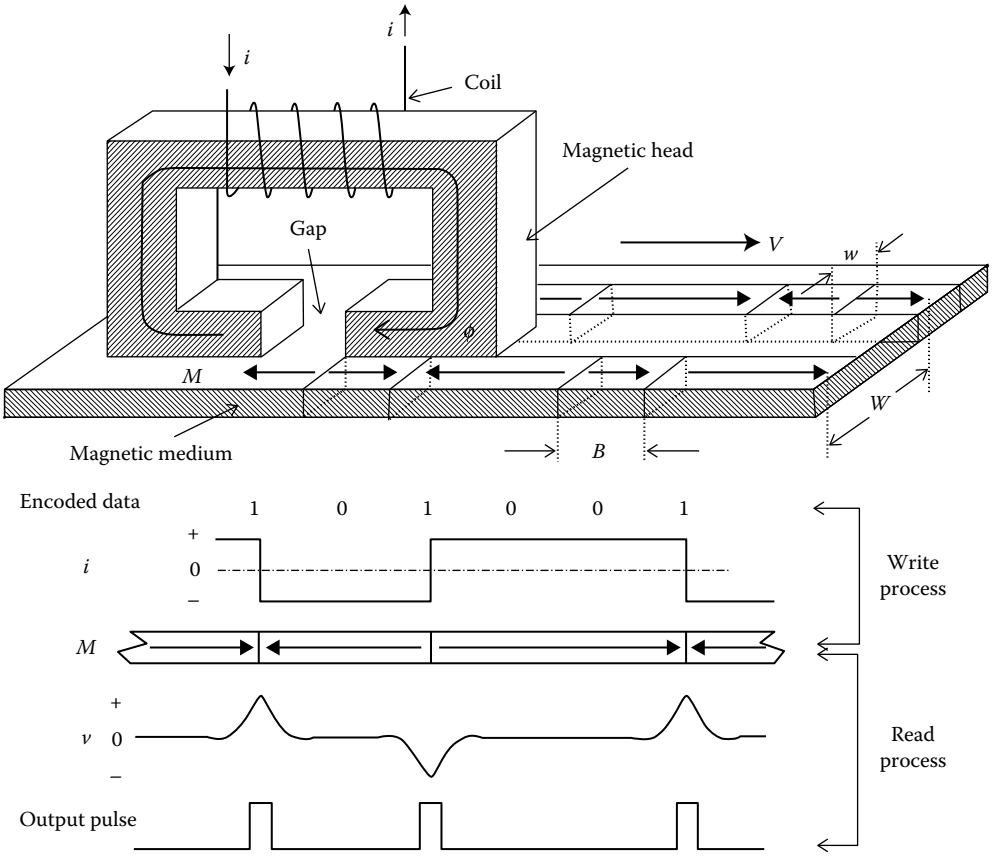

FIGURE 96.1 Conceptual diagrams illustrating the magnetic recording principle (a) and recording/reproducing process (b).

and magnetizes the magnetic medium which moves from left to right with a velocity V under the head gap. Depending on the direction of the electric current i, the medium is magnetized with magnetization M pointing either left or right. This pattern of magnetization is retained in the memory of the medium even after the head moves away.

Two types of head may be used for reproducing. One, termed the *inductive head*, senses magnetic flux change rate, and the other, named the *magnetoresistive* (MR) *head*, senses the magnetic flux. When an inductive head is used, the reproducing process is just the reverse of the recording process. The flux coming out of the magnetized medium surface is picked up by the head core. Because the medium magnetization under the head gap changes its magnitude and direction as the medium moves, an electric voltage is generated in the coil. This process is governed by Faraday's law. Figure 96.1b schematically shows the digital recording/reproducing process. First, all user data are encoded into a binary format—a serial of 1s and 0s. Then a write current i is sent to the coil. This current changes its direction whenever a 1 is being written. Correspondingly, a change of magnetization, termed a *transition*, is recorded in the medium for each 1 in the encoded data. During the reproducing process, the electric voltage induced in the head coil reaches a peak whenever there is a transition in the medium. A pulse detector generates a pulse for each transition. These pulses are decoded to yield the user data.

The minimum distance between two transitions in the medium is the flux change length B, and the distance between two adjacent signal tracks is the track pitch W, which is wider than the signal track width w. The flux change length can be directly converted into bit length with the proper

code information. The reciprocal of the bit length is called *linear density*, and the reciprocal of the track pitch is termed *track density*. The information storage areal density in the medium is the product of the linear density and the track density. This areal density roughly determines how much information a user can store in a unit surface area of storage medium, and is a figure of merit for a recording technique. Much effort has been expended to increase the areal density. For example, it has been increased 50 times during the last decade in hard disk drives, and is expected to continue increasing 60% per year in the foreseeable future. At present, state-of-the-art hard disk products feature areal densities of >7 Mbits/mm^2 ($B < 0.1$ μm and $W < 1.5$ μm). This gives a total storage capacity of up to 6 Gbytes for a disk of 95 mm diameter.

96.2.1 Magnetism and Hysteresis Loop

Magnetism is the result of uncompensated electron spin motions in an atom. Only transition elements exhibit this property, and nearly all practical interest in magnetism centers on the first transition group of elements (Mn, Cr, Fe, Ni, and Co) and their alloys. The strength of magnetism is represented by magnetization M, and is related to magnetic field H and magnetic flux density B by

$$B = \mu_0(H + M) \tag{96.1}$$

where

μ_0 is the permeability of vacuum
since M is a property of a magnetic material, it does not exist outside the magnetic material
H represents the strength acting on a magnetic material from a magnetic field which is generated either by a magnetic material or by an electric current
B is the flux density which determines the induced electric voltage in a coil. The ratio of B with and without a magnetic material is the relative permeability μ of that magnetic material

When a magnetic field H is applied to a piece of demagnetized magnetic material, the magnetization M starts increasing with H from zero. The rate of increase gradually slows down and M asymptotically approaches a value M_s at high H. If H is reduced to zero, then M is reduced to a lower value M_r. Continuous reduction of H to a very high negative value will magnetize the material to $-M_s$. In order to bring the material to demagnetized state, a positive field H_c is required. Further increase in the H field will bring the trace of M to a closed loop. This loop is the major hysteresis loop, as shown in Figure 96.2.

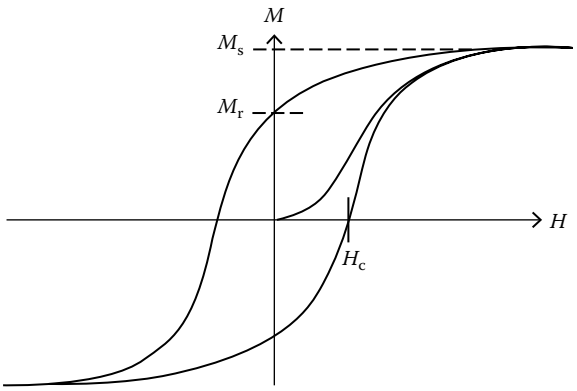

FIGURE 96.2 Hysteresis loop of a magnetic material shows the nonlinear relationship between M and H that results in magnetic memory.

The hysteresis loop shows that a magnetic material has memory. It is this memory that is used in the medium for storing information. H_c is the coercivity, indicating the strength of magnetic field required to erase the memory of a magnetic material. Magnetic materials with high H_c are "hard" magnets, and are suitable for medium applications if they have high M_r. On the other hand, magnetic materials with low H_c are "soft" magnets, and are candidates for head core materials if they have high M_s and high μ. M_r and M_s are the remanent and saturation magnetization, respectively, and their ratio is the remanent squareness. The flux density corresponding to M_s is B_s.

96.2.2 Magnetic Media

Magnetic media are used to store information in a magnetic recording system. In order to increase the areal density, we need to reduce flux change length B and track width w. Since B is limited by the term $M_r\delta/H_c$, where δ is the magnetic layer thickness, we can reduce B by either decreasing $M_r\delta$ or increasing H_c. However, the amplitude of the magnetic signal available for reproducing head is proportional to the term $M_r\delta w$. If we reduce track width w to increase areal density, we must increase $M_r\delta$ to avoid signal deterioration. In addition, if the magnetic layer is so thin that it causes thickness nonuniformity, more noise will appear in the reproducing process. Therefore, the major requirements for magnetic layer are high H_c, high M_r, and ease of making a uniform thin layer. Additional requirements include good magnetic and mechanical stability.

There are two groups of magnetic media. The first group is called particulate media because the magnetic materials are in the form of particles. This group includes iron oxide (γ-Fe_2O_3), cobalt-modified iron oxide (γ-Fe_2O_3+Co), chromium dioxide (CrO_2), metal particles, and barium ferrite ($BaFe_{12}O_{19}$). Some of these have been used in the magnetic recording for several decades. More recently, another group of media has been developed largely due to the ever-increasing demand for higher storage capacity in the computer industry. This group of media is the thin-film media, where the magnetic layer can be made as a continuous thin film. Most materials in this group are cobalt-based metal alloys. Compared with particulate media, the thin-film media usually have a higher coercivity H_c, a higher remanence M_r, and can be deposited in a very thin continuous film. Table 96.1 lists H_c and M_r for some of the most popularly used particulate and thin-film media. Note that magnetic properties are affected by the fabrication process and film structure. Therefore, their values can be out of the ranges of Table 96.1 if different processes are used.

Magnetic media can be classified into three general forms of applications. Tape is the oldest form and remains an important medium today. It is central to most audio, video, and instrumentation recording, although it is also used in the computer industry for archival storage. Tape is economical and can hold a large capacity, but suffers slow access time. Hard disk is primarily used as the storage inside a computer, providing fast data access for the user, but having poor transportability. Flexible disk is designed for easy data transportation, but is limited in capacity. Besides these three general forms of applications, a hybrid of

TABLE 96.1 Remanence (M_r) and Coercivity (H_c) Values of Some Commonly Used Magnetic Media

Group	Material	M_r (kA/m)	H_c (kA/m)	Application
Particulate	γ-Fe_2O_3	56–140	23–32	Floppy disk, audio, video, and instrumentation tapes
	γ-Fe_2O_3 + Co	60–140	44–74	Floppy disk, audio, video, and instrumentation tapes
	CrO_2	110–140	38–58	Floppy disk, audio, video, and instrumentation tapes
	$BaFe_{12}O_{19}$	56	58	Floppy disk
Thin film	Co–Ni	600–1100	30–85	Hard disk
	Co–Fe	1100–1500	60–150	Hard disk
	Co–P	600–1000	36–120	Hard disk
	Co–Ni–Pt	600–1100	60–175	Hard disk
	Co–Cr–Ta	350–900	55–190	Hard disk
	Co–Cr–Pt	300–750	56–200	Hard disk

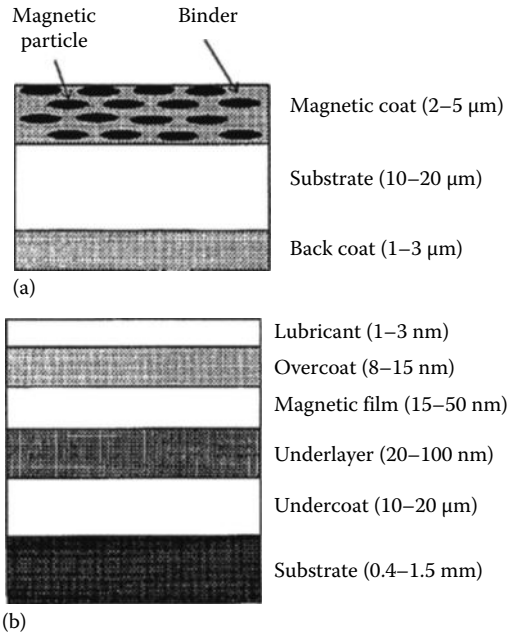

FIGURE 96.3 Cross-sectional views of a particulate magnetic tape (a) and a thin-film hard disk (b).

flexible and hard disk is being gradually accepted. It is a removable rigid disk capable of holding up to several gigabytes of digital data. In addition, magnetic stripes are getting wide use in different forms of cards.

The magnetic layer alone cannot be used as a medium. It needs additional components to improve its chemical and mechanical durability. Typical cross sections of a particulate magnetic tape and a thin-film hard disk are shown in Figure 96.3. In the case of tape application, iron particles with typical size of 0.5 μm long and 0.1 μm wide are dispersed in a polymeric binder, together with solvents, lubricants, and other fillers to improve magnetic and mechanical stability. This dispersed material is then coated on an abiaxially oriented polyethylene terephthalate substrate. An optional back coat may also be applied to the other side of the substrate. The cross section of a hard disk is more complex. A high-purity aluminum–magnesium (5 wt%) substrate is diamond turned to a fine surface finish, and then electrolessly plated with a nonmagnetic nickel–phosphorus (10 at%) undercoat. This layer is used to increase the hardness, reduce the defects, and improve the finish of the Al–Mg alloy, and is polished to a super surface finish. Next, an underlayer of chromium is sputtered to control the properties of the magnetic film, followed by sputtering the magnetic film. Finally, a layer of hydrogenated or nitrogenated carbon is overcoated on the magnetic film, and an ultrathin layer of perfluorinated hydrocarbon liquid lubricant is applied on top. The carbon and lubricant layers are used to improve the corrosion and mechanical resistance of the disk. For a 95 mm disk, the finished product should have a surface flatness better than 10 μm and a tightly control surface roughness. In some applications, an arithmetic average roughness (R_a) of <0.5 nm is required.

96.2.3 Magnetic Heads

Magnetic heads have three functions: recording, reproducing, and erasing. Usually for stationary head applications such as tape drives, multiple heads are used to perform these functions. For moving head applications such as disk drives, a single head is employed because of the requirements of simple connections and small head mass for fast data access. Most of these heads are the inductive type, where the fundamental design is an inductive coil and a magnetic core. The general requirements for the core materials are high relative permeability μ, high saturation flux density B_s, low coercivity H_c, high electric

resistivity ρ, and low magnetostriction coefficient λ. Some of the properties for the commonly used core materials are listed in Table 96.2.

The evolution of the magnetic head follows the selection of core materials, as shown in Figure 96.4. Early heads used laminated molybdenum Permalloy (Ni–Fe–Mo, 79–17–4 wt%). These heads are inexpensive to make, and have low H_c and high μ and B_s. The primary drawbacks are frequency limitation, gap dimension inaccuracy, and mechanical softness. Frequency limitation is caused by the difficulty of making the

TABLE 96.2 Relative Permeability (μ), Saturation Flux Density (B_s), Coercivity (H_c), and Resistivity (ρ) Values of Some Commonly Used Magnetic Head Materials at Low Frequency

Material	μ	B_s (T)	H_c (A/m)	ρ (μΩ cm)	Application
Ni–Fe–Mo	11,000	0.8	2.0	100	Audio tape
Ni–Zn	300–1,500	0.4–0.46	11.8–27.6	10^{11}	Floppy and hard disk drives, video and instrumentation tapes
Mn–Zn	3,000–10,000	0.4–0.6	11.8–5.8	10^{6}	Floppy and hard disk drives, video and instrumentation tapes
Fe–Si–Al	8,000	1.0	2.0	85	Floppy and hard disk drives, video and instrumentation tapes
Ni–Fe	2,000–4,000	1.0	<10	20	Hard disk drives

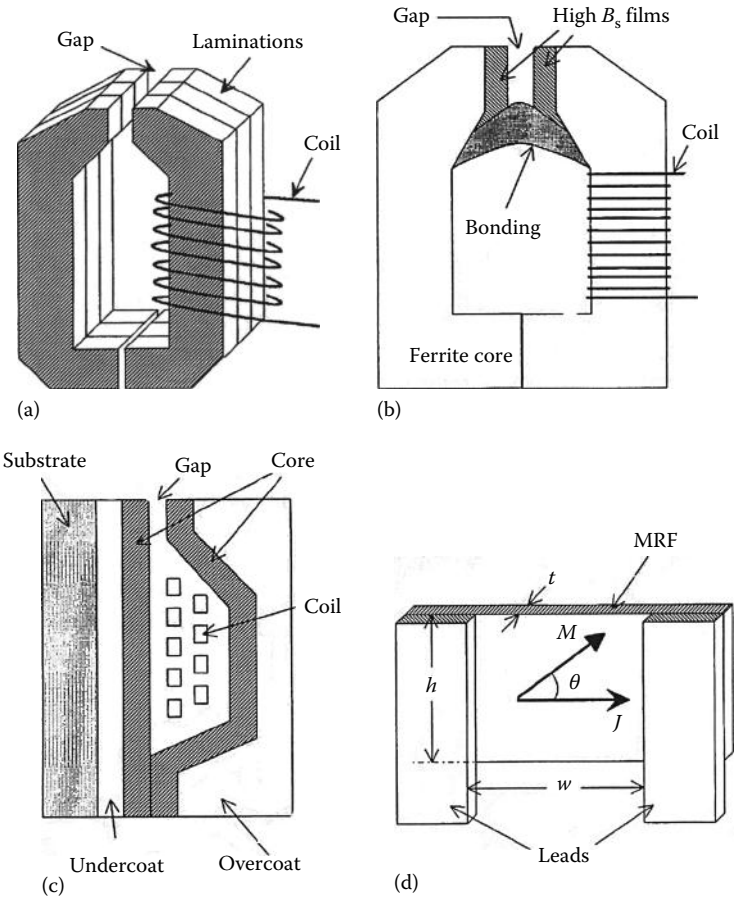

FIGURE 96.4 Schematic illustrations of (a) a laminated head, (b) cross section of a MIG head, (c) cross section of a thin-film head, and (d) an MR sensor with leads.

lamination layer thinner than 25 μm. Eddy current loss, which is proportional to layer thickness and square root of frequency, reduces the effective permeability. As a result, laminated heads are seldom used for applications exceeding 10 MHz. Gap dimension inaccuracy is associated with the head fabrication process, and makes it unsuitable for high areal density applications. Lack of mechanical hardness reduces its usable life.

One way to reduce eddy current loss is to increase core material electric resistivity. Two types of ferrite material have high resistivity (four to nine orders higher than Permalloy) and reasonable magnetic properties: Ni–Zn and Mn–Zn. These materials are also very hard, elongating head life during head/medium contacts. The major deficiency of ferrite materials is their low B_s values. In order to record in high H_c media, high flux density B is needed in the head core. When the flux density in the core material reaches its saturation B_s, it will not increase despite the increase of recording current or coil turns. This saturation starts from the corners of the gap due to its geometry. To remedy this deficiency, a layer of metallic alloy material with much higher B_s is deposited on the gap faces. This type of head is called the metal-in-gap (MIG) head. Sendust (Fe–Si–Al, 85–9.6–5.4 wt%) is one of the materials used for the deposition. MIG heads are capable of recording up to 100 MHz frequency and 180 kA/m medium coercivity.

Thin-film heads capitalize on semiconductor-like processing technology to reduce the customized fabrication steps for individual heads. The core, coil, gap, and insulator layers are all fabricated by electroplating, sputtering, or evaporation. Due to the nature of the semiconductor process, the fabrication is accurate for small dimensions. Small gap dimensions are suitable for high linear and track density, and small core dimensions allow the use of high B_s Permalloy material (Ni–Fe, 80–20 wt%) as core with low inductance for high data rate applications. Thin-film heads are used for high medium H_c, high areal density applications. The high cost of the semiconductor-like process is offset by high throughput: a 150 × 150 mm wafer can produce 16,000 nanoslider heads. One disadvantage is the limited-band recording capability because the small pole length limits low-frequency response and introduces undershoots. A second disadvantage, the Barkhausen noise, is caused by the relatively small number of magnetic domains in the core. At present, thin-film heads are used up to frequencies of 80 MHz and medium coercivity of 200 kA/m. MIG thin-film heads are also being used for high-coercivity applications.

An inductive head is often used for both recording and reproducing. The optimal performance cannot be achieved because recording and reproducing have contradictory requirements for head design. To solve this problem, the MR head has been developed. The MR head is for reproducing only, and an inductive head is used for recording. As schematically shown in Figure 96.4, an MR head has a magnetoresistive element (MRE) and two electric leads. The MRE is a Permalloy stripe (Ni–Fe, 80–20 wt%), with thickness t, width w, and height h. An electric current, with density J, passes through the MRE through the leads. The electric resistivity of the MRE is a function of the angle θ between J and MRE magnetization M:

$$\rho_\theta = \rho\left(1 + \frac{\Delta\rho}{\rho}\cos^2\theta\right) \tag{96.2}$$

where

ρ_θ is the resistivity at θ
ρ is the resistivity at $\theta = 90°$
$\Delta\rho$ is the resistivity difference between $\theta = 0°$ and $\theta = 90°$
$\Delta\rho/\rho$ is the anisotropic MR ratio (AMR) of the MRE

Usually, a transverse magnetic field is applied to the MRE so that $\theta = \theta_0$ when the head is not reading a magnetic signal. Assume that a magnetic signal from the medium rotates M from θ_0 to θ, then an electric voltage change v will be detected across the MRE as the output signal:

$$v = Jw\rho\frac{\Delta\rho}{\rho}(\sin^2\theta_0 - \sin^2\theta) \tag{96.3}$$

where θ_0 is the bias angle and is set to 45° for good linearity. In practice, a longitudinal bias is also used along the MRE width direction to stabilize the magnetic domain and reduce large Barkhausen noise. To compare the output between an MR head and an inductive head, we write the inductive head output using Faraday's equation:

$$v = -nV\frac{d\phi}{dx} \tag{96.4}$$

where

n is the number of the coil turns
V is the medium velocity
ϕ is the magnetic flux
x is the coordinate axis fixed on the medium surface

Equations 96.3 and 96.4 tell us that while inductive head output is proportional to medium velocity and not suitable for low-velocity applications, the MR head can be used for either high- or low-velocity applications.

96.2.4 Recording Process

We can imagine the recording process in two steps. First, the magnetic flux flowing in the head core generates a fringe magnetic field around the gap. Then the magnetic field magnetizes the magnetic medium and leaves a magnetization transition in it. Partly due to the nonlinear nature of the hysteresis loop, the recording process is so complex that there has been no rigorous explanation. However, we can still obtain significant insights into the recording process by using simple models if we keep in mind the limitations.

If we set the origin of a coordinate system at the center of the gap with x axis on the head surface and y axis pointing away from the head, then the longitudinal magnetic field H_x and perpendicular magnetic field H_y of this head can be expressed by the Karlqvist approximation [2]:

$$H_x = \frac{ni}{\pi(g + lA_g/\mu A_c)}\tan^{-1}\left[\frac{yg}{x^2 + y^2 - (g^2/4)}\right] \tag{96.5}$$

$$H_y = \frac{ni}{2\pi(g + lA_g/\mu A_c)}\ln\left[\frac{(x - g/2)^2 + y^2}{(x + g/2)^2 + y^2}\right] \tag{96.6}$$

where

n is the number of coil turns
i is the current in the coil
g is the gap length
l is the core length
A_g is the core cross-sectional area
μ is the relative permeability of core material
A_c is the gap cross-sectional area

Both Equations 96.5 and 96.6 give accurate results for points $0.25g$ away from gap corners. Since longitudinal recording mode dominates the magnetic recording industry, we will focus on the field H_x. Equation 96.5 shows that the contours of constant H_x field are circles nesting on the two gap corners, as shown in Figure 96.5. The greater the diameter of the circle is the weaker the magnetic field. Assume a magnetic medium, moving from left to right with a distance d above the head, has a thickness δ and a magnetization M pointing to right. At some instant, the recording current turns on and generates

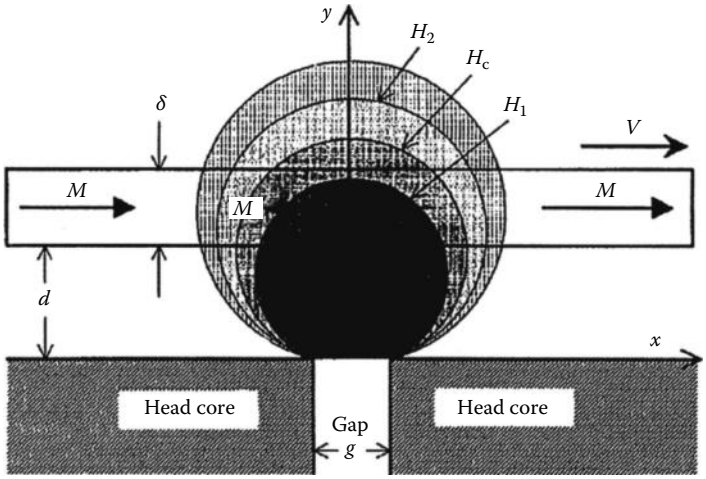

FIGURE 96.5 The constant horizontal fields of the Karlqvist approximation are circles resting on the gap corners of a head, and the change of magnetization in the medium is gradual.

the magnetic field H_x above the gap as depicted in Figure 96.6. On the circumference of $H_x = H_c$, half of medium material has its magnetization reversed and half remains the same, resulting in a zero total magnetization. Since H_x has a gradient, the medium closer to the gap (inside a smaller circle) gets its magnetization reversed more completely than the medium farther away from the gap (outside a bigger circle). Therefore, magnetic transition is gradual in the medium even if the change of recording current follows a step function. Assume the original magnetization is M_r and the completely reversed magnetization is $-M_r$, this gradual change of magnetization for an isolated transition can be modeled by [3]:

$$M = \frac{2}{\pi} M_r \tan^{-1} \frac{x}{a} \tag{96.7}$$

where

x is the distance from the center of transition

a is a parameter characterizing the sharpness of the transition as shown in Figure 96.6

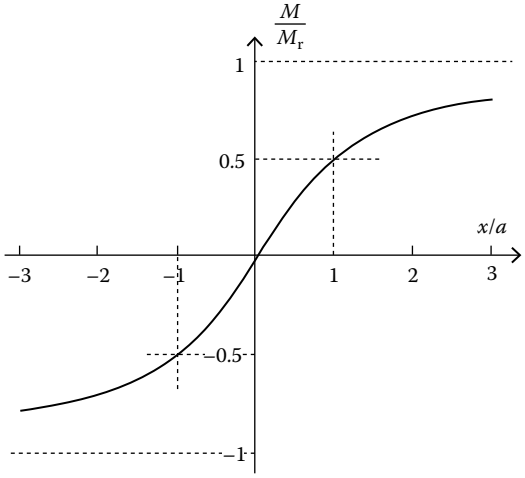

FIGURE 96.6 An isolated arctangent magnetization transition from negative M_r to positive M_r.

Assuming a thin-film medium and using the Karlqvist approximation for the head field, a is found to be [4–6]

$$a = \frac{(1-S^*)(d+\delta/2)}{\pi Q} + \sqrt{\left[\frac{(1-S^*)(d+\delta/2)}{\pi Q}\right]^2 + \frac{M_r\delta(d+\delta/2)}{\pi Q H_c}} \tag{96.8}$$

where

S^* is the medium loop squareness
Q is the head-field gradient factor

For a reasonably well-designed head, $Q \approx 0.8$. It is obvious that we want to make parameter a as small as possible so that we can record more transitions for a unit medium length. If the head gap length g and medium thickness δ are small compared with head/medium separation d, and the medium has a squareness of 1, then the minimum possible value of a is [7]

$$a_m = \begin{cases} \dfrac{M_r\delta}{2\pi H_c} & \dfrac{M_r\delta}{4\pi H_c d} \geq 1 \\ \sqrt{\dfrac{M_r\delta d}{\pi H_c}} & \dfrac{M_r\delta}{4\pi H_c d} < 1 \end{cases} \tag{96.9}$$

In order to decrease the value of a and therefore increase areal density, we need to reduce medium remanence M_r, thickness δ, head/medium separation d, and to increase coercivity H_c.

96.2.5 Reproducing Process

In contrast to the recording process, the reproducing process is well understood. The flux density induced in the head core is on the order of a few millitesla, yielding a linear process for easier mathematical treatment. The head fringe field is the Karlqvist approximation (Equation 96.5) and the foundation is the reciprocity theorem. For an isolated transition (Figure 96.6) with a thin magnetic layer $\delta \ll d$, the induced electric voltage v for an inductive head is [7]

$$v(x) = \frac{-2\mu_0 V w M_r \delta n}{\pi(g + lA_g/\mu A_c)}\left[\tan^{-1}\left(\frac{g/2+x}{a+d}\right) + \tan^{-1}\left(\frac{g/2-x}{a+d}\right)\right] \tag{96.10}$$

where

μ_0 is the permeability of vacuum
μ is the relative permeability of the core
V is the medium velocity
w is the track width
n is the number of coil turns
g is the head gap length
d is the head/medium separation
x is the distance between the center of the medium transition and the center of the head gap

The term $lA_g/\mu A_c$ is closely related to g for head efficiency. When a transition passes under the head, its voltage starts with a very low value, reaches a peak, then falls off again, as shown in Figure 96.7, where the following typical values for a hard disk drive are used: V = 20 m/s, w = 3.5 μm, M_r = 450 kA/m, δ = 50 nm, n = 50, $lA_g/\mu A_c = 0.1g$. The effects of g and $a + d$ are shown in Figure 96.7. Since a greater peak voltage and a narrower spatial response are desired for the reproducing process, smaller g and $a + d$ values are helpful.

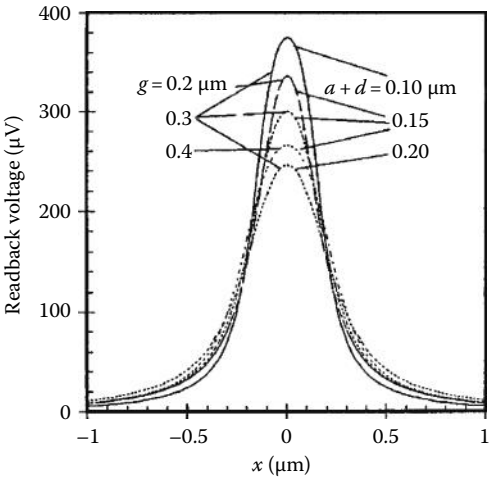

FIGURE 96.7 The reproducing voltage of an inductive head over an isolated arctangent transition shows the effects of gap length *g*, parameter *a*, and head/medium separation *d*.

When an MR head is used for reproducing, the MRE is usually sandwiched between two magnetic shields to increase its spatial resolution to medium signals, as shown in Figure 96.8. Since the MR head is flux-sensitive, the incident flux ϕ_i, on the bottom surface of the MRE, should be derived as a function of the distance (x) between the center of MRE and the center of the transition [7,8]:

$$\phi_i(x) = \frac{2\mu_0 w M_r \delta(a+d)}{\pi g}\left\{ f\left[\frac{x+(g+t)/2}{a+d}\right] - f\left[\frac{(x+t)/2}{a+d}\right] + f\left[\frac{x-(g-t)/2}{a+d}\right] - f\left[\frac{(x-t)/2}{a+d}\right]\right\} \tag{96.11}$$

where

g is the distance between the MRE and the shield

t is the MRE thickness

$$f(\beta) = \beta \tan^{-1}\beta - \ln\sqrt{1+\beta^2} \tag{96.12}$$

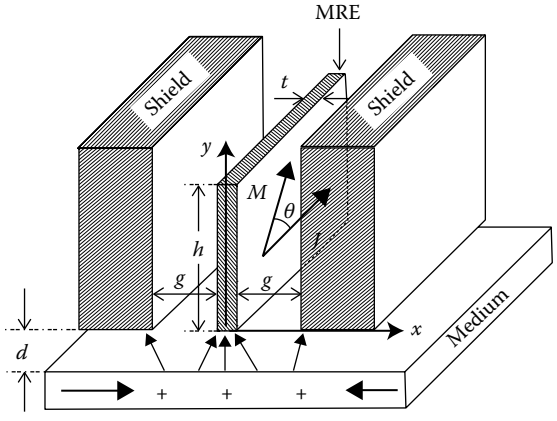

FIGURE 96.8 Schematic diagram of a shielded MR head with a shield to MRE distance *g*.

The angle between magnetization and current varies along the MRE height h. To find out the variation, we need to calculate the signal flux decay as a function of y by

$$\phi_s(y) = \phi_i \frac{\sin h[(h-y)/l_c]}{\sin h(h/l_c)} \tag{96.13}$$

where

$$l_c = \sqrt{\frac{\mu g t}{2}} \tag{96.14}$$

Then the bias angle θ_0 and signal angle θ can be calculated by

$$\sin\theta_0(y) = \frac{\phi_b(y)}{M_s t} \tag{96.15}$$

and

$$\sin\theta(y) = \frac{\phi_s(y) + \phi_b(y)}{M_s t} \tag{96.16}$$

where

ϕ_b is the biasing flux in the MRE

M_s is the saturation magnetization of the MRE

Application of Equations 96.15 and 96.16 to Equation 96.3 and integration over height h lead to

$$v = Jw\rho \frac{\Delta\rho}{\rho} \frac{1}{h} \left[\int_0^h \sin^2\theta_0(y)\,dy - \int_0^h \sin^2\theta(y)\,dy \right] \tag{96.17}$$

For an MR head with a 45° bias at the center and small height $h \ll l_c$, the peak voltage is [6]

$$v_P \approx \frac{9\Delta\rho JwM_r\delta(g+t)}{8\sqrt{2}\ tgM_s} \tan^{-1}\left[\frac{g}{2(a+d)}\right] \tag{96.18}$$

The general shape of the reproducing voltage from an MR head is similar to that in Figure 96.7.

The study of an isolated transition reveals many intrinsic features of the reproducing process. However, transitions are usually recorded closely in a magnetic medium to achieve high linear density. In this case, the magnetization variation in the medium approaches a sinusoidal wave. That is,

$$M(x) = M_r \sin\frac{2\pi}{\lambda}x \tag{96.19}$$

where λ is the wavelength. The reproducing voltage in an inductive head becomes [9,10]

$$v(x) = \frac{-\mu_0 VwM_r ng}{g + lA_g/\mu A_c} (e^{-2\pi d/\lambda})(1 - e^{-2\pi\delta/\lambda}) \left(\frac{\sin(\pi g/\lambda)}{\pi g/\lambda}\right) \cos\frac{2\pi}{\lambda}x \tag{96.20}$$

This equation presents all the important features of the high linear density–reproducing process. The term $\exp(-2\pi d/\lambda)$ is the spacing loss. It shows that the reproducing voltage falls exponentially

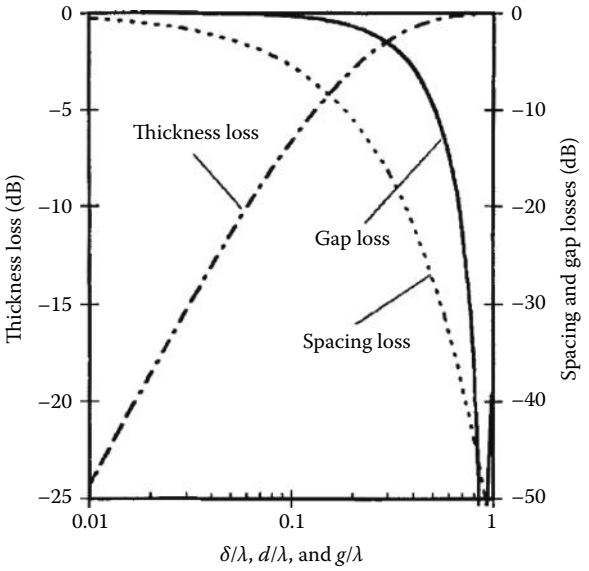

FIGURE 96.9 Spacing, thickness, and gap losses of an inductive head versus frequency for the reproducing of a sinusoidal medium magnetization.

with the ratio of head/medium spacing to wavelength. The second term $1 - \exp(-2\pi\delta/\lambda)$ is the thickness loss. The name of this term is misleading because its value increases with a greater medium thickness. However, the rate of increase diminishes for thicker medium. In fact, 80% of the maximum possible value is achieved by a medium thickness of 0.25λ. The last term $\sin(\pi g/\lambda)/(\pi g/\lambda)$ is the gap loss. This term is based on the Karlqvist approximation. If a more accurate head fringe field is used, this term is modified to $\sin(\pi g/\lambda)/(\pi g/\lambda)\cdot(1.25g^2 - \lambda^2)/(g^2 - \lambda^2)$ [11]. It shows a gap null at $\lambda = 1.12g$, and limits the shortest wavelength producible. These three terms are plotted in Figure 96.9. The most significant loss comes from the spacing loss term, which is 54.6 dB for $d = \lambda$. Therefore, one of the biggest efforts spent on magnetic recording is to reduce the head/medium spacing as much as possible without causing mechanical reliability issues. For an MR head, the reproducing voltage is [11]

$$v \propto \frac{4M_r i\Delta\rho w\lambda}{ht}(e^{-2\pi d/\lambda})(1-e^{-2\pi\delta/\lambda})\left(\frac{\sin(\pi g/\lambda)}{\pi g/\lambda}\right)\sin\frac{\pi(g+t)}{\lambda}\cos\frac{2\pi}{\lambda}x \tag{96.21}$$

96.2.6 Digital versus Analog Recording

Due to the nonlinearity of the hysteresis loop, magnetic recording is intrinsically suitable for digital recording, where only two states (1 and 0) are to be recognized. Many physical quantities, however, are received in analog form before they can be recorded, such as in consumer audio and instrumentation recording. In order to perform such recording, we need to either digitize the information or use the analog recording technique. In the case of digitization, we use an analog-to-digital converter to change a continuous signal into binary numbers. The process can be explained by using the example shown in Figure 96.10. An electric signal V, normalized to the range between 0 and 1, is to be digitized into 3 bits. The signal is sampled at time $t = 1, 2, \ldots, 6$. At each sampling point, the first bit is assigned a 1 if the value of the continuous signal is in the top half (>0.5), otherwise assigned a 0. The second bit is assigned a 1 if the value of the continuous signal is in the top half of each half ($0.25 \le V < 0.5$, or >0.75), otherwise assigned a 0. The third bit is assigned similarly. The first bit is the most significant bit (MSB), and the last bit is the least significant

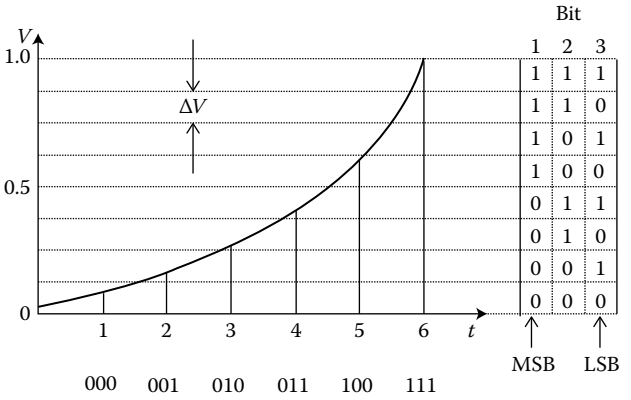

FIGURE 96.10 Schematic illustration of the quantization of a continuous signal to 3 bits.

bit (LSB). The converted binary numbers are listed below each sampling point in Figure 96.10. This process of digitization is termed *quantization*. In general, the final quantization interval is

$$\Delta V = \frac{V}{2^N} \tag{96.22}$$

where

V is the total voltage range
N is the number of bits

Because we use a finite number of bits, statistically there is a difference between the continuous signal and the quantized signal at the sampling points. This is the quantization error. It leads to a signal-to-quantization-noise ratio [12]:

$$\text{SNR} = \frac{12P_s}{\Delta V^2} \tag{96.23}$$

where P_s is the mean square average signal power. For a signal with uniform distribution over its full range, this yields

$$\text{SNR} = 2^{2N} \tag{96.24}$$

For a sinusoidal signal, it changes to

$$\text{SNR} = 1.5 \times 2^{2N} \tag{96.25}$$

The SNR can be improved by using more bits. This improvement, however, is limited by the SNR of the incoming continuous signal. The quantized signal is then pulse code modulated (PCM) for recording.

For analog recording, a linear relationship between the medium magnetization and the recording signal is required. This is achieved through the anhysteretic magnetization process. If we apply an alternating magnetic field and a unidirectional magnetic field to a previously demagnetized medium, and then reduce the amplitude of the alternating field to zero before we remove the unidirectional field, the remanent magnetization shows a pseudo-linear relationship with the unidirectional field strength H_u up to some level. Figure 96.11 shows such an anhysteretic curve. The linearity deteriorates as H_u gets greater. In applications, the recording signal current is biased with an ac current of greater amplitude

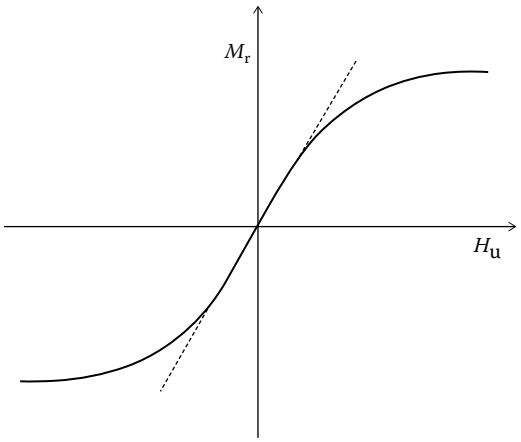

FIGURE 96.11 An anhysteretic remanent magnetization shows a pseudo-linear relationship with the applied unidirectional magnetic field to some H_u level.

and higher frequency. Therefore, it is also termed ac-biased recording. Analog recording is easy to implement, at the price of a lowered SNR because remanent magnetization is limited to about 30% of the maximum possible M_r to achieve good linearity.

96.2.7 Recording Codes

PCM is a scheme of modifying input binary data to make them more suitable for a recording and reproducing channel. These schemes are intended to achieve some of the following goals: (1) reducing the dc component, (2) increasing linear density, (3) providing self-clocking, (4) limiting error propagation, and (5) achieving error-free detection. There is numerous code schemes, only three of the ones developed early are shown in Figure 96.12. The earliest and most straightforward one is the return-to-zero (RZ) code. In this scheme, a positive and negative pulse is used to represent each 1 and 0, respectively, of the data. The main drawback is that direct recording over old data is not possible due to the existence of zero recording current between two data. It also generates two transitions for each bit, therefore reducing the linear density. In addition, it only uses half of the available recording current range for a transition. The non-return-to-zero-invert (NRZI) method was developed to alleviate some of these problems. It changes the recording current from one direction to the other for each 1 of the data, while making no changes for all 0s. However, it has a strong dc component and may lose reproducing synchronization if

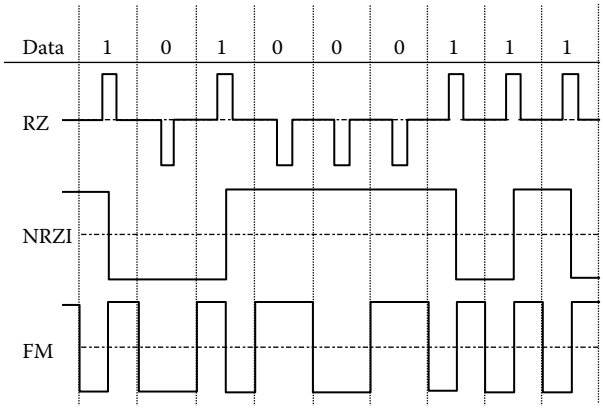

FIGURE 96.12 Comparison of some early developed codes.

TABLE 96.3 ½(2, 7) Code

Before Coding	After Coding
10	0100
11	1000
000	000100
010	100100
011	001000
0010	00100100
0011	00001000

there is a long string of 0s in the input data. In addition, reproducing circuits are usually not designed for dc signal processing. In frequency modulation (FM) code, there is always a transition at the bit-cell boundary which acts as a clock. There is also an additional transition at the bit-cell center for each 1 and no transition for 0s. It reduces the dc component significantly. The primary deficiency is the reduction of linear density since there are two transitions for each 1 in the data.

The most popularly used codes for magnetic recording are the run length–limited (RLL) codes. They have the general form of $m/n(d, k)$. In these schemes, data are encoded in groups. Each input group has m bits. After encoding, each group contains n bits. In some schemes, multiple groups are coded together. d and k are the minimum and maximum 0s, respectively, between two consecutive 1s in the encoded sequence. While d is used to limit the highest transition density and intersymbol interference, k is employed to ensure adequate transition frequency for reproducing clock synchronization. The encoding is carried out by using a lookup table, such as Table 96.3 for a ½(2, 7) code [13].

96.2.8 Head/Medium Interface Tribology

As expressed in Equation 96.20, the most effective way to increase signal amplitude, therefore areal density, is to reduce head/medium spacing d. However, wear occurs when a moving surface is in close proximity to another surface. The amount of wear is described by Archard's equation:

$$V = k\frac{WS}{H} \tag{96.26}$$

where

V is the volume worn away
W is the normal load
S is the sliding distance
H is the hardness of the surface being worn away
k is a wear coefficient

In order to increase medium hardness H, hard Al_2O_3 particles are dispersed in particulate media and a thin layer of hard carbon (≈10 nm) with either hydrogenation or natrogenation is coated on thin-film media of hard disks. A layer of liquid lubricant, typically perfluoropolyethers with various end groups and additives, is applied on top of the carbon film to reduce the wear coefficient k. Load is minimized to reduce wear while keeping adequate head/medium dynamic stability. For applications where the sliding distance s is modest over the lifetime of the products such as floppy disk drives and consumer tapes drives, the head physically contacts the medium during operations. In the case of hard disk application, heads are separated nominally from the media by a layer of air cushion. The head is carried on a slider, and the slider uses air-bearing surfaces (ABS) to create the air film based on hydrodynamic lubrication theory. Figure 96.13 shows two commonly used ABS. Tapers are used to help the slider takeoff

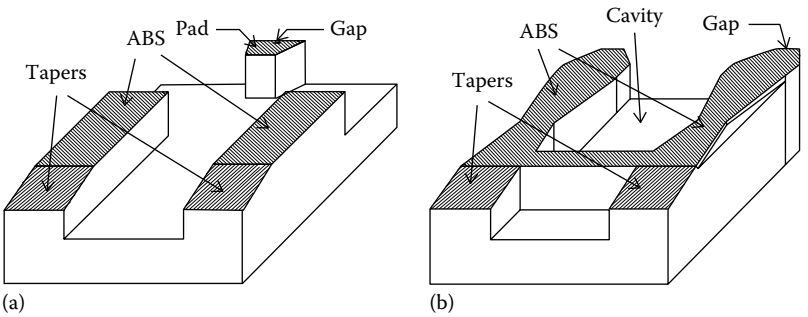

FIGURE 96.13 The ABS of (a) a tripad slider for pseudo-contact recording and (b) a SAP slider for conventional flying recording.

and maintain flying stability. ABS generates higher-than-ambient pressure to lift the slider above the medium surface during operations. The tripad slider is for pseudo-contact applications while the sub-ambient pressure (SAP) slider is for flying (such as MR head) applications. Because the relative linear velocity between the slider and the medium changes when the head moves to different radii, a cavity region is used in the SAP slider to generate suction force to reduce flying height variation. The ABS is designed based on the modified Reynolds equation:

$$\frac{\partial}{\partial X}\left(PH^3Q\frac{\partial P}{\partial X}\right)+\frac{\partial}{\partial Y}\left(PH^3Q\frac{\partial P}{\partial Y}\right)=\Lambda_x\frac{\partial(PH)}{\partial X}+\Lambda_y\frac{\partial(PH)}{\partial Y}+\sigma\frac{\partial(PH)}{\partial T} \tag{96.27}$$

where

X and Y are coordinates in the slider longitudinal and transverse directions normalized by the slider length and width, respectively
P is the hydrodynamic pressure normalized by the ambient pressure
H is the distance between the ABS and medium surface normalized by the minimum flying height
Q is the molecular slip factor
T is time normalized by the characteristic squeeze period
Λ_x and Λ_y are the bearing numbers in the x and y directions, respectively
σ is the squeeze number

A full derivation and explanation of the Reynolds equation can be found in Ref. [14]. At present, high end hard disk drives feature a flying height on the order of 20–50 nm.

When power is turned off, the slider in the popularly used Winchester-type drives rests on the medium surface. Although the ABS and medium surface look flat and smooth, they really consist of microscopic peaks and valleys. If we model an ABS/medium contact by a flat surface and a sphere tip, the liquid lubricant on the medium surface causes a meniscus force F_m as depicted in Figure 96.14 [15]:

$$F_m=\frac{4\pi R\gamma\cos\theta}{1+y/(h-y)} \tag{96.28}$$

where

R is the radius of the sphere
γ is the surface tension of the lubricant
θ is the contact angle between the lubricant and the surfaces
y is the sphere to flat surface distance
h is the lubricant thickness

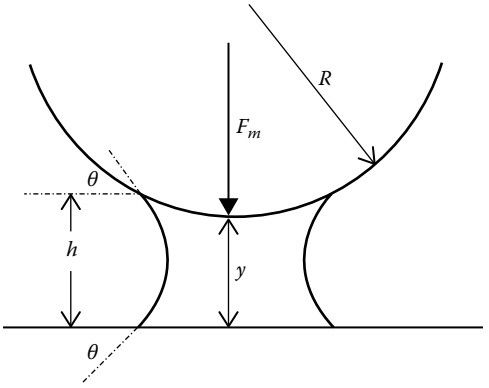

FIGURE 96.14 Formation of meniscus between a sphere tip and a flat surface.

Detailed analysis [16] shows that the static friction F at a head/medium interface is a function of several parameters:

$$F = f(h, R, A, \eta, \gamma, \theta, E', \phi, \sigma, s) \tag{96.29}$$

where

A is the ABS area
η is the peak density
E' is the effective modulus of elasticity
ϕ is the peak height distribution
σ is the rms peak roughness
s is the solid-to-solid shear strength

If friction F is too large, either the drive cannot be started or the head/medium interface is damaged. While friction can be reduced practically by reducing A, γ, and increasing θ, the most effective ways are to control h, σ, η, and ϕ. Too thin a lubricant layer will cause wear, and too thick will induce high friction. This limits h to the range of 1–3 nm. σ is controlled by surface texture. Historically, texture is created by mechanical techniques using either free or fixed abrasives. This leaves a surface with a random feature and is unsuitable for controlling η and ϕ. Recently, people started to use lasers [17]. This technique generates a surface texture with well-defined η and ϕ to improve wear and friction performance. Figure 96.15 shows AFM images of a mechanical and a laser texture.

96.3 Optical Recording

The major obstacle to achieving higher areal density in magnetic recording is the spacing loss term. It is a great engineering challenge to keep heads and media in close proximity while maintaining the head/medium interface reliable and durable. Care must also be taken in handling magnetic media since even minute contamination or scratches can destroy the recorded information. In addition, the servo technique of using magnetic patterns limits the track density to about one order lower than the linear density. Optical recording, on the other hand, promises to address all these concerns.

Optical recording can be categorized into three groups. In the first group, information is stored in the media during manufacturing. Users can reproduce the information, but cannot change or record new information. CD-ROM (compact disk–read only memory) belongs to this group. The second group is WORM (write once read many times). Instead of recording information during manufacturing, it leaves this step to the user. This is usually achieved by creating physical holes or blisters in the media during

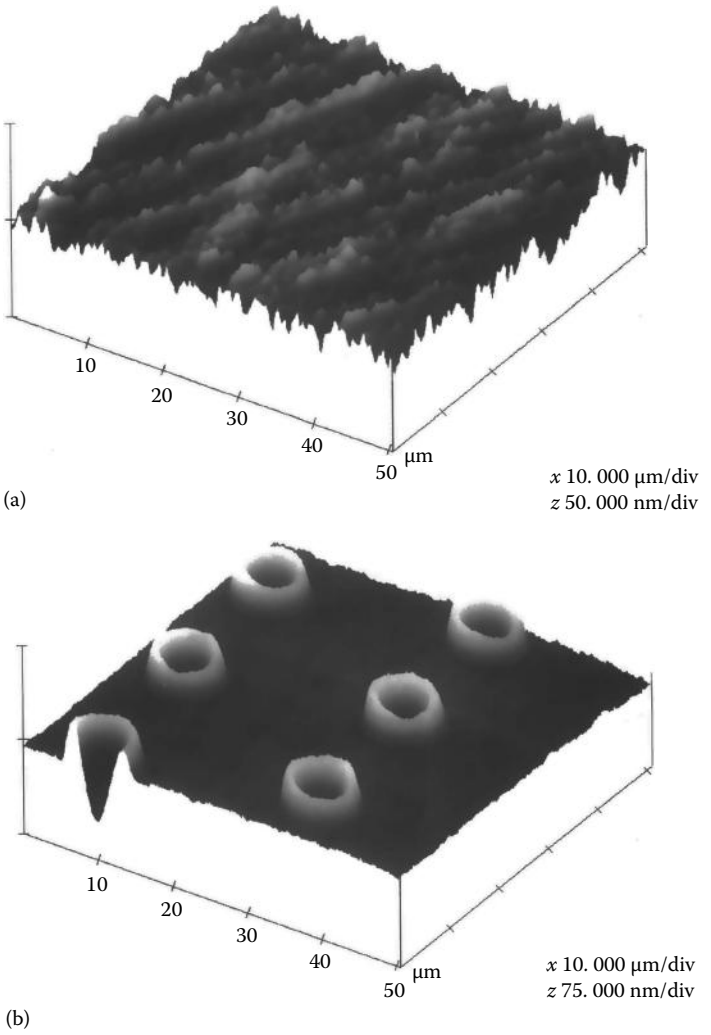

FIGURE 96.15 AFM images of (a) a mechanical texture and (b) a laser texture. (Courtesy of J. Xuan.)

the recording process. Once it is recorded, however, the medium behaves like the first group: no further recording is possible. The third group is similar to magnetic recording. Recording can be performed infinitely on the media by changing phase or magnetization of the media. The most noticeable example in this group is the magneto-optic (MO) technique [18]. Only CD-ROM and the MO recording are described in the following sections.

96.3.1 CD-ROM

Figure 96.16 shows the CD-ROM reproducing principle. Data are pressed as physical pits and lands on one surface of a plastic substrate, usually polycarbonate. A layer of aluminum is deposited on this surface to yield it reflective. Lacquer is then coated to protect the aluminum layer. During the reproducing process, an optical lens is used to focus a laser beam on the reflective pit and land surface. The diameter of the lens is D, the distance between the lens and the substrate is h_3, and the substrate thickness is h_2. The diameter of the laser beam is d_2 when entering the substrate, and becomes d_1 when focused on the reflective surface. The width of the pits is designed smaller than d_1. The reflected light consists of two

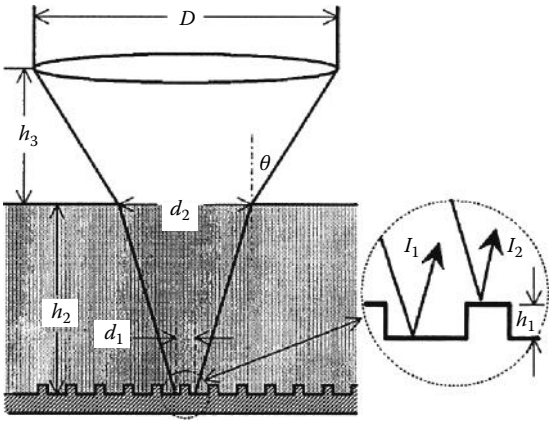

FIGURE 96.16 Schematic representation of the CD-ROM reproducing principle.

portions: I_1 from the land and I_2 from the pit. According to the theory of interference, the intensity of the reflected light is

$$I = I_1 + I_2 + 2\sqrt{I_1 I_2}\cos\frac{4\pi h_1}{\lambda} \tag{96.30}$$

where

λ is the wavelength of the laser

$h_1 \approx \lambda/4$ is the pit height

This leads to

$$I = \begin{cases} I_1 + I_2 - 2\sqrt{I_1 I_2} & \text{if there is a pit } (h_1 = \lambda/4) \\ I_1 + I_2 + 2\sqrt{I_1 I_2} & \text{if there is no pit } (h_1 = 0) \end{cases} \tag{96.31}$$

This change of light intensity is detected and decoded to yield the recorded data. The reflected light is also used for focusing and track following.

The fundamental limit on optical recording density is the focused beam diameter d_1. For a Gaussian (TEM_{00}) laser, this is the diffraction-limited diameter at which the light intensity is reduced to $1/e^2$ of the peak intensity:

$$d_1 \approx \frac{2\lambda}{\pi\theta} \tag{96.32}$$

where θ is the aperture angle. The following values are typical for a CD-ROM system: λ (gallium arsenide laser) = 780 nm, $\theta = 27°$, $h_2 = 1.2$ mm, $D = 5$ mm, $h_3 = 4.2$ mm. This yields $d_1 \approx 1.0$ μm and $d_2 \approx 0.7$ mm, and sets the areal density limit of optical (including MO) recording to about 1 Mbit/mm^2. For most CD-ROM applications, the areal density is smaller than this limit, and a disk with 120 mm diameter holds about 600 Mbyte information. In order to increase areal density, we can either reduce light wavelength or increase numerical aperture. Much of the effort has been to adopt a new light source with short wavelength such as a blue laser. Increasing numerical aperture is more difficult because increasing lens diameter is cost prohibitive and reducing h_2 or h_3 is reliability limited. Note that although the beam

size on the focus plane is on the order of 1 μm (d_1), it is two to three orders greater at the air/substrate interface (d_2). This means that optical recording can tolerate disk surface contamination and scratches much better than magnetic recording. However, the performance of optical recording does not match magnetic recording in general. The data transfer rate of CD-ROM drives is expressed as multiple (×) of 150 kB/s. Even for a 12× CD-ROM drive, the data access time and data transfer rate are still on the order of 100 ms and 1.8 MB/s, respectively, while for a high-performance rigid disk drive these values are less than 10 ms and greater than 30 MB/s, respectively.

96.3.2 Magneto-optic Recording

The primary drawback of a CD-ROM to an end user is its inability to record. This deficiency is remedied by MO recording technology, as depicted in Figure 96.17. A linearly polarized laser beam is focused on a layer of magnetic material, and a coil provides a dc magnetic field on the other side of the medium. This dc magnetic field is too weak to affect the medium magnetization at normal temperature. The recording process utilizes the thermomagnetic property of the medium, and the reproducing process is achieved by using the Kerr effect. During recording, the medium is initially magnetized vertically in one direction, and the dc magnetic field is in the opposite direction. The laser heats up the medium to its curie temperature, at which the coercivity becomes zero. During the cooling process, the dc magnetic field aligns the medium magnetization of the heated region to the magnetic field direction. In the process of reproducing, the same laser is used with a smaller intensity. The medium is heated up to its compensation temperature, at which the coercivity becomes extremely high. Depending on the direction of the magnetization, the polarization of the reflected light is rotated either clockwise or counterclockwise (Kerr rotation). This rotation of polarization is detected and decoded to get the data. The main disadvantage of MO recording is that a separate erasing process is needed to magnetize the medium in one direction before recording. Recently, some technologies have been developed to eliminate this separate erasing process at the cost of complexity.

The medium used in MO recording must have a reasonable low curie temperature (<300°C). The materials having this property are rare earth transition metal alloys, such as $Tb_{23}Fe_{77}$ and $Tb_{21}Co_{79}$. Unfortunately, the properties of these materials deteriorate in an oxygen and moisture environment. To protect them from air and humidity, they are sandwiched between an overlayer and an underlayer, such as SiO, AlN, SiN, and TiO_2. Another issue with the rare earth transition metal alloys is their small Kerr rotation, about 0.3°. To increase this Kerr rotation, multiple layers are used. In the so-called quadrilayer structure (Figure 96.17b), the overlayer is about a half-wavelength thick and the underlayer is about a quarter-wavelength thick [18]. The MO layer is very thin (≈3 nm). Light reflected from the reflector is out of phase with the light reflected from the surface of the MO layer, and is in-phase with the light reflected from the inside of the MO layer. As a result, the effective Kerr rotation is increased several times.

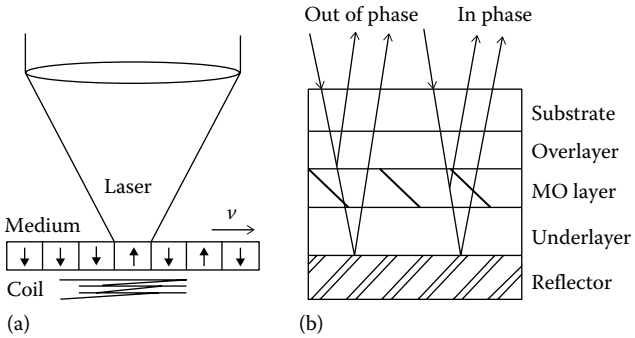

FIGURE 96.17 Schematic illustrations of (a) MO recording/reproducing and (b) quadrilayer medium cross section.

TABLE 96.4 Digital Magnetic and Optical Storage Devices

Description	Manufacturers	Approximate Price, $
Thin-film head for hard disk drive	AMC, Read-Rite, SAE	6.00–9.00
MR head for hard disk drive	AMC, Read-Rite, SAE, Seagate	8.00–12.00
Thin-film hard disk	Akashic, HMT, Komag, MCC, Stormedia	7.00–10.00
Hard disk drive	IBM, Maxtor, Quantum, Samsung, Seagate, WD	0.02–0.20/Mbytes
Floppy drive	Panasonic, Sony	20.00–40.00
Floppy disk	3M, Fuji, Memorex, Sony	0.15–0.50
Removable rigid disk drive	Iomega, Syquest	100.00–400.00
Removable rigid disk	Iomega, Maxell, Sony	5.00–20.00/100 Mbytes
Tape drive	Exabyte, HP, Seagate	100.00–400.00
Backup tape	3M, Sony, Verbatim	4.00–25.00/Gbytes
8 × CD-ROM drive	Goldstar, Panasonic	100.00–200.00
Recordable optical drive	JVC, Philips	300.00–500.00
Recordable optical disk	3M, Maxell, Memorex	3.00–15.00/650 Mbytes

Compared with magnetic recording, optical recording has the intrinsic advantages of superior reliability and portability. However, its performance is inferior due to slower data access time and transfer rate. Another advantage of optical recording, higher areal density, has been disappearing or even reversing to magnetic recording. Both magnetic and optical recording will be continuously improved in the near future, probably toward different applications. Currently, there are some emerging techniques that try to combine the magnetic and optical recording techniques [19], such as amorphous rare earth materials. Table 96.4 is a short list of representative magnetic and optical devices for digital recording.

Liquid Crystal Displays

Kalluri R. Sarma
Honeywell, Inc.

97.1 Introduction

Liquid crystals (LC) are an important class of materials with applications ranging from display devices, television screens, optoelectronic devices, sensors, and biological and structural materials. The focus of this chapter will be on LCs for display applications. In general, most substances have a single melting point where a solid possessing a positional and orientational order changes upon melting to an isotropic liquid that has neither positional nor orientational order. However, some materials when melted from the solid state change into a cloudy liquid with orientational order at one temperature, and upon further heating change into an isotropic liquid that has no order, as shown in Figure 97.1. Thus, an LC is a mesophase existing between the melting temperatures, T_m, of a crystalline phase, and clearing point T_c, of the liquid phase, i.e., below T_m, the material has a crystalline phase, above T_c, it has a liquid (isotropic) phase, and between T_m and T_c, it has an LC phase. This type of LC in which the mesophase is defined by the temperature (between T_m and T_c) is called a *thermotropic* LC. When the mesophase is defined by a solvent concentration, it is called a *lyotropic* LC. Thermotropic LCs are used for display applications. The orientational order in LC materials results in important physical properties, such as birefringence, that make these materials useful for display devices. Because LCs have the attributes of low drive voltage, low power consumption, thin form factor (flat panel displays), lightweight, full color, gray scale with a wide dynamic range, full motion video, superior image quality, and high reliability, LC displays (LCDs) are the preferred approach for battery-powered (portable) applications ranging from wristwatch displays and handheld TVs to laptop computer displays. They are also replacing cathode ray tubes (CRTs) in select applications such as avionic displays because of their high brightness and readability in sunlight.

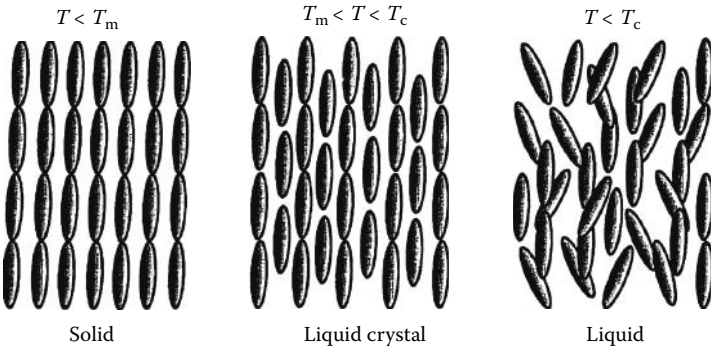

FIGURE 97.1 Illustration of a solid, an LC, and a liquid. A solid has an orientational as well as a positional order for the molecules. An LC has an orientational order only. A liquid phase is isotropic with neither positional nor orientational order.

LCDs are also being used in projection display devices for head-mounted display (HMD) and for large-screen display applications. They are widely accepted and used in computer monitors, televisions, instrument panels, vehicle dashboards, aircraft cockpits, clocks, watches, calculators, gaming devices, telephones, consumer goods, Global Positioning Systems (GPS), and many more applications. The following will discuss the various types of LC materials, their properties, LCD materials and fabrication processes, various LCD modes, and display addressing methods. There are many good general references, for example, Refs. [1–7], on LCs and LCDs. At the time of this writing, LCD technology is advancing very rapidly with respect to technology development for LCD products with improved viewing angles, improved image quality, lower power consumption, and larger display sizes. The purpose of this chapter, however, is to present the basic LCD principles and technologies, as opposed to reviewing the current state of the art.

97.2 Types of LC Materials

Most of the LC materials are organic compounds which consist of rod-shaped or disk-shaped molecules. For display applications, LC materials with rod-shaped molecules are the most commonly used. The LC materials are broadly classified into three types (phases)—smectic, nematic, and cholesteric—according to their molecular order, as shown in Figure 97.2. In a smectic LC, the rod-shaped molecules are arranged in layers with molecules parallel to each other. There are many different smectic phases, but smectic A and smectic C are the most common. In the smectic A LC the molecular axis (director) is perpendicular to the layers as shown in Figure 97.2a, and in smectic C it is tilted at an angle from the layer normal as shown in Figure 97.2b. Also, in the nematic LC, the rod-shaped molecules are parallel to each other, but the individual molecules move relatively easily in the direction along their axis

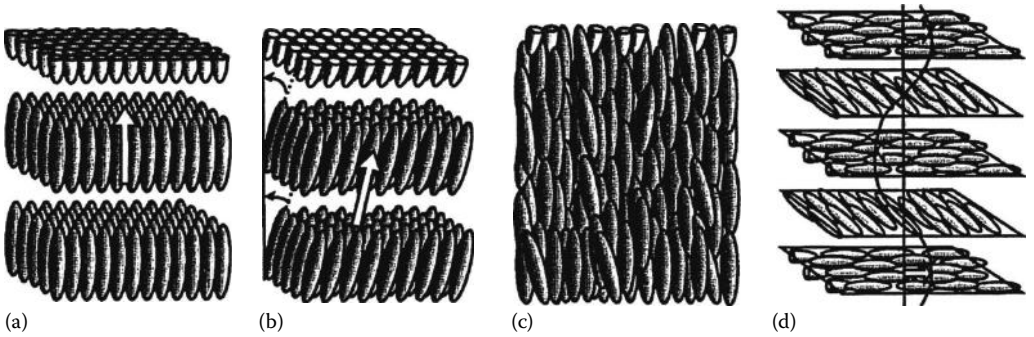

FIGURE 97.2 Molecular orientation in (a) smectic A, (b) smectic C, (c) nematic, and (d) cholesteric LC phases.

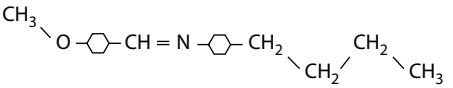
without a layer structure, as shown in Figure 97.2c. In the cholesteric LC, the molecules are arranged in a layered fashion as in smectic LC, but the molecular axis is in the plane of each layer as shown in Figure 97.2d. In addition, the cholesteric LC shows a helical structure in which the director ***n*** changes from layer to layer. The same LC material may have different LC phases at different temperatures. For example, the LC material may have a smectic C phase at a lower temperature, and as the temperature increases it may change to a smectic A phase and then to a nematic phase, before changing to an isotropic liquid phase at T_c.

The nematic LC is the basis for most widely used active matrix (AM)–addressed twisted nematic (TN) LCDs, and passive matrix (PM)–addressed supertwisted nematic (STN) LCDs. An example of a smectic C LCD is a PM-addressed ferroelectric LCD [8]. An example of a cholesteric display is a PM-addressed stabilized cholesteric texture (SCT) display with bistability [9]. A classic example of a nematic LC material is *p*-azoxyanisole (PAA) with a nematic phase in the range of 117 °C–136 °C.

In PAA, the two benzene rings are nearly coplanar and the rigid rod is about 20 Å long and 5 Å wide. Another historical example of a nematic LC is *N*-(*p*-methoxybenzylidene-*p*-butylaniline) (MBBA) with a nematic phase in the range of 22 °C–47 °C.



MBBA has a central group that connects the two ringlike cores firmly and serves to maintain the linearity of the entire LC molecule. The terminal groups and conjugated bonds in the core are largely responsible for the dielectric, optical, and other anisotropic properties of the material. Azoxy and Schiff's base compounds were among the materials used earliest in LCDs. Because of environmental stability problems, they were replaced by biphenyl materials. More recently, phenylcyclohexane, bicyclohexane, and estercyclohexane compounds are developed to satisfy the requirements of broad temperature operation and enhanced electro-optical characteristics. The LC materials used in current LCDs are highly developed mixtures of various compounds tailored to meet the requirements of environmental stability, wide operating temperature range, proper response to the applied electric field, high electrical resistivity for matrix addressing, and fast response time.

The degree of order in the LC is an important parameter and is defined by the *order parameter*, *S*, given by

$$S = \frac{1}{2}\langle 3\cos^2\theta - 1\rangle \tag{97.1}$$

where

θ is the angle between the molecular axis and the predominant molecular orientation ***n***

$\langle\rangle$ represents averaging over the whole space

The predominant molecular orientation, which is known as the LC *director* ***n***, is defined as the average alignment direction of the long molecular axis. For a perfect orientational order, i.e., when all the molecules align parallel to the director, as in a perfect crystal, $\theta = 0$ and thus $S = 1$. For no orientational order, i.e., for a completely random molecular orientation, as in an isotropic liquid, $S = 0$. In a typical nematic LC S is in the range of 0.3–0.7, and in a typical smectic LC it is in the range of 0.7–0.8, with higher values at lower temperatures. Figure 97.3 shows the temperature dependence of S for the LC material PAA [10]

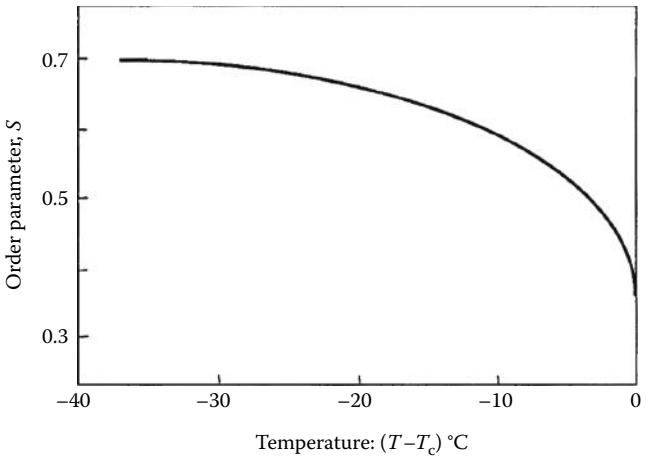


FIGURE 97.3 Temperature dependence of the order parameter S of the nematic LC P = azoxy anisole (PPA) [10]. S decreases with increasing temperature T, and rapidly approaches 0 near the clearing temperature, T_c.

as an example. The order parameter decreases rapidly to a value of around 0.3, close to the clearing point T_c, and becomes zero in the isotropic state. The exact dependence of S on temperature T depends on the type of molecules considered. However, the following analytical expression derived from theory has been shown to be useful [11]:

$$S = \left(1 - y \cdot \frac{T}{T_c}\right)^{\beta} \tag{97.2}$$

where

T_c corresponds to nematic-isotropic transition
y is of the order of 0.98
β is an exponent in the range of 0.13–0.18 depending on the material in question

97.3 Physical Properties of LCs

Because of ordered structure with the molecules aligned with their long axis parallel to each other, LC molecules exhibit anisotropic properties. That is, various physical properties, such as dielectric constant ε, refractive index n, magnetic susceptibility χ, conductivity σ, and viscosity η, have different values in the direction parallel (||) and perpendicular ($\perp$) to the molecular axis. The anisotropic physical properties, in conjunction with the ease of controlling the initial orientation (boundary condition) by surface alignment and the ease of reorienting the molecular axis by applying a voltage, is the basis for application of LCs for displays. The following will discuss the anisotropy of the dielectric constant and refractive index, elastic constants, and electro-optic characteristics which are important in the use of LCs for displays.

97.3.1 Dielectric Anisotropy

LC molecules exhibit dielectric anisotropy because of their permanent and induced dipoles. The dielectric anisotropy, $\Delta\varepsilon$, is expressed as

$$\Delta\varepsilon = \varepsilon_{\parallel} - \varepsilon_{\perp} \tag{97.3}$$

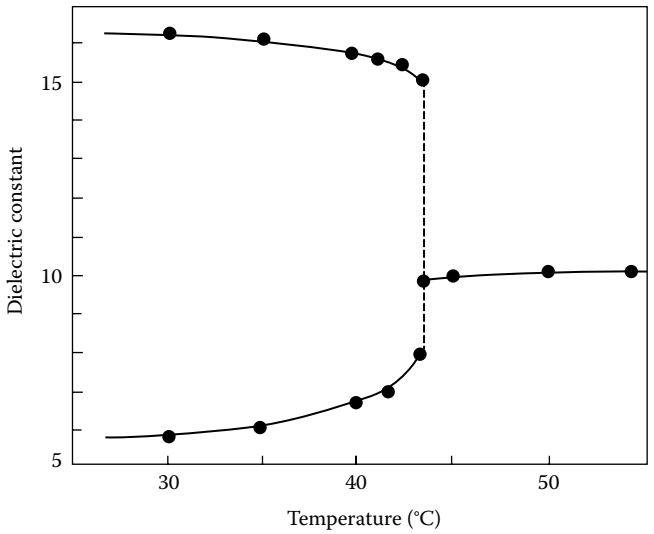

FIGURE 97.4 Temperature dependence of dielectric constant of the nematic LC cyanobiphenyl at a frequency of 100 kHz [13] exhibiting positive dielectric anisotropy ($\varepsilon_{||} > \varepsilon_{\perp}$). $\varepsilon_{||}$ decreases with temperature, whereas $\varepsilon_{\perp}$ increases with temperature until both are equal at the clearing temperature corresponding to the isotropic liquid.

where $\varepsilon_{||}$ and $\varepsilon_{\perp}$ are the dielectric constants measured parallel and perpendicular to the LC director. Materials that exhibit positive dielectric anisotropy ($\Delta\varepsilon > 0$) are referred to as *p*-type materials and the materials that exhibit negative dielectric anisotropy ($\Delta\varepsilon < 0$) are referred to as *n*-type materials. The *p*-type LC materials tend to align themselves with their molecular axis parallel to the applied electric field, whereas *n*-type materials align themselves with their molecular axis perpendicular to the applied field. Generally, the dielectric constant $\varepsilon_{||}$ decreases with increasing frequency [12] due to the relaxation phenomenon. However, $\varepsilon_{\perp}$ is independent of frequency over a large range of frequencies. At the crossover frequency, f_c, where $\varepsilon_{||} = \varepsilon_{\perp}$, the LC material becomes isotropic. Depending on the material, this frequency, f_c, falls in the range of 100 kHz to >1 MHz. The dielectric constants $\varepsilon_{||}$ and $\varepsilon_{\perp}$ also change as a function of temperature [13], as shown in Figure 97.4 for the nematic LC cyanobiphenyl. The two dielectric constants rapidly converge as the temperature approaches T_c, where $\varepsilon_{||} = \varepsilon_{\perp} = \varepsilon_{\text{isotropic}}$.

97.3.2 Refractive Index Anisotropy

An LC is birefringent with anisotropic refractive indices. It has two principal refractive indices, n_o and n_e, as shown in Figure 97.5. For the ordinary refractive index n_o, the electric field vector of the light beam oscillates perpendicular to the optic axis, and for the extraordinary refractive index n_e, the electric field vector oscillates parallel to the optic axis. In the nematic and smectic LCs, the direction of the LC director $\boldsymbol{n}$ is the optic axis of the uniaxial crystal and therefore the refractive indices for light rays with oscillations in the directions parallel and perpendicular to the director are $n_{||}$ and $n_{\perp}$, respectively, i.e., $n_o = n_{\perp}$, $n_e = n_{||}$, and the optical anisotropy or birefringence, Δn, is given by

$$\Delta n = n_{||} - n_{\perp} = n_e - n_o \tag{97.4}$$

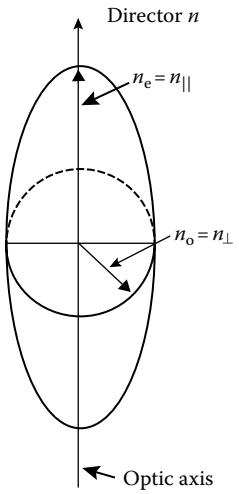

FIGURE 97.5 Refractive index anisotropy of uniaxial LC.

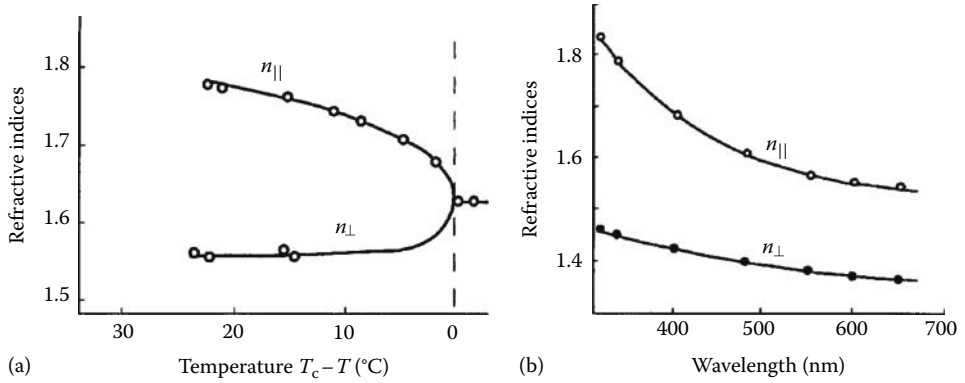

FIGURE 97.6 (a) Temperature dependence of the refractive indices $n_{||}$ and $n_\perp$ for a nematic LC MBBA at $\lambda = 546$ nm and (b) wavelength dependence of refractive indices of the nematic LC 4-butoxyphenyl ester of 4′-hexyloxybenzoic acid at 80°C.

Figure 97.6a and b shows the temperature dependence [2] and wavelength dependence [2] of the refractive indices of typical LC materials. The dependence of refractive index on wavelength λ is generally expressed by the so-called Cauchy equation:

$$n_{o,e} = n_\infty + \frac{\alpha_{o,e}}{\lambda^2} \tag{97.5}$$

where

n_∞ is the refractive index extrapolated to infinite wavelength
α is a material-specific coefficient

97.3.3 Elastic Constants

In uniaxial LCs, the preferred or equilibrium orientation of the LC molecule is given by the director ***n***, which may be imposed by the surface treatments at the boundary conditions or by an external field.

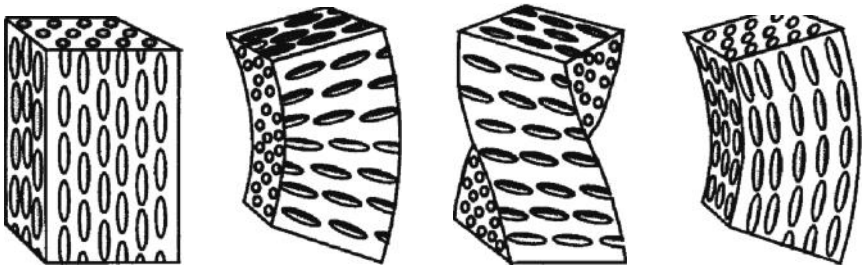

FIGURE 97.7 Deformation of nematic LC molecules from equilibrium configuration is shown in (a). Three types of deformations—(b) splay, (c) twist, and (d) bend can describe all possible types of deformations.

When the LC is perturbed from an equilibrium condition by application or removal of an external field, the elastic and electrical forces determine the static deformation pattern of the LC. The transition of the director from one direction to the other induces curvature strain in the medium. Frank [14] showed that an arbitrary deformation state can be envisaged as the combination of three basic operations: *splay*, *twist*, and *bend*, denoted by the elastic constants K_{11}, K_{22}, and K_{33} following the notation of the Oseen–Frank theory. Figure 97.7 illustrates the *splay*, *twist*, and *bend* deformations. The elastic part of the internal free energy, F, of a perturbed LC is given by the equation

$$F = \frac{1}{2}[K_{11}(\nabla \cdot n)^2 + K_{22}(n \cdot \nabla \times n)^2 + K_{33}(n \times \nabla \times n)^2] \tag{97.6}$$

The free energy density is thus a quadratic function of the curvature strains with the elastic constants appearing as constants of proportionality. The elastic constants K_{11}, K_{22}, and K_{33} are temperature-dependent, and decrease with increase in temperature. The magnitudes of the elastic constants, K_{ii}, can be approximated [15] by

$$K_{ii}\alpha S^2 \tag{97.7}$$

97.3.4 Electro-optic Characteristics

When an electric field is applied to an LC with an initial molecular (director) orientation, it will change to a new molecular orientation due to the dielectric anisotropy ($\Delta\varepsilon = \varepsilon_{\|} - \varepsilon_{\perp}$) of the LC. This change in molecular orientation is accompanied by a change in the optical transmission/reflection characteristics of the LC which forms the basis for LCDs. This phenomenon of an electrically driven optical modulation is known as the electro-optic effect of the LC. When an electric field E is applied to an LC, it produces an electric energy, f_e, given by

$$f_e = -\frac{1}{2}\varepsilon_{\perp}E^2 - \frac{1}{2}\Delta\varepsilon(n \cdot E)^2 \tag{97.8}$$

The initial molecular orientation (boundary condition achieved by surface alignment) of the LC molecules (director $\boldsymbol{n}$) is either parallel (for $\Delta\varepsilon > 0$) or perpendicular (for $\Delta\varepsilon < 0$) to the plane of the two parallel electrodes of the display. When a field is applied across the parallel electrodes with the LC material in between, the director $\boldsymbol{n}$ orients parallel to the electric field E in *+ve* $\Delta\varepsilon$ materials, and it orients perpendicular to the field in *−ve* $\Delta\varepsilon$ materials. The total free energy, F, of the LC when the initial undeformed

molecular orientation undergoes deformation due to the applied field is given by the sum of the electric energy f_e and the elastic energy. This transition from an undeformed state, known as *Freedericksz transition*, occurs as the field is increased to a critical field E_c. The Freedericksz transition is simply a transition from a uniform director configuration to a deformed director configuration, i.e., at any point in the LC, the order of the molecules relative to one another remains the same. The threshold electric field, E_c, is calculated by a free energy minimization technique [3], and it is given by

$$E_c = \left(\frac{\pi}{d}\right)\left(\frac{K_{ii}}{|\Delta\varepsilon|}\right)^{1/2} \tag{97.9}$$

Thus the threshold voltage V_{th} of the LC electro-optic effect is given by

$$V_{th} = E_c \cdot d = \pi\left(\frac{K_{ii}}{|\Delta\varepsilon|}\right)^{1/2} \tag{97.10}$$

In Equations 97.9 and 97.10, d the thickness of the LC and K_{ii} is the appropriate elastic constant. When the field is perpendicular to the initially homogeneous orientation of the director, $K_{ii} = K_{11}$ or K_{22}. When the field is parallel to the initially homogeneous orientation, $K_{ii} = K_{33}$. In the case of a twisted orientation, $K_{ii} = K_{11} + (K_{33} - 2K_{22})/4$.

97.4 LCD Materials and Fabrication Processes

There are several types of LCDs utilizing different LC materials and LCD modes which are discussed in the next section. However, the general display assembly processes and materials are very similar for all these LCD modes. Figure 97.8a shows the plan view and Figure 97.8b shows the cross-sectional view of a PM-addressed LCD. The display fabrication can be broadly divided into three parts: (1) lower and upper glass fabrication processes, (2) cell assembly processes, and (3) polarizer and driver attachment and module assembly processes as illustrated in Figure 97.9. The following will describe the various display materials and the assembly processes.

97.4.1 Glass Substrate

The quality of the glass substrate is important with regard to its chemical compatibility with the LC materials, surface flatness, defects, and dimensional stability under processing temperatures associated with various display fabrication steps. With a typical LCD cell gap in the range of 5–10 μm, the importance of the glass flatness and surface quality is clear. Glass substrate defects such as voids, scratches, streaks, and attached particles can cause electrode defects and hinder uniform LC cell spacing. Therefore, depending on the type of display, glass substrates are sometimes polished to achieve the required surface quality. Typical display glass materials include borosilicate (e.g., Corning 7059) and aluminosilicate glasses (e.g., Corning 1737), with a thickness of 0.7 or 1.1 mm.

97.4.2 Color Filters

In full-color LCDs, color most often is generated by use of red, green, and blue (R, G, B) color filters fabricated at each pixel, as shown in Figure 97.8b, using a white backlight system. The color filter requirements include proper spectral transmission characteristics and chemical, thermal, and dimensional stability. The display color gamut is a function of the spectral characteristics of the backlight used and the color filter transmission characteristics. By a suitable choice of these parameters, an LCD can achieve a color gamut comparable to that of a high-quality CRT. However, trade-offs are sometimes

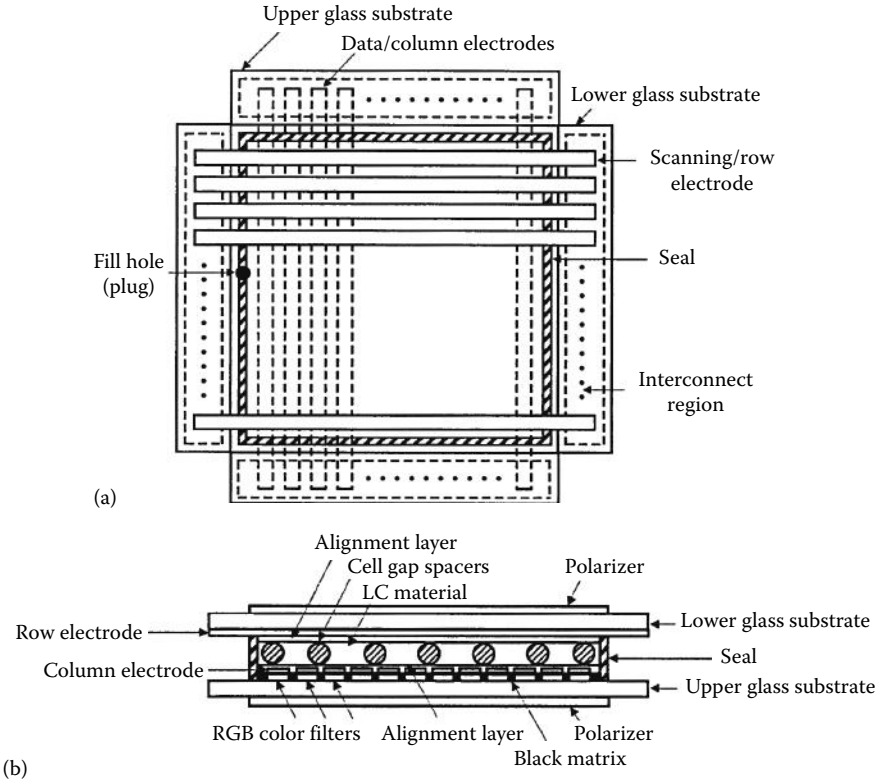

FIGURE 97.8 Plan (a) and cross-sectional view (b) of a passive matrix–addressed LCD.

made between color purity and transmission (brightness) characteristics of the LCD. Typical color filter thickness is about 2 μm. Color filter materials include dye- and pigment-dispersed polyimides and photoresists. The color filter materials are applied on the display glass by various processes, such as spin coating, printing, electrodeposition, and photolithography. First, color filter material of the first color is applied and photolithographically patterned. Then, the color filter material for the second color is processed, and then the third. A black matrix material is also applied and patterned between the color filters to block the light transmission from the interpixel regions. In some cases, a passivation layer such as low-temperature SiO_2 dielectric is deposited on the color filters to act as a barrier for impurities and to achieve a smooth surface for the subsequent transparent electrode deposition.

97.4.3 Transparent Electrodes

Most often, indium tin oxide (ITO) with a typical concentration of 90% In_2O_3 and 10% SnO_2 is used as the transparent conducting electrode material. The typical transmission of ITO is about 90%. It is generally deposited by e-beam evaporation or sputtering in an oxygen-containing atmosphere. The film thickness is typically 50–300 nm depending on the required sheet resistance and transmission. Typical resistivity is in the range of 2×10^{-4} Ω cm. Light transmission through ITO is not linearly proportional to the film thickness because of light interference.

97.4.4 Alignment Materials and Techniques

After the transparent electrodes are patterned, an LC alignment coating is applied. Depending on the display mode of interest, either a homogeneous (parallel), tilted, or a homeotropic (vertical) alignment is

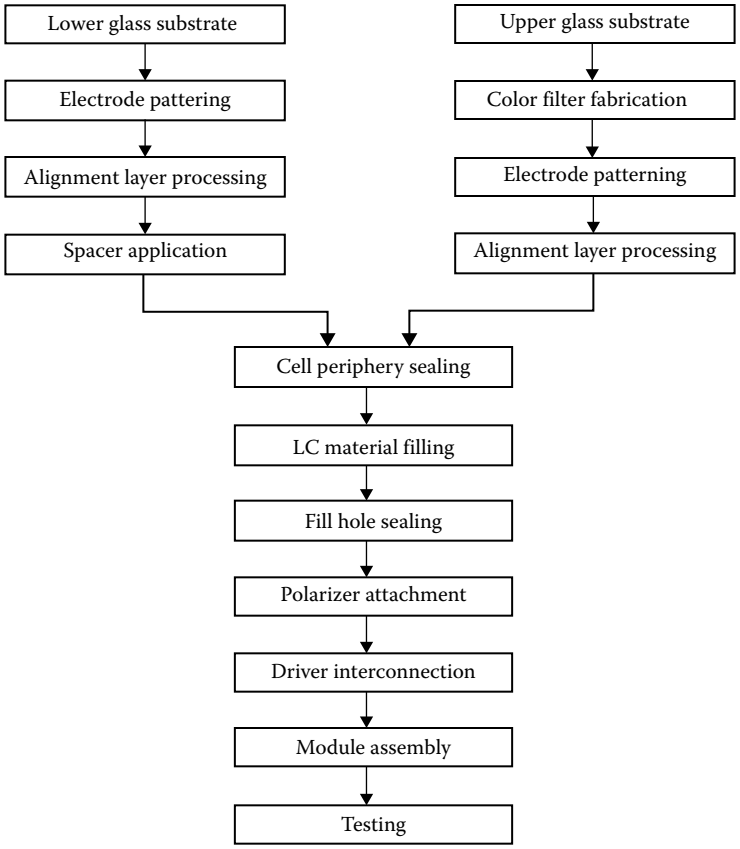

FIGURE 97.9 LCD assembly flowchart.

achieved using an appropriate alignment material and process. The most commonly used TN LCD requires a tilted alignment to eliminate reverse tilt disclinations. Inorganic films such as an obliquely evaporated SiO, as well as organic materials such as polyimide, can be used as alignment materials. Polyimide is most commonly used as an alignment layer. It is spin-coated or printed to achieve a layer thickness of about 50 nm, and cured around 150 °C–200 °C. It is then buffed (rubbed) using a roller covered with cotton or a synthetic fabric. For TN LCD, the alignment process is selected to achieve a pretilt angle of around 2°–5°.

97.4.5 Cell Spacing and Sealing

The cell assembly process starts after the alignment layer treatment of the two substrates by rubbing. To control the LC cell spacing (thickness) accurately, spacing materials are applied in the active area of the display as well as in the peripheral seal area, where the two glass substrates are sealed. Typical spacing materials include glass or plastic fibers (cylinders) or spheres (balls), with a tightly controlled size (diameter) distribution. A sealing adhesive material such as an epoxy is then applied at the seal area with an opening (fill hole) left for LC material injection after the sealing process. The seal is typically 1–3 mm wide and is a few millimeters from the active display area. The requirement for the seal material is that it must not chemically react with (contaminate) the LC material and must be a barrier against moisture and contamination from outside. After the spacers and seal materials are applied on the first (active) substrate, it is precisely aligned to the second (color filter) substrate, and the seal is cured either by heating it to a higher temperature, typically 100 °C–150 °C, or by ultraviolet exposure depending on the type of epoxy seal material used.

97.4.6 LC Material Filling

After the empty cell is fabricated, it is filled with the LC material. Because the cell thickness (spacing) is small (~5–10 μm), it is filled using special techniques. The most popular filling method is by evacuating the cell in a vacuum chamber, dipping the fill hole into a vessel containing the LC material, and increasing the pressure in the chamber. As the chamber pressure is raised, the cell gets filled by capillary action. After the cell is completely filled, the fill hole is capped by using an epoxy adhesive that is chemically compatible with the LC material.

97.4.7 External Components

The external components of an LCD include polarizers, reflectors, display drivers, and a backlight assembly. A reflective LCD uses a reflector at the back of the display, works by modulating the ambient light, and does not require backlighting. In the most commonly used transmissive mode TN LCDs, a polarizer is attached on the front as well as back surfaces of the LCD after the cell assembly is complete. Also, in the most commonly used NW mode TN LCD, the polarizers are attached with their polarization axis crossed and along the rubbing directions of the alignment layers. The polarizer is a three-layer composite film with a stretched iodine-doped polyvinyl alcohol (PVA) polarizing film in the center, and two outer films of triacetyl cellulose (TAC) for protecting the PVA film from the ambient (moisture, temperature, and harsh environment) conditions. A typical transmission range of a polarizer is 41%–45%, with polarization efficiency in the range of 99.9%–99.99%.

The display row and column IC drivers are attached to the row and column bond pads of the display either by tape-automated bonding (TAB) using an ACA (anisotropic conductive adhesive), or chip on glass (COG) approaches. For backlighting transmissive LCDs, a fluorescent lamp is generally used. The R, G, B emission spectrum of the backlight and transmission spectrum of the R, G, B color filters are tuned together to achieve the desired color coordinates for the primary colors. Also, a diffuser is used to achieve uniform backlighting of the display. The backlight system may also use brightness enhancement films to tailor the light intensity distribution in the viewing cone. In addition to the earlier components, LCDs for specialized applications requiring enhanced performance may use a cover glass with EMI and antireflection coatings at the front, and a heater glass at the back side (between the backlight and the LCD) that facilitates low-temperature operation.

97.5 LCD Modes

LCDs based on many different modes of operation have been developed. Historically, the phase change (PC) effect was discovered first in 1968 by Wysocki et al. [16]. The same year, dynamic scattering (DS) mode [17] and guest–host (GH) mode [18] were announced by Heilmeier et al. Then in 1971, the TN mode [19] was reported by Schadt and Helfrich and electrically controlled birefringence (ECB) was reported by Schiekel and Fahrenschon [20] and Hareng et al. [21]. The physical effects and the various display modes based on these effects include

Current effects	• DS effect
Electric field effects	• TN effect
	• STN effect
	• ECB
	• GH effect
	• PC effect
Thermal effects	• Smectic effect

The DS effect is based on the anisotropy of the conductivity. Because of higher voltage operation and higher power consumption, the DS mode is not currently used. The TN and STN effects are most widely used among all the LCDs. The following sections will discuss various display modes.

97.5.1 TN Effect

Figure 97.10 shows a schematic of a display based on the TN effect. It consists of nematic LC material with a positive dielectric anisotropy ($\Delta\varepsilon > 0$) with a layer thickness of about 5 μm, sandwiched between two transparent substrates with transparent electrodes. The surfaces of the transparent electrodes are coated with a polyimide alignment layer and rubbed to orient LC molecules at the substrate surfaces along the rubbing direction with a small (~3°) pretilt angle. The molecules on the two substrates are oriented 90° from each other as shown in Figure 97.10a, i.e., the LC molecular axis rotates (twists) continuously through 90° from the first substrate to the second substrate. The TN display can be fabricated to operate in a normally black (NB) or normally white (NW) mode based on how the polarizers are attached to the outer surface of the two glass substrates. Figure 97.10a and b shows the on- and off-state of a NW mode TN LCD with crossed (orthogonal) polarizers attached with their polarization direction parallel to the LC director orientation on that substrate. Since the pitch of the twist is sufficiently large compared with the wavelength of the visible light, the direction of polarization of linearly polarized

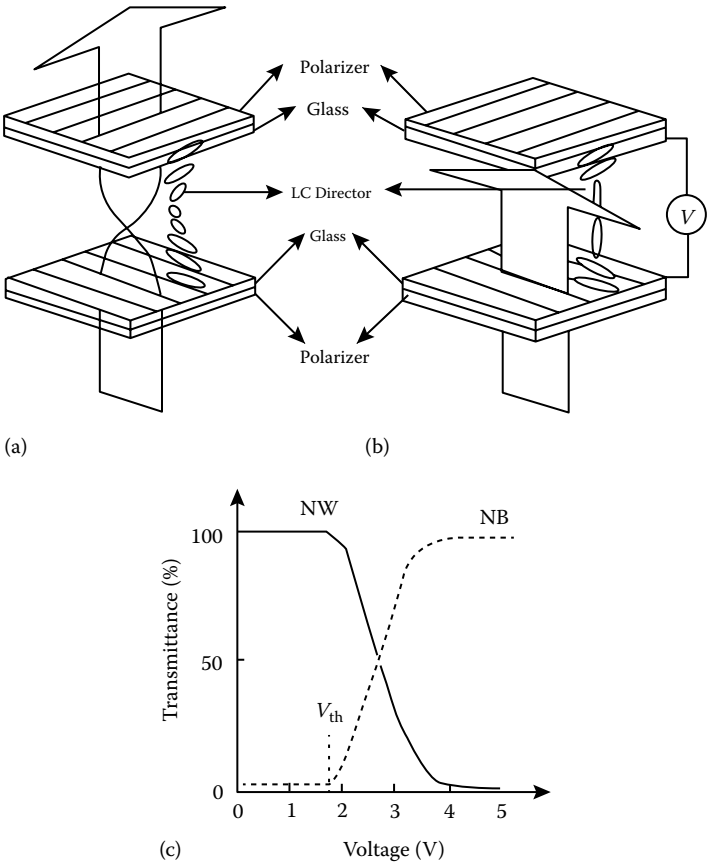

FIGURE 97.10 Illustration of TN effect: (a) in the off-state, the incident polarized light is transmitted through the entrance polarizer, the 90° TN LC, and the crossed exit polarizer; (b) in the on-state; (c) the solid line shows the voltage-transmission behavior for the NW configuration, shown in (a) and (b), with crossed polarizers. The dashed line is for an NB configuration with parallel polarizers.

light incident normally on one surface of the display rotates through 90° by the twist of the LC molecules as it propagates through the cell and exits through the second polarizer. When a voltage is applied to the TN cell, the molecules align parallel to the direction of the field as shown in Figure 97.10b, and the 90° optical rotatory power is eliminated. Thus, the incident polarized light from the first polarizer is not rotated as it goes through the LC cell and gets blocked by the crossed exit polarizer.

Figure 97.10c shows the voltage-transmission characteristics of a TN cell for NB and NW modes of operation. For an NW mode, when a sufficiently high voltage is applied, LC molecules are aligned homeotropically (parallel to the field) and there is no rotation of the electrical field vector of the polarized light. This results in complete suppression of transmission regardless of the wavelength of light. The transmission in the on-state is, however, wavelength-dependent, but this does not have a significant effect on the contrast ratio, although it can influence the color balance. In the NB mode of operation, the transmission is suppressed to zero [22] for the off-state only for a monochromatic light of wavelength, $\lambda = 2d\Delta n/\sqrt{3}$. Therefore, in a practical display using a broadband backlight, there is a small amount of light leakage which lowers the display contrast ratio. In a color display, the cell gaps for the R, G, B pixels can be optimized to eliminate the light leakage and improve contrast [22].

The threshold voltage of a TN mode LCD is given by

$$V_{\text{th}} = \pi \sqrt{\left\{ \frac{[K_{11} + (K_{33} - 2K_{22})/4]}{\varepsilon_0 \cdot \Delta\varepsilon} \right\}} \tag{97.11}$$

V_{th} depends on the dielectric anisotropy and elastic constants, and is generally in the range of 2–3 V, with the maximum operating voltage being in the range of 5–8 V. This low-voltage driving, coupled with low current due to high resistivity of LC materials, contributes to the very low power consumption (~1 μW/cm^2) of LCDs. The response times measured by the rise and decay times of the display τ_r, τ_f are given by [23]

$$\tau_{\text{d}} = \gamma \cdot \frac{d^2}{\Delta\varepsilon \left(V^2 - V_{\text{th}}^2 \right)} \tag{97.12}$$

$$\tau_{\text{d}} = \gamma \cdot \frac{d^2}{\left(\Delta\varepsilon \cdot V_{\text{th}}^2 \right)} \tag{97.13}$$

where γ is the rotational viscosity coefficient. The earlier equations show that rise time can be improved by using a thinner cell gap d, a higher $\Delta\varepsilon$, and a higher drive voltage V. Similarly, the decay time can be improved by reducing the cell gap. The turn-on time τ_r is usually shorter than the turn-off time τ_d. At room temperature, these times are of the order of 10 ms, which is adequate for many common applications such as computer and TV displays. In a TN LCD, gray scale is generated by varying the voltage using the electro-optic curve shown in Figure 97.10c. The shallow slope of the electro-optic curve works well for the gray-scale generation in AM-addressed displays (see next section). However, in the case of PM addressing, the shallow slope greatly limits the multiplexibility (number of addressable rows) of the display, which led to the development of the STN effect.

97.5.2 STN Effect

In a PM-addressed display, the addressability or the maximum number of addressable rows N is given by the Alt and Pleshko [24] limit:

$$\frac{V_{\text{on}}}{V_{\text{off}}} = \sqrt{\frac{(N^{1/2} + 1)}{(N^{1/2} - 1)}} \tag{97.14}$$

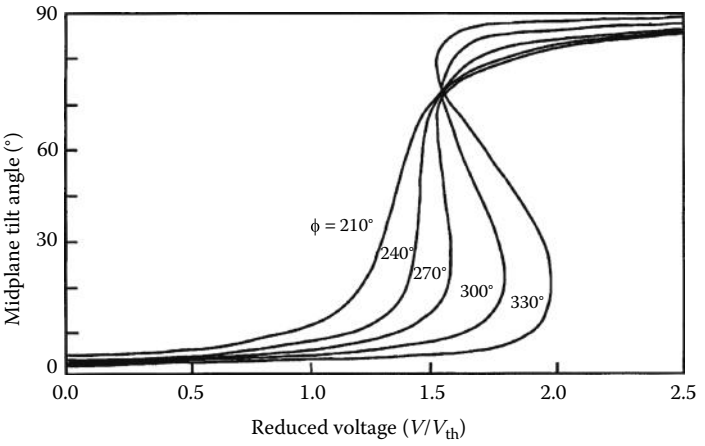

FIGURE 97.11 Calculated curves of tilt angle of local directors in the midplane of an STN cell as a function of reduced voltage V/V_{th}, where V_{th} is the Freedericksz threshold voltage of a nontwisted layer with a zero pretilt angle. The steepness of the curves increases as the twist angle, Φ, is increased, and bistability is achieved when $\Phi > 240°$.

where V_{on} and V_{off} are the rms voltages at the select and nonselect pixels. Equation 97.14 shows that as N increases V_{off} approaches V_{on} and the contrast ratio becomes 1, which makes the display not viewable. For $N = 100$, $V_{on} = 1.11\ V_{off}$, i.e., select voltage is only 11% higher than the nonselect voltage. This will result in a very low contrast ratio when using a TN mode with a shallow turn-on curve (Figure 97.10c). STN displays have been developed [25,26] to achieve a steep electro-optic curve, so that large numbers of rows can be multiplexed. The STN effect uses a twist angle of 180° to about 270° with a relatively high pretilt angle alignment. Figure 97.11 [25] illustrates the STN effect. The figure shows the voltage dependence of the midplane director tilt of a chiral nematic layer with a pretilt of 28° at both substrates. Bistability is achieved when a twist angle, φ, greater than 245° is used. In highly multiplexed displays, twist angles in the range of 240°–275° and tilt angles in the range of 5°–30° are generally used. High pretilts ensure that competing distortional structure which has 180° less twist is eliminated. For a 270° left-handed twist, optimum results are achieved when the front polarizer is oriented with its polarization axis at 30° with the LC director and the rear polarizer is oriented at an angle of 60° with the projection of the director at the rear substrate. Due to interference of the optical normal modes propagating in the LC layer, the display has a yellow birefringence color in the nonselect state (yellow mode). Rotation of one of the polarizers by 90° results in a complementary image with a bright colorless state, and a blue nonselect state (blue mode). White-mode STN displays are made using retardation films. The response time of a typical STN display is on the order of 150 ms. These displays typically have a lower contrast ratio and a narrow viewing angle.

97.5.3 Electrically Controlled Birefringence

This display technique is based on controlling the birefringence of the LC cell by application of an electric field. There are a number of types of this display depending on the molecular orientation of the LC cell used; examples include DAP type, homogeneous type, hybrid-aligned nematic (HAN) type, and in-plane switching (IPS) type. A DAP type (homeotropic orientation) is made using an LC with a negative $\Delta\varepsilon$, sandwiched between transparent electrode substrates and placed between crossed polarizers, as shown in Figure 97.12. In the off-state (with no electric field), the incident polarized light does not see birefringence when passing through the cell, and thus gets blocked by the crossed exit polarizer. In the on-state (when a voltage is applied), the molecular axis of the LC is inclined at an angle θ (as shown in Figure 97.12), so the linearly polarized light becomes elliptically polarized as it passes through the cell

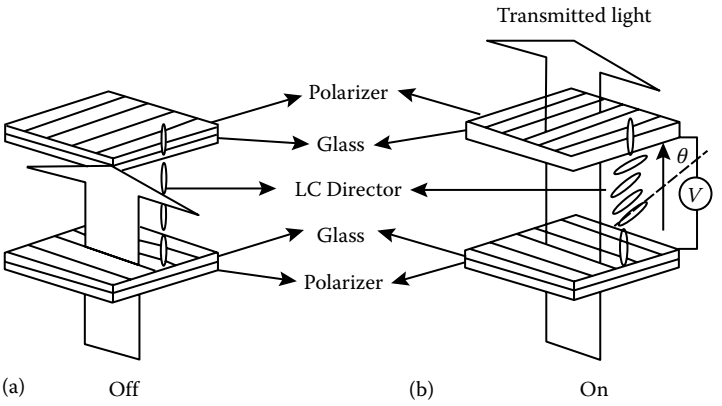

FIGURE 97.12 Illustration of an ECB display: (a) with homeotropic alignment and crossed polarizers, the off-state is black and (b) in the on-state, the output light through the LC is elliptically polarized due to the LC birefringence and the light is transmitted through the crossed polarizer.

due to birefringence. Hence, a portion of the light passes through the crossed exit polarizer; the intensity I of the transmitted light through the cell is given by [20]

$$I = I_0 \sin^2 2\theta \sin^2\left(\frac{\pi d\Delta n(V)}{\lambda}\right) \tag{97.15}$$

where

I_0 is the intensity of the incident light
θ is the angle between the direction of polarization of the incident light and the direction of oscillation of the ordinary light within the cell
d is the cell spacing
$\Delta n(V)$ is the birefringence of the cell
$d\Delta n$ is the optical phase difference
λ is the wavelength of the incident light

The equation shows that I depends on the applied voltage and λ.

In case of the homogeneous technique, the LC cell uses positive material with a homogeneous orientation. With this method, the threshold voltage is obtained by replacing the bend elastic coefficient K_{33}, with splay elastic coefficient K_{11}. The HAN cell is characterized by a hybrid orientation cell in which the molecules are aligned perpendicular to one substrate, but parallel to the second substrate. In this mode, both positive and negative $\Delta\varepsilon$ materials can be used, and since there is no clear threshold voltage, it has the advantage of a very low drive voltage. Recently, an ECB mode based on an IPS-type display has been developed to produce LCDs with extremely wide viewing angles. In the IPS mode displays, LC is homogeneously aligned and switched between on- and off-states using interdigitated electrodes fabricated on one of the display substrates [27]. The IPS mode displays use an NB mode with either positive or negative $\Delta\varepsilon$ LC materials.

97.5.4 GH Type

Some organic dyes show anisotropy of light absorption, i.e., they absorb more light in a specific wavelength band when the **E** vector of the light is parallel to the optic axis of the dye molecules, than they do when it is perpendicular. LCDs based on this principle are called GH displays. In these displays, a small

amount of a dichroic dye (guest) is mixed in the LC material (host). These dye molecules get aligned to the LC molecules; hence, their orientation can be changed (by changing the orientation of the LC molecules) by application of an electric field. When an LC material with a positive $\Delta\varepsilon$ is used, in the off-state, the **E** vector of the polarized light coincides with the light absorption axis of the dichroic dye; hence, light is absorbed and transmitted light is colored. When a voltage is applied for the on-state, the **E** vector of the polarized light is orthogonal to the absorption axis of the dye; hence, no absorption takes place, and transmitted light is not colored (white). GH LCD requires only one polarizer. Further, because the optical effect is based on absorption, the display provides a better viewing angle than a TN mode LCD.

97.5.5 Phase Change Type

The PC type of display is based on a change in molecular orientation from a helical cholesteric phase to a homeotropic nematic phase, and vice versa. For this technique, a cholesteric LC with a long helical pitch with a positive or negative $\Delta\varepsilon$ is used. No polarizers are used in this display. In the off-state of this display, the incident light passing through the cholesteric cell with a focal conic orientation is optically dispersed (scattered), and the cell looks cloudy. However, when a voltage is applied, helical structure of the cholesteric phase changes to a nematic phase with a homeotropic orientation, and the cell becomes transparent.

97.5.6 Thermal Effects

Thermal effect is based on a change in the electro-optic behavior due to a change in the molecular orientation of the LC when it is heated or cooled. This effect is utilized with smectic LCs with a homeotropic alignment. When this cell is heated until the isotropic phase is reached and cooled, and then if the cooling is sudden, the cell becomes cloudy, whereas, if the cooling is gradual, the cell becomes transparent. These cloudy and transparent states correspond, respectively, to the focal conic and homeotropic orientations of the smectic A LC. This effect is used for large-size memory-type displays, in which a laser beam is used to write the image thermally. The heating can also be accomplished by one of the transparent electrodes, while the other transparent electrode is used as a signal electrode.

97.6 Display Addressing

Display addressing (driving) techniques has a major influence on the LCD image quality. The addressing techniques can be classified in three essential types, namely, direct (static) addressing, PM addressing, and AM addressing. In the case of low-information-content displays such as numeric displays, bar graph displays, and other fixed pattern displays, using segmented electrodes, direct addressing is used. A common example of direct-addressed displays is a numeric display using seven segmented electrodes for each digit. Each of these segmented electrodes on the front substrate and the common electrode on the back substrate are directly connected to drive signals. A voltage is selectively applied to each of the segments so that any of the digits between 0 and 9 can be displayed. For high-information-content displays, this approach becomes impractical because of the huge number of interconnects, and hence, either PM or AM addressing is used.

97.6.1 PM Addressing

A PM display comprising an LC between a matrix of transparent conducting row and column electrodes (Figure 97.8) is the simplest and least expensive matrix-addressed LCD to manufacture. An example of a PM LCD is a color (R, G, B) video graphics array (VGA) display using the STN effect, with a pixel format of 640 ($\times$ 3 = 1920) $H \times$ 480 V, with 1920 columns and 480 rows, for a total of 2400 interconnects used for addressing a display containing 921,600 pixels. In PM addressing, the row voltages are scanned in succession with a voltage, V_r, while all the columns in a given row are driven in parallel, during the

row time, with a voltage of $\pm V_c$ depending on whether the pixel is selected to be ON or OFF. As discussed earlier under Section 97.5.2, the contrast ratio of PMLCDs is influenced by the Alt and Pleshko [24] addressability limitation. To enhance the operating margin for improved contrast ratio, dual-scan STN (DSTN) configuration is used in higher-information-content displays. In a DSTN, the display is separated into two halves, and the rows in each half are scanned simultaneously and synchronously, to essentially double the duty ratio of the ON pixels to increase the contrast ratio. One of the major shortcomings of the PM-addressed STN display is the slow response time of the LC, which is of the order of 150 ms. This slow response time is not adequate for video applications and is barely fast enough for the graphical interface of a computer. The response time of the STN LCDs can be improved by active addressing or multiline addressing techniques [28,29]. These techniques involve simultaneous addressing of several rows of a display to suppress the frame response problems of conventional STN LCDs.

97.6.2 AM Addressing

AM addressing removes the multiplexing limitations [24] of the PM LCDs by incorporating a nonlinear control element in series with each pixel, and provides 100% duty ratio for the pixel using the charge stored at the pixel during the row addressing time. Figure 97.13a illustrates an AM array with row and column drivers and the associated display module electronics. Figure 97.13b shows a magnified view of the AM array in the AM LCD panel. In the figure, C_{LC} and C_S represent the pixel capacitance and the pixel storage capacitance. Typically a storage capacitor, C_S, is incorporated at each pixel to reduce the pixel voltage offset (see Equation 97.16) and for a broad temperature operation. Figure 97.14 shows the cross section through an AM LCD illustrating various elements of the display. Figure 97.15 shows a typical AM LCD pixel, showing the gate and data buses, thin-film transistor (TFT), ITO pixel electrode, and the storage capacitor. Fabrication of the AM substrate is one of the major aspects of AM LCD manufacturing. Both two-terminal devices such as back-to-back diodes, and metal–insulator–metal (MIM) diodes as well as three-terminal TFTs are developed for AM addressing. While two-terminal devices are simple to fabricate and cost less, their limitations include lack of uniform device performance (breakdown voltage/threshold voltage) over a large display area, and lack of total isolation of the pixel when neighboring pixels are addressed. For a superior image quality AM LCDs use TFT for the AM device, which provides a complete isolation of the pixel from the neighboring pixels. Large-area AM LCDs use amorphous silicon (a-Si) TFTs [6], while polysilicon TFTs with integrated row and column drivers are used in small high-resolution LCDs [30].

Figure 97.16 shows the electric equivalent of a TFT-LCD pixel, display drive waveforms, and the resulting pixel voltage. As in most matrix-addressed displays with line-at-a-time addressing, the rows (gates) are scanned with a select gate pulse $V_{g,sel}$, during the frame time t_f, while all the pixels in a row are addressed simultaneously with the data voltage $\pm V_d$ during the row time t_r (= t_f/N). During the row time the select gate voltage, $V_{g,sel}$, "turns on" the TFT and charges the pixel and the storage capacitor to the data voltage V_d. After the row time, the TFT is "switched off" by application of the nonselect gate voltage, $V_{g,nonsel}$; hence, the voltage (charge) at this pixel is isolated from the rest of the matrix structure until it is time to charge the pixel during the next frame time. Note that the LC pixel must be driven in an ac fashion with $+V_d$ and $-V_d$, during alternate frame periods, with no net dc across the pixel. A net dc voltage across the pixel results in flicker and image sticking effects [31], resulting from LC conductivity. Large and sustained dc voltages also degrade the LC material due to electrolysis. The shift in pixel voltage, ΔV_p, shown in Figure 97.16, at the end of the row time is due to the parasitic gate-to-drain capacitance, C_{gd}, of the TFT. When the gate voltage is switched, the distribution of the charge from the TFT gate dielectric causes the pixel voltage shift ΔV_p, given by

$$\Delta V_p = \frac{(\Delta V_g) C_{gd}}{(C_{gd} + C_{lc} + C_s)} \tag{97.16}$$

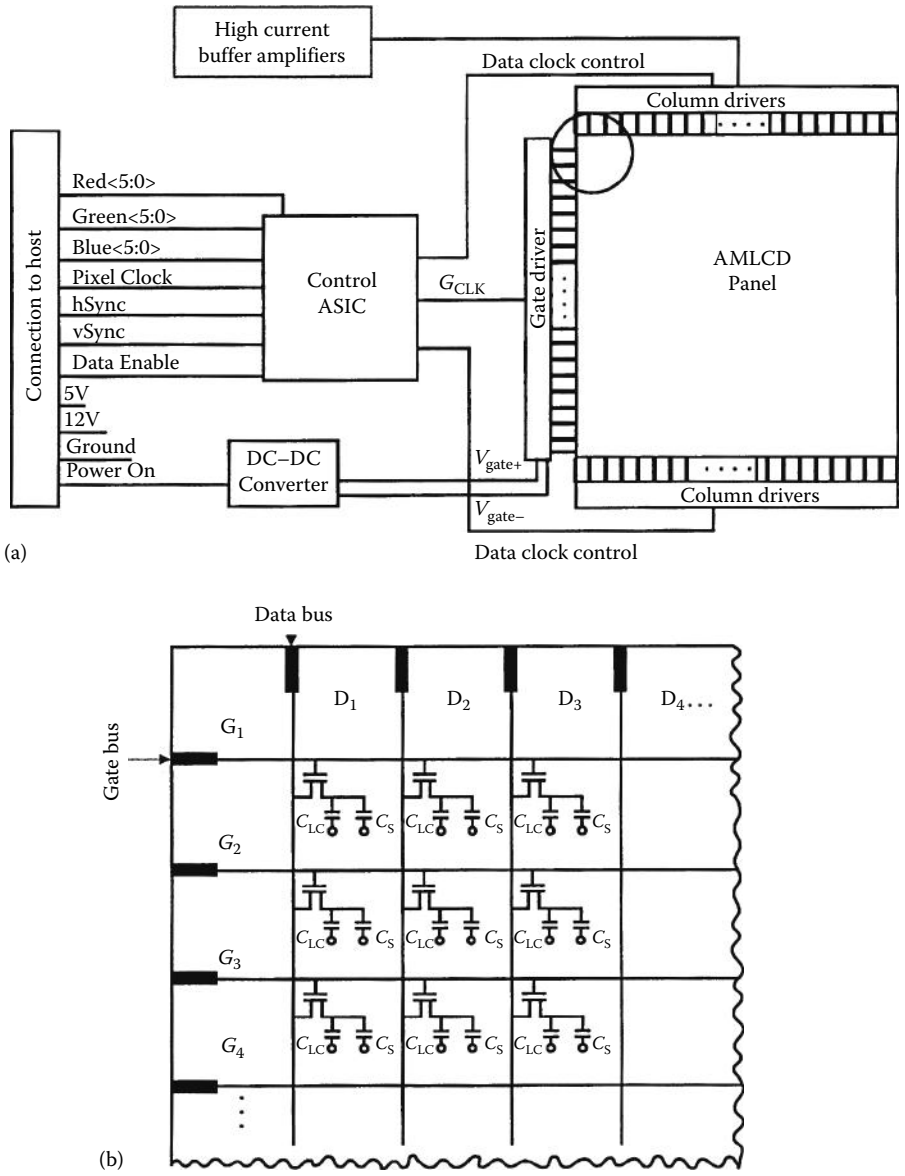

FIGURE 97.13 (a) AM LCD module electronics block diagram and (b) magnified view of the region shown in (a) illustrating active matrix TFT array.

For the *n*-channel enhancement mode a-Si TFT, this voltage shift ΔV_p is negative for both the positive and negative frames; thus, it helps pixel charging in the negative frame and hinders it in the positive frame. Further, due to increased gate bias during the negative frame, the pixel attains the data voltage much more rapidly during the addressing period. Hence, the TFT is designed for the worst-case positive frame conditions. ΔV_p is reduced by minimizing C_{gd} by decreasing the source drain overlap area of the TFT and by using a storage capacitor. Further, ΔV_p is compensated by adjusting the common electrode voltage V_{com} as shown in Figure 97.16. Note that C_{LC} is a function of the V_p (V_{LC}) due to the dielectric anisotropy of the LC; hence, adjustment to V_{com} alone does not eliminate dc for all gray levels, and modification of the gray-scale voltages is required to compensate for the dielectric anisotropy of the LC.

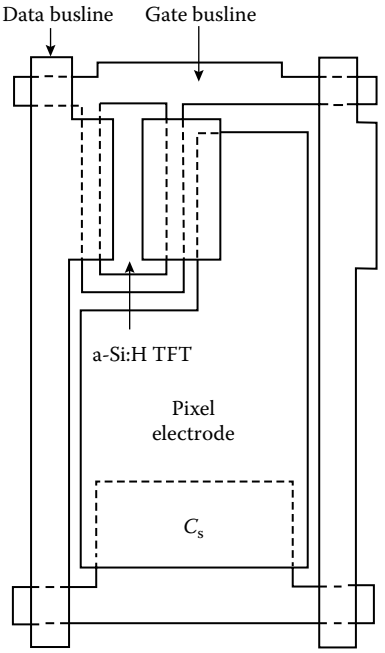

FIGURE 97.15 Layout of a pixel in a TFT-LCD showing the TFT, pixel electrode, and storage capacitor.

97.6.3 Display Module Electronics

Figure 97.13 shows a block diagram for an AM LCD module electronics. The control block and power supply generation means are separately mounted on a PC board and connected to the row and column drivers of the LCD on one side and to the host controller on the other. The control block may include level shifters, timing generators, and analog functions in some cases; the control block takes in digital data from the host system, which is typically a graphics controller chip, and converts it into timing and signal levels required by the row and column drivers. The architecture and design of the module

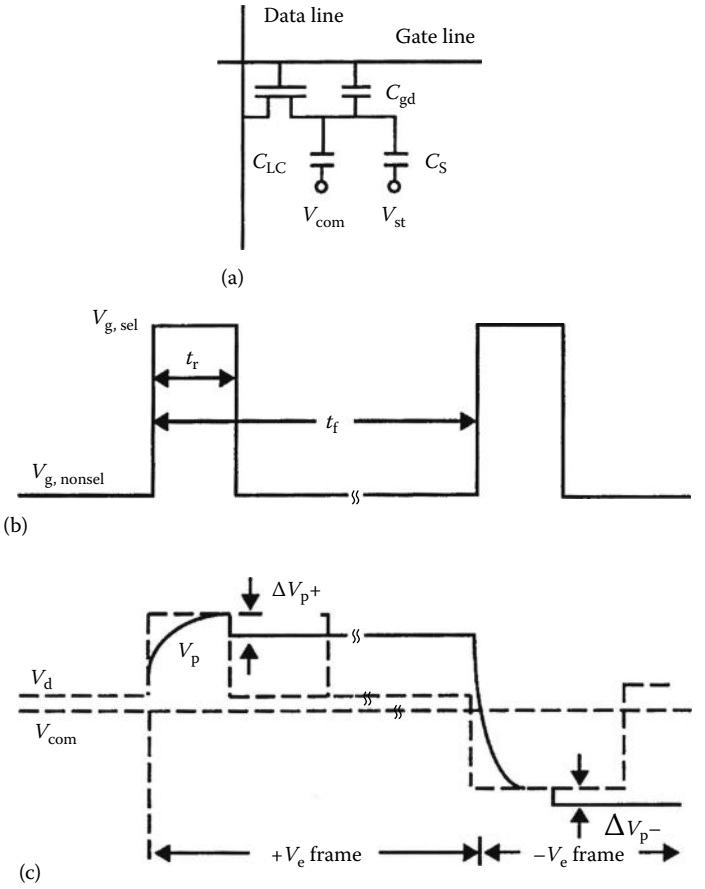

FIGURE 97.16 (a) Electric equivalent of a TFT-LCD pixel, (b) gate drive voltage waveform, and (c) data voltage waveform and pixel charging behavior in the positive and negative frames.

electronics encompassing row and column drivers have a significant impact not only on the display system cost and power consumption, but also on the image quality. The LC material typically requires about 5 V to achieve optical saturation (see Figure 97.10c). Considering the need for an ac drive, the required voltage swing across the LC material is about 10 V. To achieve this 10 V swing across the LC material, the column drivers typically use 12 V power supplies. Column driver voltage can be reduced by using a V_{com} modulation drive method. In this method, the V_{com} node (which is connected to all pixels in the display) is driven above and below a 5 V range of the column drivers. Each and every row time, the V_{com} node is alternated between a voltage above and a voltage below the 5 V output ranges of the column drivers. This achieves 10 V across the LC material using 5 V column drivers. This method requires additional components and consumes additional power due to the oscillation of the V_{com} node. In addition, to avoid capacitive injection problems, the row drivers usually have their negative supply modulated with the same frequency as the V_{com} node. Note, however, that compared to 10 V column drivers, 5 V column drivers consume less power, and are simpler to design and fabricate using small-geometry CMOS. The V_{com} modulation drive method can be used with a row (polarity) inversion scheme only (for elimination of pixel flicker) which results in some horizontal cross talk. However, column inversion and pixel inversion schemes provide better image quality with much-reduced cross talk, but they cannot be used with the V_{com} modulation drive.

Cathode Ray Tube Displays

Christopher J. Sherman
Merrimack

98.1 Introduction

The cathode ray tube (CRT) is unequaled in its ability to produce dynamic, quality, high-information-content imagery at high resolution. Even more impressive is that it achieves this for a lower cost per pixel than any other comparable electronic display technology. For the instrument designer requiring a high-information-content display, it offers numerous advantages. As a raw image tube, it is commonly available as an off-the-shelf item with a broad infrastructure of vendors, integrators, support, and part suppliers. Interface standards are well established and as a complete system, ready to take a standard signal input, it is available worldwide in a variety of performance ranges. To meet different application requirements, it is available in diagonal sizes from 12 mm to over 1 m with resolution from thousands of pixels to over 5 million pixels per frame. Tube characteristics improve on a yearly basis, and prices continue to decrease. Although CRTs have been superseded by other display technologies, they are still used in many applications in laboratories, photography, transportation industry, and in military. They are used in medical applications for color comparisons [1,2].

98.2 History

The CRT has a rich and distinguished history. The roots of today's CRT technology extend back more than 100 years to the latter half of the nineteenth century. Eugene Goldstein first introduced the term *cathode rays*; John W. Hittorf, Heinrich Geissler, Julius Plücker, and others made important contributions specific to CRT technology [3]. Throughout the nineteenth century, researchers were interested in the nature of a luminous gas discharge and shadowy rays that occurred when a high voltage potential was applied between two electrodes in a vacuum. Sir William Crookes was an active experimentalist in this field, and early cathode ray devices came to be known as Crookes tubes. Crookes noted that a glow was generated by the surface that the rays struck; the rays themselves were not the source of light. By producing tubes with a vacuum of 1.3×10^{-4} Pa (10^{-6} torr), he eliminated the luminous gas discharge and worked directly with the cathode rays [4]. Crookes demonstrated the following: luminance depended directly upon the material properties of the surface the rays struck; a magnetic field would deflect the path of the rays; the deflection was proportional to the strength of the magnetic field; and a magnetic field could be used to focus the rays into a beam. He also suggested the rays emitted by the cathode were a stream of charged tiny particles, which were soon to be identified by Joseph John Thomson as electrons. Continuing CRT experimentation lead to the discovery of x-rays by Wilhelm Konrad Röntgen in 1895.

Ferdinand Braun was the first person to envision the CRT as a tool for the display of information and is generally credited with the invention of the first device to be a direct forerunner to the modern CRT [5]. Braun in 1896 designed a CRT "indicator tube" for monitoring high frequencies in power-generating equipment. His design contained all of the same elements as today's CRTs. It utilized a cathode as an electron source, two control coils for vertical and horizontal deflection, an anode for electron acceleration and beam control, and a focusing slit. He also incorporated a phosphor screen normal to the beam for tracing its path. Although crude by later standards, this was the direct prototype for CRT oscilloscopes. In 1903–1905, Arthur Wehnelt added several very significant advances to Braun's design. Wehnelt developed and implemented a hot oxide-coated cathode and a beam control grid [5]. This lowered the voltage necessary to generate the electron stream and provided for much finer control of the beam current. These developments were the forerunner of the modern electron gun.

The CRT remained mostly a laboratory device until three important applications ushered it onto the center stage of information display: oscilloscopes, television, and military radar. By the early 1900s, oscilloscopes were being widely used for the study of time-varying electric circuits in communication. Television was developed in the 1920s and in July of 1930 the National Broadcasting Company began the experimental broadcast of television in New York City. During World War II, the CRT underwent a second wave of maturation with the advent of radar technology. By the end of the 1940s, the TV-CRT was available as a consumer product. In the 1950s, RCA perfected shadow mask technology and before long color became a new standard, gaining wide consumer acceptance in the 1960s. While the principal components of a CRT system have not fundamentally changed in many decades, the CRT has continued to improve.

98.3 Image Formation with a CRT

Although there are many different CRT designs, some of which are quite intricate, the process of forming an image using a CRT is straightforward. The procedure can be divided into four basic stages: beam formation, beam focusing, beam deflection, and energy conversion. These stages occur in four different regions of the CRT and follow in order from the rear of the tube (the neck) to the faceplate. As shown in Figure 98.1, the elements at the rear of the tube are collectively called the electron gun.

98.3.1 Beam Generation with the Electron Gun

The cathode generates the stream of electrons used to form the image-writing beam. The traditional cathode is a metal conductor such as nickel coated with a thin layer of oxide, typically a barium strontium compound.

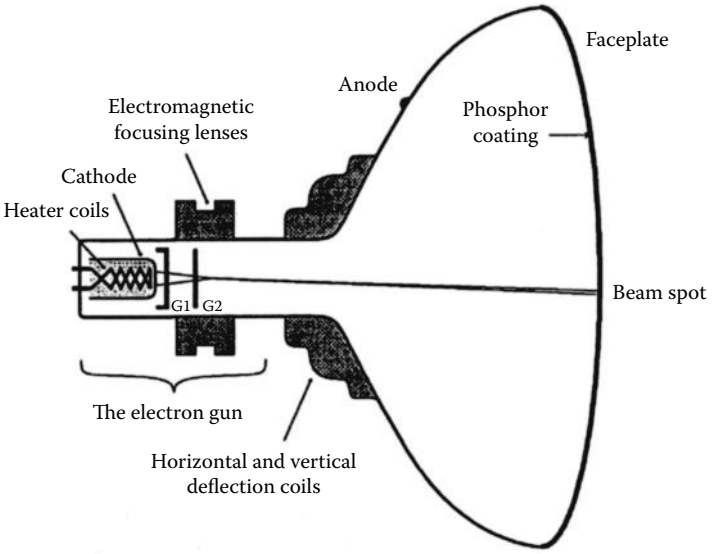

FIGURE 98.1 Example of a typical CRT with electromagnetic focus, and electromagnetic deflection. This type of tube design is normally used for demanding applications such as bright, high-resolution image projection. Tubes like this are available from a number of manufacturers such as Sony, Matsushita, and Thomson.

To reduce the voltage required to generate electron emission, the cathode is heated to 700 °C–1200 °C. Applications that require high brightness often use more advanced and expensive dispenser cathode designs to increase the beam current while maintaining reasonable cathode life. These designs incorporate complex cathode structures and materials such as barium ceramics, molybdenum, rhenium, and tungsten. Readers interested in advanced cathode designs and additional information on CRT materials technology should refer to References [6–10]. The flow of electrons from the cathode is controlled by varying the potential between the cathode and a series of control grids commonly known as G1 (the control grid) and G2 (the acceleration grid). A voltage potential of 100–1000 V between G2 and the cathode creates the potential necessary to pull a stream of electrons off the cathode, forming the beam. The beam amplitude can be controlled and even completely shut off by varying the potential on G1. Thus, the voltage at G1 controls brightness because the brightness is proportional to beam current. The design of the cathode with respect to impedance and loading influences the maximum rate at which the beam can be modulated. The cathode and its associated control grids can be designed to produce a crossover flow of electrons or a laminar flow. In crossover gun designs, the emitted electrons converge to a point in front of the cathode. By using electron optics, this beam spot is imaged onto the phosphor screen. Due to inherent advantages, the crossover design is widely used. A crossover beam is narrow, making it easier to deflect than a thicker beam, and the spot can be very small, improving resolution at the screen. In theory, a laminar flow design provides for the possibility of higher beam current from a similar-sized cathode. In practice, the improvement is not usually advantageous enough to offset the added difficulty of controlling a wider beam.

98.3.2 Electron Beam Focusing

Beam focusing and beam current are critical in determining the final spot size and thus the resolution of the CRT. Focusing a beam of electrons is directly analogous to focusing a beam of light; the discipline is called electron optics. Concerns familiar to optical imaging such as magnification, spherical aberration, and astigmatism also confront electron optics. As CRTs become larger, and operate at higher deflection angles, spot control becomes critical. Beam focusing is achieved using either electrostatic focusing grids or electromagnetic focusing coils. Electrostatic focus is the most extensively used technique. It can be

found in use in applications from television to desktop computer monitors. Electrostatic focus is achieved by applying a succession of potentials across a complex sequence of focusing grids built into the electron gun. As designers seek to improve performance further, grid designs have become intricate [11,12]. Magnetic focus is the system of choice for all high-performance systems where resolution and brightness are design objectives. Magnetic lenses are better at producing a small spot with few aberrations. External coils in a yoke around the neck of the tube control the beam. Since it provides superior performance, electromagnetic focus is common on high-resolution commercial systems. Magnetic focus can also be achieved using permanent magnets and specialized hybrid electrostatic/magnetic focus components. Due to the tremendous impact focus has on resolution, tube suppliers continue to improve focus control [13,14]. For an excellent and comprehensive treatment of electron physics in CRTs, beam control, detailed design discussions, and other aspects of CRT devices, refer to Sol Sherr's textbook [15].

98.3.3 Electron Beam Deflection

The beam deflection system is responsible for controlling the position of the spot on the front face of the CRT. As with focusing, beam deflection techniques can be electromagnetic or electrostatic. A magnetic deflection system consists of two electromagnetic yolks on opposite sides of the CRT neck: a horizontal deflection coil and a vertical deflection coil. The position of the beam is easily controlled; the amount of beam deflection is directly proportional to the current in the coil. Deflection coil design also influences spot size and shape. Coil designs can incorporate correction for coma, convergence errors, and pincushion distortion [16]. Because of its low cost and efficiency, CRTs for both moderate- and high-resolution applications normally use magnetic deflection. Electrostatic deflection provides faster beam displacement but less spot size control. It is typically used in oscilloscope systems, where resolution requirements are moderate and deflection speed is paramount.

98.4 CRT Addressing: Raster Scanning vs. Stroke

Raster scanning is the most common CRT addressing technique. In raster scanning, the electron beam writes each frame one line at a time. This means the horizontal deflection system requires a higher bandwidth than the vertical deflection system. High-performance raster CRTs have a horizontal bandwidth of 15–150 kHz, and a vertical deflection bandwidth of 30–180 Hz. The information is written onto the front face of the CRT from left to right and top to bottom, one line at a time. Raster scanning can be interlaced or progressive (noninterlaced). In interlace scanning, each frame of information is decomposed into two fields. The first field consists of all of the odd-numbered lines in the original frame, and the second field contains all of the even-numbered lines. Each field is scanned onto the CRT at twice the frame rate. Commercial television is interlaced. In the United States, the frame rate is 30 Hz and the field rate is 60 Hz; this scheme is known as the NTSC standard. PAL and SECAM are two other well-known commercial formats in use today. There are numerous other standards, both analog and digital, in use worldwide, each with slightly different scan rates, resolution/addressing formats, luminance and color encoding, and timing protocols [17,18]. Interlace scanning is an engineering compromise that conserves transmission bandwidth, electronics bandwidth, and CRT bandwidth, while maintaining acceptable performance with respect to moving imagery, resolution, and flicker. Computer monitors employ a progressive raster scan. Each frame has one field. The display is generated line by line, in order from the first pixel to the last pixel. Frame rates for the typical desktop monitor vary from 60 to 85 Hz to over 180 Hz for specialized systems.

Stroke is an alternative addressing technique that was once quite common. The name for the technique comes from the phrase "the stroke of a pen." Stroke is a point-to-point addressing system. The beam is directed to the starting point of a line, turned on, and then moved directly to the end of the line. Because there are no raster lines, stroke CRT resolution is independent of direction and is limited primarily by spot size. Stroke addressing is excellent for low-information-content screens with detailed graphic characters or simple vector graphics. It provides extremely high-quality drawing, clean lines,

precise detail, and high speed while conserving power and bandwidth. Stroke systems address the CRT only where there is information, not the entire screen as in raster scanning. This technique is uncommon today because it is too slow and computationally intensive for systems that have high information content, gray scale, or imagery.

98.5 Phosphor Screen

The phosphor functions as the CRT transducer. It converts the energy of the electron beam into light. This conversion process is called cathodoluminescence. CRT phosphors are inorganic crystalline materials doped with one or more impurities called activators and coactivators. Phosphors emit light in two ways: fluorescence and phosphorescence. Fluorescence is the emission of light by the phosphor material while it is under bombardment by the electron beam. The continued emission of light after the bombardment has ceased is called phosphorescence. The length of time phosphorescence lasts is known as persistence. Persistence can vary from tens of nanoseconds to many minutes, or even hours. CRTs take advantage of both forms of cathodoluminescence. Briefly, cathodoluminescence occurs when the electron beam excites the electrons of the phosphor into higher, unstable energy states available due to the presence of the activators. Light is emitted, when the electrons transition back to their stable states. The choice of phosphor depends on the requirements of the application with respect to wavelength characteristics (narrow emission spectra or broadband emission), color, brightness, resolution, and persistence. Commercial television CRTs typically make use of the following phosphor powders: ZnS:Ag:Cl (blue), Zn(Cd)S:Cu:Al or ZnS:Cu:Au:Al (green), and Y_2O_2S:Eu [19]. Television CRTs use moderately short-persistence phosphors. This ensures that a new frame does not exhibit blurring due to the previous frame. Traditionally, phosphors for radar displays, where the screen is refreshed infrequently, had a mix of short and long persistence. However, with the advent of today's digital systems, the use of long-persistence phosphors has declined. The Electronics Industries Association maintains an information database of commercial phosphors for CRTs. The interested reader should refer to its publication TEP116-C [20]. Figure 98.2 illustrates the spectral characteristics of several typical phosphors.

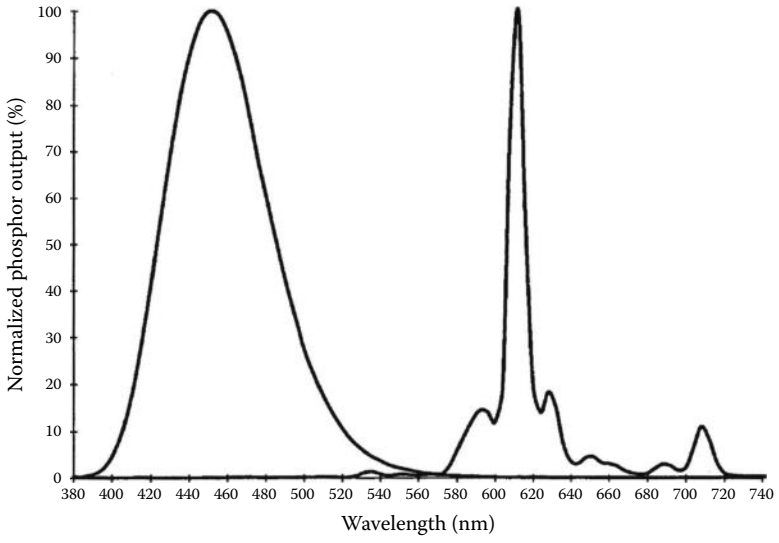

FIGURE 98.2 Phosphors can have a wide range of spectral characteristics. This graph illustrates the spectral profiles of two representative cases. The blue source is an example of a phosphor with a wide and smooth profile. The maximum output for this phosphor is in the blue at a wavelength of 452 nm. The red phosphor shows a sharper profile with several narrow peaks. The largest peak for this phosphor is at 612 nm.

98.6 Color CRTs Using Shadow Masks

Color has been a part of the CRT world since the early 1950s. A sound understanding of human color perception is important for a detailed understanding of color in CRTs. Readers interested in an excellent comprehensive treatment of color science should refer to Wyszecki and Stiles [21] or Robertson and Fisher [22] for a brief overview. The most common method of introducing color to the CRT is the three-gun shadow mask technique. The shadow mask is a metal grid of many tiny apertures held in place immediately before the phosphor screen. The phosphor screen is an array of three different phosphor subpixels. Three electron guns are placed closely together in the neck of the tube, one gun for each one of the primary colors (red, green, and blue). The guns make a small angle with respect to each other. The shadow mask and beams are aligned so that each beam falls on the appropriate phosphor dot. The dots are placed closely together so the eye spatially integrates the subpixels into a continuous blend of color. There are two common configurations: delta and in-line. Delta, the traditional method, arranges the electron guns and the phosphor dots in a triad. This requires a shadow mask consisting of a grid of circular apertures. More recently, Sony introduced the Trinitron™ design. In the Trinitron tube the guns are placed in line, the shadow mask consists of vertical slots, and the phosphors are in vertical stripes. The design offers improved vertical resolution and is easier to converge, but the mask is slightly more difficult to support and is subject to thermal stress problems.

Trinitron continues to be an important and popular design [23]. The shadow mask technique of producing a color image has three main drawbacks. First, the shadow mask typically absorbs >75% of the electron beam energy, limiting brightness and causing undesirable thermal effects. Second, both require precise beam control to converge the three different images from the electron guns. Third, the resolution of the display is limited by the requirements of spatial color; three subpixels are needed to make each full-color pixel.

98.7 Alternative Techniques for Realizing Color Using CRTs

There are alternative approaches to producing color with CRTs. In its own way, each seeks to improve upon one or more of the enormously successful shadow mask designs. The three most noteworthy challengers are beam index tubes, penetration phosphor tubes, and field sequential color (FSC) systems. All three have been around for decades, but only FSC systems are commercially available.

98.7.1 Beam Index and Penetration Phosphor Tube Designs

A beam index tube uses a slotted mask and vertical phosphor stripes. One electron beam is focused to less than the width of a phosphor stripe. A reflected ultraviolet signal from the mask provides a feedback signal. This signal is used to index the position of the beam very accurately. Color selection is achieved by precise beam positioning and rapid beam modulation. Although beam indexing offers perfect convergence, few guns, energy savings, and high resolution, practical problems in control and manufacturing have left this approach unrealized. Penetration tubes are potentially even more advantageous since color is produced with one electron gun and no mask is required. The phosphor screen consists of a layering of several different phosphors. There are many approaches to the layering structure, but the basic principle is that each layer produces a different color. To select among the different colors, the beam energy is varied, altering its layer penetration. In theory, multiple layers of phosphors could be used to produce a full-color display. Unfortunately, this design requires high switching voltages, and the color purity is poor because of the dilution caused by leakage from the unselected phosphor layers. In the past, a few two-color systems have been produced on a limited basis with stroke writer systems.

98.7.2 Field Sequential Color

FSC is a different approach to realizing color using a monochrome CRT and color filters [24]. The shadow mask relies on the ability of the eye to perform a *spatial integration on a group of color elements*. FSC exploits

the ability of the eye to perform a *temporal integration of color fields*. FSC is not a new concept; it was an early design suggestion for commercial color television. To implement FSC, each full-color frame is decomposed into primary color fields (red, green, and blue). Each of these color fields is displayed sequentially on a monochrome CRT while simultaneously a color filter is placed over the front of the CRT. The filters must be rapidly changed to stay in sequence with the individual fields which are displayed at three times the desired frame rate. This sequence is so quick that the eye fuses the individual color fields into a steady blend of continuous color. FSC systems have all of the advantages of a monochrome CRT, namely, superior resolution and simplicity. The major historical drawbacks to FSC have been the difficulty in controlling a bulky, spinning, mechanical filter wheel, and two-thirds of the light energy of the phosphor is thrown away in each field. In the past, some viewers have reported the ability to perceive the individual color fields intermittently; this artifact is known as "color breakup." FSC systems have seen a commercial rebirth due to several factors. The luminous efficiency of several phosphors has improved to the point where the light loss penalty is no longer a severe price to pay. Awkward, mechanical filter wheels have been replaced by several different types of compact, low-power, liquid crystal shutters. The use of faster frame rates and digital sampling techniques has reduced color artifacts. Finally, monochrome CRTs using FSC meet the growing market need for small high-resolution displays.

98.8 Image Quality and Performance

For any display technology, the ultimate test of performance and quality is how the image looks to the viewer in a real-world environment. This is highly subjective, but critical none the less. Table 98.1 highlights some important parameters associated with performance and image quality. Resolution is the most

TABLE 98.1 Parameters That Influence CRT Performance and Image Quality

Resolution	Spot size and shape
	Focus accuracy
	Line width
	Addressing/scan format
	Shadow mask design
Luminance	Dynamic range
	Maximum brightness
	Gray scale in high and low ambient light
	Gray scale vs. display brightness
	Phosphor luminous efficiency
Contrast	Contrast under high ambient illumination
	Contrast under low ambient illumination
	Large area contrast
	Pixel-to-pixel contrast (small area)
Image fidelity	Frame rate
	Flicker/refresh
	Uniformity and linearity
	Aberrations (linearity, pincushion, barrel distortion, keystone, and focus)
Color	Phosphor selection
	Convergence accuracy
	Color gamut and saturation
	Color uniformity
	Color accuracy
Bandwidth	Video bandwidth (cathode design)
	Horizontal deflection design
	Vertical deflection design
	Bandwidth of the CRT supporting electronics
	Bandwidth of the signal delivery electronics

critical characteristic of any CRT. A note of caution, resolution should not be confused with addressing. A system can have a precise addressing format, but if the spot is too large, the CRT resolution capability will be poor despite the addressing format. Alternatively, if the spot is precise and the addressing format is coarse, the *image* will be low resolution, but the CRT resolution will be high. Resolution is affected by almost every system parameter: spot size, focus, deflection, raster format, the mask, and beam current. For a perfectly designed system, line width and spot size will ultimately determine the resolution. Spot diameter is limited by the quality of the electron optics, the particle size and thickness of the phosphor layer, and beam current. The cross-section energy distribution of the electron beam is approximately Gaussian. The higher the current is the larger the beam cross section. Scattering by individual phosphor particles also increases the spot size. Thus, high resolution is much more difficult to achieve for high-brightness applications. The champions of small spot sizes are the small 12–25 mm monochrome CRTs. Several commercial systems achieve ≤25 μm spot sizes, and sizes ≤15 μm have been reported [25]. Monochrome CRTs in the 53 cm class (21 in.) have spot diameters ≤150 μm. Color CRTs with shadow mask pitches ≤250 μm are available in sizes up to 21 in. at commodity prices, and this will continue to improve. Spot size does not tell the whole resolution story. In most systems, something other than spot size limits performance. The scan format may be well below the performance of the CRT, the bandwidth of the support electronics is frequently less than the tube bandwidth, and, for color, the shadow mask will limit resolution more than spot size. Engineers can still design a CRT that maintains its performance even with state-of-the-art electronics. Modulation transfer function (MTF) is the standard metric for resolution. MTF compares the modulation of the displayed output with the modulation of a known input signal. As the spatial frequency of the input increases, the performance of the output will show a steady roll-off in modulation depth and quality. Readers interested in an introduction to this complex topic should refer to Infante's review [26]. Contrast and its related companion, gray scale, are also important to CRT image quality. Since contrast can be measured and stated in so many different terms, gray scale is probably a more practical indicator of performance from a user's standpoint. As it attempts to replace traditional film, the medical imaging community demands the most of the monochrome CRT. Medical CRTs can produce up to 256 shades of gray with 8 bit controllers. Systems are available that will do 10 bit monochrome and color. Although frequently quoted, *shades of gray* are not a true indication of CRT performance and should not be confused with true *gray-scale* capability. Shades of gray are a characteristic of the image source and the capability of the electronics; gray scale reflects the capability of the CRT. Gray scale is typically defined as a series of steps in brightness in increments of $2^{1/2}$ from black to maximum CRT output. Thus, gray scale is a realistic indicator that combines CRT dynamic range, contrast ratio, halation, and ambient reflections. More than 12 steps of gray scale are considered good performance.

The subject of display image quality and evaluation is an important topic. In addition to resolution and gray scale, users and designers need to consider many other metrics, such as luminance, dimmability, contrast, readability, color, persistence, and convergence. Users may also be aware of visual distortions such as pincushion, barrel, and keystone. A discussion of these topics and the other issues raised by Table 98.1 is beyond the scope of a single chapter; indeed, it has been the subject of books. There are good sources of information in this area [15,27]; in particular, Keller's [28] text is superb. It is essential to remember that no matter which metrics are used, the most single most important metric is the subjective determination of the end users. Although many factors will affect final display performance, the bottom line remains *how good does the display look* in the real-world application environment it was designed to meet.

98.9 CRT and Phosphor Lifetime

The lifetime of a CRT depends on how it is driven. The higher the beam current, the more rapidly its performance will degrade. In general, degradation is due to a failure of three parts of the CRT—the cathode, the phosphor, and the glass. Brighter displays require higher beam current, and this, in turn, requires a higher level of cathode loading. Oxide cathodes can comfortably operate with a loading range

of 0.1–10 A/cm^2. This will provide a typical lifetime in the range of 10,000 h. Dispenser cathode designs can improve cathode life two to three times, but again individual cathode life depends on how much brightness the user regularly demands from the tube. Phosphor degradation is the second mechanism affecting CRT lifetime and performance. All phosphors degrade under constant electron bombardment, an effect called phosphor burning. The rate of degradation is related to beam current, anode voltage, and material parameters specific to each phosphor. Today, there is a broad range of good phosphor materials with greatly improved aging characteristics. The third mechanism is glass browning. This effect is a complicated interaction between the high energy of the electron beam and the molecular structure of the glass [10]. In recent years, glass suppliers have made great strides in providing CRT manufacturers with improved glass materials. However, phosphor aging and glass browning are still important concerns, especially in extremely bright (high beam current) applications, such as CRT projection.

98.10 CRT Strengths and Weaknesses

With a century of development behind it, the CRT has abundant advantages that make it an attractive display option for the system designer dealing with high information content or dynamic imagery. Table 98.2 lists some attributes, positive and negative, which the system designer should consider in evaluating whether or not to use CRT technology. The most notable traits of the CRT are flexibility and cost. CRTs can operate over a wide range of resolution formats from commercial television to the strict requirements of medical imaging and digital-to-film recording. One unit can easily be designed to accept a myriad of scan formats and resolutions from static text to dynamic imagery with megapixels at frame rates of hundreds of frames per second. This flexibility means the system can be upgraded later without having to redesign the display subsystem. Interfacing with the CRT is also straightforward; there are well-established standards and hardware for many scan formats from the television NTSC to the RGB standards of the personal computer industry. Finally, cost is important to emphasize; CRTs are inexpensive. The desktop CRT delivers its performance for $\leq$\$0.00005 per color resolution element! Currently, no other high-information-content display technology can match this cost.

TABLE 98.2 Strength and Weakness of CRT Technology

Advantage	Weakness
Highest resolution technology	High power consumption
Versatile addressing formats	Weight of glass
Excellent image fidelity	Size of footprint
High speed	Emits EM radiation
Bandwidth ($\geq$350 MHz)	Must be refreshed
Excellent contrast/gray scale	
Good selection of phosphors	
High luminous efficiency	
Bright display (up to 20,000 fL)	
Excellent color gamut	
Simplicity of interface	
Universal interface standards	
Good design flexibility	
Broad application base	
Long life and reliability	
Mature and broad knowledge base	
Worldwide sources of tubes and parts	
Inexpensive—low cost per resolution element	

TABLE 98.3 Companies That Manufacture Cathode Ray Tubes

Clinton Electronics Corporation

Sunnyvale, California 94086-4020
Tel. 408-737-9844

98.11 CRT Selection

The design requirements for (1) resolution, (2) brightness, and (3) screen size will quickly steer the system designer to a particular class of CRTs. If the design requirements are close to either television or desktop computer monitors, the choice is easy. There are literally hundreds of vendors offering integrated CRTs and electronic drivers as off-the-shelf items. Color shadow mask systems with >40 elements per cm are commonly available. If higher resolution is required, then medical imaging and film recorder CRTs may meet the requirements. Physically large display requirements can be supplied by projection CRTs or by tiled CRTs using video wall processors. Small to miniature CRTs provide resolutions up to 500 to 600 elements/cm and portability. If the application falls out of the mainstream, the designer will need to speak directly with CRT vendors. Table 98.3 is a partial list of CRT suppliers. Since CRTs have been designed to satisfy a broad range of specialty applications, the chances are excellent that an acceptable design will already exist. If not, the CRT is so mature that vendors working from a proven experience base can design a tube directly to customer specifications with little in the way of design problems or surprises.

98.12 Future Trends in CRT Technology

CRT technology is mature, and the industry does not foresee major surprises on the horizon. The CRT will continue to evolve, resolution will improve, screens will be flatter, deflections angles will be larger, and footprints will be reduced. The computer world continues to demand more resolution. In 1987, the 36 cm (14 in.) VGA class monitor (640 × 480) with its 300,000 pixels and 16 colors was the new standard. In 1998, the 43 cm (17 in.) desktop monitor is now capable of 1600 × 1200 performance (1.9 megapixels) with 24 bit color. The 53 cm (21 in.) monitor class, once an expensive custom device, is also widely available. The trend of increasing resolution and performance for decreasing cost shows every sign of continuing. The medical community is quickly moving to monochrome systems with 12 bit gray scale at a resolution of 2560 × 2048 (5 megapixels). All of this means the instrument designer has better resolution and fidelity for less money.

There is a quiet revolution taking place in the information display industry, which may have a significant effect on CRTs and all information display technology. There is a design trend to decouple the resolution and fidelity of the display device from its physical size. There are a number of applications motivating this change: communications, military, portable computing, simulation, and virtual reality. This is why miniature CRT technology has been more active in recent years. This is also the engine driving some of the major competitors to the miniature CRT, such as on-chip field emission displays (FED), deformable mirror devices (DMD), ferroelectric liquid crystal integrated circuit displays, and on-chip active matrix liquid crystal display (LCD) technology. However, the CRT backed by its formidable 100 years of design evolution and maturity is not standing still; its assets and market remains. Although it is one of the few vacuum tubes still in use today, the traditional CRT is not doomed for obsolescence any time in the immediate future.

Appendix: Units and Conversions

B.W. Petley
National Physical Laboratory

This appendix contains several tables that list the SI base units (Table A.1), define the SI base units (Table A.2), list their derived units (Table A.3), list their prefixes (Table A.4), and list their conversion units (Table A.5).

TABLE A.1 SI Base Units

Base Quantity	Name of Base Unit	Symbol
Length	Meter	m
Mass	Kilogram	kg
Time	Second	s
Electric current	Ampere	A
Thermodynamic temperature	Kelvin	K
Amount of substance	Mole	mol
Luminous intensity	Candela	cd

TABLE A.2 International Definitions of the SI Base Units[a]

Unit of length (m)

Meter is the length of the path traveled by light in vacuum during a time interval of 1/299 792 458 of a second (17th CGPM,[b] 1983, Resolution 1).

Note: The original international prototype, made of platinum–iridium, is kept at the BIPM[c] under conditions specified by the 1st CGPM in 1889.

Unit of mass (kg)

Kilogram is the unit of mass: it is equal to the mass of the international prototype of the kilogram (3rd CGPM, 1901).

Unit of time (s)

Second is the duration of 9 192 631 770 periods of the radiation corresponding to the transition between the two hyperfine levels of the ground state of the cesium-133 atom (13th CGPM, 1967, Resolution 1).

Unit of electric current (A)

Ampere is that constant current that, if maintained in two straight parallel conductors of infinite length, of negligible cross section, and placed 1 m apart in vacuum, would produce between these conductors a force equal to 2×10^{-7} N/m of length (CIPM, 1946, Resolution 2 approved by the 9th CGPM, 1948).

Note: The expression "MKS unit of force" that occurs in the original text has been replaced here by "newton," a name adopted for this unit by the 9th CGPM (1948), Resolution 7.

Unit of thermodynamic temperature (K)

Kelvin, unit of thermodynamic temperature, is the fraction 1/273.16 of the thermodynamic temperature of the triple point of water (13th CGPM, 1967, Resolution 4).

The 13th CGPM (1967, Resolution 3) also decided that the unit kelvin and its symbol K should be used to express an interval or a difference in temperature.

Note: In addition to the thermodynamic temperature (symbol T), expressed in kelvin, use is also made of Celsius temperature (symbol t) defined by the equation.

$t = T - T_0$

where $T_0 = 273.15$ K by definition. To express Celsius temperature, the unit "degree Celsius" that is equal to the unit "kelvin" is used; in this case, "degree Celsius" is a special name used in place of "kelvin." An interval or difference of Celsius temperature can, however, be expressed in kelvins as well as degrees Celsius.

Unit of amount of substance (mol)

1. Mole is the amount of substance of a system that contains as many elementary entities as there are atoms in 0.012 kg of carbon-12.
2. When the mole is used, the elementary entities must be specified and may be atoms, molecules, ions, electrons, other particles, or specified groups of such particles.

In the definition of the mole, it is understood that unbound atoms of carbon-12, at rest and in their ground state, are referred to.

Note: This definition specifies at the same time the nature of the quantity whose unit is the mole.

Unit of luminous intensity (cd)

Candela is the luminous intensity, in a given direction, of a source that emits monochromatic radiation of frequency 540×10^{12} Hz and that has a radiant intensity in that direction of (1/683) watt per steradian (16th CGPM, 1979, Resolution 3).

[a] The United States denotes the unit of length by "meter" in place of the international usage of "meter."

[b] CGPM, Conférence Général de Poids et Mesures; CIPM, Comité International des Poids et Mesures.

[c] BIPM: Bureau International des Poids et Mesures.

TABLE A.3 SI-Derived Units with Special Names[a]

Derived Quantity	Name	Symbol	Expressed in Terms of Other Units	Expressed in Terms of SI Base Units
Plane angle	Radian	rad		$m\ m^{-1}$
Solid angle	Steradian	sr		$m^2\ m^{-2}$
Frequency	hertz	Hz		s^{-1}
Force	newton	N		$m\ kg\ s^{-2}$
Pressure, stress	pascal	Pa	$N\ m^{-2}$	$m^{-1}\ kg\ s^{-2}$
Energy, work, quantity of heat	joule	J		$m^2\ kg\ s^{-2}$
Power, radiant flux	watt	W		$m^2\ kg\ s^{-3}$
Electric charge, quantity of electricity	coulomb	C		s A
Electric potential, potential difference, electromotive force	volt	V	W/A	$m^2\ kg\ s^{-3}\ A^{-1}$
Capacitance	farad	F	C/V	$m^{-2}\ kg^{-1}\ s^4\ A^2$
Electric resistance	ohm	Ω	V/A	$m^2\ kg\ s^{-3}\ A^{-2}$
Electric conductance	siemens	S	A/V	$m^{-2}\ kg^{-1}\ s^3\ A^2$
Magnetic flux	weber	Wb	V s	$m^2\ kg\ s^{-2}\ A^{-1}$
Magnetic flux density	tesla	T	Wb/m^2	$kg\ s^{-2}\ A^{-1}$
Inductance	henry	H	Wb/A	$m^2\ kg\ s^{-2}\ A^{-2}$
Celsius temperature	Degree Celsius	°C		K
Luminous flux	Lumen	lm	cd sr	$cd\ m^2\ m^{-2} = cd$
Illuminance	Lux	lx	m^{-2} cd sr	m^{-2} cd
Activity (referred to a radio nuclide)	becquerel	Bq		s^{-1}
Absorbed dose, specific energy imparted, kerma	gray	Gy	J/kg	$m^2\ s^{-2}$
Dose equivalent, ambient dose equivalent, organ equivalent dose	sievert	Sr	J/kg	$m^2\ s^{-2}$

[a] Note that when a unit is named after a person, the *symbol* takes a capital letter and the name takes a lowercase letter.

TABLE A.4 SI Prefixes[a]

Factor	Prefix	Symbol	Factor	Prefix	Symbol
10^{24}	Yotta	Y	10^{-1}	Deci	d
10^{21}	Zetta	Z	10^{-2}	Centi	c
10^{18}	Exa	E	10^{-3}	Milli	m
10^{15}	Peta	P	10^{-6}	Micro	μ
10^{12}	Tera	T	10^{-9}	Nano	n
10^{9}	Giga	G	10^{-12}	Pico	p
10^{6}	Mega	M	10^{-15}	Femto	f
10^{3}	Kilo	k	10^{-18}	Atto	a
10^{2}	Hecto	h	10^{-21}	Zepto	z
10	Deca	da	10^{-24}	Yocto	y

[a] The 11th CGPM (1960, Resolution 12) adopted a first series of prefixes and symbols of prefixes to form the names and symbols of the decimal multiples and submultiples of SI units. Prefixes for 10^{-15} and 10^{-18} were added by the 12th CGPM (1964, Resolution 8), those for 10^{15} and 10^{18} were proposed by the 15th CGPM (1975, Resolution 10), and those for 10^{21}, 10^{24}, 10^{-21}, and 10^{-24} were proposed by the CIPM (1990) for approval by the 19th CGPM (1991).

TABLE A.5 Conversion Factors from English Measures to SI Units[a]

Unit	Equivalent
1. *Acceleration*	
Acceleration of free fall, standard gravity	9.806 65 m s^{-2}
1 ft/s^2	0.304 8 m s^{-2}
1 gal	0.01 m s^{-2}
2. *Angle*	
1 second (″)	$4.484\ 81 \times 10^{-6}$ rad
1 minute (′)	$2.908\ 9 \times 10^{4}$ rad
1 degree (°)	0.0174 532 rad
1 rad	206 264.8″
3. *Area*	
1 barn (b)	10^{-28} m^2
1 $in.^2$	$6.451\ 6 \times 10^{-4}$ m
1 ft^2	0.092 903 04 m^2
1 yd^2	0.836 127 36 m^2
1 are	100 m^2
1 acre [43560 (statute ft)^2]	4046.86 m^2
1 hectare	10,000 m^2
1 mi^2	$2.590\ 0 \times 10^{6}$ m^2
1 square mile (based on U.S. survey foot)	2.589 998 km^2
4. *Concentration, density, mass density*	
1 grain/gal (United States)	0.017 118 kg/m^3
1 lb/ft^3	16.018 46 kg/m^3
1 lb/gal (United States)	119.826 4 kg/m^3
1 short ton/yd^3	1186.6 kg/m^3
1 long ton/yd^3	1328.9 kg/m^3
1 oz (avdp)/$in.^3$	1730.0 kg/m^3
1 oz (avd)/gal (United States)	7.489 152 kg/m^3
1 $lb/in.^3$	27,680 kg/m^3
5. *Energy*	
1 ft lbf	1.355 818 J
1 cal_{th} (thermochemical calorie)	4.184 J
1 cal_{15} (15 °C calorie)	4.185 5 J
1 cal_{IT}[b]	4.186 8 J
1 kilocalorie (nutrition)[c]	4.186.8 J
1 watt second (W s)	1 J
1 watt hour (W h)	3600 J
1 therm (EC)	$1.055\ 06 \times 10^{8}$ J
1 therm (United States)	$1.054\ 804 \times 10^{8}$ J
1 ton TNT (equivalent)	4.184×10^{9} J
1 BT_{th}	1 054.350 J
1 Btu_{15}	1 054.728 J
1 Btu_{ST}	1 055.055 852 62 J
1 quad (=10^{15} Btu)	≈10^{18} J = 1 EJ

TABLE A.5 (continued) Conversion Factors from English Measures to SI Units[a]

Unit	Equivalent
6. *Force*	
1 dyne	10^{-5} N
1 ounce-force	0.278 013 9 N
1 pound-force	4.448 222 N
1 kilogram-force	9.806 65 N
1 kip (1000 lbf)	4448.222 N
1 ton-force (2000 lbf)	8.896 443 N
7. *Fuel consumption*	
1 gallon (United States) per horsepower hour	$1.410\,089 \times 10^{-9}$ m^3/J
1 gallon (United States)/mile	2.352 15 1/km
1 gallon (United Kingdom)/mile	2.824 81 1/km
1 mile/gallon (United States), mpg	0.425 144 km/L
1 mile/gallon (United Kingdom)	0.354 006 km/L
1 pound per horsepower	$1.689\,659 \times 10^{-7}$ kg/J
1 1/(100 km)	235.215/(mpg) (United States)
8. *Length*	
1 fermi	10^{-15} m = 1 fm
1 angstrom (Å)	10^{-10} m
1 microinch	2.54×10^{-8} m
1 mil	2.54×10^{-5} m
1 point (pt) [0.013837 in.][d]	—
1 pica (12 pt)	4.217 5 mm
1 inch (in.)	0.025 4 m
1 hand (4 in.)	0.101 6 m
1 foot (12 in.) (0.999998 statute ft.)	0.304 8 m
1 foot (U.S. survey)	0.304 800 6 m
1 statute foot [(1200/3937) m]	0.304 800 6 m
1 yard (yd)	0.914 4 m
1 fathom (6 ft, U.S. survey)	1.828 8 m
1 rod (16.5 statute ft)	5.029 2 m
1 chain (4 rod)	20.116 8 m
1 furlong (10 chain)	201.168 m
1 mile (8 furlong, 5280 ft)	1609.344 m
1 statute mile (8 furlong, 5280 statute ft)	1609.347 2 m
1 nautical mile (international)[e]	1852 m
1 light-year[f]	$9.640\,73 \times 10^{15}$ m
9. *Light*	
1 foot-candle	10.763 91 lx
1 phot	10,000 lx
1 $cd/in.^2$	1550.003 cd/m^2
1 footlambert	3.426 259 cd/m^2
1 lambert	3183.099 cd/m^2
1 stilb	10,000 cd/m^2

Unit	Equivalent
10. *Mass*	
1 pound (avdp.) (lb) (7000 g)	0.453 592 37 kg
1 pound (troy) (5760 g)	0.373 241 721 6 kg
1 grain (g)	64.798 91 mg
1 scruple (20 g)	1.296 0 g
1 pennyweight (24 g)	1.555 174 g
1 dram (60 g)	3.887 9 g
1 ounce (avdp) (437.5 g)	28.349 52 g
1 ounce (troy) (480 g)	31.103 48 g
1 carat (metric)	0.2 g
1 stone (14 lb)	6.350 29 kg
1 slug	14.593 9 kg
1 hundredweight (long)	50.802 35 kg
1 ton (short) (2000 lb)	907.184 7 kg
1 ton (long) (2240 lb)	1016.047 kg
	1.016 047 t
Mass per unit length	
1 tex	10^{-6} kg/m
1 denier	$1.111\,111 \times 10^{-7}$ kg/m
1 pound per foot	1.488 164 kg/m
1 pound per inch	17.857 97 kg/m
1 ton/mile	0.631 342 mg/km
1 ton/1000 yd	1.111 6 kg/m
1 lb/ft	1.488 16 kg/m
Mass per unit area	
1 ton/mile^2	3.922 98 kg/ha
1 ton/acre	2510.71 kg/ha
1 oz/yd^2	33.905 7 g/m^2
Mass carried × distance (traffic factor)	
1 ton mile	1635.17 kg km
Mass carried × distance/volume (traffic factor)	
1 ton mile/gal (United States)	431.967 6 mg km/m^3
11. *Power*	
1 erg/s	10^{-7} W
1 ft lbf/h	$3.766\,161 \times 10^{-4}$ W
(1 Btu_{ST})	1.000 669 Btu_{th}
1 metric horsepower (force de cheval)	735.498 8 W
1 horsepower (550 ft lbf/s)	745.70 W
1 electric horsepower	746 W
12. *Pressure, stress*	
1 standard atmosphere	101 325 Pa
1 dyne/cm^2	0.1 Pa
1 torr [(101th 325/760) Pa]	133.322 4 Pa
1 N/cm^2	10,000 Pa
1 bar	100,000 Pa
1 lbf/ft^2	47.880 26 Pa
1 lbf/in.^{2} (psi)	6894.8 Pa

TABLE A.5 (continued) Conversion Factors from English Measures to SI Units[a]

Unit	Equivalent
1 kgf/cm^2	98 066.5 Pa
1 cm water (4 °C)	98.063 7 Pa
1 mm of mercury (0 °C)	133.322 4 Pa
1 in of water (39.2 °F)	249.082 Pa
1 in of mercury (60 °F)	3376.85 Pa
1 ft water (39.2 °F)	2988.98 Pa
13. *Thermal quantities*	
Fixed points	
Triple point of natural water T_{tp}	273.16 K
Zero Celsius (= $T_0 = t_{F,0}$)	273.15 K = 32 °F
Temperature conversions	
Kelvin to Rankine (T_R)	$T = (5/9)\ T_R$
Kelvin to Celsius	$t = T - T_0$
Kelvin to Fahrenheit	$t_F = (9/5)(T - T_0) + t_{F,0}$
Celsius to Fahrenheit	$t_F = (9/5)\ t + t_{F,0}$
[Numerically, $5(\{t_F\} + 40) = 9(\{t\} + 40)$, where $\{t\}$ and $\{t_F\}$ are the numerical values of the Celsius and Fahrenheit temperatures, respectively.]	
Temperature interval conversions	
1 degree centigrade	1 degree Celsius, denoted 1 °C
1 °C	1 K
1 °F	(1/1.8) K
1 °R	(1/1.8) K
Other thermal quantities	
1 Btu$_{th}$/h	0.292 875 W
1 Btu$_{IT}$/h	0.293 071th 1 W
1 cal$_{IT}$/s	4.186 8 W
1 cal$_{th}$/s	4.184 W
1 cal$_{IT}$/(g°C)	4186.8 J/(kg K)
1 Btu ft/(ft^2 h°F)	1.730 735 W m^{-1} K^{-1}
1 Btu in./(ft^2 s°F)	519.220 4 W m^{-1} K^{-1}
1 clo	0.155 m^2 K/kW
1 °F h ft^2/Btu	0.176 110 2 K m^2/W
1 °F h ft^2/Btu in	6.933 472 K m/W
1 Btu/lb°F ≡ 1 cal$_{ST}$/g°C	4186.8 J/kg.K
14. *Torque, moment of force*	
1 dyne·cm	10^{-7} N m
1 kgf·m	9.806 65 N m
1 ozf·in.	0.007 061 552 N m
1 lbf·in.	0.112 984 8 N m
1 lbf·ft	1.355 818 N m
15. *Velocity (includes speed)*	
1 foot per hour	8.466 667 × 10^{-5} m/s
1 foot per minute	0.005 08 m/s
1 knot (nautical mile per hour)	0.514 444 m/s
1 mile per hour (mi/h)	0.447 04 m/s

(*continued*)

1 slug/ft s	47.880 26 Pa s
1 stokes, St	1.0×10^{-4} m^2/s
17. *Volume (includes capacity)*	
1 stere, st	1 m^3
1 liter[g]	0.001 m^3
1 ft^3	0.028 316 8 m^3
1 $in.^3$	$1.638\,7 \times 10^{-5}$ m^3
1 board foot	$2.359\,7 \times 10^{-3}$ m^3
1 acre-foot	1233.48 m^3
1 dram (U.S. fluid)	$3.696\,7 \times 10^{-6}$ m^3
1 gill (United States)	$1.182\,941 \times 10^{-4}$ m^3
1 ounce (U.S. fluid)	$2.957\,353 \times 10^{-5}$ m^3
1 teaspoon (tsp)[h]	$4.9288\,922 \times 10^{-6}$ m^3
1 tablespoon (tbsp)	$1.4787\,676 \times 10^{-5}$ m^3
1 pint (U.S. fluid)	$4.731\,765 \times 10^{-4}$ m^3
1 quart (U.S. fluid)	$9.463\,529 \times 10^{-4}$ m^3
1 gallon (U.S. liquid) [231 $in.^3$]	$3.785\,412 \times 10^{-3}$ m^3
1 wine barrel (bbl) [31.5 gal (United States)]	0.119 240 m^3
1 barrel (petroleum, 42 gal, United States), bbl	0.158 987
1 ounce (U.K. fluid)	$2.841\,3 \times 10^{-5}$ m^3
1 gill (Canada and United Kingdom)	$1.420\,6 \times 10^{-4}$ m^q
1 gallon (Canada and United Kingdom)	$4.546\,09 \times 10^{-3}$ m^3
	1.200 950 gal (United States)
1 pint (U.S. dry)	$5.506\,105 \times 10^{-4}$ m^3
1 quart (U.S. dry)	$1.101\,221 \times 10^{-3}$ m^3
1 gallon (U.S. dry)	$4.404\,884 \times 10^{-3}$ m^3
1 peck	$8.809\,768 \times 10^{-3}$ m^3
1 bushel (United States) [2150.42 $in.^3$]	$3.523\,907 \times 10^{-2}$ m^3

[a] The conversion factor for a compound unit is usually not given here if it may easily be derived from simpler conversions; e.g., the conversion factors for "ft/s" to "m/s" or "ft/s^2" to "m/s^2" are not given, since they may be obtained from the conversion factor for "ft." Values are given to five or six significant digits except for exact values, which are usually indicated in bold type. A few former cgs measures are also included.

[b] The International Steam Table calorie of 1956.

[c] In practice, the prefix kilo is usually omitted. The kilogram calorie or large calorie is an obsolete term for the kilocalorie that is used to express the energy content of foods.

[d] Typographer's definition, 1886.

[e] Originally, in 1929, the international nautical mile.

[f] Based on 1 day = 86,400 s and 1 Julian century = 36,525 days.

[g] Post-1964 value, SI symbol l or L. Between 1901 and 1964, the liter was defined as 1.000th 028 dm^3.

[h] Although often given, it is doubtful whether normal usage justifies this accuracy. In Europe and elsewhere, teaspoon and tablespoon are usually exactly 5 and 15 mL, respectively.

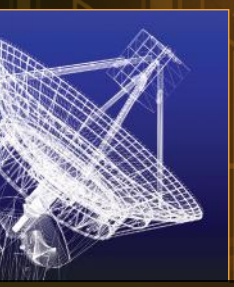
Electrical Engineering



SECOND EDITION

Measurement, Instrumentation, and Sensors Handbook

Electromagnetic, Optical, Radiation, Chemical, and Biomedical Measurement

The **Second Edition** of the bestselling **Measurement, Instrumentation, and Sensors Handbook** brings together all aspects of the design and implementation of measurement, instrumentation, and sensors. Reflecting the current state of the art, it describes the use of instruments and techniques for performing practical measurements in engineering, physics, chemistry, and the life sciences and discusses processing systems, automatic data acquisition, reduction and analysis, operation characteristics, accuracy, errors, calibrations, and the incorporation of standards for control purposes.

Organized according to measurement problem, the **Electromagnetic, Optical, Radiation, Chemical, and Biomedical Measurement** volume of the **Second Edition**:

- Contains contributions from field experts, new chapters, and updates to all 98 existing chapters
- Covers sensors and sensor technology, time and frequency, signal processing, displays and recorders, and optical, medical, biomedical, health, environmental, electrical, electromagnetic, and chemical variables

A concise and useful reference for engineers, scientists, academic faculty, students, designers, managers, and industry professionals involved in instrumentation and measurement research and development, **Measurement, Instrumentation, and Sensors Handbook, Second Edition: Electromagnetic, Optical, Radiation, Chemical, and Biomedical Measurement** provides readers with a greater understanding of advanced applications.
