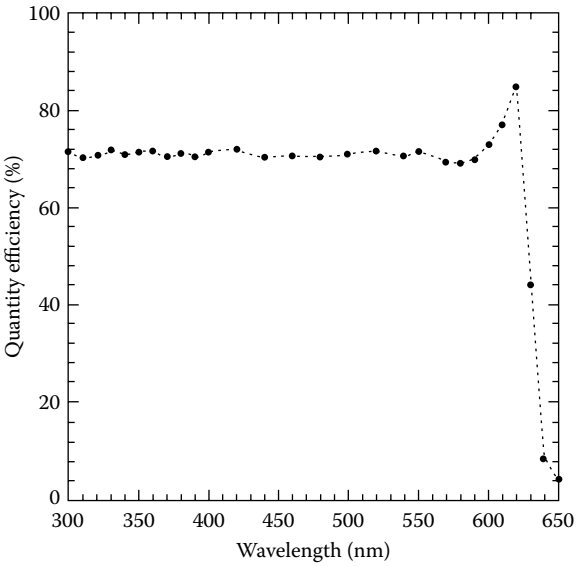

FIGURE 44.17 QE of an InI photodiode. The QE peaks at over 80% near the band edge and has a spectral sensitivity of about 70% into the near UV.

provides the ability to tune the peak wavelength of a photodiode. When two binary compounds are combined, the resulting ternary material usually has properties that lie between those of the constituent binary compounds. Examples of some alloys developed in this manner include $Hg_xCd_{1-x}Te$ for IR detection, created from HgTe (E_g = 0.14 eV) and CdTe (E_g = 1.45 eV); Si_xGe_{1-x}, which is a mixture of Si (E_g = 1.1 eV) and Ge (E_g = 0.7 eV) for IR and visible detection; and $TlBr_xI_{1-x}$, which is a mixture of TIBr (E_g = 2.7 eV) and T1I (E_g = 2.1 eV) for visible detection. A discussion of some recent novel materials being developed is presented in the following section, and a compilation of relevant properties of various semiconductor materials is presented in Table 44.2.

44.7.6 III–V Ternary Materials

Ternary alloys of GaN and AlN (E_g = 6.2 eV), $Ga_xAl_{1-x}N$, are also being investigated to create optimized UV detectors for desired wavelengths. In the ternary compound, the bandgap depends on the material composition, or x, and varies almost linearly from 3.4 to 6.2 eV. Such bandgap engineering is desirable to create material with required photoresponse. These devices are also expected to be capable of high-temperature operation due to the wide semiconducting bandgap of the material. Similar devices have also been studied, such as GaP (E_g = 2.1 eV) and A1P (E_g = 2.9 eV), for visible and near-UV detection.

Another example is indium gallium arsenide, which is a mixture of InAs (E_g = 0.36 eV) and GaAs (E_g = 1.43 eV) and has been recently commercialized as an IR detector material in the 1000–1700 nm region. InGaAs photodiodes in *p-n* diode, *p-i-n* diode, and APD configurations are available. InGaAs photodiode arrays coupled to amorphous silicon TFTs are being developed for large-area IR imaging. Other ternary III–V materials that have been investigated for similar reasons include GaAsP, GaNP, and BNP.

$Al_xGa_{1-x}As$ is an indirect bandgap material when the mole fraction of Al reaches 80%. The bandgap energy for such an arrangement is approximately 2.16 eV. This is suitable especially for photon detection in the shallow UV region. The impact ionization ratio is also low (<0.1), which indicates low excess noise associated with impact ionization. AlGaAs is epitaxially grown from GaAs wafers, and since GaAs material and processing is a mature technology, it is very suitable for developing high-quality photodetectors.

For the shallow silicon devices, the trade-off between the reflectance and the absorption depth as a function of wavelength mimics the QE curve. Specifically, at low wavelengths, that is, blue to UV light, the reflectance increases, one minus the reflectance decreases, and the collection of photocurrent decreases because of a "dead layer" at the surface, where charge is inefficiently collected when the absorption coefficient is too large. At long wavelengths, that is, red light, the DE decreases because the light passes through the active region, as predicted by the decrease in the absorption coefficient. The reflectance and absorption coefficient are important in determining the expected DE of the detector. Figure 44.18 shows plots of one minus the reflectance, on the left axis, against the absorption coefficient, in μm^{-1} on the right axis as a function of wavelength for silicon [83], $Al_xGa_{1-x}As$ [84],

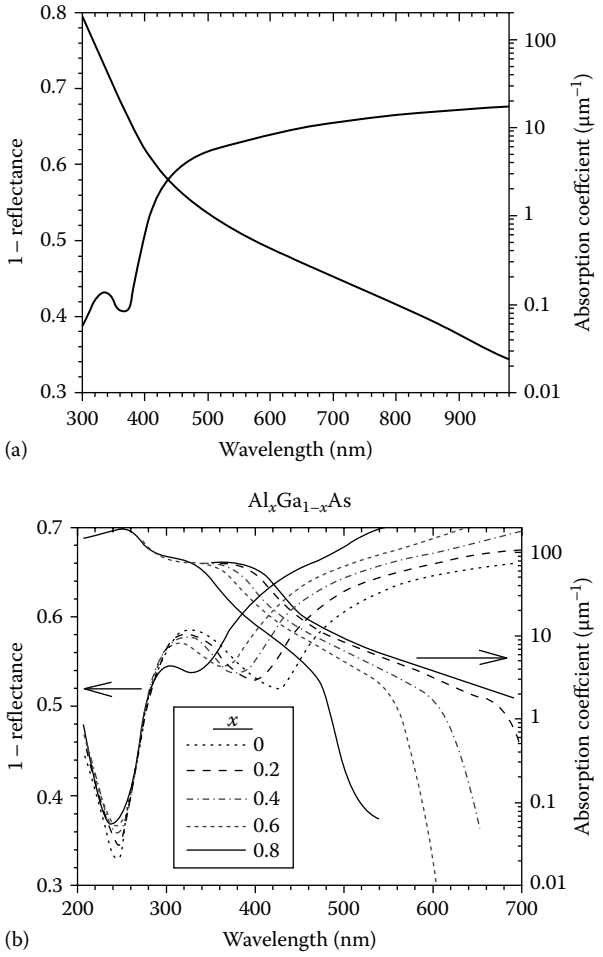

FIGURE 44.18 Plot of 1 – reflectance, which should be roughly proportional to the light that can be absorbed, against the absorption coefficient, in μm^{-1}, which should be roughly proportional to the light that can be absorbed, for (a) silicon, (b) Si, $Al_xGa_{1-x}As$, respectively. These two factors often contribute to the wavelength dependence of the QE. At short wavelengths, the QE is expected to decrease because the reflectance increases, and the collection of the photocurrent from the surface decreases, as indicated by the large absorption coefficients. At long wavelengths, the QE is expected to decrease because the absorption length decreases, so the light passes through the material. The purpose of these plots is to examine anticipated correlations to the QE and to estimate the penetration depth, which corresponds to the maximum thickness of any "dead layer" at the surface for the wavelengths of interest.

(*continued*)

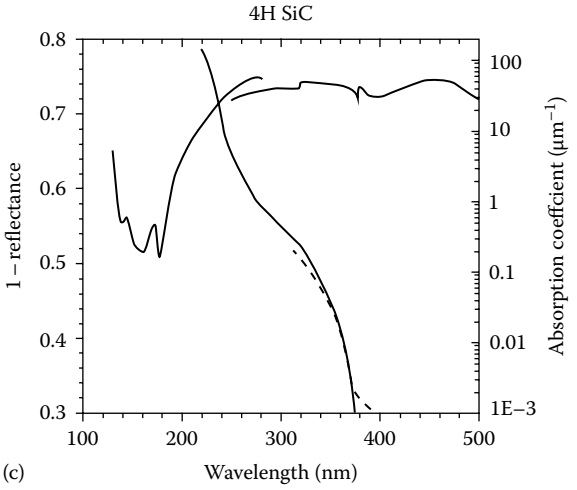

FIGURE 44.18 (continued) Plot of 1 – reflectance, which should be roughly proportional to the light that can be absorbed, against the absorption coefficient, in μm^{-1}, which should be roughly proportional to the light that can be absorbed, for (c) 4H SiC, respectively. These two factors often contribute to the wavelength dependence of the QE. At short wavelengths, the QE is expected to decrease because the reflectance increases, and the collection of the photocurrent from the surface decreases, as indicated by the large absorption coefficients. At long wavelengths, the QE is expected to decrease because the absorption length decreases, so the light passes through the material. The purpose of these plots is to examine anticipated correlations to the QE and to estimate the penetration depth, which corresponds to the maximum thickness of any "dead layer" at the surface for the wavelengths of interest.

and SiC (4H) [85–87]. Note that the reflectance is plotted on a linear scale, whereas the absorption coefficient is plotted on a log scale.

As seen in the plot for GaAs, which is $Al_xGa_{1-x}As$ for $x = 0$, the absorption depths at 320 and 380 nm are 75 and 72 μm, respectively. This suggests that a "dead layer" of more than 10 nm would have a significant impact on reducing the DE for these wavelengths. The absorption depths at 320 and 380 nm for $Al_{0.8}Ga_{0.2}As$ are 80 and 20 μm, respectively. This suggests that a "dead layer" of 10 nm would effectively block 320 nm, but some 380 nm light would pass through. The values for the absorption depths for other compositions are between those for $x = 0$ and $x = 0.8$.

The plot for the combination of 1 – reflectance and the absorption depth mimics the QE plot shown in Figure 44.16. The absorption depth is 0.2 μm at 320 nm. At 380 nm and other wavelengths near and in the visible region, the absorption depth is smaller, suggesting that the material is relatively transparent in this region. For SiC (4H), the effect of the "dead layer" at 320 nm is expected to be insignificant for layer thicknesses of <5 μm.

44.7.7 Heterojunction Photojunction Detectors

A heterojunction exists at the interface of two different semiconductors. This concept can be exploited to produce photodiodes with unique properties such as tuned optical response in the region of interest (by adjusting the composition) and reduced optical absorption at the entrance (by irradiating the wider bandgap semiconductor that is transparent to the optical signal). A number of optical sensors have been fabricated using this concept with III–V compounds that can be tuned in composition to create heterojunctions with similar lattice constants in both the semiconductors. The research in the heterojunction devices has been aided considerably by the progress in molecular beam epitaxy.

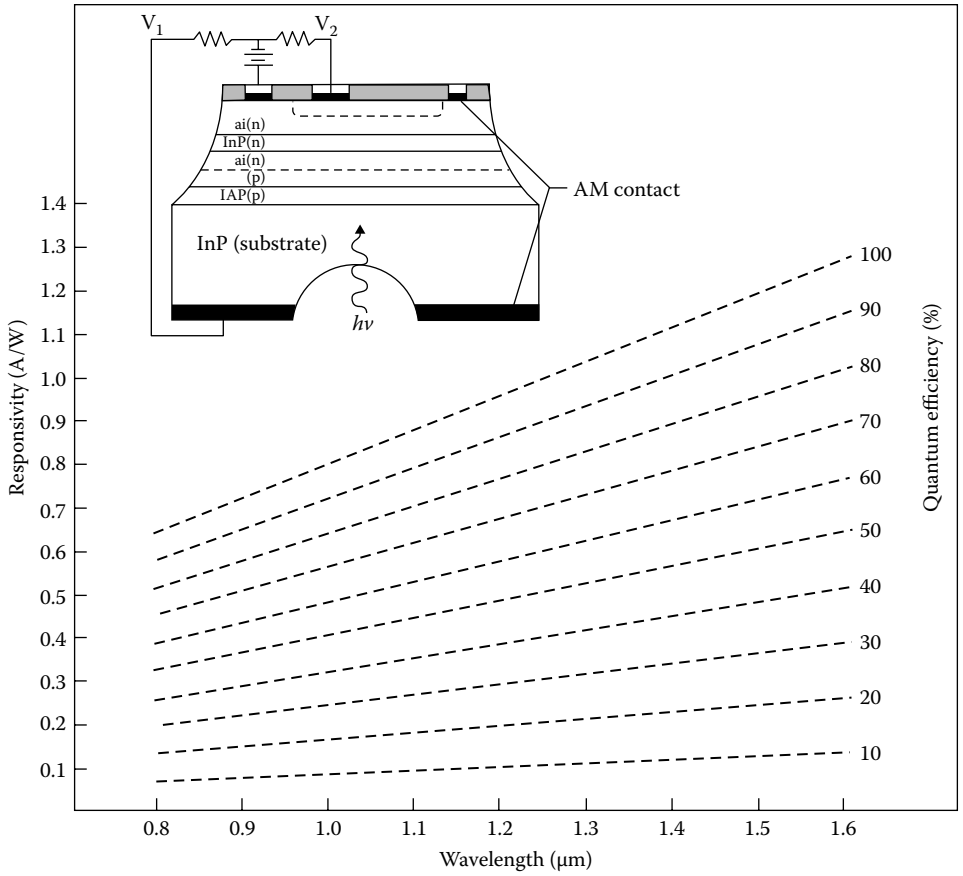

FIGURE 44.19 Responsivity and QE of a heterojunction photodiode versus wavelength. The insert shows the cross section of the photodiode. (From Sze, S.M., *Physics of Semiconductors*, 2nd edn., John Wiley & Sons, New York, 1981, p. 765.)

One unique application of the heterojunction concept is to fabricate detectors that are capable of distinguishing wavelengths above or below a certain level. This has been accomplished using a multilayer device (see Figure 44.19) that consists of two layers of $Ga_xIn_{1-x}As_yP_{1-y}$, which have different compositions and, therefore, different bandgaps. The layer Q1 has a larger bandgap than Q2, and both are grown on InP. The optical response of this device when irradiated through the InP substrate is shown in Figure 44.19 and shows minimal overlap in the desired bands indicating successful wavelength discrimination.

Defining Terms

Bandwidth, *B*: The range of frequencies over which the photodiode operates.

Breakdown voltage, V_b: The reverse-bias voltage at which the applied field overcomes the ability of the junction to block current and the device acts like a resistor. The reverse leakage current increases abruptly near this voltage.

Dark current or reverse leakage current, I_d: The leakage current through the device when at the operating voltage with no incident signal.

Depletion region thickness: The depth of the depleted portion of the diode when at the operating voltage. Photodiodes are frequently operated fully depleted.

Junction capacitance, C_j: Capacitance of the photodiode that decreases as the depletion width increases.

Noise equivalent power, NEP: The incident power that generates a signal equal to the noise, that is, S/N or SNR equals one.

Operating bias: The applied voltage at which the device operates.

Peak wavelength: The wavelength with the highest QE.

Quantum efficiency, η, or QE: The efficiency of converting photon incident on the photodiode into electrons that are detected. Reflection of light from the surface and loss of electrons in the semiconductor reduce the efficiency. Reflection losses can be minimized using an antireflection coating on the surface of the device.

Responsivity, R (A/W): A measure of the signal current produced as a function of the optical power incident on the photodiode.

Spectral response: The QE as a function of wavelength.

Vision and Image Sensors

Stanley S. Ipson

Vision is the act of seeing, a human capability derived from the combination of the image-forming optical system of the eye, the array of light-sensitive receptors in the retina of the eye, and the information processing capacity of the retina and human brain. Applications for instruments with a similar ability to sense a scene include broadcast television, monitoring industrial processes, quality control during manufacture, viewing inaccessible or hazardous places, aiding medical diagnosis, and remote sensing from satellites and space probes, to name but a few. Each application often has particular requirements more critical than others, and the problem is to find the most economical solution satisfying requirements closely.

The human eye is a familiar imaging system, highly optimized to aid survival under the naturally occurring range of illumination conditions. It is useful to describe its basic characteristics [1] to provide a benchmark against which machine vision can be compared. Light intensity can be measured using radiometric quantities such as radiant power, which is the radiant energy transferred per second in watts; irradiance, which is the radiant power falling onto a surface of unit area in W/m^2; and radiance, which is the radiant power leaving unit area of a surface per unit solid angle in $W/st/m^2$. It can also be measured using photometric units that take into account the variation in response of a standard human eye with wavelength, the Commission Internationale de l'Éclairage (CIE) response curve. The photometric equivalent of radiant power is luminous flux, measured in lumens (lm); the photometric equivalent of irradiance is illuminance, measured in lm/m^2 or lux; and the photometric equivalent of radiance is luminance, measured in $lm/st/m^2$ or cd/m^2. At the wavelength of peak sensitivity (555 nm) in the CIE sensitivity curve, the conversion factor from radiometric to photometric units is 680 lm/W.

The eye has a response (observed brightness) to incident light intensity, which is roughly logarithmic and is capable of adapting, given time, to an enormous range of different illuminance levels, from full sunlight (100,000 lux) to starlight (0.001 lux). The illumination generally recommended for surfaces in an office environment (about 100 lux) represents a comfortable working level. It takes about 30 min for the eye to become fully dark adapted and a further 3 min to adapt again to increased lighting levels. Despite this adaption capability, when viewing any one point in a scene

under bright light conditions, the eye is capable of discerning only about 25 different intensity levels. The eye achieves its enormous range of brightness adaptation partly through the action of a variable size iris (about 2–8 mm in diameter) but mainly through the presence of two types of light-sensitive receptor in the retina of the eye.

At high illumination levels, corresponding to photopic vision, the eye perceives color due to the excitation of three different types of cone receptors. There is considerable overlap in the spectral sensitivity curves of these red, green, and blue receptors, which have peak responses near 600, 550, and 500 nm, respectively. The overall photopic response is greatest at a wavelength near 555 nm in the yellow-green region of the spectrum and falls to zero toward the red and the blue ends of the spectrum at about 750 and 380 nm, respectively. At low levels of illumination, corresponding to scotopic vision, only the rod receptors are excited with a peak luminous efficiency of about 1700 lm/W near 510 nm in the green region of the spectrum. The sensitivity to contrast of the dark-adapted eye is much poorer than that of the light-adapted eye. The transition between photopic and scotopic vision is gradual, with both excited over a luminance range from about 0.001 to 0.1 cd/m^2. The photopic response extends higher to the glare limit, about five orders of magnitude brighter, while the scotopic response extends lower to the threshold of vision, about three orders of magnitude lower. The photopic (CIE) and scotopic spectral responses of the eye are shown in Figure 45.1 with the response of a typical silicon-based sensor for comparison. The latter has a spectral response that is quite different from that of the human eye, extending well beyond the red end of the visible spectrum toward 1100 nm, with maximum sensitivity around 800 nm. Assuming the average spectral response of silicon, an irradiation of 1 μW/cm^2 corresponds to an illumination of about 0.22 lux.

The distribution of the cones and rods over the inner surface of the eyeball is nonuniform, with the cones most densely packed in the region of the fovea, a circular region about 1.5 mm in diameter situated toward the rear of the eyeball. To achieve sharpest vision, the eye muscles automatically rotate the eyeball so that the object of interest in the scene is imaged onto the fovea. The separation of the approximately 400,000 cones in the fovea is such that a normal young eye is able to distinguish alternating black and white bands, each 1 mm wide at a distance of about 5 m, corresponding to an angular resolution of about 0.2 mrad. The resolution of the dark-adapted eye is very much poorer because, although the maximum number of rods per square millimeter is similar to that of cones, several rods are connected to a single nerve end, whereas only a single cone is connected to a nerve end.

The overall performance of the eye is difficult to equal. However, a machine vision system can surpass it in individual respects such as sensitivity to infrared and ultraviolet (UV) radiations invisible to the eye, speed of response (which can be as short as nanoseconds), and sensitivity to low-light

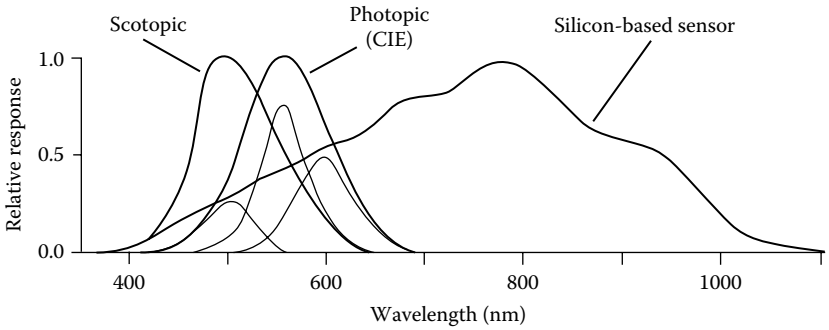

FIGURE 45.1 The linear responses, normalized to unity, of a typical bright-adapted human eye (photopic), a typical dark-adapted eye (scotopic), and a typical charge-coupled-device sensor to different wavelengths of light. The CIE response curve is an internationally agreed response curve for the photopic vision of a standard observer, which is used to convert radiometric measurements to photometric. The individual responses of the red, green, and blue cones are also shown, drawn using thinner lines, beneath the photopic curve.

levels corresponding to the detection of individual photons of radiation over periods of several hours. Machine vision characteristics depend on the type of image sensor employed and the modifying effects of additional components such as image intensifiers or optical fiberscopes. The machine vision equivalent of the eye includes a lens to project a 2-D image of the 3-D object of interest onto a sensor that transforms the light energy into an electric signal. In this form, it may then be transmitted to a remote location, subjected to computer analysis, or displayed on a television screen. A rectangular 2-D image can be sensed using three different approaches. A single, small sensor can be moved in a zigzag or raster fashion to sense the light intensity on a grid of points covering the whole image. A second approach is to use a line sensor composed of many individual sensors. If it is equal in length to one side of the image, it need only be moved in steps equal to the width of the individual sensors, a distance equal to the other side to cover the whole image. The third approach is to use an area sensor comprising a 2-D array of individual sensors. Whatever method is used, each individually sensed small region of the image is called a *picture element* or *pixel*, and in general, the resolution of the imaging system improves with increasing number of pixels. Although the first two methods require relative movement between sensor and scene, they are not limited by the sensor in the amount of resolution that can be achieved along the direction of motion. In addition, the inevitable variation in response between different sensors is easier to correct than with comparable area sensors, because there are fewer sensors. Two common applications of line sensors are monitoring objects on moving conveyer belts and scanning documents. In many cases, however, it is not practical to arrange relative movement of image and sensor, and the majority of image sensors in use are monochrome or color area sensors designed for use in television cameras. Monochrome and color cameras both use the same basic sensors, which have an inherently broad spectral response. Color sensitivity is achieved with the aid of color filters. A common approach is to deposit color filters directly on the sensor surface in a mosaic or stripe pattern. This is a cheap and compact solution but results in a lower spatial resolution in each color, compared with the resolution of the equivalent unfiltered sensor, and loses much of the incident light through absorption in the filters. Better sensitivity and resolution are obtained using three-sensor cameras that incorporate an optical arrangement (based on dichroic mirrors) that separates the incident light into three components—say red, green, and blue—which are each directed at a different sensor. However, this approach is both bulky and expensive, because it requires three sensors rather than one and precision optics to align the images correctly on the individual sensors.

Most area sensors currently sold are designed to produce electric signals compatible with either the 525-line American television standards (RS-170 for monochrome and National Television System Committee (NTSC) for color) or the 625-line European television standards (Comité Consultatif International des Radio Communications (CCIR) for monochrome and Phase Alternating Line (PAL) for color) [2]. These are interlaced television standards in which each complete image or frame is made up of two fields, each containing either odd- or even-numbered lines from the frame. Half the remaining lines, making up the odd total number in the frame, appear in each field, ensuring that the two fields interlace properly on the television display. Interlacing is used to avoid picture flicker without having to double the rate of information transmitted. According to the Ferry–Porter law, the critical frequency below which flicker is observed depends on the logarithm of the luminance of the picture highlights. At the brightness levels corresponding to normal viewing, flicker would be observable in pictures interrupted at 25 or 30 Hz, but it is reduced to an acceptable level at the repetition rates of the fields (60 Hz for NTSC and 50 Hz for PAL). A consequence of the Ferry–Porter law is that an NTSC picture can be about six times brighter than a PAL picture and still be acceptable in terms of flicker. Many companies supply frame grabber computer boards that sample the TV-compatible voltage signals (about 1 V range) at a frequency of at least 10 MHz (for at least 512 samples per line), quantize the analog voltage to 256 or more discrete levels (8 bits), and store the resulting digital data for computer analysis. Interlaced operation is not ideal for some applications, and at higher cost, cameras are available that provide higher frame rates, higher resolutions, or progressive scan (no interlacing). These usually produce a standard digital output signal for easy input into a computer. A very wide range of

sensors and cameras are currently commercially available, based on several different types of technology. Although each technology has particular advantages, the characteristics of different devices based on a specific technology can vary significantly. For example, the spectral responses of photodiode-based sensors generally extend to shorter wavelengths than those of CCD (charge-coupled device)-based sensors, but some CCD devices are available with extended blue-end responses. Improved and/or cheaper sensors and cameras are appearing on the market all the time, and when considering a new imaging system, it is wise to review the characteristics of the devices currently available in comparison with the requirements of the application in order to select the most suitable. One of the first steps in the creation of a machine vision system for a new application is the design or selection of an appropriate optical system, and this is the subject of the next section. Later sections discuss the various sensor technologies that are available and other related devices that can be used to improve sensitivity or to allow image sensing in restricted spaces such as body or machine cavities.

45.1 Image Formation

The machine vision optical system has the tasks of matching the required field of view to the dimensions of the sensor and gathering sufficient light to achieve a sensor signal that has adequate signal-to-noise ratio (SNR) while maintaining the image sharpness required by the application. Resolutions of area sensors are sometimes specified by manufacturers as the maximum number of horizontal TV lines that can be distinguished. This value may be obtained from measurements of the visibility of a test chart (Electronic Industries Alliance (IEA) test pattern), or it may simply be the number of horizontal pixels divided by 1.33, in the case of a monochrome sensor. In special circumstances, measurements to subpixel accuracy can be achieved by interpolation between pixel values, and Ref. [3] describes the measurement of a knife edge to about 0.1 pixel accuracy. As a rule of thumb, however, for size measurement applications, the sensor should have a number of pixels at least equal to twice the ratio of the largest to smallest object sizes of interest [4], and a lens is then selected to provide the required magnification and working distance. A lens operating in a single medium such as air is characterized [5] by two focal points and two principal planes as indicated in Figure 45.2. The principal planes coincide with the lens center in the case of an ideal thin lens but may be separated by +20 to –10 mm (the negative sign indicating reversed order), depending on the design, in multielement lenses. They can be determined by

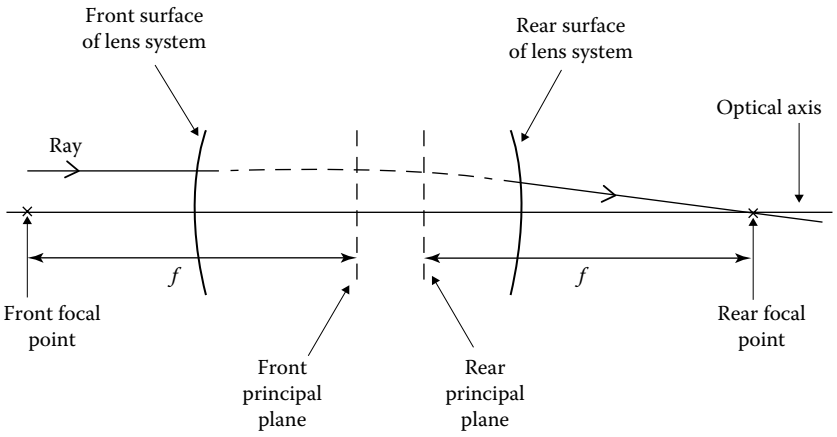

FIGURE 45.2 The trace of a ray from a distant object through a typical multielement lens system showing typical positions of focal points and principal planes. The distance from the back focal length to the lens flange mount is 17.3 mm for C-mount lenses, 12.5 mm for CS-mount lenses, and 46.5 mm for 35 mm photographic format Nikon F (bayonet) mount lenses. Adapters are available to accommodate the differences in distances and fittings of the different mounting systems.

first locating the two focal points and then measuring along the axis from these distances equal to the focal length. A lens of focal length f produces an image in best focus at a distance l_i when the object is at distance l_o where

$$\frac{1}{l_o}+\frac{1}{l_i}=\frac{1}{f} \tag{45.1}$$

and the distances are measured to the corresponding principal planes. The image magnification m, defined as the ratio of image to object size, is equal to the ratio of the image to object distances and is related to the total distance between object and image D_T by

$$D_T=\frac{F(m+1)^2}{m}+D_N \tag{45.2}$$

where D_N is the separation between the principal planes. Lenses generally have a focusing adjustment of 5%–10% of the focal length, and extension rings between the lens and sensor are required for image magnifications greater than about 0.05. The lens extension required is simply the product of the magnification and the focal length. The depth of field F_o of an imaging system [6] is the displacement of the object along the optic axis that produces no significant degradation in the sharpness of the image. The corresponding movement of the image is the depth of focus. In the case of a lens with *f*/number $f_\#$ (equal to the ratio of focal length to lens iris diameter) and an image sensor with pixel size P, it is given by

$$F_o=2f_\#\frac{P(m+1)}{m^2} \tag{45.3}$$

Television camera sensors are manufactured to standard sizes such as 1, 2/3, 1/2, or 1/3 in. The size is defined to be twice the horizontal dimension of a rectangular image with 4:3 aspect ratios so that a 1 in. sensor has a width of 12.7 mm, a height of 9.5 mm, and a diagonal length of 15.9 mm. Lens sizes are similarly specified to allow easy matching of lenses to sensors. Because image distortion and sharpness worsen toward the edges of the field of view, it is permissible, for example, to use a 2/3 in. lens with a 1/2 in. sensor, but not the converse. A 35 mm camera lens, designed for a 24 by 36 mm image size, generally performs much better, at relatively low cost, than a corresponding C-mount lens supplied for a TV camera, but a C-mount to Pentax, Canon, or Nikon mount converter will then be required.

It is frequently necessary to relate lighting of a scene to camera sensitivity. Accurate calculations are difficult, and it is usually better to make a simple estimate and then make fine adjustments to the lighting or lens aperture. Manufacturers often specify camera sensitivities by quoting an illumination level in lux at the sensor faceplate. This may be the illumination required to achieve maximum signal output, some proportion of this maximum, or simply a "usable" signal level from the camera. The illumination of the sensor L_S in lux is related to the luminance of the object B in cd/m^2 by

$$L_S=\frac{TB\pi}{[2f_\#(m+1)]^2} \tag{45.4}$$

where losses in the lens are characterized by a transmission coefficient T. If the object is a uniform diffuse reflector (Lambertian surface) illuminated by L_o lux, then the luminance of the object is given by

$$B=L_o\frac{R}{\pi} \tag{45.5}$$

where R is the reflection coefficient of the surface. Some practical examples of radiometric calculations are given in a Dalsa application note [7].

45.2 Image Sensing

The primary functions occurring within a standard image sensor are the conversion of light photons falling onto the image plane into a corresponding spatial distribution of electric charge, the accumulation and storage of this charge at the point of generation, the transfer or readout of this charge, and the conversion of charge to a usable voltage signal. Each of these functions can be accomplished by a variety of approaches, but only the principal sensor types will be considered here. Sensors can be divided into two groups: (1) vacuum tube devices in which the charge readout is accomplished by an electron beam sweeping across the charge in a raster fashion similar to that in a television picture tube and (2) solid-state devices based on CCDs or photodiodes. These three types of sensor will be described in the next three sections.

45.2.1 Television Camera Tubes

For many years, vacuum tubes [8] provided the only technology available for television applications, and they are still widely used because of the high-quality image signals they provide. Companies supplying tubes include Burle and Philips. Most modern tube cameras are based on the vidicon design whose basic components are indicated in Figure 45.3. Light from the scene is imaged by a lens onto a photoconductive target formed on the inner surface of an end window in a vacuum tube. An electron gun is placed at the opposite end of the tube to the window, and it provides a source of electrons that are focused into a beam, accelerated toward the target by a positive potential on a fine mesh placed just in front of the target, and scanned across the target by an electrostatic or magnetic deflector system. The target consists of a glass faceplate on the inner surface, upon which is placed a transparent electrically conducting coating of indium tin oxide. On top of this is deposited a thin layer of photoconductive material in a pattern of

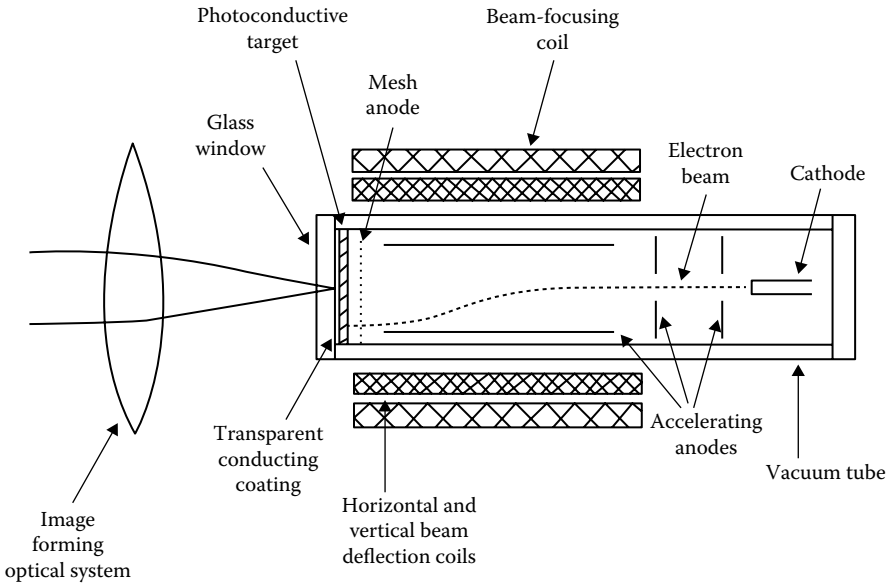

FIGURE 45.3 A schematic diagram of the major components of a vidicon camera tube. Many variants of this existing basic design utilize different target materials to improve particular characteristics. The electron beam readout of the optically generated charge in the target makes the tube bulky and less reliable than solid-state sensors. Most tubes currently sold are for replacement in existing equipment rather than in new cameras, which almost always incorporate solid-state sensors.

tiny squares, each insulated laterally from its neighbors. The transparent coating is connected to a positive voltage through an electric load resistor across which the signal voltage is developed. In the absence of light, the electron beam causes the external surface of the photoconductor to be charged to near zero potential. Light causes the resistance of the photoconductor to decrease and its surface to acquire a more positive potential, due to the accumulation of positive charge. At each point on the surface touched by the electron beam, some of the beam current is deposited to neutralize the positive charge present due to the illumination. The rest passes through the load resistor generating an output voltage that is a function of the light intensity at that point. The precise timing of the scanning process ensures that the location of the beam is known at each instant in time.

Vidicons have some unique characteristics. They can have spectral responses extending into the UV and infrared regions of the spectrum, and they allow scan rate and adjustments in scan alignment to be made electronically by adjusting the scanning pattern. This allows very simple region-of-interest readouts. On the other hand, the electron beam readout method confers a number of disadvantages, which are not found in solid-state devices, including large size, fragility, susceptibility to shock and vibration, high-power consumption, and a high degree of sensitivity to external electric and magnetic fields. The principal imaging defects, which again are not present in solid-state devices, include

- Lag when displaying changing images, due to slow response speed
- Image burn that is damage to the sensor surface caused by intense light
- Geometric distortion
- Drift in the apparent position of the image
- A nonlinear relationship between signal output and light intensity that varies with target voltage

The degree to which these effects are present depends on the type of tube and its particular construction.

The original vidicon tube design employed antimony trisulfide as the photoconductive material and a low-velocity electron beam and gave only adequate performance. Newer tubes employ the same basic design but use better electron beam readout techniques and target materials to improve characteristics such as spectral response, sensitivity, dark current, lag, and burn-in. Two tubes suitable for broadcast television use are the plumbicon developed by Philips and the saticon introduced more recently by Hitachi. The plumbicon employs a lead-oxide photoconductive target, while the saticon target comprises several layers with different combinations of selenium, arsenic, and tellurium. It can provide greater resolution than the plumbicon, but the lag performance and range of operating temperature are worse. Examples of nonbroadcast quality tubes are the newvicon, chalnicon, and si-vidicon. The newvicon target has a double layer of cadmium and zinc tellurium, which achieves exceptional sensitivity, but lag and nonuniformity are excessive. The chalnicon employs a cadmium selenide target and provides good performance in most respects but has excessive lag. The si-vidicon target effectively consists of an array of silicon photodiodes that are reverse biased and store charge released by the incident light. The resulting tube has very high sensitivity and little lag, and it is virtually burn proof. However, it exhibits excessive blooming and nonuniformity. The silicon-intensified camera, or SIT camera, is a modification of the si-vidicon camera that employs a photocathode that generates electrons when struck by light photons. These electrons are accelerated by a voltage of several hundred volts and focused on the target of the si-vidicon sensor that produces an output in the normal way. The high-speed electrons landing on the target produce large numbers of electron–hole pairs and a corresponding larger response. The resulting SIT sensor is used in very low-light-level applications such as tracking satellite debris and can produce useful video images at illumination levels down to 0.001 lux. By comparison, a solid-state CCD sensor (without an image intensifier) typically requires about 1 lux to produce a useful video signal.

45.2.2 Charge-Coupled Devices

A CCD is fabricated on a single crystal wafer of *p*-type silicon and consists of a 1-D or 2-D array of charge storage cells on centers typically about 10 μm apart. Each cell has several closely spaced

electrodes (gates) on top, separated from the silicon by an insulating layer of silicon dioxide. The charge is stored under one of the electrodes, and its location within the cell is defined by the pattern of positive voltages applied to the electrodes. By applying a coordinated sequence of clock pulses to all the electrodes in the array, packets of stored charge (of between 10 and 10^6 electrons) are transferred from one cell to the next until they finally reach a sensing amplifier (floating gate diffusion) that generates a voltage signal proportional to charge, usually assumed to be 1 μV per electron. The result is a device that has an inherently linear variation of output voltage with light from the minimum useful level set by noise to the maximum useful level set by saturation of the output amplifier or the limited capacity of the charge storage cells. The dynamic range of the device is defined as the ratio of the maximum output signal to the output resulting from noise. Manufacturers published figures that may use peak-to-peak or root-mean-square noise values (typically five times smaller) in this calculation, but the former is more relevant for imaging applications.

Any light penetrating into the underlying silicon generates electron–hole pairs. The holes are swept away to the substrate electrode, while the electrons accumulate beneath the nearest electrode in a potential well created by the applied voltage. The sensitivity of silicon is of the order of 1 μA of generated charge per microwatt of incident light. The cells intended to function as light-sensitive photosites have electrodes made of semitransparent polysilicon so that the light can penetrate into the storage region, whereas those intended to function only as part of a shift register for charge transfer are covered by an opaque surface layer. Due to manufacturing imperfections, the photosites do not have perfectly uniform characteristics, and a photoresponse nonuniformity (PRNU) of about 5%–10% is fairly typical. This is easy to measure using uniform sensor illumination, and its effects can be removed if necessary by calibration. The basic spectral response of the silicon extends from 200 to 1100 nm, but the first figure is typically reduced to 450 nm by absorption in the surface layers of the CCD photosites. Infrared radiation penetrates deeper into the silicon than shorter wavelengths, and charge created by an infrared photon may be collected by a different cell to the one entered by the photon. This reduces the resolution of the device, and if infrared operation is not required but the illumination contains infrared (e.g., from a tungsten lamp), then an infrared reflecting filter (a hot-mirror filter) is often used. CCD cells also accumulate charge linearly with time due to thermally generated electrons produced within the cells and at electrode interfaces. Like the photoresponse, this dark signal varies from cell to cell and can be compensated for by calibration. These thermally generated contributions are most significant for low-light-level applications and can be reduced by cooling the sensor using either a thermoelectric cooler, a Joule–Thomson cooler, or a liquid nitrogen Dewar. The dark signal reduces by 50% for every 7 °C reduction in temperature, and at −60 °C, produced by a Peltier cooler, the dark signal is typically reduced to about one electron per pixel per second. Another important temperature-dependent characteristic of the CCD sensor that improves with cooling is the noise floor of the output amplifier, which is proportional to $T^{1/2}$ and typically equivalent to about 300 electrons at room temperature. A particular CCD device used in astronomy, for example, and operated at about −110 °C has a readout noise of about 10 electrons, a dark current less than 0.3 electrons/min, and quantum efficiency for converting visible photons into electrons of between 70% and 80%. Light can be integrated for periods of hours, compared with the approximately 1/8–1/4 s integration period of the dark-adapted eye. Compared with photographic film previously used for low-light level imaging in astronomy, CCDs are from 10 to 100 times more sensitive, linear in response rather than nonlinear, and have a much greater dynamic range so that both faint and bright objects can be recorded in the same exposure.

The short-exposure, high-frequency performance of CCD devices is limited by another effect. The process of transporting charge in a CCD sensor is not 100% efficient, and in practice, a small amount of charge is left behind at each transfer to the next cell, contributing noise and degrading resolution. This effect limits the maximum clock frequency and the maximum number of transfers in a CCD sensor. Manufacturers' data sheets for commonly available CCD sensors quote values ranging from 0.9995 to 0.99999 for the charge-transfer efficiency (CTE) of a single transfer. There are many variations in CCD technology. For example, virtual-phase CCDs [9] have some of the electrodes replaced by ion-implanted

regions, resulting in improved blue response and higher sensitivity because of the removal of some of the blocking surface gates and simpler drive circuitry because of the reduction in number of gates per cell. A manufacturing technique known as *pinning* can be used to passivate the interface states, which are the biggest contribution to the dark signal, producing an order of magnitude improvement in dark signal as well as improved quantum efficiency and CTE. A signal-processing technique called *correlated double sampling* can also be applied to the output signal from the sense amplifier to improve the readout noise performance.

45.2.3 Linear Charge-Coupled Devices

The basic structure of a linear CCD sensor is shown in Figure 45.4. It consists of a line of up to several thousand photosites and a parallel CCD shift register terminated by a sensing amplifier. Each photosite is separated from a shift register cell by a transfer gate. During operation, a voltage is applied to each photosite gate to create empty storage wells, which then accumulate amounts of charge proportional to the integral of the light intensity over time. At the end of the desired integration period, the application of a transfer pulse causes the accumulated charge packets to be transferred simultaneously to the shift register cells through the transfer gates. The charges are clocked through the shift register to the sensing amplifier at a rate of up to 20 MHz, producing a sequence of voltage pulses with amplitudes proportional to the integrated light falling on the photosites. In practice, it is common for shift registers to be placed on both sides of the photosites, with alternate photosites connected by transfer gates to the right and left registers. This halves the number of cells in each register and the time required to clock out all the data. Another 2 × reduction of transfer time is achieved if each shift register is split in two with an output amplifier at each end. There is a limit, typically between 10^5 and 10^6 depending on photosite size and dimensions, to the number of electrons that can be stored in a particular cell, beyond which electrons start to spill over into adjacent cells. The saturation charge in electrons is about 1000–2000 times the area of the photosite in square micrometers. This spread of charge or blooming is a problem with images containing intense highlights. It is reduced by about a factor of 100 by adding antiblooming gates between adjacent photosites and transfer gates and channel stops between adjacent photosites.

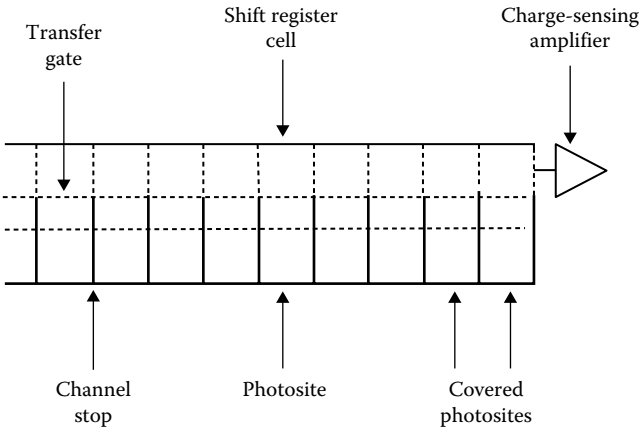

FIGURE 45.4 The architecture of a basic linear CCD showing the arrangement of photosites, transfer gates, shift register cells, and sensing amplifier. The latter produces a sequence of voltage pulses each proportional to the charge accumulated in one of the photosites. Although these pulses are often displayed on an oscilloscope during setting up of the optics and illumination, in normal use, they are digitized to 8 or 12 bits, and the resulting values are stored in memory. In practice, most CCDs have two or more covered cells at each end of a line of photosites to allow the dark current to be monitored and subtracted during signal processing. Applying uniform illumination to the CCD enables the relative response of the individual photosites to be measured and compensated for.

The voltage on the antiblooming gates is set at a value that allows surplus charge to drain away instead of entering the transfer gates and shift register. By clocking this voltage, variable integration times that are less than the frame pulse to frame pulse exposure time can also be attained.

45.2.4 Area Charge-Coupled Devices

Three basic architectures are used in area CCDs and are illustrated in Figure 45.5. The simplest is the full-frame CCD, consisting of an imaging area separated from a horizontal CCD shift register by a transfer gate. In the imaging area, each photosite is one stage of a vertical shift register separated from neighboring shift registers by channel stops and antiblooming structures. During the light integration period, the vertical clocks are stopped, creating potential wells that collect photoelectrons. At the end of this period, the charge is clocked out vertically, one row at a time, into the horizontal shift register. The charge in the horizontal shift register is then very rapidly shifted toward the output amplifier by the application of a horizontal clock signal. An example of full-frame CCD is the RA1001J from EG&G Reticon, which has pixels arranged in a 1024 × 1024 configuration and dual horizontal shift registers and outputs to achieve a 30 frame/s readout rate. To avoid image smearing during the readout period, full-frame CCD sensors must be operated with external shutters, as in digital cameras produced by Kodak and other companies, or used in low-light-level applications requiring very long integration times compared with the readout time, as in astronomy. The full-frame CCD is also the basis for time delay and integration (TDI) sensor manufactured by companies such as Dalsa and EG&G Reticon. In the application of this device, which may have 96 rows each with 1024 pixels, a moving scene illuminates a region on the sensor only one pixel high, and this is arranged to move vertically down the sensor at the same rate that the generated photocharge is shifted down the sensor. This mode of operation achieves an output signal identical to that from a linear CCD sensor except for an increased light sensitivity proportional to the number of horizontal rows in the TDI sensor. It can be appropriate in applications where both high speed and high sensitivity are required, providing a cheaper alternative to the combination of a line sensor and an image intensifier. An application of this technique to capturing images of web systems moving at up to 5 m/s is described in Ref. [10].

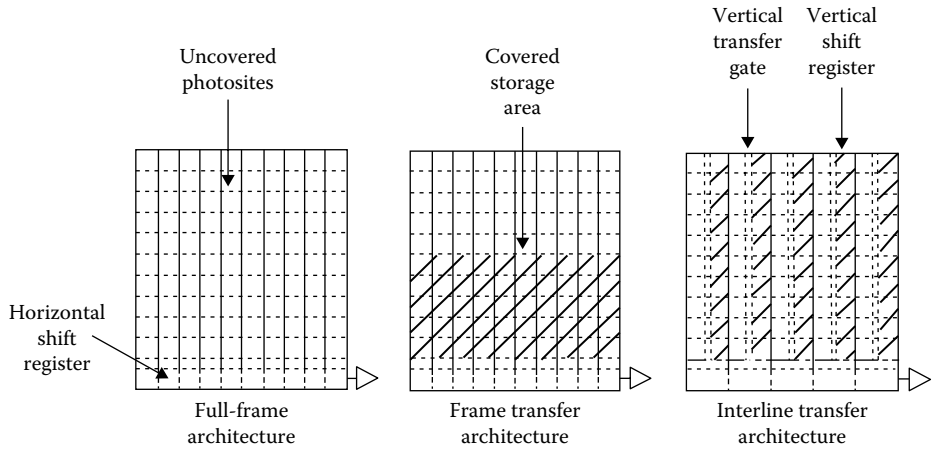

FIGURE 45.5 The basic architectures used in area CCDs. Full frame (FF) devices fully utilize the available area for image detection and therefore achieve the largest number of pixels, currently about 5000 × 5000, but need an external shutter. Frame transfer (FT) devices are normally used at standard video rates without an external shutter. The InterLine Transfer (ILT) architecture allows exposure times down to less than 0.1 ms. The lower fill factor of ILT devices compared with FF and FT devices results in higher values of modulation transfer function at the Nyquist limit. This increases the visibility of aliasing artifacts in images containing high spatial frequencies. A low-pass optical filter must be used if aliasing is a problem.

The requirement for an external shutter is greatly reduced in the frame-transfer CCD sensor by the provision of a light-shielded storage section into which the entire 2-D image charge is shifted at a much higher rate (limited primarily by CTE considerations) than is possible in a full-frame CCD. The charge can then be read from the storage region during the next integration period without any further image smearing. Some sensors, such as the EG&G Reticon RA1102 devices, have the storage area divided into halves placed on opposite sides of the imaging areas. This improves performance by halving the maximum number of transfers required to reach the nearest storage region. The same reduction occurs automatically in sensors designed for interlaced video applications where each integration period corresponds to one video field, and only half the number of rows in the frame is required at any one time. For example, to produce an interlaced video frame containing 576 image lines (CCIR standard), a frame-transfer sensor with only 288 rows of storage is required. By changing the clock signals, the odd field can be displaced vertically by half a line width relative to the even field. This ensures that the odd and even lines contain different information and reduces aliasing, because the cell width is twice the separation between the lines in the frame. Some of the companies that produce frame-transfer CCD sensors and cameras are Cohu, Dalsa, EG&G Reticon, EEV, Kodak, Philips, and Thomson-CSF.

Image smear is virtually eliminated by the interline-transfer (ILT) architecture in which each column of photosites has an adjacent light-shielded vertical CCD shift register into which the charge is transferred by a transfer pulse. The contents of the entire vertical shift registers are then shifted simultaneously one pixel at a time into a horizontal shift register where they are then rapidly shifted to an output amplifier. This approach makes it easy to implement exposure control and achieve short integration times, but it introduces *dead space* between the active pixels, reducing the sensitivity of the image sensing area and increasing aliasing effects compared with frame-transfer sensors. For the latter, the fill factor, which is the percentage of the imaging area that is light sensitive, can be close to 100%, whereas it is usually less than 50% for ILT devices. Localized bright objects tend to produce vertical streaks in an ILT device because strong light can leak under the narrow light shield covering the vertical shift registers, causing image smearing similar to that in a full-frame device. This reduces the usefulness of ILT sensors for scenes containing pronounced highlights. For interlaced operation, two adjacent pixels, for example, 1 and 2 and 3 and 4, are transferred to a single shift register cell on one field, and in the next field, pixels 2 and 3, 4 and 5, etc., are transferred together. This is rather similar to the interlaced operation of a frame-transfer CCD. The primary advantages of the ILT sensor are low-noise and good-exposure control, providing true *stop-motion* control on every field, because all photosites integrate light over the same period of time. Many companies manufacture ILT CCD sensors and cameras, including Hitachi, NEC, Panasonic, Pulnix, and Sony.

The frame-transfer and ILT approaches both have performance advantages and disadvantages, and the hybrid frame-interline-transfer (FIT) approach [11] combines some of the advantages of both. This architecture includes a light-shielded field storage area between an interline imaging area and the horizontal output shift register. With this arrangement, the charge associated with the whole image is first transferred horizontally into the interline storage area, which facilitates exposure control. The charge is then transferred at maximum speed (as in the FT sensor) into the field storage area, which minimizes the occurrence of vertical streaking. For example, the NEC microPD 3541 array clocks the vertical registers at 100 times the normal rate for an ILT sensor. This gives a 20 dB improvement in streaking threshold and an overall threshold of 80 dB, making streaking effects less than other optical effects such as lens flare. On the other hand, the FIT approach does not improve the fill factor, and aliasing artifacts associated with ILT sensors and the noise levels are somewhat higher, and the CTE reduced, because of the higher clock frequencies. Manufacturers of FIT sensors and cameras include JVC, Panasonic, and Sony.

45.2.5 Photodiode Arrays

Because photodiode arrays generally have less extensive electrode structures over each sensing element compared with CCD arrays, the spectral response is smoother and extends further at the blue end of the

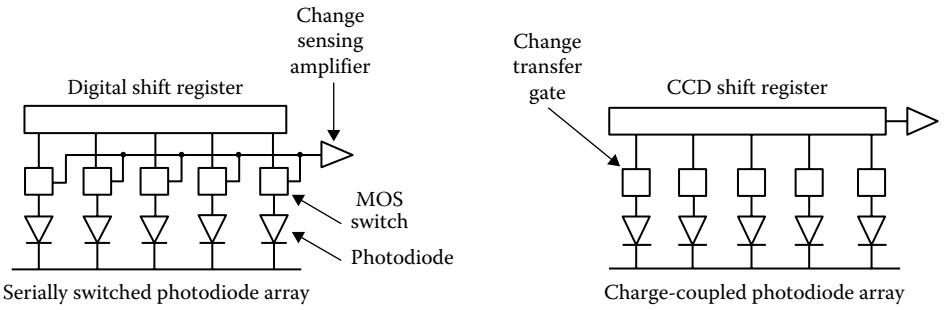

FIGURE 45.6 Readout architectures associated with photodiode array sensors. In the SSPD approach shown, each photodiode is connected in turn via an MOS switch to the sensing amplifier. This eliminates smearing, because the charge does not move between photosites. The device noise and speed characteristics are poorer than CCD sensors because of nonuniformity in the MOS switches and the large capacitance of the sensing bus. The CCPD approach combines the excellent blue-end response of the photodiode with the low-noise transfer characteristics of the CCD shift register to produce very high-quality linear devices.

spectrum. The peak quantum efficiency is also higher ranging from 60% to 80% compared with 10% to 60% for photogates, leading to almost twice the electric output power for a given light input power. Photodiode arrays would therefore appear to be attractive alternatives to CCD array sensors, but in practice, CCD sensors have lower noise levels because they do not have reverse-bias leakage current. A photodiode consists of a thin surface region of p-type silicon formed in an n-type silicon substrate. A negative voltage applied to surface electrode reverse biases the p-n junction and creates a depletion region in the n-silicon containing only immobile positive charge. When the electrode is isolated, the p-n junction is left charged and is effectively a charged capacitor. Light penetrating into the depletion region creates electron–hole pairs, which, with dark current, discharge the capacitor linearly with time. The penetration depth in silicon increases with wavelength, and the depletion region should be wide enough to absorb all wavelengths of interest. Dark current and most of the noise sources operating in the photodiode increase with reverse bias but can be reduced by employing a thicker p-type region, which allows a wide depletion region to be achieved with low bias voltage. However, this also degrades the blue-end response of the photodiode. To achieve good blue and UV response along with low bias voltage operation, a three-layer structure comprising thin p-type, intrinsic, and n-type substrates is employed. The intrinsic layer is so pure that the depletion region extends halfway across it at zero bias and extends right across it at a small reverse-bias voltage. This structure provides photodiodes with excellent linearity, noise performance, and speed of response at low operating voltages. At the end of an integration period, the states of charge of the photodiodes are measured, and image sensors based on two different types of readout approach are commercially available. These are the serially switched (sometimes called self-scanned) photodiode (SSPD) arrays and the charge-coupled photodiode (CCPD) arrays illustrated in Figure 45.6.

45.2.6 Serially Switched Photodiode Arrays

Associated with each photodiode in the sensor array is a metal-oxide semiconductor (MOS) switch, which, when turned on by a digital voltage level applied to its control line, connects the photodiode to a readout amplifier. Each control line is connected to one of the outputs of a digital shift register and, shifting a bit through the register, sequentially reads the charge on each photodiode in the array. This type of readout is very flexible, and random readout is achieved by replacing the digital shift register by an address decoder connected to an address bus as in the SR series linear arrays from EG&G Reticon. The 2-D arrays of photodiodes are connected in a configuration similar to a cross-point switching

matrix with a switch and diode at each cross point and separate vertical and horizontal shift registers. To scan the array, the vertical shift register turns on a complete row of switches, which causes the photodiodes in the corresponding row to dump their charge into vertical signal lines. These are in turn connected to the output amplifier by a set of horizontal switches controlled by the horizontal shift register. Switched arrays of photodiodes are made using processes similar to those employed in the manufacture of dynamic RAM, and this along with their simple structure and small size yields higher densities and lower manufacturing costs. However, the SSPD approach has one shortcoming, namely, the large capacitances of the readout buses. This reduces the speed of the device, increases the noise, and reduces the dynamic range, which are all generally significantly worse than those of CCD sensors. The dynamic range, for example, is typically 250–300 compared to more than 2500 for commercially available CCD sensors. SSPD arrays also suffer from fixed-pattern noise due to nonuniformities in the switches, which can be as high as 20% of the saturated output. The SSPD approach does have unique advantages:

- The readout method is extremely flexible and can be programmable.
- It is relatively free from blooming effects, because the sensors can be optimally isolated from each other.
- The blue response is good, which is particularly important for spectroscopic applications and for studio quality color television cameras.

Manufacturers supplying SSPD-based sensors include EG&G Reticon, Hamamatsu, and VLSI Vision.

45.2.7 Charge-Coupled Photodiode Arrays

Although individual photodiode elements are superior to individual CCD photogate elements in terms of dynamic range, the dynamic range of the SSPD is limited by fixed-pattern noise, switching noise, and the difficulty of transferring charge packets over the high capacitance output bus. Replacing the horizontal digital shift registers by a low-noise CCD shift register significantly improves the dynamic range of the device, and the resulting hybrid design is the CCPD array. During operation, the charges on an entire row of photodiodes are simultaneously transferred via MOS switches into the analog CCD shift register and then shifted out in sequence to the output amplifier. By providing a reset pulse (from a second vertical digital shift register) to eliminate all prestored charge in one row a fixed interval before the charge is transferred to the CCD shift register, it is relatively easy to implement an electronic equivalent of a focal-plane shutter [12] and control exposures in increments of one horizontal scan period. However, images of moving objects will be subject to distortions similar to those found using photographic cameras with focal-plane shutters. In the case of 2-D arrays, there are inefficiencies in the movement of small charge packets over the vertical transport lines, which get worse the smaller the packet. The solution adopted is to turn a small charge into a large one by precharging the lines with a priming charge equal to 10%–15% of the maximum charge capacity before transferring the photocharge to the CCD in a process known as charge-primed transfer. This requires several MOS switches forming a sequence of transfer gates and storage capacitors between each vertical transport line and CCD cell and depends critically on correct phasing of a large number of timing signals for proper operation. The CCPD approach appears to be most successful for linear arrays, which do not require a vertical transport bus. Manufacturers supplying linear CCPD-based sensors include Dalsa and EG&G Reticon.

45.3 Image Intensifiers

When the available solid-state image sensors do not have enough sensitivity for the scene illumination, it is necessary either to use a more sensitive tube camera or to amplify the available light. Companies supplying intensified cameras include Cohu, Kodak, Pulnix, and Philips. Intensified cameras are

standard video cameras fitted with image intensifiers that increase the number of available photons falling onto the image sensor. In addition to allowing operation over a wide range of lighting of the order of 0.0001 lux from overcast starlight to 100,000 lux of full sunlight, intensified cameras can be used to stop motion in nanosecond frame times, count photons, and observe images with very high intrascene dynamic ranges. However, this increased flexibility is achieved at a considerable increase in cost, usually some loss in resolution, reduced lifetime, and increases in geometric distortion, lag, and smear. Image intensifier tubes (IITs) are usually classified as generation I, II, and III devices.

45.3.1 Generation I Tubes

In a generation I intensifier, illustrated in Figure 45.7, the incoming photons strike a multialkali photocathode within a vacuum tube, and the resulting photoelectrons emitted into the vacuum are accelerated and focused onto a phosphor coating on the rear wall of the tube. The impact of the high-energy electrons on the phosphor creates many electron–hole pairs that in turn generate light at a higher level than that striking the photocathode. The electron gain depends strongly on the accelerating voltage and also on the photocathode and phosphor materials, and it is typically around 200 with a 12 kV accelerating voltage. These tubes tend to be bulkier than later-generation tubes and have relatively low gains, although tubes can be cascaded to achieve higher gains. They are also relatively intolerant of bright sources and rapid changes of scene illumination, with increased tendency toward highlight blooming. The light output from the intensifier tube is transferred to the solid-state sensor by either a relay lens or a fiber-optic coupler. The latter is shorter and much more efficient (typically 60% compared with 6%) but requires a sensor whose protective glass or quartz window has been replaced by the fiber-optic coupler resting against the sensor surface. The narrow gaps between couplers and between the coupler and sensor are filled by index-matching optical grease. The spectral response of the photocathode should be chosen to match the scene requirements, while the narrower phosphor response should be optimally matched to the image sensor for greatest sensitivity [13]. In general, for largest output, a phosphor with the maximum persistence that is acceptable in terms of image lag should be selected. But, if the scene includes object motion, a shorter-persistence phosphor may be necessary to avoid image smear. For night vision, P20 and P39 phosphors are frequently used. The former emits 550 nm light with very high luminous efficiency (65%) and relatively short persistence (0.2 ms), while the latter has a persistence of about 80 ms, which reduces high-frequency jitters. For high-speed imaging, the yellowish-green P46

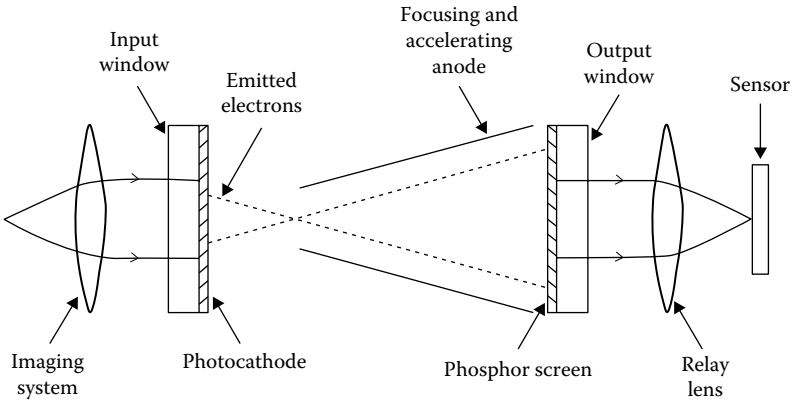

FIGURE 45.7 A schematic diagram showing the major components of a generation I IIT coupled to a sensor. Combined with a CCD sensor, the sensitivity of a SIT tube camera is achieved but with much higher reliability and greatly reduced lag, geometric distortion, and power consumption. An example is the Cohu 5512 generation I optical fiber coupled intensified CCD camera, sensitive down to 0.00015 lux and with 460 TV line horizontal resolution, currently costing about $12,000.

phosphor has a persistence of only 0.16 μs, while the purplish-blue P47 phosphor has a persistence of only 0.08 μs. However, both these phosphors have luminous efficiencies of only 3%. The resolution of an intensified camera is generally quoted in line pairs per millimeter (lp/mm) and is the harmonic mean of the individual resolutions of the intensifier (typically 20–30 lp/mm), the coupler (typically 80 lp/mm), and the image sensor (typically 20–50 lp/mm).

45.3.2 Generation II and III Tubes

Generation II intensifiers are similar to generation I devices except that gain is achieved using a microchannel plate (MCP) instead of an accelerating potential difference in vacuum (see Figure 45.8). Generation III intensifiers are similar to generation II except that the multialkali photocathode is replaced by a gallium arsenic solid-state structure. The resulting device has double the gain of a type II device and improved SNR and resolution. The heart of both types is an MCP disk about 25 mm diameter and 0.5 mm thick, consisting of an array of millions of glass tubes (called *microchannels*) with holes about 10 μm diameter coated with a secondary electron emitting substance. The two faces of the MCP are coated with conducting layers, allowing a voltage (typically 50–900 V) to be applied between the entrance and exit of each microchannel. An energetic electron from the photocathode enters a microchannel and produces secondary electrons on striking the wall. These electrons are accelerated by the axial electric field and, in turn, dislodge more secondary electrons. This process is repeated many times down the channel. The number of electrons continues to increase until either the end of the channel is reached or current saturation occurs because the electron cloud is so dense that it inhibits further secondary emission. The electrons exit the MCP and may be accelerated further before striking a phosphor screen. The light generated is then transported to the image sensor by fiber-optic couplers. A thick phosphor layer increases light gain but allows electrons and light scattering in the phosphor, which causes some loss of resolution. Improved performance is achieved by integrating the phosphor into the fiber-optic bundle in a so-called *intagliated construction*. Each glass core in the fiber-optic bundle is etched out to a predetermined depth, leaving a small cup of cladding glass at the entrance to each fiber, which is filled with phosphor. Electrons striking the phosphor produce light that is confined to one fiber,

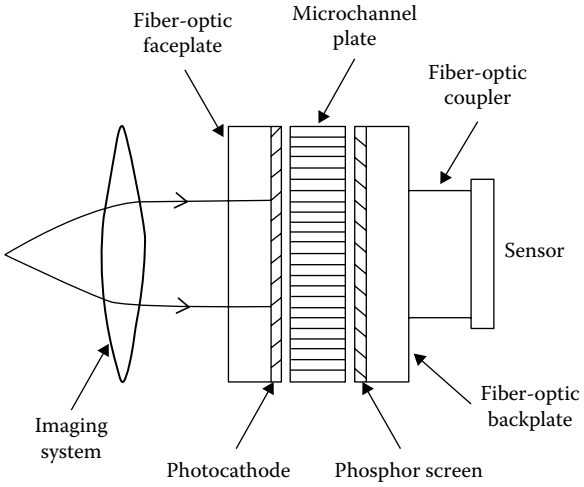

FIGURE 45.8 The basic components of a generation II or III intensified image sensor. These are typically two and four times more sensitive than generation I intensifiers. Narrow vacuum gaps between the photocathode, MCP, and phosphor screen achieve proximity focusing. An example is the Philips 1800 low-light video camera, which couples an XX1410 generation image intensifier with an FT800 1/2 in., 760 × 576 resolution frame-transfer CCD at a cost of around $8000.

minimizing cross talk and improving resolution. The overall light amplification achieved is of the order of 10^4, and higher gains can be achieved by stacking multiple MCPs and by increasing the accelerating voltages. The MCP has a nonlinear response, because the current density increases at an exponential rate until limited by saturation. The IIT can be gated in only a few nanoseconds by pulsing the cathode potential from the cutoff level (a few volts positive) to the normal operating voltage. This provides a high-speed shutter capability for stopping motion as well as a means of exposure control. Generation II devices have high gain and dynamic range and are easy to gate on and off, but they have relatively low output levels compared with generation I devices. The Kodak EktaPro 1000 high-speed video camera uses a generation II intensifier as a high-gain first stage coupled to a generation I intensifier to provide the required level of light output.

45.4 Fiber-Optic Scopes

It is sometimes necessary to acquire images within confined and inaccessible spaces. In some cases, this can be achieved with the aid of mirrors, but when the image must be conducted around bends, a fiberscope may be needed. This consists of a semirigid flexible sheathing around a bundle of optical fibers, each about 10 μm diameter aligned coherently so that fibers have the same relative location at entrance and exit of the bundle. An image formed on one end of the bundle therefore appears undistorted but dimmer at the other end. Between 20% and 35% of the bundle face area consists of fiber cladding and epoxy filler and does not transmit light. Light passing through fiber cores suffers Fresnel reflection losses of about 4% on entering and leaving and attenuation within the fibers of the order of 10%–15% for each meter of length. A 1 m fiberscope therefore transmits only about 40%–60% of the incident light. Fiberscopes range in diameter from about 2 to 18 mm and in length from about 0.6 to 3 m, with a minimum bend radius of about 75 mm for an 8 mm insertion diameter tube. To illuminate the object, a coaxial arrangement of fibers is often used, as in the flexible boroscope marketed by Edmund Scientific. The inner fibers are used for imaging, while fibers in the outer, noncoherent bundle are used to transport light to the object. Alternatively, a separate fiber-optic light guide may be used. Fiberscopes may be fitted with optics for viewing in the forward, oblique, side, and rearward directions but may not allow easy quantitative measurements of distances and areas because of distortions introduced by wide-angle optics. Fiberscopes are generally supplied with an eyepiece for direct observation, but C-mount couplers are often available to allow a CCD camera to be connected.

45.5 Components and Trends

A wide range of image sensors and cameras based on tube and solid-state technologies is now available, and a few examples are listed in Table 45.1 to give an indication of some of the currently available devices and their approximate prices, if purchased in the United Kingdom. It is advisable to contact local suppliers to determine actual prices and availability. Contact information for some companies is listed in Table 45.2. Manufacturers are continuing the incremental development of sensors with greater resolutions, readout rates, and signal-to-noise performances, and new application areas such as high-definition television (HDTV) and digital photography should cause prices to come down as the markets for these products expand. Some examples of this type of development are as follows:

- EG&G Reticon is currently developing a 1000 frames/s, 1024 × 1024 ILT CCD sensor for high-speed imaging.
- Thomson Components (France) has developed the THX-31163 CCD sensor specifically for use in HDTV. This chip is designed to output 1152 × 1260 pixel frames in 40 ms at a transfer frequency of 47 MHz.

TABLE 45.1 Cameras, Sensors, and Other Components

Manufacturer	Designation	Function	Specification
Cohu	4712	Monochrome TV camera	1/2 in. FT CCD, 754 × 484 pixels, 0.04 lux minimum, RS-170 output
Cohu	4110	Digital output camera	1/2 in. FT CCD, 755 × 484 pixels, 0.01 lux minimum, 8 bit per pixel RS-422 outputs
Cohu	4912	Monochrome TV camera	1/2 in. ILT CCD, 768 × 494 pixels, 0.02 lux minimum, RS-170 output
Cohu	2252	Color TV camera	1/2 in. microlens ILT CCD, CMYG mosaic filter, 0.3 lux minimum, NTSC/Y-C/RGB outputs
Edmund Scientific	A52999	Fiberscope	8 mm diameter, bend radius 75 mm, 60° field, 10–100 mm focus
EG&G Reticon	D Series	Line sensors	256, 512, 1024, or 2048 pixel CCPD arrays
EG&G Reticon	LC1911	Line scan camera	10 MHz data rate, D series sensors, RS-422 outputs
EG&G Reticon	RA1001	Area sensor	FF CCD, 1024 × 1024 pixels, dual outputs, 30 frames /s
EG&G Reticon	TD Series	TDI CCD array	1024 × 96 pixels, single output
Hamamatsu	S5464–1024Q	Spectroscopic line sensor	CMOS SSPD 1024 array, 2.5 mm by 25 μm pixels, quartz window
Kodak	DCS 410	Color digital camera	FF CCD, 1524 × 1012 pixels, mosaic filter, Nikon N90S camera
Kodak	DCS 460	Color digital camera	FF CCD, 3060 × 2036 pixels, mosaic filter, Nikon N90S camera
Panasonic	GP-US502	Remote head color camera	3 1/2 in. ILT CCDs, 768 × 494 pixels, 3 lux minimum, NTSC/Y-C/RGB outputs
Philips	XX1410	Intensifier	18 mm generation II
Philips	XQ3427	Tube	2/3 in. plumbicon, 400 TV lines at 55% modulation
Philips	XQ1270	Tube	2/3 in. vidicon, resolution 500 TV lines
VLSI Vision	Imputer 3	Intelligent camera	2/3 in. CMOS sensor, 512 × 512 × 8 bit, 32 bit RISC CPU
VLSI Vision	IDS	Development system	Software and hardware to create imputer 3 applications

- Manufacturers such as Kanimage, Kodak, and Leaf Systems supply digital cameras based on very high-resolution area array sensors. The Kodak professional range of color and monochrome digital cameras, for example, incorporate CCD full-frame-transfer sensors with resolutions ranging from 1024 × 1536 to 2036 × 3060 into standard 35 mm photographic cameras.

A separate trend is the development of smart cameras and smart sensors [14] for industrial and scientific applications. There are two basic motivations. One is to correct for imperfect behavior of sensors (such as pixel to pixel nonuniformity associated with MOS devices), and the other is to reduce the communications or processing bottlenecks associated with handling very large amounts of image data. A smart camera is a single-image acquisition subsystem incorporating image sensor, analog-to-digital conversion, and microprocessor that provides processed image data in a standard format such as SCSI or RS-423. Pulnix already supplies a series of smart line scan cameras that implement application functions such as object detection, size measurement, and go, no-go comparison. Another example is the imputer 3 [15] from VLSI Vision incorporating a complementary MOS (CMOS) area sensor with 512 × 512 digital resolution and an i960 32 bit reduced instruction set processor. Using VLSI technology, but not CCD technology, it is possible to integrate both image acquisition and low-level processing onto a single chip to achieve a kind of electronic retina. One way of constructing such chips

is to integrate photodetector and processing element at the photosite, but this produces very poor fill factors. This can be alleviated to some extent by using microlenses to focus the light onto the sensitive region. An alternative approach is to implement the photodetection and processing as separate arrays on the chip. This allows a large fill factor but requires high-frequency data paths between the two arrays. The development of smart image sensors is still in its infancy, but nevertheless the creation of an artificial eye is now on the horizon.

46.1 Introduction

Charge-coupled devices (*CCDs*) have become the detector of choice for sensitive, highly precise measurement of light over the electromagnetic spectrum from the near-infrared (IR) (<1.1 μm) to the x-ray band (up to 10 keV). Key advantages of CCDs over their predecessors (photographic emulsions and vacuum tube, electron beam readout devices such as vidicons and Silicon-intensifier target (SIT) tubes) are high quantum efficiency (QE), high linearity, large dynamic range, relatively uniform cosmetic response, low noise, and intrinsically digital image capture.

CCDs were initially designed as serial data storage media (an electronic analogy to the magnetic bubble memory units) in which charge packets were injected into linked capacitors to store data and read back by moving the packets back out of the device. When it was found that charge packets could be directly induced in the capacitors by exposing them to light, the CCD as light sensor was born.

Physically, *CCD operation* consists of four critical stages. First, an incident light photon must be photoabsorbed in the sensitive portion of the CCD chip (called the *depletion region*). At optical and IR wavelengths, the absorption results in a single electron being promoted into the conduction band (leaving a hole in the valence band); at shorter wavelengths, the photon has enough energy to make additional electrons via secondary ionizations by the photoelectron.

Second, the photon-induced electrons must be collected, via an electric field within the silicon, into localized regions near the front surface of the chip. The electric field is shaped by implanted dopants and by electric potentials applied to thin conducting strips (*gates*) that prevent the electrons from diffusing away. The resulting charge distribution corresponds to an electronic analog of the light intensity pattern shone on the CCD. The resolution of this pattern is governed by the size of the potential wells, which are designed to be periodic. Each well is called a *pixel* and corresponds to the minimum picture element detected by the CCD.

Third, after exposure is completed, the CCD charge pattern must be transferred out of the CCD. This is accomplished by modulating the potential applied to the CCD gates in such a way that no charge packets are mixed, but that each packet moves into the next pixel. The end pixel is transferred into a special pixel array called the *serial register*. Each movement of charge resulting from gate potential changes is called a clock cycle, and the serial register receives many clock cycles for each cycle of the full pixel array. The net result is a sequence of charge packets emerging from the serial register, each of which is directly proportional to the amount of light striking a particular location on the CCD.

Fourth, the emerging charges are converted into electric signals by a charge-sensitive preamplifier on the CCD chip. These signals are often digitized by electronics in the camera immediately outside the chip, but analog readouts that produce signals compatible with video standards are also used (the popular handheld video cameras are examples of this). Research-grade camera readouts are able to measure the charge pulses with accuracies as good as one or two electrons rms, if the CCD and electronics are cooled.

Currently available CCDs carry out these steps so well that they are nearly the ideal detector for precision low-light-level applications, especially in astronomy. Such an ideal detector would have perfect QE (i.e., convert every incident photon into detectable signal), no noise, unlimited dynamic range, linearity in response to incident intensity and position, and completely understandable characteristics.

CCDs have high QE because photons interact via photoabsorption in the depletion layer, which directly results in one or more electrons promoted into the conduction band of the silicon lattice, and are very efficiently collected by the CCD. The main obstacles to perfect QE are absorption of photons by the gate and insulator materials before they ever reach the depletion regions (or optically, by reflection off the front surfaces) or if the photon passes entirely through the depletion region without interacting.

There are many approaches to enhancing *CCD QE* for various applications. In soft x-ray and ultraviolet (UV) wavelengths, the gate and insulator layers on the front of the CCD absorb too much light. To solve this, CCDs are built with thin gates or thinned substrates and backside illumination. CCDs are also coated with phosphor coatings that down-convert UV light to longer wavelengths where the gate transmission is higher.

At hard x-ray and IR wavelengths, too much light can pass through the depletion region without interacting at all. The depletion region is the part of the CCD pixel that is swept clean of free charges during the readout process. The depletion region gets deeper if higher purity silicon is used and if higher voltage biases are applied during the readout.

Above 1.1 μm, photons do not have sufficient energy to promote electrons into the silicon conduction band, so other materials, such as germanium or a compound semiconductor such as InAs, InSb, or HgCdTe, must be used.

CCD noise results from four major factors: (1) thermal background noise, (2) charge transfer imperfections, (3) charge-to-voltage amplification noise, and (4) cosmetic imperfections in the CCDs due to, for example, microscopic shorts in the insulating layers of the CCD. Factor (1) results from a "dark current" of thermally excited electrons that accumulate in the pixels and can be eliminated by cooling the CCD (typically to −60°C to −120°C). Factor (2) results from traps that hold electrons long enough to

shift them into following charge packets identified with other pixels. Factor (3) is a fundamental limit related to the temperature and capacitance of the output mode (kT/C), but it can be suppressed by signal processing techniques such as "correlated double sampling" to the equivalent of a few electrons (1–5 in state-of-the-art cameras). Factors (2) and (4) can be greatly reduced by improved manufacturing technique, especially scrupulous contamination control during the process.

CCD dynamic range is set by the maximum charge packet that can be stored in a pixel. Termed "full-well capacity," this is set by the depth of the potential well. When the full-well capacity is exceeded, the image of a point source "blooms" as a result of charge leaking into surrounding pixels, and a trail of brighter pixels forms in the readout direction of the CCD due to charge incompletely transferring from pixel to pixel during a clock cycle. Modern CCDs have full-well capacities in excess of 10^5 electrons and can be designed even larger. (Note that larger full well also requires larger output capacitance, so a trade-off is generally required between blooming and low noise.)

CCD linearity in intensity response and position response is very good because the conduction band in the CCD has so many states that the very small injected photocharge does not affect subsequent photon interactions. The position linearity results from the photolithography of the manufacturing process, which must be accurate to less than 1 μm. The primary limitation on linearity results from imperfect *charge transfer efficiency* (CTE) in the process of clocking charge packets from pixel to pixel. At readout rates below 100,000 pixels/s, CTE imperfections have four causes:

1. *Design imperfections*: errors in CCD design can leave potential minima that are incompletely drained during clocking.
2. *Process-induced traps*: random cosmetic defects, presumably due to imperfections in manufacturing.
3. *Bulk traps*: lattice defects or impurities that introduce local potential minima, which temporarily capture electrons long enough to remove them from the original charge packet, but reemit them later.
4. *Radiation-induced traps*: similar to (3) but resulting from lattice defects caused by low-energy protons. This damage is most commonly seen by spacecraft CCD cameras.

46.2 CCD Operation and Data Reduction

In order to achieve ultimate *CCD performance* for a given goal, the CCD camera can be operated in special ways, and the postcamera data reduction can be optimized. Typical optical use of CCDs involves timed exposures, where the CCD pixels are exposed to light and the total charge integrated in pixels for a preselected time. At the conclusion of the integration, a shutter closes and the CCD is read out. As noise reduction limits the readout to about 100 kpixels/s, a large CCD (2048 × 2048 pixels) readout can take many seconds to complete.

To avoid the dead time associated with the closed shutter, some CCDs are made with framestore regions. The framestore is a pixel array equal to the integration region that is permanently blocked by a cover from any additional light. The pixels containing the charge pattern resulting from the integration are very rapidly clocked into the framestore region (typically requiring much less than 1 s) and then slowly clocked out into the readout region without moving the integration pixels.

Operationally, CCD reduction requires calibration exposures. These include bias frames, which are readouts with the same integration time but no light striking the CCD, and flat-field frames, which have a uniform illumination over the CCD. The bias frames are subtracted from the data frames to set the zero point corresponding to zero incident radiation. (Note that CCDs will accumulate charge due to thermal electrons and low-level shorts in the gates, even if no light hits the CCD.) The flat field allows correction for pixel-to-pixel sensitivity variations. Proper flat fielding can remove variations of arbitrary amplitude and spatial scale.

The CCD dark current bias can be reduced by cooling the CCD or by operating it in an inverted phase mode. In inverted phase operation, the gate electrode is given a suitable negative bias that attracts hole

carriers to the front surface of the CCD. These holes fill interface states at the Si–SiO_2 boundary between the conducting depletion region and the insulating layer under the gates. Suppression of these interface states dramatically lowers the dark current because the interface states are much more efficient at thermal electron promotion to the conduction band than the bulk material. Not all phases can be operated in inverted mode in a normal CCD because, without the restraining potentials provided by gates held at positive voltage, the pixel charge packets can intermingle. A special CCD called a multiphase pinned (MPP) device has extra implant doping that isolates the pixels even with all three phases inverted, yielding dark current so low that integration times up to minutes become possible in room-temperature MPP CCDs.

Other important uses of CCDs include cases where the CCD is continuously clocked, without any shutter. Suitable for high-light-level conditions, the effective integration time becomes the time to transfer a pixel charge across the source point spread function (PSF) on the CCD. This allows sensitive timing of source intensity changes.

A similar technique is called *drift scanning*, where the rate of clocking of pixels equals the rate of motion of the target across the CCD. Such a condition is common in astronomy, where a fixed detector on the Earth sees slow motion of stars in the field of view due to the Earth's rotation.

Drifts and instabilities in the camera electronics can be corrected using a technique called "overclocking." If the serial registers are clocked more times than there are physical pixels in the CCD, then the excess clocks will produce charge pulses corresponding to zero input light and zero dark current. The distribution of the overclock pulse is then a measure of the readnoise of the CCD chip-camera system, and the mean of the distribution sets the zero point of the energy to output voltage curve. Frequently, CCD cameras subtract the mean of the overclock pixels from all output values in a row (called "baseline restoration").

46.3 CCD Signal-to-Noise Ratios

To see how these characteristics of the CCD relate to measurement, it is instructive to study the signal-to-noise ratio (SNR) predicted for a given exposure time. In a single pixel illuminated by a source that contributes S_o counts (electrons) to the pixel, one also sees contributions from dark current (S_d) and background illumination (S_s, usually called the "sky" in astronomical usages), all in units of counts per pixel per second. The source contribution (S_o) can be expanded into the intensity of light from the source, I; the QE of the CCD, Q; and the integration time, t, to provide

$$S_o = I \times Q \times t \tag{46.1}$$

The camera readout contributes a randomly distributed but fixed Gaussian noise with variance N_r. The SNR of a particular pixel is then

$$\text{SNR} = I \times Q \times t = (I \times Q \times t + N_r^2 + S_d + S_s)^{1/2} \tag{46.2}$$

If the light from a source is distributed over a number of pixels, n (as might arise from a star viewed through a telescope with a PSF covering n pixels), then if the integral of S_o over the PSF is C_o and the integral of S_s over the pixels is C_s, then

$$\text{SNR} = \frac{C_o^{1/2}}{(1 + C_s C_o + n + r^2 C_o)^{1/2}} \tag{46.3}$$

Clearly, high Q and low r are desirable, and t should be chosen to make C_o greater than both C_s and r. It is worth noting that, in most optical applications (except for extremely faint sources), it is the uncertainty in the flat fielding (i.e., the corrections made for pixel-to-pixel sensitivity variations and background) that ultimately limits the achievable SNR.

46.4 CCD Structure and Charge Transport

46.4.1 CCD Structure and Its Potential Profile under Bias

A CCD is a semiconductor device operating under the principle that charges can be temporarily stored and transported along a string or array of metal oxide semiconductor (MOS) capacitors. The basic storage unit is called a pixel and is made up of several MOS capacitors. In almost all CCDs, charges are stored either directly at the oxide–semiconductor interface (surface-channel device) or deeper within an epitaxial layer (buried-channel device). Theoretically, a surface-channel CCD has a larger charge capacity, but it also is prone to noise arising from interface states at the boundary.

The CCD is operated by varying voltages applied to the surface electrodes. Typically, the CCD is kept for a long period in an integration state, where photon-induced electrons accumulate in the potential wells under the CCD pixels. After the integration finishes, the voltages are changed to transport the charge from one capacitor to the next. This sequence of moving charge packets by potential clocking is sometimes called "bucket-brigade" charge transfer.

The storage unit of the CCD is the MOS capacitor, and it is possible to deplete, invert, or form a surface accumulation layer in the MOS capacitor by simply changing the surface potential. CCDs operate in the so-called "deep depletion" mode when the surface layers are fully depleted. For a buried-channel CCD with an *n*-type buried layer within a *p*-type epilayer, this would require the application of a positive bias to the surface electrodes. The equations governing the 1D calculations of the potential distribution in the MOS capacitor are [1] as follows:

$$\begin{aligned}
&\frac{d^2\psi}{d_x^2} = 0 \quad -d < x < 0 \\
&\frac{d^2\psi}{d_x^2} = -q \cdot \frac{N_D}{\varepsilon_s} \quad 0 < x < t \\
&\frac{d^2\psi}{d_x^2} = q \cdot \frac{N_A}{\varepsilon_s} \quad t < x < x_p
\end{aligned} \tag{46.4}$$

where

ψ is the potential
N_A is the substrate acceptor density
N_D is the donor density in the epilayer
x_p is the depletion edge in the *p*-type substrate
ε_s is the semiconductor permittivity

Note also that d is the oxide thickness and the origin ($x = 0$) is located at the oxide–semiconductor boundary.

The boundary conditions will be

$$\begin{aligned}
&\psi(x = -d) = V_G \quad \left.\frac{d\psi}{d_x}\right|_{x=t^-} = \left.\frac{d\psi}{d_x}\right|_{x=t^+} \\
&\varepsilon_{ox} \cdot \left.\frac{d\psi}{d_x}\right|_{0^+} = \varepsilon_s \cdot \left.\frac{d\psi}{d_x}\right|_{0^+} \quad \psi(x = t^-) = \psi(x = t^+) \\
&\psi(x = 0^-) = \psi(x = 0^+) \quad \psi(x = t + x_p) = 0
\end{aligned} \tag{46.5}$$

and the solutions are

$$\psi = V_G - E_{ox} \cdot (x + d) \quad -d < x < 0$$
$$\psi = \psi_{max} \frac{-q \cdot N_D \cdot (x - x_n)^2}{(2\varepsilon_s)} \quad 0 < x < t \tag{46.6}$$
$$\psi = \frac{q \cdot N_A \cdot (x - t - x_p)^2}{(2\varepsilon_s)} \quad t < x < t + x_p$$

where

E_{ox} is the electric field in the oxide layer
V_G is the gate bias voltage
x_n is the position of the potential maximum

Figure 46.1 shows a typical potential profile across the MOS capacitor in a buried-channel CCD. Note the presence of a potential maximum, ψ_{max}, where the electrons will reside. It is given by

$$\psi_{max} = \psi_J \cdot \left(1 + \frac{N_A}{N_D}\right) \tag{46.7}$$

where $\psi_J = q \cdot N_A \cdot x_p^2/(2\varepsilon_S)$.

Since x_p increases linearly with N_D, the potential maximum ψ_{max} and hence the charge storage capability also increase for a heavily doped epilayer. The derivation of the potential profile in a surface-channel CCD will be similar, but with d set to zero.

46.4.2 Charge Transport

Charge transport in a CCD refers to the transfer of charges along the MOS capacitors (i.e., from one pixel to the next). There are several clocking schemes used, generally divided according to how many external voltage regions are applied per pixel, ranging from one (uniphase) to four phases.

Computation of charge transport in a CCD requires solving the 2D Poisson equation with appropriate boundary conditions to obtain the potential distribution within the pixel for each separate phase

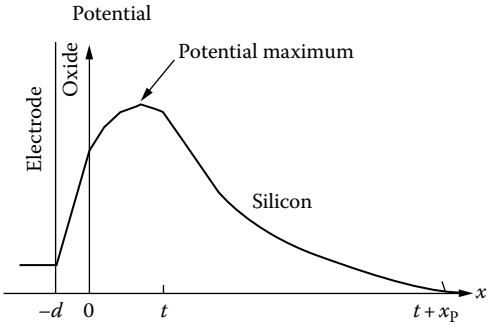

FIGURE 46.1 Potential profile across MOS capacitor.

within the clocking cycle. Numerical techniques using finite-difference or finite-element methods have been used. For charge transfer in an *n*-type epilayer, the electron flux, $F(x)$, is given by

$$F(x) = n_s(x,t) \cdot \upsilon(E(x)) - D(E(x)) \cdot (n_s(x + \Delta x, t) - n_s(x,t)) = \Delta x \tag{46.8}$$

where

$n_s(x, t)$ is the electron density
$E(x)$ is the electric field in the x-direction
$\upsilon(E(x))$ is the field-dependent velocity
$D(E(x))$ is the electron diffusivity

Figure 46.2 shows the time evolution of charges along a CCD. Some "smoothing" of the output charge profile is often observed, and, for high-speed devices, velocity saturation will be important. Computations of charge transfer are sometimes carried out using an equivalent circuit model for the CCD in a Simulation Program with Integrated Circuit Emphasis (SPICE)-type simulator. It has been shown to offer both faster computation time and the ability to include external support circuits into the model.

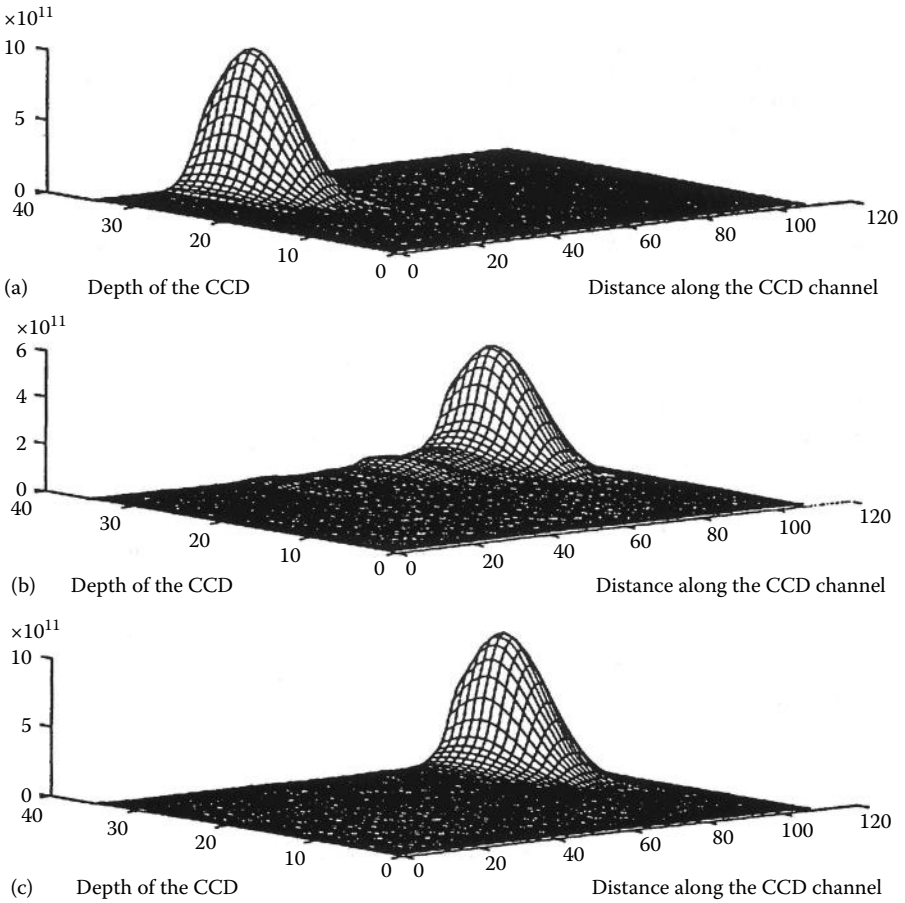

FIGURE 46.2 Time evolution of charges along a CCD: (a) t = 200 ps, (b) t = 400 ps, and (c) t = 600 ps.

CTE, η, is the key figure of merit in a CCD, at least comparable to QE. A common technique to determine η is to measure the amplitude response of the CCD using a network analyzer. η is then related to the amplitude response of the output, G_V, through the following relationship:

$$G_V = \exp\left\{-N_T \cdot (1-\eta) \cdot \left[1 - \cos\left(\frac{2\pi f}{f_c}\right)\right]\right\} \tag{46.9}$$

where
N_T is the number of transfers
f is the signal frequency
f_c is the clock frequency

For the relatively mature Si CCD technology, CTE of 0.99999 can be easily achieved. Note, however, that this analysis applies to sinusoid illuminated scenes and test signals, but does not apply to delta function injections of charge that are infrequently transferred, as applies to the x-ray photon-counting case.

46.4.3 Input and Output Structures

The input structure of the CCD usually consists of a *p–n* junction and two or more input gates as shown in Figure 46.3. Initially, when the input voltage V_{id} is pulsed low, charges will flow through the input (electrode) into the potential well created under the input gates G_1 and G_2. When V_{id} returns to its equilibrium value, charges will be withdrawn except those residing in the potential well formed by the potential difference between G_1 and G_2. Charge injection is now complete and a drop in the potential ϕ_1 at the transfer gate will allow charges to enter into the first CCD pixel. The input charge, Q_{in}, is approximately given by

$$Q_{in} = C_{ox} \cdot (V_{G_1} - V_{G_2}) \tag{46.10}$$

where
C_{ox} is the oxide capacitance
V_{G_1} and V_{G_2} refer to the voltage difference between G_1 and G_2

In CCD sensors and detectors, signal input normally relies on the incident photons liberating charge within the depletion region (after traversing either the front gates [front-illuminated] or the back surface [back-illuminated]). Charges so created will be collected in the potential wells formed by the clock voltages.

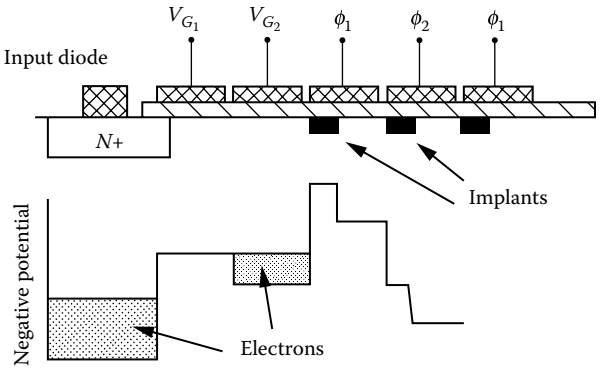

FIGURE 46.3 Input structure of a CCD.

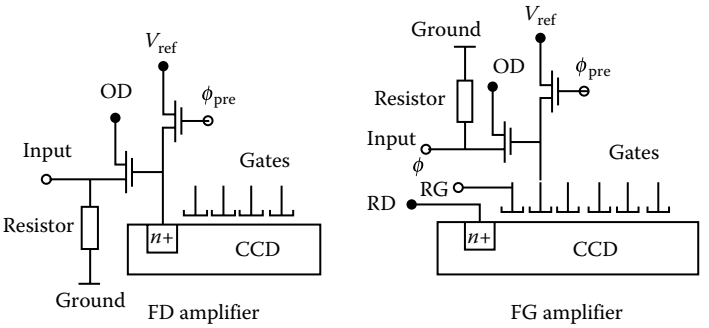

FIGURE 46.4 Output structures of a CCD.

Normally, the output structure of the CCD consists of a reset switch and a floating-diffusion amplifier (FDA) or floating-gate amplifier (FGA). These are shown in Figure 46.4. During sampling, the output charge flows into the floating node and a voltage is developed across the output capacitance, which is a combination of the depletion capacitance of the floating node and the input gate capacitance of the source follower. In general, the voltage output, V_{sig}, can be expressed as

$$V_{sig} = \frac{Q_{inj} \cdot A_v}{C_{fd}} \tag{46.11}$$

where

Q_{inj} is the injected charge
A_v is the small-signal voltage gain of the output amplifier
C_{fd} is the capacitance between the floating node and ground

Since both A_v and C_{fd} are sensitive to the output charge and temperature, this type of output structure is not generally linear. Improvements in the output structure can be achieved using either an FGA or Miller feedback at the output to reduce parasitic capacitances.

46.4.4 Noise in CCDs

CCD noise will degrade the SNR. The following are important noise sources in CCDs:

1. Thermal noise, or dark current, is due to thermally excited electrons that accumulate in the pixels during the integration. In applications where the clocking time is short compared to the integration time, the equivalent noise election, n_{th}, is given by

$$n_{th} = \sqrt{J_d \cdot A_E \cdot t_{int}} \tag{46.12}$$

where

J_d is the leakage current density
A_E is the area of the transport electrode
t_{int} is the integration time

A lowering of the operating temperature will normally reduce the leakage current density and hence the equivalent noise electron.

2. Bulk traps are the dominant noise sources for buried-channel CCDs, and the equivalent noise electron from this source is

$$n_{\text{trap}} = \sqrt{N_{\text{t}} \cdot V_{\text{sig}} \cdot Nt \cdot e^{-T_{\text{t}}/\tau_{\text{e}}}}\,[1 - e^{-T_{\text{t}}/\tau_{\text{e}}}] \tag{46.13}$$

where
V_{sig} is the volume of the charge packet under the transfer electrode
N_{t} is the density of the bulk trap states
T_{t} is the transfer time
τ_{e} is the electron emission time constant

It can be observed that the equivalent noise electron increases as the size of the charge packet increases, an indication that bulk traps do not generally affect the SNR in CCDs. In x-ray photon-counting applications, some effects of bulk trapping noise have been seen.

3. Both the input and output of a CCD involve charge storage across capacitors that will be affected by fluctuations in the circuit. The equivalent noise electron for this process is

$$n_{\text{inp}} = \sqrt{kT \cdot C_{\text{inp}}} \quad n_{\text{out}} = \sqrt{kT \cdot C_{\text{out}}} \tag{46.14}$$

where
kT is the thermal voltage
C_{inp} and C_{out} are the input and output capacitances

A special signal processing technique known as "correlated double sampling" can be used to reduce this kTC noise at the CCD output.

$1/f$ noise is also present in the output amplifier and is only significant at low frequencies. Methods to reduce $1/f$ noise include multiple sampling using distributed floating-gate amplifiers (DFGAs) [2] and noise cancellation techniques using alternate gain inversion (AGI) [3].

4. The maximum SNR of a CCD is limited by the maximum amount of charge that can be stored in a pixel, divided by the equivalent noise electron. Expressed in decibels, it is

$$\text{SNR} = 20\log(Q_{\text{max}} = Q_{\text{noise}}) \tag{46.15}$$

The maximum charge is

$$Q_{\text{max}} = C_{\text{e}} \cdot \psi_{\text{BH}} \tag{46.16}$$

where
C_{e} is the depletion capacitance associated with the electrode
ψ_{BH} is the depth of the potential well

46.4.5 CCD Power Dissipation

CCD power dissipation is primarily linked to the charging and discharging of the gate capacitances. This power is mainly consumed by the clock driver and is given by

$$P_{\text{clock}} = C_{\text{c}} \cdot V^2 \cdot f_{\text{c}} \tag{46.17}$$

where
C_{c} is the clock line capacitance associated with the electrodes
V is the clock voltage
f_{c} is the clock frequency

For f_{c} = 100 MHz and V = 5 V, typical values of P_{clock} are 50 μW per pixel.

In addition to P_{clock}, the on-chip power dissipation per pixel is approximately given by

$$P_{CCD} \approx \left(\frac{nq(f_c L)^2}{\mu_e + 2nqf_c} \right) \left(\frac{\psi_{BH} - nq}{2C_e} \right) \tag{46.18}$$

where

n is the number of electrons in a pixel
L is the pixel length
μ_e is the electron mobility

The overall power dissipation in a CCD is therefore the sum of P_{clock} and P_{CCD}.

46.5 CCD Applications to Light Sensing

46.5.1 Optical Imaging and Spectroscopy

The many fine properties of CCDs have made them the detector of choice for the recording and readout of images at both high and low light levels. The applications include (1) reconnaissance, both civilian and defensive, (2) scene and personnel monitoring, (3) robotics, and (4) astronomy. In astronomy, CCD cameras have found their way into almost all observatories in the world, both for direct readout of images and as the readout cameras for spectrographs.

Perhaps the most exacting application of CCDs has been to astronomy, a discipline in which the characteristics of the CCD need to be pushed to their limits in order to gain the optimum performance. As well as the attempt to optimize this performance in order to gain as much science as possible from the images, it has also been crucial to calibrate the devices as precisely as possible and to fully understand their behavior. In this sense, astronomy has been the "driver" for the scientific development of CCDs. Large-scale commercial applications, such as video recorders and monitoring cameras, have driven the need for improved manufacturing yield, blemish-free operation, uniformity in performance, and reliability.

In order to illustrate the importance of CCDs to exacting scientific requirements, this section will focus largely on the applications to astronomy.

The early demonstration of the performance of a commercial CCD at the focus of a telescope quickly led to the realization of their potential for both space and ground-based astronomical cameras and instruments. Fortunately, this development in the early 1970s was just in time for the first major optical observatory in Earth orbit, the Hubble space telescope (HST). Perhaps the most spectacular application of CCDs to visible light imaging has been within the cameras on board this telescope, that is, the wide field and planetary cameras built at the Jet Propulsion Laboratory. The CCDs in these cameras consisted of 800 × 800 pixel arrays, with each pixel of size 25 μm. The first version of this camera contained eight thinned, back-illuminated devices that were more or less fully depleted. An accumulation layer at the back surface was achieved by flooding the devices with UV light from a lamp internal to the instrument. This accumulation layer allowed the collection of charge resulting from the photoelectric absorption of blue light and accelerated the charge to the front-side potential wells. Furthermore, the devices were coated in a down-converting coronene phosphor that converted UV light into the yellow-green wavelength band, thus allowing a 20% efficiency in the UV. These devices thus had relatively high QE from the UV through to about 1 μm, vitally important for an instrument collecting photons from galaxies billions of light years away in the universe. As well as their high QE, these devices had high CTE and relatively low readout noise at the time of their development. All of these characteristics have since been superseded—at first by an improved version of the camera installed in the HST in late 1993 and then in the Advanced Camera for Surveys, to be

installed in 1999. These later instruments had larger format, higher QE, and lower readout noise. During the 1980s, devices were developed with these large formats and with readout noise levels approaching one electron.

Starting with modest arrays of size on the order of a few hundred pixels in the 1970s, the devices that became available in the 1990s were as large as 4096 pixels square. As well as in space, these devices have been employed at the prime foci of the world's largest telescopes to give images covering more than 10 arc minutes on a side while still sampling the atmospheric-limited resolution (arcsecond or subarcsecond) adequately. Such devices, when exposed to the sky for up to an hour through a broadband filter, can produce images with tens of thousands of objects for statistical studies in astronomy.

Typical pixel readout rates for astronomical cameras are of the order of 50 kHz, taking tens of seconds for a full readout. Integration times for astronomical CCD cameras can vary from fractions of a second to tens of minutes or even times in excess of an hour, usually limited by the background noise induced by cosmic-ray particles and their secondaries. These cosmic-ray "events" can be removed by taking at least two frames of data and cross-comparing them. This is important even on the ground, where the radioactive background and muon-induced events total about one per cm^2 per minute; but the cosmic-ray background in space is about one per cm^2 per second, so that camera exposures are rarely longer than 10–20 min. Sophisticated computer algorithms have been developed in order to remove the effects of this background radiation.

Of special importance to applications in space research is the packaging of the devices. Contamination of the cold CCD surface by as much as a monolayer of a heavy molecule will effectively render the CCD useless in the vacuum UV, for example. Careful attention must therefore be paid to the local instrument environment. The CCDs on the HST were in hermetically sealed packages, and the contamination problem was transferred to the lenses covering the CCD packages. In order to achieve optimum performance, the overall camera has to be designed to satisfy the exacting requirements of the CCD, from the point of view of thermal control and stability, absence of electronic interference, and rigorous attention to the elimination of water or heavy molecule contamination. For space application, it may also be advantageous to surround the CCD package with a cosmic-ray shield, such as the 1 cm (0.4 in.) of tantalum used in the CCD cameras on the HST and the Galileo mission to Jupiter. Such radiation shields have to be designed with caution, lest they introduce more secondary particles and induced radioactivity than the primary protons that they stop.

Finally, much effort is put into the processing of astronomical CCD data [4]. Special techniques have been developed to calibrate the pixel-to-pixel nonuniformity in QE (a function of wavelength), both on large and small scales. With some effort, this nonuniformity can be calibrated to levels below 1%. Although it may be easy to expose the CCD to a diffuse source such that there are at least 10,000 electrons per pixel, the corresponding flat-field calibration accuracy may be compromised at low light levels. For astronomical applications, especially in space, most of the pixels may receive only tens of electrons or fewer during an exposure. Low-level traps (including those caused by cosmic radiation) will then manifest themselves in the form of charge transfer inefficiencies over localized areas or columns. It may be important to calibrate the CCD at the same exposure levels as those typically encountered during the science observation. One way of improving this is to use hundreds or thousands of frames of data taken in different parts of the sky and to reject the astronomical objects in them. These "sky frames" can then be used to produce a "super sky flat," which is the average of the individual frames of data.

46.5.2 CCD X-Ray Imaging Spectroscopy

Scientific applications such as astronomy have been responsible for driving improvements in CCD technology. In the x-ray domain, for example, CCDs are starting to be employed for medical radiography, where the digital imaging capability and high sensitivity allow for lower patient doses and online image processing. As high-resolution readout detectors of dispersive x-ray spectrometers, CCDs are becoming

widely used in the new generation of high brilliance synchrotron beamlines. As spectrometers, they are also being considered in some applications as replacement for Si(Li) diodes, where the higher operating temperatures and improved resolution and efficiency down to x-ray energies below 1 keV lead to applications of interest to biological science and technology.

In contrast to optical imaging applications with many photons per charge packet, to measure x-ray spectral information directly with CCD, single photons per pixel per image frame are required. To use the CCD as a nondispersive x-ray spectrometer requires that the correspondence between the magnitude of the electron charge packet generated initially by the x-ray photon and the signal measured at the CCD output must be maintained. This places a very stringent requirement on the efficiency of charge transfer. However, even before the process of charge transfer is initiated, the physics of the charge collection may also degrade the energy measurement process.

The absorption process for a photon of energy E begins with the ejection of a photoelectron, of energy $E - E_B$, where E_B is the binding energy of the appropriate silicon atom electron shell. The range of the photoelectron may be only a fraction of 1 μm. In a few percent of cases, a silicon K shell fluorescence photon may be emitted, and this has a range of about 10 μm, so that there is a finite probability of the event energy splitting into more than one pixel.

Eventually, a proportion of the energy is converted to free electrons and the rest into phonons. The average energy to create an electron–hole pair is roughly constant at about 3.6 eV of incident photon energy per pair produced in silicon. If this free electron charge packet is created in the depletion layer of the CCD, it is promptly drifted under the influence of the electric field to the buried-channel collection site. During this drift time (t_d), the charge can laterally diffuse within a radius $\sim\sqrt{2Dt_d}$, where D is the diffusion constant. Except for the charge clouds originating deep in the depletion layer, this radius is small compared with the typical pixel size. If the charge is generated in a field-free layer *outside* the depleted volume, it will radially diffuse until a fraction recombines or reaches the depletion layer. The latter fraction then starts to drift with the same additional lateral drift as the depletion layer charge packets.

The pixel boundaries are loosely defined by the asymmetric fields created by electrode biasing schemes and surface-channel stop implants, and not hard physical boundaries. Hence, any lateral spreading processes may allow some splitting of the initial charge packet between pixels. Furthermore, charge *loss* may be experienced either by the partial recombination of events when liberated deep below the depletion layer or if the fraction of split charge is too low to be recognized against the device noise level.

In astronomical applications, in space-borne observatories, there is a continuous low-level background of charged particles. Rather than liberating point-like charge clouds, they liberate a population of signal electrons along their tracks throughout the silicon. They may be easily discriminated against x-rays if these tracks are highly skewed with respect to the silicon surface and cross many pixels. Also, if the track is long enough, the magnitude of total charge cloud generated may be large compared with the typical x-ray charge packet.

These features impose a requirement to perform event recognition and analysis. To perform this on ground would require transmission of all pixel data, including empty pixels, which for megapixel CCD frames generated on second time scales are quite infeasible. Performing this recognition on board first requires a comparison against some lower threshold. Selection of this level is critical—too high—and some split charge may be neglected with a consequent degradation of energy resolution. Too low a threshold and many spurious events will be counted. If there is a drift or change in the zero-energy signal upon which this threshold is applied, the energy scale may be misregistered, and/or the relative fraction of events selected at different x-ray energies may be unknowingly altered. Simulations show that for the potential energy resolution of CCDs, spectral analysis of cosmic plasmas will demand a calibration of relative detection efficiency versus energy to ~3%. If the threshold value is set at about 4σ times the readout noise, this calibration may be degraded by as little as a single digital bit of a commonly used 12 bit ADC in the CCD readout electronics. Thus, the real-time digital processing of events is required to be fast and complex.

A further complication of the event splitting is that to avoid pileup in CCD frames, the probability of having multiple events per pixel is made more stringent by requiring surrounding pixels to have no signal and allow this recognition process. Typically, an event rate of 1 photon per 200 pixels per CCD frame is therefore imposed, but this places a rather low limit on attainable count rate performance. Especially with high-resolution focusing optics of observatories such as AXAF [5], this can be much lower than for many previous experiments. If the core of the PSF of the mirror is not to be degraded by this effect, then special readout formats that reduce the imaged area, in order to accelerate frame readout times, must be employed.

46.6 Future Improvements to CCDs

46.6.1 Backside CCDs

The useful spectral range of conventional CCD detectors, although quite broad, is limited in part by the presence of the polysilicon gates on the front surface. As is illustrated in Figure 46.5, photons with wavelengths in the range ~3 nm < λ < ~400 nm have attenuation lengths in silicon less than the typical thickness of the gate structure (~0:4 μm). Photons in this spectral range are therefore absorbed before they can enter the photosensitive volume of the detector. For conventional CCDs, the detection efficiency is no more than a few percent in this band. If the gates can be made thinner by an order of magnitude or avoided altogether, then the detection efficiency can be improved dramatically in both the very soft x-ray and the UV. Efforts following the former approach are described later. The latter strategy, which requires illumination of the back surface of the CCD (i.e., the surface opposite the gates), is discussed here.

There are a number of techniques that can be used to produce back-illuminated devices [6–8], but they must all deal with two constraints: lateral diffusion of the photoelectrons before they are captured in the buried channel of a specific pixel and the tendency for photoelectrons to recombine at the back surface of the Si.

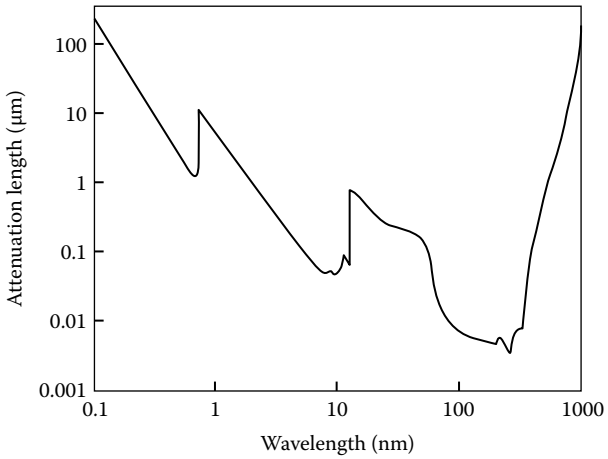

FIGURE 46.5 Attenuation length in silicon in the soft x-ray through near-IR spectral range. The polysilicon gates of front-illuminated devices, which are typically ~0.4 μm thick, are strongly absorbing at wavelengths for which the attenuation length is less than the gate thickness, viz. wavelengths (~3 mn < λ < ~400 nm). Thin-gate and back-illuminated CCDs, with much thinner dead layers, offer improved detection efficiency in the soft x-ray and UV portions of the spectrum. (From Edwards, D.F., in *Handbook of Optical Constants of Solids*, E.P. Palik, ed., Academic Press, New York, p. 547, 1985; Henke, B.L. et al., Low energy X-ray diagnostics, D.T. Attwood, B.L. Henke, eds., *AIP Conference Proceedings No. 75,* American Institute of Physics, New York, p. 340, 1981.)

The lateral diffusion of electrons can lead to a loss of resolution of the CCD since they may cross the boundary between one pixel and another, leading to an erroneous assignment of the origin of the photon that created the electron. This problem is minimized by thinning the *back-illuminated CCD* to thicknesses that are on the order of the depletion depth of the Si, so the least drift occurs before the electron is captured in the potential well of the buried channel. This thinning is accomplished by a combination of methods, including mechanical grinding and polishing and wet etching. Handling of back-illuminated CCDs after thinning, however, is a problem since the remaining Si is between 10 and 100 μm thick and is not strong enough to support rough handling, or even the intrinsic stresses arising from the initial fabrication of the CCD. To circumvent this problem, rim thinning or frame thinning can be used; in the first case, a rim several millimeters wide around the circumference of the wafer is protected during the thinning process, while in the latter, a region 1 or 2 mm wide around each device is protected.

Lateral diffusion can also be reduced by imposing an electric field through the thickness of the thinned membrane; but if this is done by imposing an electrode on the back surface, then the device will have a reduced QE due to absorption in this layer. The presence of a depletion region in the CCD will also give rise to an electric field, which reduces the lateral diffusion of electrons; but if the desired depletion region is on the order of tens of micrometers, in order to image high-energy x-rays or IR photons, then the induced field will be small, due to the low doping levels in the silicon and Gauss' law.

Although the lateral spread of photoelectrons is a problem, the loss of carriers to recombination at the back surface presents a greater technical difficulty. The recombination velocity can be minimized by introducing a strong electric field at the back surface and by passivating this surface. There are several methods employed to generate this electric field: one is by implanting carriers (p-type for the case where photoelectrons are to be captured) and annealing the sample to activate these carriers [7], a second is to deposit a thin layer of metal with the appropriate work function difference (typically Pt or another transition metal) [6], and a third method is to grow a heavily doped epitaxial layer on the back surface [9]. In the implant method, strong electric fields can be generated and the annealing process can help to passivate the back surface, but high-temperature annealing of the wafer can present a problem if metallization is present, unless excimer laser annealing is employed [10]. Deposition of a thin metallic layer can lead to long-term instability of QE and does not appear to yield the highest QEs. Deposition of an epitaxial layer relies on the use of sophisticated equipment and surface cleaning methods.

In addition to introducing an electric field on the back surface, it is necessary to electrically passivate that surface to lower the electron recombination velocity. Again, there are several approaches. The flash gate technique is probably the simplest, relying on inserting the sample in a steam atmosphere, but it is not stable over time [6]. Another method is to grow a high-quality oxide on the back surface [7], but this requires the use of high temperatures, which could melt metallizations and allow any dopant layer to diffuse too deeply into the silicon.

Although the aim of the backside treatment process is always to maximize the fraction of charge collected from the vicinity of the back surface, there are subtle differences in requirements that depend on the application. In the UV (100 nm < λ < 400 nm), the extremely small attenuation lengths (see Figure 46.5) place a premium on nonnegligible (more than ∼50%) charge collection efficiency very close to the back surface. Therefore, in UV sensors, the field in the immediate vicinity of the back surface is extremely important. Moreover, the real part of the index of refraction of silicon is quite high in the UV and optical bands, and Fresnel reflections limit the external detection efficiency that can be achieved. Thus, significant improvements in the UV response of back-illuminated CCDs have been obtained via the application of antireflection coatings as a part of the backside treatment process [8].

In the very soft x-ray range (2 nm < λ < 100 nm), the attenuation length can be larger by a factor of 10 than in the UV. Moreover, the range of the secondary photoelectrons is large enough to be comparable to the attenuation length [11], so the physics of the secondary ionization process becomes important. Thus, in the very soft x-ray regime, it is the average properties of the device over scales of a few hundred nanometers that determine performance. However, for spectroscopic applications,

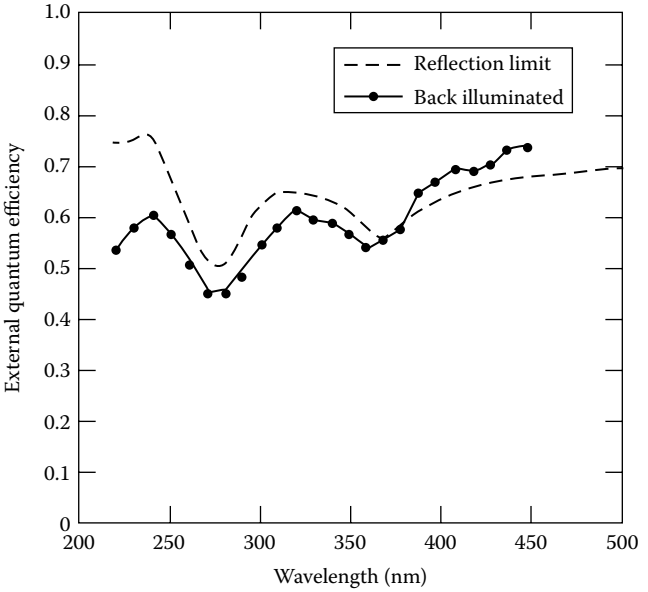

FIGURE 46.6 External QE of back-illuminated CCD using an implanted and annealed backside. For comparison purposes, the external QE of an ideal detector is shown, after modeling for the antireflection coating present on the back-illuminated detector.

the theoretical limit of device performance cannot be reached unless the charge collection efficiency substantially exceeds ~90%. Thus, in the soft x-ray, one requires very high collection efficiency over a relatively large volume in the vicinity of the back surface.

Any backside fabrication techniques will probably require compromises to be made, but it is possible to achieve very high external QE in the UV, as shown in the accompanying Figure 46.6 and in the soft x-ray region where 77% QE has been achieved at 277 eV [12]. Further improvements are necessary to achieve good results in the vacuum UV and theoretical limits for energy resolution in the soft x-ray. These improvements are possible, but will probably depend on the continued development of sophisticated processing tools.

46.6.2 Thinned Gate CCDs

Recently, a new type of CCD was developed that was optimized for spectroscopy below 1 keV. This detector, called a thin-gate CCD (TGCCD), contained two novel features: FGAs (or "skippers") and thin gates (electrodes) [2]. The goal was to develop a detector that had Fano-limited energy resolution with nonnegligible QE over the 200–1000 eV bandpass. This section briefly describes this detector and compares it with more conventional CCDs.

Most conventional CCDs use an FDA to read out the signal charge. The readnoise of the FDA has improved from several hundred electrons (rms) in the 1970s to less than three electrons in the last few years [13]. The energy resolution of CCDs over the entire soft x-ray bandpass is now limited by factors other than readnoise. It is desirable to push the readnoise down from a few electrons to a fraction of an electron because it allows photons of lower energy to be detected in single-photon-counting mode.

One method to further reduce the readnoise is to read out the same charge packet multiple times. The signal charge is destroyed when read out through an FDA. In the FGA, however, an insulating gate is placed between the charge transfer channel and the output node. Gates around the output node are used to read out and withdraw the signal charge multiple times. The readnoise is then reduced by the square root of the number of readouts. Effective readnoises of less than 1 electron have been demonstrated

using the FGA [2,14], and photons of energy 66 eV (Al L_α) have been detected using the TGCCD. If the readnoise could be pushed to a fraction of an electron, it would be possible to detect optical photons in the single-photon-counting mode.

46.6.3 Lower Readnoise

The other novel feature of the TGCCD is its electrode structure designed to maximize soft x-ray QE. Most conventional front-side-illuminated CCDs have several hundred nanometers of SiO_2/Si_3N_4 insulator and Si electrode on the surface. These layers strongly limit the QE of the device below 1 keV, but Fano-limited energy resolution is routinely achieved. The conventional solution to increase the low-energy QE has been to etch away the back surface of the device and illuminate it from behind (a backside-illuminated CCD). The difficulty with this technique is that the energy resolution is seriously degraded due to charge diffusion and poor charge collection.

The TGCCD is a front-side-illuminated device with a unique gate structure that gives reasonable soft x-ray QE (0.20 at 277 eV), while retaining the good energy resolution of front-side illumination. The detector is a three-phase CCD. The first two phases (comprising only 1/3 of the active area of the device) are covered with 400 nm of polysilicon (or just poly) in the usual way. A third layer of poly is deposited on top of the first two and acts as a bus for a fourth (40 nm thick) layer of poly that defines the third clock phase. Two-thirds of the active area of the detector is therefore covered with only the insulator (100 nm of SiO_2 and Si_3N_4) and this fourth layer of poly. The measured energy resolution of this device is 34 eV at C K_α (277 eV). This is approximately a factor of 3 better than the best energy resolution obtained with the ACIS backside-illuminated CCDs [5]. Simulations show that an astrophysical spectrum obtained with TGCCD contains as much or more information than one obtained with a backside-illuminated CCD [15].

46.6.4 Radiation Damage

CCDs are often used in environments in which they are subject to ionizing radiation, and this radiation can degrade their performance. In particular, radiation damage plays an important role in the performance of most space-borne detectors. The Van Allen belts contain protons and electrons with energies of tens of MeV. These particles can produce damage by several mechanisms. Protons can generate vacancy-interstitial pairs in the Si lattice, which diffuse freely, even at cryogenic temperatures, and it is possible for the vacancy to form a complex with P atoms in the *n*-Si buried channel that traps electrons. The trap reduces CTE by preventing signal electrons from leaving the pixel during the clocking cycle. Electrons can also produce vacancies (although with much lower cross section than the protons), but they can also create dangling bonds at the SiO_2–Si interface above the buried channel, leading to a shift in operating voltage in the CCD and contributing to noise.

The P–V complexes remove electrons from a charge packet in the conduction band of silicon. In the worst-case limit, when the illumination levels are so low that each charge packet transferred encounters each trap in its empty trap state, the degradation of CTE is approximately 5×10^{-7} rad^{-1} (radiation doses are expressed here in total ionizing rads in Si, although it should be noted that the fraction of proton energy that goes into production of vacancy-interstitial pairs, the nonionizing energy loss, is about 1/2000 of the total ionizing dose [16].) This degradation is significant: If the device is subjected to 1000 rad $year^{-1}$ and there are 1000 transfers necessary to clock out the charge, then 40% of the charge packet would be lost due to proton-induced defects. At higher illumination levels, the traps greatly complicate the device response, particularly in single-photon-counting applications. In this case, for example, the spectral response of the CCD becomes a function of the spatial distribution of the incident radiation.

This loss of CTE can be circumvented in several ways, including the use of increased shielding, a fat zero, annealing out the damage, implanting a narrow trough along the direction of transfer in the buried channel, or operating the device at a different (generally lower) temperature.

Relatively thick shielding, up to the equivalent 4–5 cm (1.6–2 in.) of aluminum, can provide significant attenuation (factors of several) of proton dose encountered in the radiation belts [17]. A fat zero is a uniform charge added to all the pixels of the CCD, usually induced by flooding the CCD with a low light level. Although a fat zero can reduce the CTE loss by filling the traps so they cannot be occupied by electrons from the charge packet of interest, they also add to the noise of the system. The P–V complex will dissociate at temperatures around 135 °C [18], but the annealing is incomplete and may interfere with other requirements or constraints of the satellite mission. Using photolithography, a narrow trough or notch can be included in the buried channel parallel to the direction of transfer during fabrication, so charge packets are kept constrained and are less likely to interact with traps generated randomly across the buried channel [19]. It is not difficult to introduce a channel that is approximately 2 μm wide and can handle a charge packet of tens of thousands of electrons; this can decrease the CTE loss to 7×10^{-8} rad^{-1} or less. Reducing the operating temperature slows the kinetics of trap emptying [20], so a single electron can be lost from the charge packet and fill the trap for the integration time of the frame. The effectiveness of this process depends on the clock speed and integration time, as well as the ability to operate the CCD at temperatures that approach –150 °C, but CTE loss can be as low as 10^{-8} rad^{-1} if troughs are included with low-temperature operation. Cosmic rays and electrons can also cause damage by displacing Si atoms from the lattice, but the flux of cosmic rays is much lower than protons in low Earth orbits, and the electrons are much less effective in creating a vacancy. The approaches to hardening against proton damage will also be effective with these latter two particles.

The major effect of electrons on CCDs is to shift the flat-band voltage of the CCDs and MOSFETs, but for doses around 1000 rads, this change is on the order of 10 mV. If further hardening of the gate oxide is desired, it can be accomplished using established methods [21]. The passage of electrons and other energetic charged particles through a device also creates free carriers that constitute an interfering signal. One electron–hole pair is created for each 3.65 eV absorbed in the Si, and charged particles can deposit charge packets of up to a full-well level and more, depending on the species, energy, and the active depth of the device. In astronomy, such events are an annoyance, even in terrestrial observatories, and are removed by comparing images of the same scene. In some applications, such as x-ray spectroscopy, these events are more serious because they can masquerade as desired signals unless careful analysis of the data is performed to exclude them. On the other hand, this sensitivity to charged particles can actually be used to advantage. The known conversion between particle energy deposition and liberated charge means that CCDs can be used as spectroscopic detectors, and such an application has been proposed for inertial-confinement fusion diagnostics [22].

Radiation hardening of CCDs has made rapid progress in the last few years, allowing devices to have much longer lives for scientific applications. Fabrication and operational changes have increased the hardness to displacement damage, and the process requirements of high-quality ICs have led to a gate dielectric that is quite robust to ionizing radiation.

Densitometry Measurement

Joseph H. Altman
Pittsford, New York

47.1 Introduction

As the name indicates, densitometry is the measurement of optical density (OD). OD, in turn, can be broadly defined as a measure of the attenuation of radiant flux by some sort of optical element that can be transmitting, reflecting, or both. Densitometry is most widely applied in photographic science, and measurements in this field are covered by a four-part ANSI/ISO standard [1]. The treatment here follows that document. The measurement of transmission and reflection from the standpoint of optics has been discussed by Palmer [2]. This chapter uses the single word density, without the adjective, and uses the words "light" and "flux" interchangeably (although density can be measured in the UV and infrared [IR] also, of course).

It turns out that, in practice, the measured density of a given sample can be affected significantly both by the design of the equipment and the nature of the sample. Therefore, the first rule of practical densitometry is that the sample must be measured in a way that is meaningful with respect to its intended use.

47.2 Monochrome Transmission Density

It is convenient to start by discussing transmitting samples, without the color aspect. Such samples can be either black-and-white photographic films or filter layers of various sorts. If light falls on such an element, a fraction of the flux is reflected from the first surface. The remainder penetrates the surface, and a part of this flux is absorbed. What is neither reflected nor absorbed exits the layer, as shown in Figure 47.1. Let these fractions be denoted, *r, a*, and *t*, where lowercase *t* indicates internal transmittance. If the element is in air, reflection can occur at the rear surface also, but this can be neglected. By the conservation of energy, one obtains

$$r + a + t = 1 \tag{47.1}$$

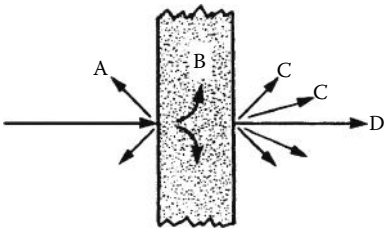

FIGURE 47.1 Cross section of emulsion layer showing (A) reflection, (B) absorption, (C) diffuse transmission, and (D) specular transmission.

The fractions r and t can be measured independently by spectrophotographic techniques, so that a is readily determined. This fraction is termed the absorptance of the layer, and its measurement is also discussed by Palmer [2].

Some applications require the measurement of absorptance, but in most practical work, what is important is the fraction of the incident light that exits the element, regardless of where attenuation takes place. Therefore, transmittance is defined by

$$T = \frac{\Phi_e}{\Phi_i} \tag{47.2}$$

where e and i refer to emergent and incident flux, respectively. Note that all losses are lumped together. In silver halide photographic layers, the first-surface reflection is usually small; in thin-film filters, a significant proportion of the total loss may occur by reflection. Following Hurter and Driffield [3], the English pioneers of densitometry, one can define the transmission density D

$$D = -\log_{10} T = \log_{10} \frac{1}{T} \tag{47.3}$$

Density is therefore a nonlinear dimensionless quantity ≥ 0. McCamy has published an extensive review of densitometry and sensitometry [4].

The operation of a practical densitometer can be discussed with reference to Figure 47.2. The system consists of a light source, an aperture to define the area being measured, a sensor, logging circuitry, and a suitable readout display. In many instruments, the output is fed to a computer.

To measure transmittance/density, a reading is first taken with no sample over the aperture. This reading is a measure of the incoming light Φ_i. A second reading with the sample in place then determines Φ_e. It should be clearly understood that what the system actually does is to sense the flux passing through the aperture in the two cases and then displays the negative logarithm of the ratio. This fact

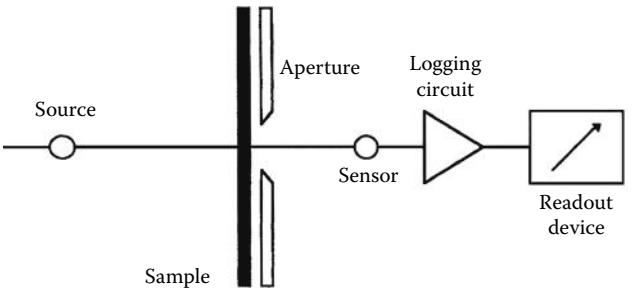

FIGURE 47.2 Schematic of transmission densitometer.

explains some of its operating characteristics. Starting from this basis, for example, McCamy [5] has treated measurement errors for the case when the sample is not uniform ("wedged") over the aperture.

The basic procedure also means that any source having enough power to operate the sensor can be used, and filters and apertures can readily be interchanged; it is only necessary to "zero" the instrument before making a measurement. The measuring aperture is usually of the order of 1 mm in diameter. If the area of this aperture is reduced to, say, 0.1 mm^2, the device becomes a microdensitometer. Such instruments present special problems not discussed here but treated in the literature [6].

Now consider the complications introduced by the nature of samples, especially photographic samples. Developed black-and-white photographic layers consist of discrete grains of silver metal dispersed in a thin layer of gelatin. Such grains act as scatterers, which means that some of the photons exiting the layer will not be traveling in their original directions. Such photons are identified by "C" in Figure 47.1. Clearly, the measured transmittance/density will depend on how much of this scattered light reaches the sensor. The effect of scattering can be quite large, and therefore in order to obtain values that are both reproducible and meaningful, it is necessary to control what is termed the "geometry" of the system, that is, the angular subtenses of the influx and efflux beams at the sample.

In Figure 47.3, Θ_i and Θ_e are these half angles, respectively, referred to the normal to the element surface. The current standard [1b] prescribes two configurations, the first of which is as follows: $\Theta_i = 5°$; $\Theta_e = 90°$. The reverse of this configuration, that is, $\Theta_i = 90°$ and $\Theta_e \leq 5°$, yields the same density readings and is also permitted by the standard. This case is termed "diffuse density" and is the most important practical case because most commercial densitometers conform to this mode. Essentially, all the light exiting the sample, whatever its direction, reaches the sensor and is evaluated. This configuration simulates the case of contact printing a photographic negative or of viewing a transparency on a diffuse illuminator. The practical construction of such an instrument is described later.

The second case occurs when the sample is illuminated and the emergent flux collected by lenses of finite aperture. In principle, in this case, the angles Θ_i and Θ_e can vary between, say, 5° and 90° and may differ from one another, but the standard specifies two sets of optics with matched apertures of *f*/1.6 and *f*/4.5. These relative apertures are representative of motion picture projectors and microfilm readers, respectively. The corresponding half angles are 18.2° and 6.4°. (For a lens in air, *f*/no. = $1/(2\sin\Theta)$, where Θ is the half angle shown in Figure 47.3.) This case is termed "projection" density.

It is useful to define a ratio

$$Q' = \frac{\text{Projection density}}{\text{Diffuse density}} \tag{47.4}$$

which has been termed the "effective Callier coefficient." As would be expected, projection density is greater than diffuse density for a given sample so that $Q' = 1$. The exact ratio between the two densities

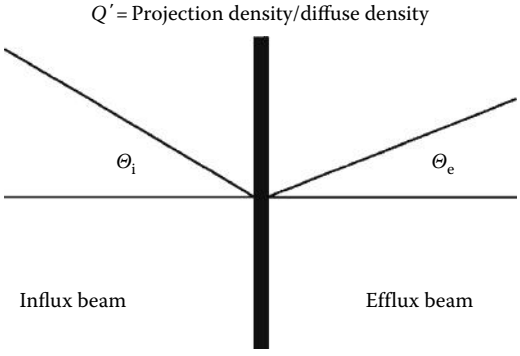

FIGURE 47.3 Angular subtenses of influx and efflux beams at sample.

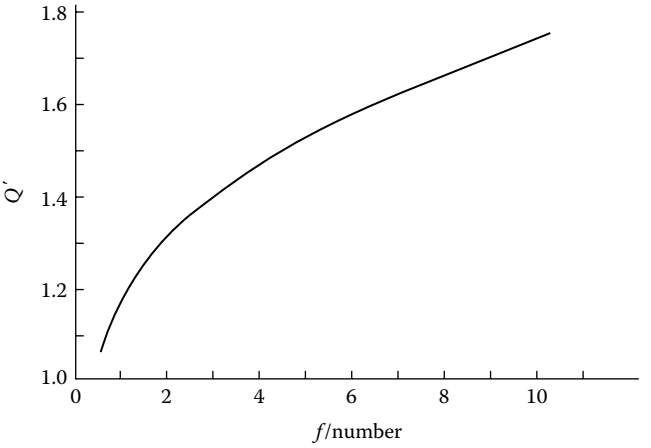

FIGURE 47.4 Variation of the effective Callier Q'-factor with the f-numbers of the influx and efflux beams, which were matched.

depends on the scattering characteristics of the sample and the f-numbers involved. Only limited information on Q' has appeared in the literature [7] but, as Figure 47.4 shows, this parameter behaves as might be expected.

The dependence of the effective density on aperture shown in Figure 47.4 may be important in practice. Amateur photographers are aware that a B&W negative usually produces a more contrasty print in a condenser enlarger than it does in a diffuser enlarger, and this behavior can easily be deduced from Equation 47.4. It may also be important in microdensitometry, since these instruments measure a projection density and a wide range of apertures may be encountered in various instruments. In such cases it is usually recommended that the data be reduced to diffuse density. This is easily done by measuring a sufficiently large sample in both projection and diffuse densitometers. It might be remarked that the scattering characteristics of individual films can vary significantly, and Q' should be measured for the samples at hand. Except for very low densities, Q' is relatively unchanged as the diffuse density varies.

For completeness, it is noted that earlier editions of density standards listed two other forms of density. The first of these was the case of angle Θ_i = angle $\Theta_e \leq 5°$. This case was termed "specular density" and was intended to simulate the use of the attenuating element in a collimated beam. The second case was the case of angle Θ_i = angle $\Theta_e = 90°$. This type of density was termed "doubly diffuse" and was intended to simulate the use of a negative in certain contact printers. Neither of these densities is important in modern practice; discussions of them can be found in the literature [8].

In a color film, the "grains" are actually tiny volumes of dyed gelatin. Since the index of refraction of such a "grain" is only slightly different from the surround, it does not act as a scatterer. Thus, the density differences found on color films as a function of densitometer geometry are usually negligible and often ignored in practice.

In recent years, the photographic industry has introduced a new type of grain, the "tabular" grain, whose thickness is much smaller than the dimensions in the plane parallel to the coating surface. It has been demonstrated that, in the undeveloped state, these grains scatter light significantly less than the older "3-D" types of grains. No studies of developed T-grains have appeared in the literature, but it seems possible that developed B&W layers consisting of T-grains may scatter less than the traditional types of layers, thus reducing the sensitivity of density measurement to instrument geometry. (The data of Figure 47.4 were obtained with "3-D" grains.)

One can now turn to the optical configuration of a practical diffuse densitometer. From an optical standpoint, a good way to collect all the flux exiting the sample would be to use an integrating sphere, and instruments have been built using such spheres. However, in an actual contact-printing

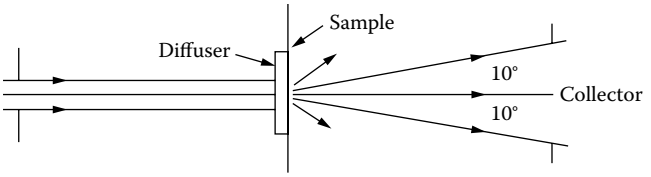

FIGURE 47.5 Optical system for measuring ISO diffuse density.

case, there will be some light reflected back to the negative from the paper surface. Any retroreflection from an integrating sphere will of course be quite different from that coming from a paper surface. To represent the contact-printing case, the present ANSI/ISO standard specifies that, in diffuse densitometers, the emulsion side of the sample shall be in contact with opal glass, which both acts as the diffuser and provides the desired back reflection. The optics of a diffuse densitometer is shown in Figure 47.5.

In the system shown, the sample is illuminated by diffuse light, which is the reverse of what is shown in Figure 47.3; however, as noted, diffuse density optics are reversible. Weaver studied the differences between opal-glass and integrating-sphere densities and found that because of the interreflections, the values were slightly lower in the opal-glass case [9]. The difference was ~0.04 density unit for very low densities, decreasing to 0.01–0.02 for samples whose densities were between 2.0 and 3.0. The opal-glass construction was also adopted in the standard because such instruments are easier to build and maintain. Care must be taken, however, to ensure that the diffuser meets the standard's specifications.

In actual operations, it is too time-consuming to zero the instrument before each reading. Likewise, the fraction Φ_e/Φ_i is rarely calculated specifically; the instrument simply provides a reading based on the amount of flux reaching the sensor. Because of the possibility of electronic drift however, it is advisable to zero the instrument periodically, unless it is known to be dependably stable. Likewise, the readings produced for some accurately known calibration sample of high density should be checked, a procedure known as "sloping" the instrument. Standard samples are available for this purpose; see the Appendix 47.A.

47.3 Monochrome Reflection Density

By definition, the reflectance factor

$$R = \frac{\Phi_r}{\Phi_o} \tag{47.5}$$

where

Φ_r is the flux returned to the sensor from the sample

Φ_o is the flux returned by a "perfectly reflecting, perfectly diffusing material located in place of the specimen" [1d]

Reflection density is then

$$D_R = -\log_{10} R = \log_{10} \frac{1}{R} \tag{47.6}$$

The optical configuration specified in the standard is shown in Figure 47.6. With reference to the normal to the specimen surface, one beam subtends an angle of 0° ± 5° and the other an angle of 45° ± 5°. Also, the 45° beam is annular. As in the case of transmission optics, the influx and efflux beams are interchangeable. When the influx beam is at 45°, the system is termed "45/0"; when the efflux beam is at 45°, the designation is "0/45." The angle between the two beams was selected to avoid the specular reflection from the surface. The 45° beam is made annular to minimize the effects of any texture pattern that might be embossed on the sample surface. The standard also specifies that when measured, samples

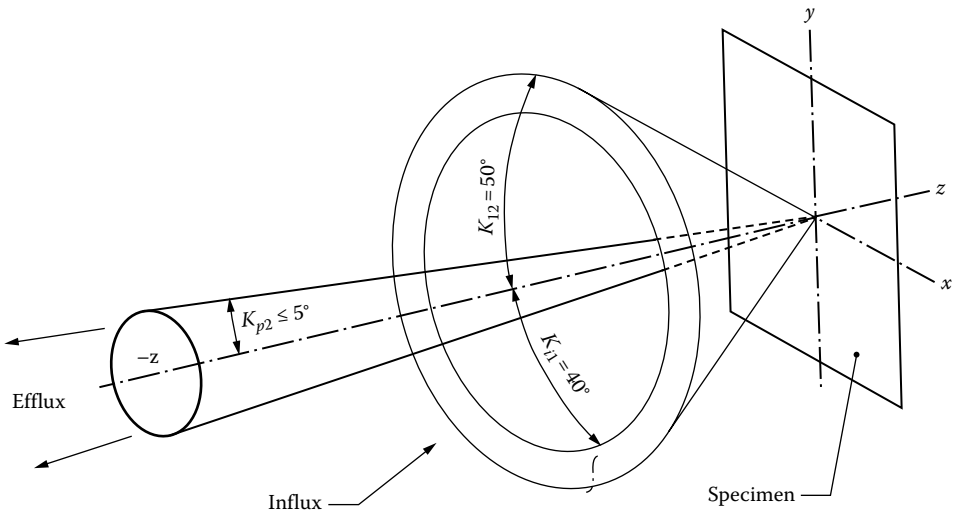

FIGURE 47.6 Annular geometry for measurement of reflection density.

shall be backed by a black diffusing material having a reflection density not less than 1.5. This procedure is specified to improve reproducibility, especially for thin samples.

It will be obvious that a reflection densitometer cannot be "zeroed" by taking a reading with no sample in place. Instead, as prescribed by the standard [1d], calibration samples that have been measured on other primary instruments are used both to zero and slope the densitometer. Formerly, coatings of MgO_2 or $BaSO_4$ were used as reference "whites," but these layers are difficult to use. An ASTM standard [10] discusses the preparation of reference whites from pressed powders. For routine work, "plaques" consisting of stove enamel of various gray levels on a metal substrate are widely used. These plaques are very durable, but their physical form is quite different from actual paper samples. Photographic paper strips that have been calibrated in primary instruments can also be used. Physically, these strips are exactly like the samples to be read, but they are very easily damaged and must be used with care. Any scratch in the surface can cause a specular reflection to reach the sensor, which will produce a false reading.

Actually, the reflection of light from a photographic paper is more complicated than might appear at first glance. A typical B&W paper is shown in cross section in Figure 47.7. As with film samples, the emulsion layer consists of Ag grains suspended in gelatin. The support is a diffuse reflector. It turns out that reflection to the sensor occurs in three ways, as sketched. (The specular reflection is omitted in Figure 47.7.) Note that the component r_2 traverses the emulsion layer twice and r_3 at least four times and that r_1 does not traverse

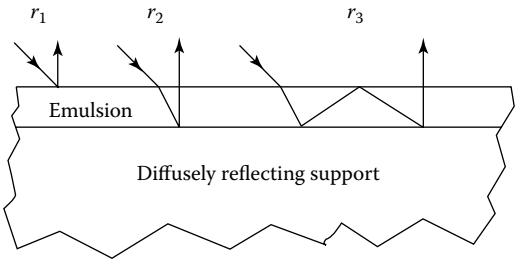

FIGURE 47.7 Cross section of photographic paper showing different reflection paths for influx beam: r_1, surface reflection; r_2, direct reflection from support to sensor; and r_3, one or more internal reflections before reaching sensor.

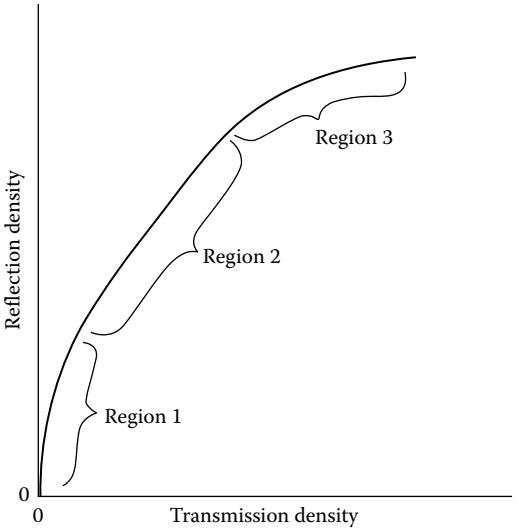

FIGURE 47.8 Densities measured on a film sample, both by transmission and after cementing the emulsion side to a diffusing reflector.

the layer. For low densities, all three components contribute to the reflection reading. As the population of grains in the emulsion layer grows, the multiply-reflected beam r_3 rapidly becomes negligible. With continued increases in the grain population, the component r_2 also reduces to insignificance, and only the r_1 component remains. This component, being a surface reflection, remains essentially constant at about $0.005I_0$.

The mechanism previously described can be confirmed by measuring the densities of a test strip by transmission and then cementing the strip to a diffuse reflector and measuring the same densities by reflection. The results of such an experiment are shown in Figure 47.8. This curve has three regions, as expected. In the first region, the slope is greater than 2, corresponding to the rapid loss of the r_3 component. In region 2, $\Delta D_R = 2\Delta D_T$; in this region, most of the photons reaching the sensor are those that have traversed the layer twice. Finally, in the third region of the curve, the r_2 component has become negligible, and only the surface component r_1 remains significant. Since, as noted, this component $\sim 0.005I_0$, the maximum reflection density attainable in a photographic paper should be about 2.0–2.3, and this is found to be the case for actual papers. (We have assumed a glossy paper. If the paper surface is textured, as it is in some products, specular reflections may be directed to the sensor from microareas, and the maximum density attainable on the sample will drop, in some cases significantly.) The curve of Figure 47.8 also becomes very important in color reflection work, as is discussed later.

47.4 Color Transmission Densitometry

So far, we have assumed either that the measuring beam was monochromatic or that the sample was neutral, that is, that transmittance or reflectance was constant across the spectrum of interest. Actually, the assumption of neutrality is reasonable for many B&W materials. However, of course, the densitometry of color images is extremely important, and this aspect is discussed later.

Before doing so, however, it will be useful to make a brief digression into the structure of photographic color materials [11]. Although an oversimplification, we can consider such materials to be three separate films coated one over the other on a single support. From the top down, the spectral sensitivities of these three layers are adjusted to record the blue, green, and red regions of the visible spectrum, respectively. In accordance with the principles of subtractive color reproduction, the images recorded in these layers are formed of yellow, magenta, and cyan dyes (again from the top down). The problem is

to densitometer these dyes. As before, we start with transmitting samples. Referring back to Figure 47.2, for any wavelength λ, the reading of the instrument with no sample in place will be

$$KS_\lambda s_\lambda F_\lambda = KJ_\lambda \tag{47.7}$$

where

K is the proportionality constant
S_λ is the spectral power of the influx beam at λ
s_λ is the relative spectral sensitivity of the receiver at λ
F_λ is the transmittance of any filters in the beam at λ

(The transmission of the instrument optics may be significant, but this can be included with S_λ, since it is a fixed characteristic of the device.) The product J is termed the "response" or the "spectral product" of the instrument.

If a sample whose transmission at wavelength λ is T_λ is now placed over the aperture, the reading will be

$$KS_\lambda s_\lambda F_\lambda T_\lambda = KJ_\lambda T_\lambda \tag{47.8}$$

and the measured transmittance reduces to T_λ, as it should. Thus, in the monochromatic case, the measured value is independent of the system response. When the influx beam contains two discrete wavelengths, the no sample reading becomes

$$K(J_1 + J_2) \tag{47.9}$$

and with the sample in place, it will be

$$K(J_1T_1 + J_2T_2) \tag{47.10}$$

The measured transmittance

$$T = \frac{J_1T_1 + J_2T_2}{J_1 + J_2} \tag{47.11}$$

Note that when the sample is neutral, Equation 47.11 again reduces to the case where the transmittance is independent of the instrument response. But when the sample is not neutral, Equation 47.11 can no longer be simplified. In other words, in the general case the transmittance/density values depend on the system response as well as on the sample.

For continuous bands of radiation, Equation 47.9 becomes

$$T = \frac{\int J_\lambda T_\lambda d\lambda}{\int J_\lambda d\lambda} \tag{47.12}$$

and

$$D = -\log_{10}\left[\frac{\int J_\lambda T_\lambda d\lambda}{\int J_\lambda d\lambda}\right] = \log_{10}\left[\frac{\int J_\lambda d\lambda}{\int J_\lambda T_\lambda d\lambda}\right] \tag{47.13}$$

The integration limits are set by the distributions.

From the previous analysis, it is clear that in order to obtain meaningful density values, the spectral characteristics of the densitometer must be made equal to those of the receiver that will "view" the sample in actual use. Furthermore, of course, the actual receiver will vary from application to application.

The densitometer characteristics are set by inserting appropriate filters in the beam. A number of spectral distributions are specified in Ref. [1c] as follows:

1. For reflection densitometry, the influx spectrum shall be ICI Illuminant A, which is essentially 2856 K.
2. For transmission densitometry, the influx spectrum shall be Illuminant A modified by an IR-absorbing filter, as tabulated in the standard.
3. For samples to be viewed by an observer, the spectral characteristic of the system shall match the relative luminosity function $V(\lambda)$. This case is termed "visual" density.
4. For color negative films, a set of three distributions in the red, green, and blue regions of the spectrum is specified. This set is identified Status *M* and approximates the spectral sensitivities of the three layers of color print materials.
5. For measuring red, blue, and green densities of color materials other than color negatives, a set of three responses identified Status *A* is provided.
6. To evaluate color images to be used in graphic arts processes, two sets of distributions are specified and are identified as Status *T* and Status *E*.
7. In the microfilm industry, prints are often made onto diazo or vesicular films. A narrow distribution centered at 400 nm is specified for this application, and the resulting densities are termed ISO printing densities type 1.
8. A spectral distribution covering the range $\lambda \approx 360$–540 nm is provided for measuring samples to be printed onto B&W photographic papers. Such densities are designated ISO printing densities type 2.
9. Status *I* response consists of three passbands centered at 420, 535, and 625 nm ± 5 nm. This set is used in evaluating graphic arts materials such as process inks on paper.
10. A narrowband response centered at 800 ± 20 nm is provided for measuring effective densities to *S*–1 photosurfaces, such as those used in optical sound systems. Densities measured with this response are identified "ISO type 3."

These responses are shown in Figure 47.9a through e, which is reproduced from the current standard.

The next problem in color densitometry stems from the fact that the three layers are superimposed and from the nature of the dyes. The spectrophotometer curves for a typical dye set are shown in Figure 47.10. In this figure, the lower three curves refer to the dyes measured individually, while the upper curve shows the result of superimposing them. The values for the individual dyes are termed "spectral analytical densities," and those for the tripack are termed "spectral integral densities." Since superimposed densities may be considered to add, at any wavelength the spectral integral value is the sum of the three analytical values. Note that all three of the individual dyes absorb light outside the spectral regions in which they are supposed to work.

This unwanted absorption can cause problems in color reproduction and, more to the point for this chapter, in densitometry, because straightforward measurements of a real film at any wavelengths yield integral values. In many cases, these integral values are required. In the manufacture and processing of films, however, it may become necessary to determine the densities in an individual layer. It is not sufficient to coat and measure a layer by itself, since layers coated in a tripack may respond differently from the same layers operated singly.

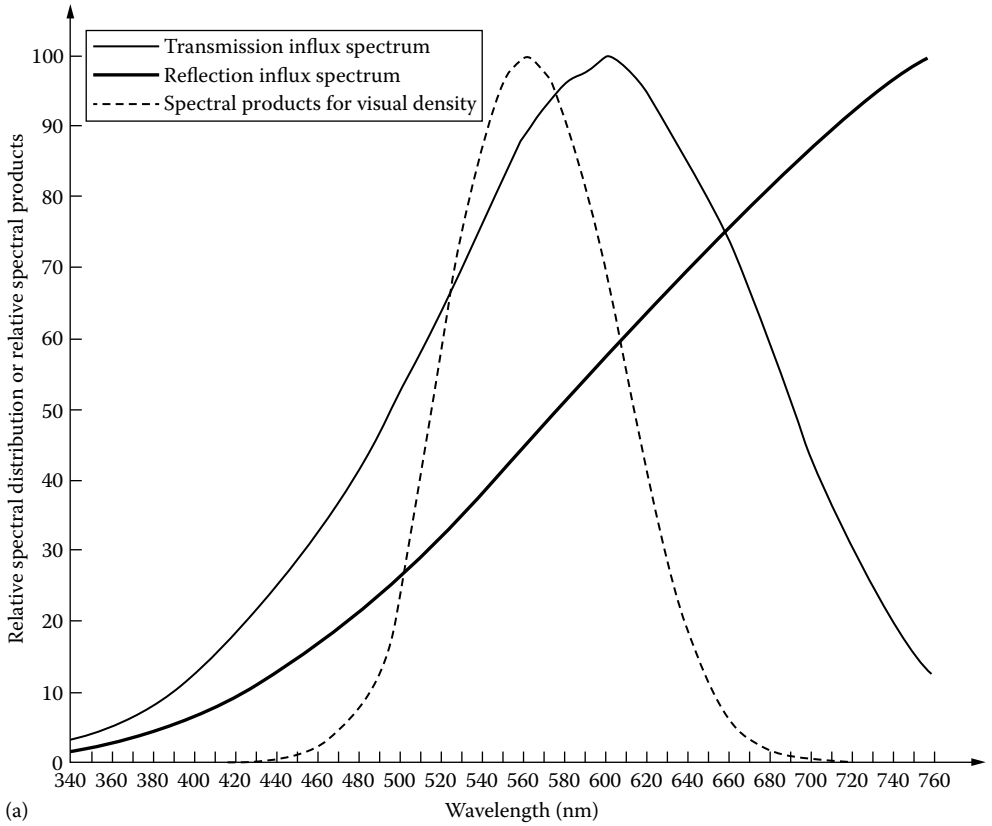
This problem is solved by taking advantage of two rules called the "additivity rule" and the "proportionality rule." The first of these is merely the rule that densities add. The proportionality rule is an extension of Beer's law. Consider an element, such as a glass cell or a layer of a color film, containing a dye whose concentration can be varied. Beer's law states that

$$T_\lambda = e^{-\beta_\lambda c} \tag{47.14}$$

where

c is the dye concentration

β_λ is the extinction coefficient at wavelength λ



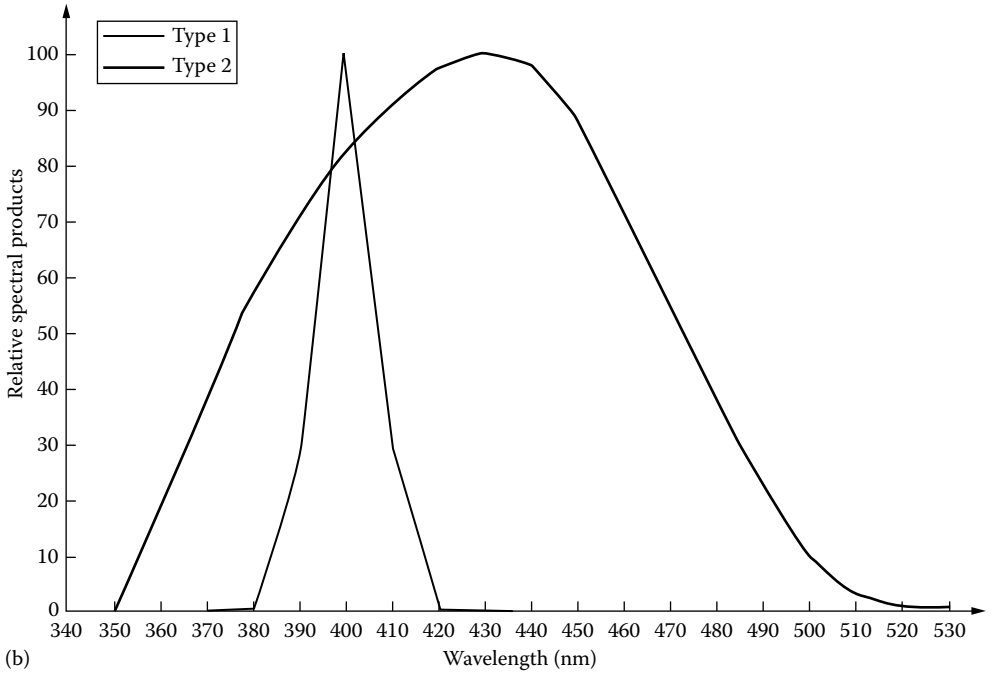


FIGURE 47.9 (a) Spectral products for ISO density and relative spectral power distributions for influxes. (b) Spectral products for type 1 and 2 densities.

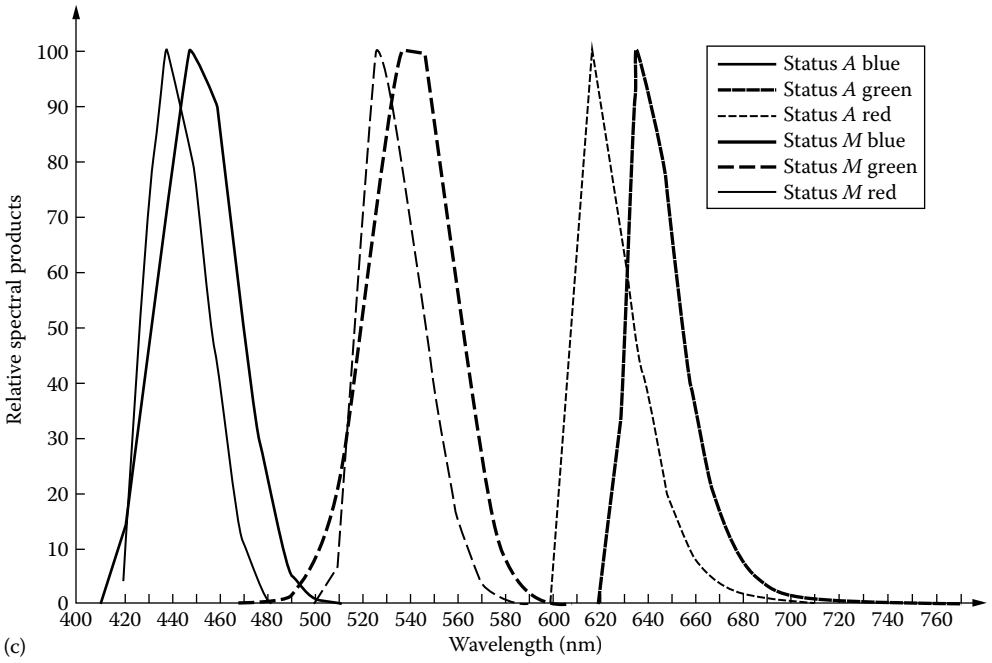

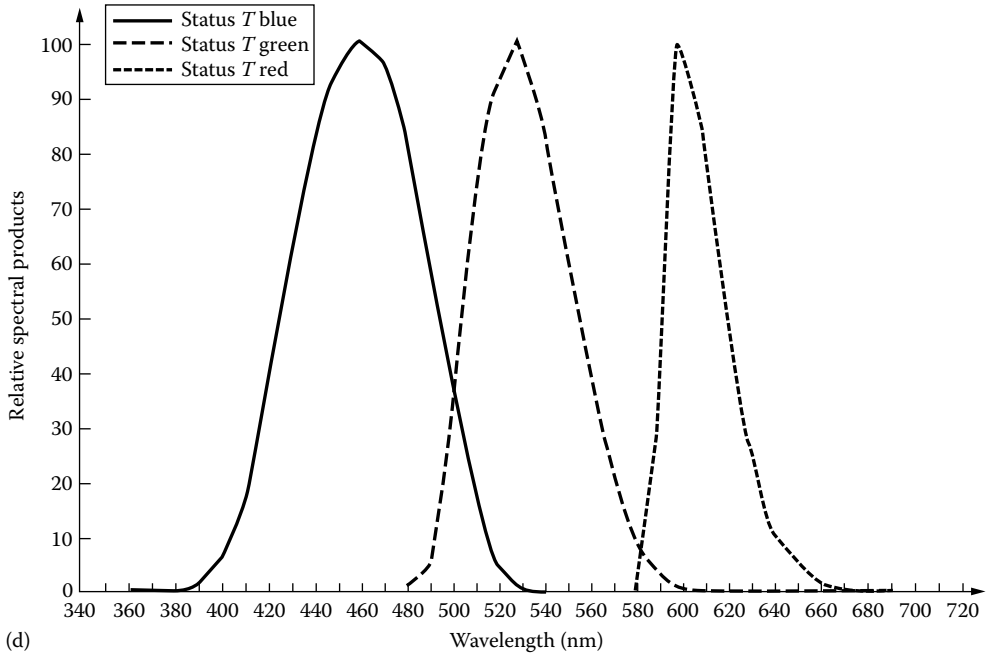

FIGURE 47.9 (continued) (c) Spectral products for Status *A* and *M* densities. (d) Spectral products for Status *T* densities.

(*continued*)

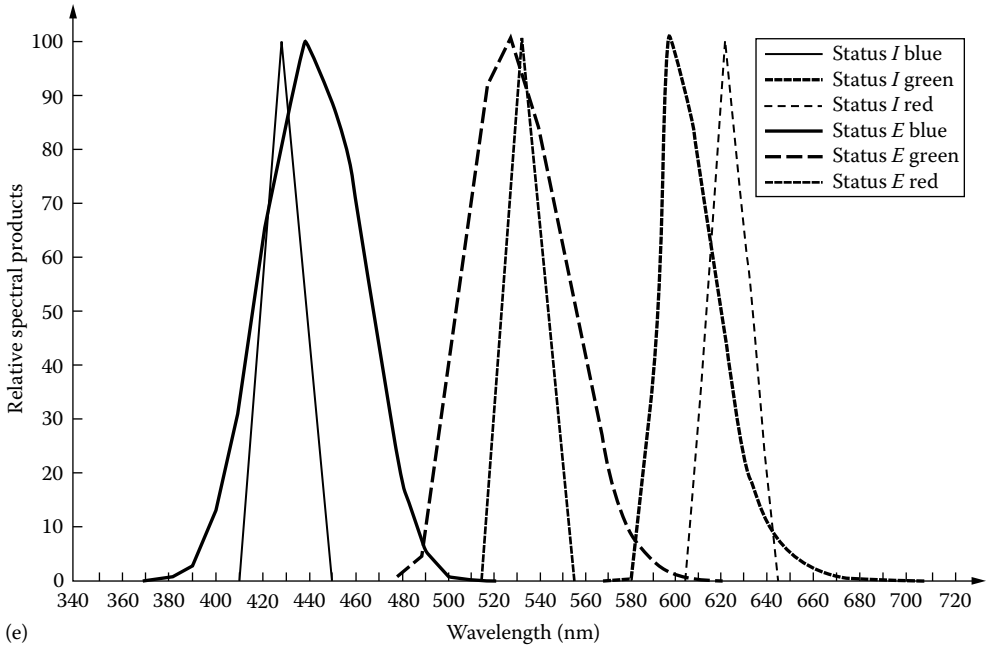

FIGURE 47.9 (continued) (e) Spectral products for Status *E* and *I* densities.

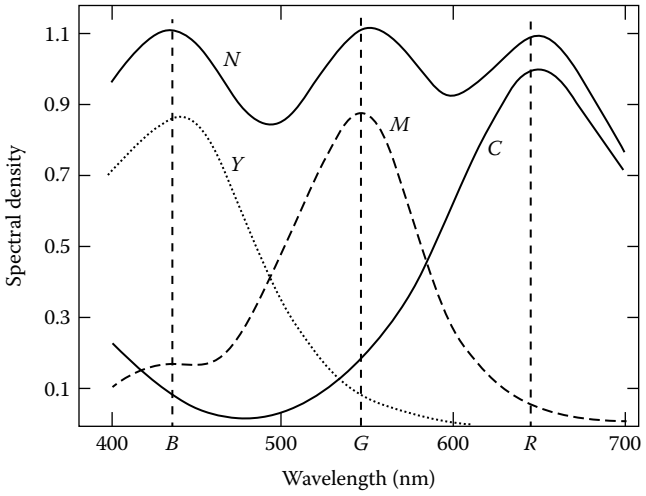

FIGURE 47.10 Spectral density distributions of the *C*, *M*, and *Y* components as functions of wavelength for a hypothetical color film and of the composite absorber (*N*).

The coefficient β varies with wavelength, of course, but will be constant at a given wavelength (unless changes in dye concentration produce chemical reactions.) Strictly speaking, Beer's law applies to the internal transmittance, but in the case of photographic layers, the surface reflectance is negligible. From Equation 47.14, it follows that

$$\ln T_\lambda = -\beta_\lambda c \tag{47.15}$$

and therefore,

$$D_\lambda = 0.434\beta_\lambda c \tag{47.16}$$

Consider now the density at two wavelengths for any given dye sample. Clearly,

$$\frac{D_{\lambda 1}}{D_{\lambda 2}} = \frac{\beta_{\lambda 1}}{\beta_{\lambda 2}} \tag{47.17}$$

Thus, for a given dye sample, the ratio of the densities at any two wavelengths is fixed regardless of dye concentration (i.e., assuming Beer's law holds), and this is a statement of the proportionality rule.

As noted, straightforward density measurements on a real sample yield integral densities. The proportionality rule can be used to derive analytical densities in the following manner [12]. Assume spectral densities for simplicity. With reference to Figure 47.10, we select three wavelengths at or near the peak absorptances of the three dyes. Consider first the blue wavelength. By the additivity rule, the blue integral density is

$$D_b = Y_b + M_b + C_b \tag{47.18}$$

where Y_b, M_b, and C_b are the blue analytical densities of the yellow, magenta, and cyan dyes, respectively. But by the proportionality rule, M_b/M_g = constant, where M_g is the analytical density of the magenta dye measured at the peak wavelength in the green. The value of this ratio is readily determined from a spectrophotometric curve of the dye. Denoting such ratios a_n, for measurements at the three peak wavelengths, we have

$$\begin{aligned} D_b &= Y_b + a_1 M_g + a_2 C_r \\ D_g &= a_3 Y_b + M_g + a_4 C_r \\ D_r &= a_5 Y_b + a_6 M_g + C_r \end{aligned} \tag{47.19}$$

This constitutes a set of three equations with three unknowns. The solution has the form

$$\begin{aligned} Y_b &= b_1 D_b + b_2 D_g + b_3 D_r \\ M_g &= b_4 D_b + b_5 D_g + b_6 D_r \\ C_r &= b_7 D_b + b_8 D_g + b_9 D_r \end{aligned} \tag{47.20}$$

where Y_b, M_g, and C_r are the desired values of the three analytical densities. The b-coefficients are algebraic combinations of the a-coefficients, which can be reduced to numerical values since the a-coefficients are known. In practical work, the determination of the a-coefficients is usually done using data for a number of different dye density levels. The off-peak density for each level is plotted against the peak density, giving a straight line whose slope is a good measure of the a-coefficient. Thus, for example, the coefficient a, in Equation 47.19, would be found by plotting M_b versus M_g for several levels. The values of the coefficients can also be found by doing narrowband densitometry on the samples instead of spectrophotometry.

So far, we have been assuming spectral densities. By the first law of densitometry, however, any sample should be measured with a system whose spectral response is equal to that used in actual practice—in other words, color negative samples should be measured with the Status *M* filters as described above. However, the analysis previously described works satisfactorily with the status filters, which are relatively narrowband, and much practical densitometry is performed in this manner.

Finally, because of its practical importance, we must introduce one more type of color density: the "equivalent neutral density" (END). END is defined as the neutral density that a given dye

deposit—yellow, magenta, or cyan—will produce when it is combined with the correct amounts of the other two dyes, whatever those amounts may be. It is important in practical film building, because one of the most important properties of a color film is its ability to produce a neutral as a neutral—in other words, to image a gray object as a gray that shows no residual tint of another color. Such a film is said to be "balanced," and good balance is considered extremely important by discriminating users. When the ENDs of the three layers of a color film are equal, the image will indeed be balanced, and color film sensitometry may be done in terms of ENDs. The END is a form of analytical density because it is a property of an individual layer. Originally, ENDs were measured in a special densitometer, but they are now calculated from the normal analytical densities by an equation of the form

$$\text{END} = m\,[\text{analytical spectral density}] + K \tag{47.21}$$

where the constants m and K are determined by comparing the visual densities of satisfactory neutral images with the corresponding analytical spectral densities. In some cases, a second-order equation has been found to yield better results [12b].

47.5 Color Reflection Densitometry

Color reflection densitometry follows the previously mentioned general principles set forth for the B&W reflection case. Since color prints are for the most part intended to be viewed by a human observer, in many cases a visual integral density provides the needed information. The film builder or process controller, however, may need information about the analytical densities of his layers, and here the approach used for transmitting samples does not work. The reason why it fails is that, for such samples, Beer's law fails, as is shown by the curve of Figure 47.8. If the law held, the reflection density would be proportional to the dye concentration (see Equation 47.11).

Pinney and Vogelsong [13] have described a method of obtaining reflection analytical densities in such cases. The method involves the empirical determination of a calibration curve similar to Figure 47.8 for the material at hand, relating the reflection densities of a dye deposit to the transmission densities. The reflection integral densities of the sample are then measured and converted to transmission densities. The analytical values for these transmission densities are calculated using the method previously described for such samples. Finally, the derived transmission values are converted back to reflection analyticals by going through the calibration curve in the reverse direction.

One last comment on the densitometry of color print papers should be added. In the commercial production of color prints, it may be extremely important to measure chemical stain in what should be the white areas of the picture. The passbands of the Status *A* filters are not well placed to monitor such stain, and it may be necessary to make additional measurements.

47.6 Densitometry of Halftone Patterns

Halftone patterns are used in the printing industry to reproduce continuous-tone images using two levels of ink: either ink or no ink. Various gray levels are produced by printing a pattern of repetitive "dots" too small to be resolved by the unaided eye. Essentially, the size of the dots is varied to produce a gray scale. Halftone patterns to be measured may be transmitting or reflecting, monochrome or color. A number of standards for densitometry in the graphic arts have been approved or are under development [14]. These standards provide much practical guidance and are consistent with ISO 5. Densitometry in this field is an example of the basic mechanism by which the instrument operates—comparing the flux reaching the sensor with and without the sample in place. When the

sample is a halftone, the flux reaching the sensor depends on the fractions of the area that are dense and clear. Adopting the notation of Ref. [13b] and assuming a transmitting sample, the measured density will be

$$D_t = -\log_{10}\overline{T} = -\log_{10}[fT_s + (1-f)T_b] \tag{47.22}$$

where

D_t is the measured density of pattern
$\overline{T}$ is the average pattern transmittance
f is the fraction of pattern area that is dense
T_s is the transmittance of "solid" areas (essentially equal to dot density)
T_b is the transmittance of clear areas

It is interesting to calculate the measured density of a halftone pattern, half of which is perfectly dense ($D = \infty$; $T = 0$) and half of which is perfectly clear ($D = 0$; $T = 1$). The calculated value for $D \approx 0.3$; and this value will indeed be found if such a pattern is densitometered.

If D_t, T_s, and T_b are known, Equation 47.22 provides an easy way to determine the fractional area covered by the pattern dots with an ordinary densitometer, and this is often done in graphic arts work. In practical work, T_s and T_b are measured in terms of density also, and this can be done satisfactorily on large areas. Since by definition $T = 10^{-D}$, the solution of Equation 47.22 for f can be written

$$f = \frac{1-10^{-(D_t - D_b)}}{1-10^{-(D_s - D_b)}} \tag{47.23}$$

In this form, the equation is known as the Murray–Davies equation.

47.7 Summary

A densitometer measures the flux reaching the sensor with a sample in place and calculates the ratio of this value to that obtained either with no sample in place (in the transmission case) or with a reference white in place (in the reflection case). The instrument then displays the negative log of this value.

The observed reading may depend significantly on the characteristics of the instrument, that is, on the

1. Angular substance of the influx beam
2. Angular substance of the efflux beam
3. Spectral power distribution of the influx beam
4. Spectral sensitivity of the receiver

For a complete specification of the density in a given case, these four parameters should be indicated. ISO 5.1 (Ref. [1a]) provides a standardized notation.

Colorimetry

Robert T. Marcus
Datacolor International

48.1 Introduction

Imagine how dull a world without color would be. Until the 1960s, many products were available in only a limited variety of colors. Consumers demand a variety of colors, and the materials available today allow manufacturers to meet those demands.

For many centuries, color was controlled by master color matchers adjusting the color of their products visually in natural daylight. It was about the 1950s when color-measuring instruments began to make a significant impact in the manufacturing process, and by the 1970s they were commonly used in most industries. Color-measuring instruments are used mostly for quality control but also for computerized color-matching systems, process control, and evaluation of raw materials and as an aid to solving color problems.

While it is common to speak of a red car or a red light, color is a perception—not an intrinsic property of the object or the light. Color perception is influenced by the light source, the reflectance or transmittance properties of the object, the eye, and the brain. Color is one aspect of appearance. Gloss and texture are other aspects.

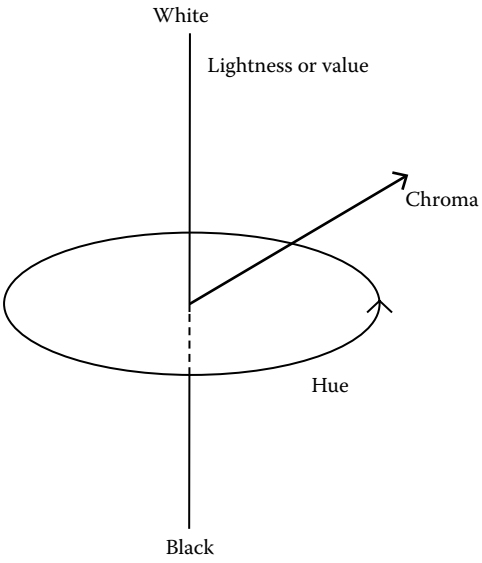

FIGURE 48.1 The three dimensions of color.

Color perception is 3D, that is, three terms are needed to describe a color. Hue, lightness (sometimes called value), and chroma are one set of terms often used to describe color. Hue distinguishes blue from green from yellow, etc. Lightness distinguishes light colors from dark colors—for example, a light-blue fabric from a dark-blue fabric. Chroma, the most difficult of the three terms to understand, describes how different a color is from gray—for example, distinguishing a pastel green from a bright green. If the two greens are of the same hue (one is neither yellower nor bluer than the other) and have the same lightness, then the pastel green would be described as having a low chroma and the bright green as having a high chroma. Figure 48.1 is a diagram illustrating the three dimensions of color.

Daylight, fluorescent lamps, and incandescent lamps are widely used light sources for color evaluation. The perceived color of an object changes as the light changes. The human visual systems attempt to compensate for the change in light source and hold the color constant. Light booths provide standardized and controlled light sources for the visual evaluation of color. Most light booths contain a simulated daylight lamp, a cool white fluorescent lamp, an incandescent lamp, and an ultraviolet lamp for detecting fluorescence. By use of a switch, a light booth can be used to examine how the perception of a colored material changes with different light sources.

Two objects may appear the same when viewed under one light source but different when viewed under another light source. This effect, called metamerism, is one of the major industrial problems for color matching. Metamerism usually occurs when attempts are made to produce objects that are the same color but made out of different materials, such as trying to match the dyed textile interior of a car with paint on the exterior and the plastic on the dashboard.

Colorimetry, the measurement of color, attempts to quantify the perception of color. The Commission Internationale de l'Éclairage (International Commission on Illumination [CIE]) is a voluntary organization of scientists and engineers from all over the world who are interested in light and color. The recommendations constituting modern colorimetry were first published by the CIE in 1931 and have been regularly updated since then [1].

Electromagnetic radiation (x-rays, gamma rays, light, and radio waves) irradiates the Earth constantly. Visible light is the name given to the electromagnetic radiation that the human eye perceives. The wavelength of visible light ranges from about 380 to about 780 nm. Sunlight is a mixture of all the wavelengths of light. Water vapor can spatially separate the light into its various wavelengths—the rainbow. Prisms and diffraction gratings can also spatially separate light into its component wavelengths.

Light sources can be described numerically by their spectral power distribution, the relative amount of power the source emits at each wavelength of interest. A light source may emit power at wavelengths below (ultraviolet "light") or above (infrared "light") those of visible light. Ultraviolet radiation is important to colorimetry because it can cause fluorescence. Infrared radiation is the basis of "heat lamps" but is not important in colorimetry. Spectroradiometers measure the spectral power distribution of light sources.

Illuminants and sources are sometimes confused. Sources are actual physical entities that produce visible radiation, whereas an illuminant may only be a numerical table of values of a spectral power distribution. Initially, the CIE recommended three light sources for colorimetry in 1931. Source A, which is still in use, is an incandescent, tungsten filament light. An illuminant is the spectral power distribution of a light source. Thus, Illuminant A is the spectral power distribution of Source A. An illuminant may be defined, even when a source for that illuminant does not exist. Examples of illuminants without sources are the D series of illuminants recommended by the CIE. The D illuminants represent various phases of daylight. Illuminant D65 represents average daylight and is the most common illuminant used in colorimetry. No sources were recommended for the D series of illuminants.

Fluorescent lights have great commercial importance. Cool white fluorescent lamps are the most common light sources in offices in the United States. There are a variety of other types of fluorescent lamps used in stores and offices. The CIE also recommended a series of illuminants to represent fluorescent lamps. F2 represents cool white fluorescent lamps. Figure 48.2 shows the spectral power distributions of Illuminants A, D65, and F2.

Color vision and perception is complex and has been extensively studied. Ninety-two percent of men and 99.5% of women have "normal" color vision. The eye's lens focuses images on the light-sensitive retina. Rod cells make up the majority of the retina and are sensitive to low levels of illumination (night vision). Cone cells provide color vision and are located in a small area of the retina called the *foveal pit*. There are three types of cone cells. One type of cone cells has peak sensitivity to blue light, one type to green light, and one type to red light. Signals from the cone cells are transmitted to the brain where they are processed into color perceptions.

Color perception is an extremely complex phenomenon. For example, the background on which a material is viewed can have a major effect on the perceived color of that material. The ambient light to which the eye becomes adapted also influences the color of materials. Basic colorimetry, the topic of this chapter, provides the rather simple concept of dealing with the measurement of single independent colors. Most of industrial color control is adequately described using basic colorimetry. Advanced colorimetry attempts to use physical measurements to describe the perceived color of a material when viewed in a complex scene.

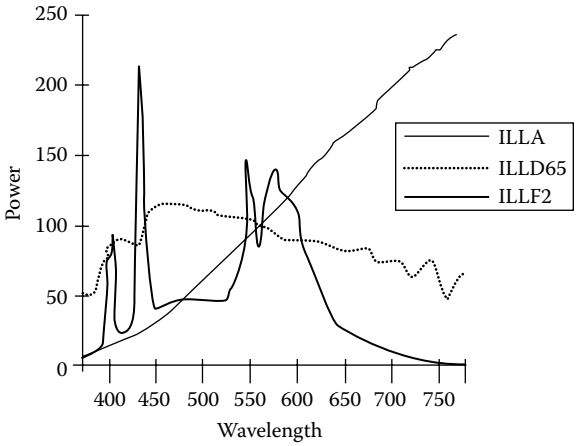

FIGURE 48.2 The spectral power distribution of CIE standard Illuminants A, D65, and F2.

All colors are perceived by stimulating combinations of the three cones. Computer monitors and color television tubes produce colors by lighting combinations of red, green, and blue phosphors. In 1931 when the CIE was developing the system for modern colorimetry, they transformed the data from real experiments that had human observers match each wavelength of visible light with combinations of red, green, and blue lights to three mathematical imaginary "lights" labeled *X*, *Y*, and *Z*. All colors can be matched by varying amounts of *X*, *Y*, and *Z*. The amounts of each *X*, *Y*, and *Z* imaginary light that must be mixed together to match a color are called the tristimulus values (see "CIE Standard Observers," explained in Section 48.3).

Most objects absorb, transmit, or reflect (scatter) light. Transparent objects absorb and transmit light. Opaque objects absorb and reflect light. Light sources emit light. Fluorescent objects absorb, reflect, and emit light. Translucent or hazy objects absorb, transmit, and scatter light. Measuring the color of fluorescent, translucent, and hazy objects is difficult and will be covered in later sections.

Objects are characterized by the amount of light they reflect or transmit at each wavelength of interest. Most spectrophotometers measure reflectance factors rather than reflectance. Reflectance is the amount of light reflected from an object compared to the amount of light illuminating that object. The reflectance factor is the amount of light reflected from an object compared to the amount of light reflected from a perfect diffuser under the same conditions. A perfect diffuser is a theoretical material that diffusely reflects 100% of the light incident upon it. The term reflectance is often used in a general sense, or as an abbreviation for, reflectance factor. Such usage may be assumed unless the term reflectance is specifically required by the context [48]. Spectrophotometers designed for color measurement usually measure reflectance or transmittance at 10 or 20 nm intervals throughout the visible spectrum.

When the reflectance or transmittance of an object is low, the object absorbs most of the incident light; when it is high, the object reflects or transmits most of the incident light. Figure 48.3 shows the reflectance curve of a printed yellow ink. Note that the yellow ink absorbs light in the blue portion of the spectrum and reflects light in the yellow and red portions of the spectrum. A green plastic (Figure 48.4) absorbs light in the blue and red portions of the spectrum and transmits light in the green portion.

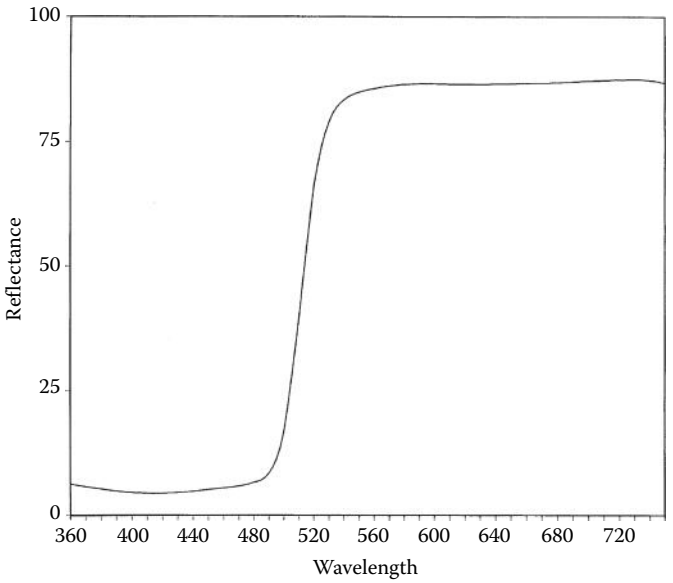

FIGURE 48.3 The spectral reflectance curve of a printed yellow ink.

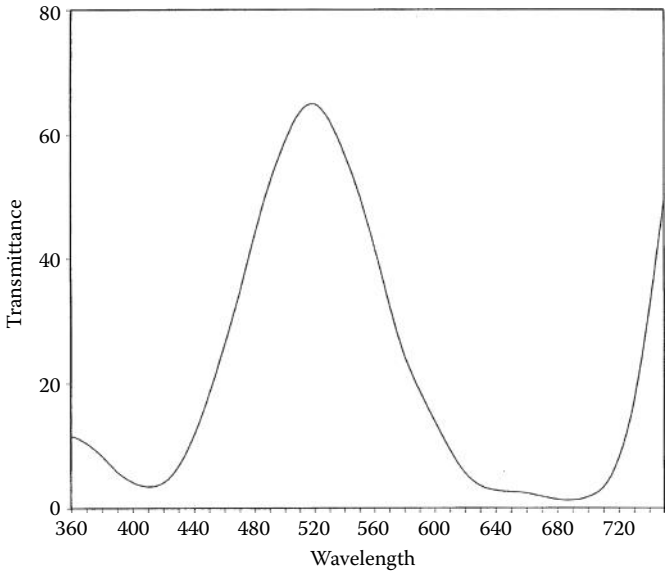

FIGURE 48.4 The spectral reflectance curve of a green transparent plastic.

The tristimulus values of an object can be calculated by combining the reflectance or transmittance of the object with the spectral power distribution of an illuminant and the color-matching functions of a standard observer. The yellow ink's tristimulus values for Illuminant D65 and the 10° standard observer are $X = 66.62$, $Y = 69.72$, and $Z = 7.03$. Those for the green plastic are $X = 21.03$, $Y = 39.40$, and $Z = 24.06$. An object's tristimulus values will change with the illuminant. For example, the tristimulus values for the yellow object for Illuminant A and the 10° standard observer are $X = 91.15$, $Y = 77.83$, and $Z = 2.80$.

Pairs of objects are said to match when their tristimulus values are the same. However, since the calculation of the tristimulus values included the source and observer as well as the object, when one of these changes, the objects may no longer match, that is, they may have different tristimulus values. Metameric colored objects have the same tristimulus values for the illuminant under which they match but different tristimulus values for illuminants where they do not match.

Color measurements are most often made to determine quantitatively whether or not the colors of two objects or batches of material are the same. But what happens when they do not match? Color difference equations were developed to quantify the difference. Starting with the objects' tristimulus values, a color difference equation will calculate the total color difference, ΔE or DE, and its component parts—the differences in lightness (ΔL or DL), chroma (ΔC or DC), and hue (ΔH or DH) or the differences in lightness, yellowness–blueness (Δb or Db), and redness–greenness (Δa or Da). Numerical color differences may be used for setting tolerances for quality control applications, to answer the question: is the match close enough?

48.2 Standardized Light Sources

48.2.1 Color Temperature

Light sources may be described by their color temperature. A block of carbon would look completely black when its temperature was at absolute zero, 0 K. When the carbon block is heated to about 2850 K, it looks yellow—about the same color as an incandescent light bulb. Heat the block to 5000 K, and it looks whitish. At 7500 K, the block would have the bluish color of north sky daylight. A full (blackbody)

radiator is a theoretically perfect emitter and absorber of radiation that changes color like the carbon block just described. The color temperature of a light source is the temperature of a full radiator that has the same color as the light source. When a light source does not exactly match the color of a full radiator, the correlated color temperature is used to describe the light source. The correlated color temperature is the temperature of a full radiator whose color is closest to the source.

Daylight varies during the day—redder in the morning and evening and bluer at noon. Average daylight (diffuse skylight without direct sunlight) has a color temperature of 6500 K. North sky daylight is preferred by many people for the visual evaluation of color and has a color temperature of 7500 K.

48.2.2 CIE Recommendations

Source A has a color temperature of 2856 K. The CIE recommended daylight illuminants are referred to by the prefix D, followed by the first two digits of their color temperature. Thus, CIE Illuminant D65 has a color temperature of 6500 K. Illuminant D50 has a color temperature of 5000 K and is preferred by the graphic arts community. Illuminant D75 would be used for north sky daylight having a color temperature of 7500 K. Illuminant F2 has a color temperature of about 4100 K.

48.3 CIE Standard Observers

The CIE adopted two standard observers based on color-matching experiments. The CIE 2° standard observer was recommended in 1931, and the CIE 10° standard observer was recommended in 1964.

In the CIE experiments, observers having normal color vision matched spectrum colors with combinations of red, green, and blue light. Figure 48.5 illustrates the experimental setup used in the standard observer experiments. One-half of a circular field was illuminated with the spectrum color, while the other half was illuminated with a mixture of red, green, and blue lights. The observer adjusted the amounts of red, green, and blue until the mixture matched the spectrum color. Unfortunately, not all of the spectrum colors could be matched with combinations of the red, green, and blue lights used in the experiment. In those cases, one of the lights had to be moved so that it illuminated the test field. By "diluting" the spectrum color with one of the lights, the resultant color could be matched with the remaining two lights. The amount of light used to dilute the spectrum color was considered

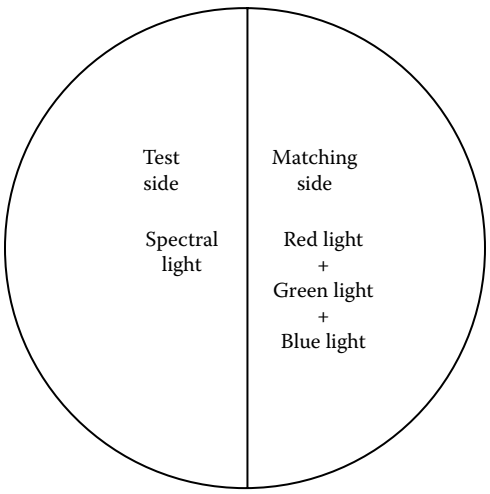

FIGURE 48.5 Experimental field of view for determining the CIE standard observers.

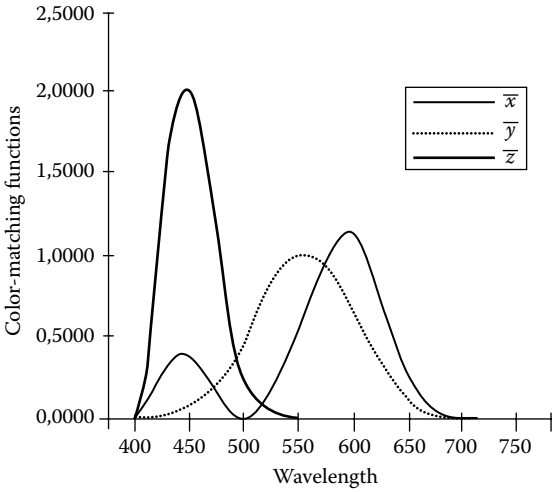

FIGURE 48.6 The color-matching functions for the CIE 10° standard observer.

to be a negative amount. To avoid having color-matching functions with negative amounts of light, three "imaginary" lights (X, Y, and Z) were created by performing a mathematical transformation. Color-matching functions are the amounts of X, Y, and Z required to match the colors of the spectrum and are used in the calculation of tristimulus values. Figure 48.6 shows the color-matching functions, ($\bar{x}$, $\bar{y}$, and $\bar{z}$) for the 10° standard observer.

In the first experiments, the circular field viewed was projected on the foveal pit and subtended a solid angle of 2°. This is about the size of a dime held at arm's length. The 2° standard observer developed from these experiments is very useful when viewing small fields, such as the signal lights of ships or small colored chips. Industrial color matchers view larger fields, such as two 5 × 12 in. panels. The 10° standard observer should be used when viewing larger fields. Observers for those experiments viewed a 10° visual field, which is about the size of a fist held at arm's length.

The standard observers represent combinations of the color-matching functions of a number of observers. Standard observer color-matching experiments are tedious and difficult to do. Few people can do them with reproducibility. Individual's color-matching functions are likely to vary from that of a CIE standard observer. Although these differences do not generally present a problem, they can affect the evaluation of metameric samples.

48.4 Calculating Tristimulus Values

Tristimulus values for reflecting samples are calculated from the following equations:

$$X = k \int_{380}^{780} R_\lambda S_\lambda \bar{x}_\lambda d\lambda \cong k \sum_{380}^{780} R_\lambda S_\lambda \bar{x}_\lambda \Delta\lambda \tag{48.1}$$

$$Y = k \int_{380}^{780} R_\lambda S_\lambda \bar{y}_\lambda d\lambda \cong k \sum_{380}^{780} R_\lambda S_\lambda \bar{y}_\lambda \Delta\lambda \tag{48.2}$$

$$Z = k \int_{380}^{780} R_\lambda S_\lambda \bar{z}_\lambda d\lambda \cong k \sum_{380}^{780} R_\lambda S_\lambda \bar{z}_\lambda \Delta\lambda \tag{48.3}$$

$$k = \frac{100}{\int_{380}^{780} S_\lambda \bar{y} d\lambda} \cong \frac{100}{\sum_{380}^{780} S_\lambda \bar{y} \Delta\lambda} \tag{48.4}$$

where

S_λ is the relative spectral power distribution of the illuminant at wavelength λ
R_λ is the reflectance factor of the sample at wavelength λ
$\bar{x}_y$, $\bar{y}_\lambda$, and $\bar{z}_\lambda$ are the color-matching functions of the observer at wavelength λ

For transmitting objects, substitute the transmission factor, T_λ, of the sample at wavelength λ for the reflectance factor. The factor k normalizes Y so that it will equal 100.00 for a perfect reflector or transmitter, that is, R_λ or T_λ is 100.00 at all wavelengths of interest. The summations in the previous equations are only valid if the reflectance or transmittance of the sample is measured at wavelength intervals of 1 or 5 nm from 380 to 780 nm.

Many commercial spectrophotometers measure wavelength intervals of 10 or 20 nm. To accurately calculate tristimulus values of samples measured with those instruments, the following equations should be used:

$$X = \sum W_{x\lambda} R_\lambda \tag{48.5}$$

$$Y = \sum W_{y\lambda} R_\lambda \tag{48.6}$$

$$Z = \sum W_{z\lambda} R_\lambda \tag{48.7}$$

in which $W_{x\lambda}$, $W_{y\lambda}$, and $W_{z\lambda}$ are weighting factors designed for 10 and 20 nm wavelength intervals. T_λ can be substituted for R_λ for transmitting samples. Although a number of weighting factors have been developed over the years [2–7], those recommended by ASTM in E 308 Standard Practice for Computing the Colors of Objects by Using the CIE System [7] are recommended.

Tristimulus values for a light source can be calculated easily from measurements taken at 1 or 5 nm intervals from the following equations:

$$X = \frac{k_m}{\sum \bar{y}_\lambda} \sum S_\lambda \bar{x}_\lambda \tag{48.8}$$

$$Y = \frac{k_m}{\sum \bar{y}_\lambda} \sum S_\lambda \bar{y}_\lambda \tag{48.9}$$

$$Z = \frac{k_m}{\sum \bar{y}_\lambda} \sum S_\lambda \bar{z}_\lambda \tag{48.10}$$

where

S_λ is the relative spectral power of the light source at wavelength λ
k_m is the maximum spectral luminous efficacy function (683 lm W^{-1})
$\bar{x}_y$, $\bar{y}_\lambda$, and $\bar{z}_\lambda$ are the color-matching functions for the standard observer

48.5 Reflectance Measurements

48.5.1 Specular and Diffuse Reflectance

Specular (sometimes called *regular*) reflection is the mirrorlike reflection from an object. If you shine a beam of light on a mirror, it will be entirely reflected at the same angle on the opposite side of a normal plane to the mirror's surface. However, if you shine a beam of light on a pellet of compressed barium sulfate ($BaSO_4$) powder, it will enter the surface, be scattered a number of times, and exit the pellet in many directions. This is called diffuse reflection. Glossy and semiglossy materials contain a combination of specular and diffuse reflection as shown in Figure 48.7. Observers usually discount the specular reflection when visually evaluating the color of a material.

48.5.2 Illuminating and Viewing Geometries for Reflectance

Instruments designed for measuring the color of reflecting objects consist of an illuminator, a sample holder, and a receiver. The CIE has recommended four illuminating and viewing geometries for making reflectance measurements.

Bidirectional geometries illuminate the sample with a narrow beam of light and view the sample with a receiver having a narrow entrance field. In the most commonly used bidirectional geometry, the sample is illuminated at a 45° angle (+2°) from the sample's normal and viewed along the sample's normal (±10°). The other recommended geometry illuminates the sample along its normal and views the sample at 45° from its normal. Bidirectional geometries measure only diffuse reflection and can be sensitive to the surface texture of the sample. The two bidirectional geometries produce equivalent results [8,9].

In the most common diffuse geometry, the illuminator includes an integrating sphere. An integrating sphere is a hollow metal sphere coated with a highly reflecting white coating with openings for the light source, the sample, and the receiver. The instrument's light source projects a beam of light onto the integrating sphere's wall. The light is reflected many times by the sphere's wall, and the sample is illuminated from all angles. When measuring in the diffuse/normal mode, *d*/0, the receiver views the sample along its normal. When the receiver is positioned in this manner, the specular reflection is directed back toward the light source and is not measured.

For some applications, it is useful to remove the specular reflection off of the sample's surface from the reflection of the light that is reflected back from the interior of the sample. This can be done by moving the receiver 6° or 8° from the sample's normal as shown in Figure 48.8. A specular inclusion port is placed at the equal angle on the opposite side of the sample's normal. By placing a white plug having the same reflectance as the sphere wall in the port, the specular reflection can be included in the measurement. By using a light trap at the specular inclusion port, some or all of the specular reflection can be excluded from the measurement. The narrower the specular reflection peak, that is, the glossier

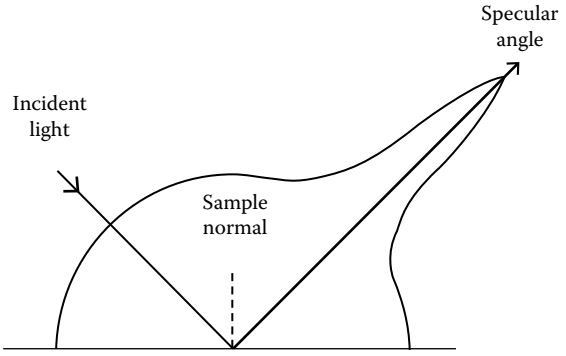

FIGURE 48.7 A semiglossy material showing a combination of specular and diffuse reflection.

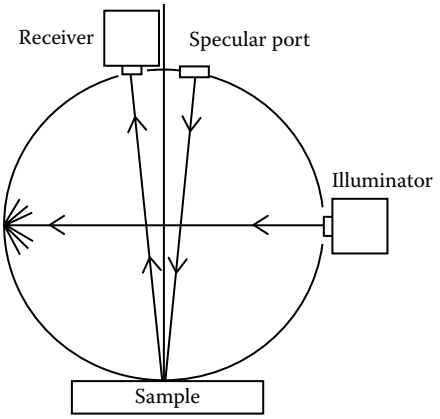

FIGURE 48.8 The diffuse/normal illuminating/viewing geometry with the ability to include or exclude the specular surface reflection.

the material, the more specular reflection is excluded. Specular-included measurements are normally abbreviated as SCI, while specular-excluded measurements are abbreviated as SCE. This geometry is referred to as diffuse/near normal but still abbreviated as *d*/0. When the specular reflection is included, this geometry is sometimes referred to as total/normal, *t*/0.

The last of the CIE recommended illuminating and viewing geometries is the normal/diffuse or near normal/diffuse, 0/*d* and 0/*t*. This is the reverse of the *d*/0 geometry. The illuminator illuminates the sample along its normal or slightly off of its normal. For this geometry, the integrating sphere is part of the receiver. Light reflected from the sample is captured by the integrating sphere, and the remaining optics of the receiver views the sphere wall. The two diffuse geometries produce equivalent results [8,9].

48.5.3 Monochromatic and Polychromatic Illumination

An instrument's illuminator may illuminate the sample with either a narrow band of wavelengths, 1–10 nm wide, called monochromatic illumination, or a wide band of wavelengths, usually simulating a daylight illuminant and called polychromatic illumination. For nonfluorescent samples, either illumination method can be used with equivalent results. However, for fluorescent samples, only polychromatic illumination can produce valid results.

48.5.4 Sample Texture and Bidirectional Geometries

Bidirectional illuminating and viewing geometries can be very sensitive to surface texture and any polarization of reflected light. Keeping the illuminator and receiver in the same plane maximizes this sensitivity. To reduce or eliminate this sensitivity, circumferential or annular illumination (or receiving) can be used. When an illuminator provides light (or the receiver possesses responsivity) at many points distributed uniformly around a 45° cone centered at the sample's normal, we refer to circumferential illumination (or viewing). When the illuminator provides light continuously and uniformly around the cone, we refer to annular illumination (or viewing).

48.5.5 Which Illuminating and Viewing Geometry Is Best?

"Which illuminating and viewing geometry is best for color measurement?" is a difficult question to answer [9–12]. For matte samples, all of the geometries produce equivalent results. For high-gloss samples, the diffuse geometries with the specular reflection excluded provide measurements very close

to the bidirectional geometries. For semigloss samples, the problem becomes more complex. The two bidirectional geometries are similar to the way a person evaluates color visually and are often thought to agree better with visual evaluation. On the other hand, the diffuse geometries measured with the specular reflection included minimize the effect of the sample's texture and gloss and are quite useful for computerized color matching. Rather than purchasing multiple instruments, most users select the geometry most suited to their major needs and compromise on other measurements.

48.5.6 Spectrophotometers

Spectrophotometers are used to measure an object's reflection characteristics throughout the visible spectrum. Double-beam spectrophotometers monitor a reference standard to compensate dynamically for fluctuations in source output, detector response, and atmospheric absorption to increase the instrument's stability [13]. Improvements in electronics and optics have allowed single-beam spectrophotometers to achieve the stability of double-beam instruments [14]. Single-beam instruments with an integrating sphere require a correction for the reduction of sphere efficiency caused by sample absorption [14].

Reflectance measurements are referred to as if they take place at a single wavelength. In actuality, a spectrophotometer has a finite spectral bandwidth or bandpass centered about that wavelength. Some instruments will have a bandpass as narrow as 1 nm, while others may exceed 20 nm. Bandpass is important because it influences the color measurement. The extent of this influence depends on the sample being measured [15,16]. The spectral bandpass should be equal to the wavelength increment used in the calculation of tristimulus values to obtain the best color measurement results [17].

Spectrophotometers must be standardized before making reflectance factor measurements. The high point of the measurement scale is set by measuring a white standard of known reflectance factor [18]. The zero point is set by measuring a light trap or a black calibration standard. Single-beam, integrating sphere spectrophotometers may also require a sphere wall calibration, which is often done with a gray standard.

Some spectrophotometers allow the user to vary the size of the area measured. For most applications, the largest area possible should be measured. A number of documentary standards exist for making and reporting reflectance measurements [9,17,19–25].

48.5.7 Colorimeters and Spectrocolorimeters

Colorimeters were developed in the 1920s–1930s as a less expensive alternative to spectrophotometers for quality control and color difference applications. They are simple to use and directly measure a sample's tristimulus values or related color coordinates. Three or four filters modify the light source and attempt to duplicate a standard illuminant/standard observer combination. Because of the difficulty in matching the CIE illuminant and standard observer functions, they are less accurate than spectrophotometers for determining a sample's tristimulus values. Colorimeters determine the color difference between two samples more accurately than they determine tristimulus values, and they are often called color difference meters. Since only one standard illuminant/standard observer combination is usually possible, colorimeters cannot be used to determine metamerism. Standards also exist for making colorimeter measurements [24–26].

A new class of instruments, spectrocolorimeters, began to appear in the 1980s. Spectrocolorimeters are spectrophotometers that only output tristimulus values or related color coordinates. They are less expensive and often have fewer options (such as variable area of view) than fully functional spectrophotometers. However, because they are spectrophotometers, they are capable of measuring metamerism.

48.5.8 Sample Preparation

Accurate color measurement is often dependent on sample preparation. Ideally, a sample for reflectance measurement is flat, has a uniform gloss and texture, is opaque, and is nondirectional. Always strive for sample preparation techniques that are reproducible. Consult standard test methods [24], standard practices [19,27–29], books, and articles [30–33] for help and advice on sample preparation.

48.6 Transmittance Measurement

48.6.1 Regular and Diffuse Transmittance

When a beam of light passes through a "transparent" material along its normal, the intensity of the beam will be decreased by absorption, but the direction of the beam will be unchanged. This is called regular transmittance. When a beam of light passes through a hazy or translucent material along its normal, the material scatters light and spreads the beam. This is called diffuse transmittance.

48.6.2 Illuminating and Viewing Geometries for Transmittance

The CIE has recommended three illuminating and viewing geometries for transmittance measurements. [1] Most transmittance measurements are made with spectrophotometers designed for analytical chemistry applications that use a normal/normal, 0/0, geometry. The illuminator directs the incident beam along the sample's normal, and the receiver views the sample along its normal. Only regular transmittance can be measured accurately using this geometry.

Regular and diffuse transmittance can be measured using the normal/diffuse, 0/*d*, geometries (or the equivalent diffuse/normal, *d*/0), which the CIE also recommended for reflectance measurements. Regular transmittance is measured by keeping the sample as far away as possible from the integrating sphere, whereas diffuse transmittance is measured by placing the sample in contact with the sphere. Instruments designed specifically for transmittance measurements would have only a sample or illuminator port and a receiver port. Instruments designed for reflectance measurements can be used for making transmittance measurements by placing a white material in the sample port and using the specular-included mode of measurement. The illuminator or receiver port would then serve as the sample port.

The third geometry recommended by the CIE, diffuse/diffuse, *d*/*d*, is not often used for industrial color measurement. One integrating sphere is used to illuminate the sample, and a second integrating sphere is used to view the sample.

The two bidirectional reflectance geometries (45/0 and 0/45) have also been used for making regular transmittance measurements.

48.6.3 Monochromatic and Polychromatic Illumination

Instruments for measuring transmittance may have either monochromatic or polychromatic illumination. The transmittance of nonfluorescent samples can be measured using either type of illumination, but fluorescent samples can only be measured using polychromatic illumination.

48.6.4 Standardizing Instruments for Transmittance Measurements

Three techniques exist for setting the high end of the measurement scale, a transmittance factor of 1.0. Each technique produces different results, so it is important to document the method used.

Setting the instrument to read a transmittance factor of 1.0 with no sample in the sample compartment is the easiest technique. The transmittance measurements will then be relative to air. This technique is often used when solid samples are being measured.

Transmittance measurements of solid materials may also be made relative to a clear blank of similar material. To make these measurements, the clear blank is placed in the sample compartment before the instrument is standardized.

When liquids are to be measured, a holder containing solvent or nonabsorbing liquid of the same refractive index as the liquid to be measured should be placed in the sample compartment before standardizing the instrument. This eliminates any effects of the holder's transmittance.

48.6.5 Sample Preparation

Ideal samples will be flat with parallel sides. Liquid sample holders should be made from optical glass. Because transmittance will change with sample thickness and the concentration of colorant, it is important that sample holders and blanks used for standardization have the same path length or thickness as the sample. When two different samples must be compared, they should be prepared using the same technique and have the same thickness.

It is extremely difficult to measure the transmittance of curved materials because the curvature of the object may act as a lens and deflect the incident light away from the receiver. If the curvature is not too great, it may be possible to make a diffuse transmittance measurement.

48.7 Color Difference Calculations

A number of equations have been developed over the years for calculating the color difference between two objects [1,10,24,30,34–36]. One of the most common equations is the CIELAB recommended by the CIE in 1976 [1]. In CIELAB, L^* represents the difference between light (where $L^* = 100$) and dark (where $L^* = 0$). A^* represents the difference between green ($-a^*$) and red ($+a^*$), and b^* represents the difference between yellow ($+b^*$) and blue ($-b^*$).

First, the CIELAB coordinates, L^* (lightness), a^*, b^*, C^*_{ab} (chroma), and h_{ab} (hue angle), are calculated with Equations 48.11 through 48.15:

$$L^* = 116 f\left(\frac{Y}{Y_n}\right) - 16 \tag{48.11}$$

$$a^* = 500\left[f\left(\frac{X}{X_n}\right) - f\left(\frac{Y}{Y_n}\right)\right] \tag{48.12}$$

$$b^* = 200\left[f\left(\frac{Y}{Y_n}\right) - f\left(\frac{Z}{Z_n}\right)\right] \tag{48.13}$$

$$C^*_{ab} = [a^{*2} + b^{*2}]^{1/2} \tag{48.14}$$

$$h_{ab} = \arctan\left[\frac{b^*}{a^*}\right] \tag{48.15}$$

in which X, Y, and Z are tristimulus values and the subscript n refers to the tristimulus values of the perfect diffuser for the given illuminant and standard observer; $f(X/X_n) = (X/X_n)^{1/3}$ for values of (X/X_n) greater than 0.008856 and $f(X/X_n) = 7.787(X/X_n) + 16/116$ for values of (X/X_n) equal to or less than 0.008856 and the same with Y and Z replacing X in turn. The hue angle is 0° along the $+a^*$ axis, 90° along the $+b^*$ axis, 180° along the $-a^*$ axis, and 270° along the $-b^*$ axis.

The total color difference, ΔE^*_{ab}, and its components—the lightness difference, ΔL^*; the chroma difference, ΔC^*_{ab}; and the hue difference, ΔH^*_{ab}—are calculated using Equations 48.16 through 48.21:

$$\Delta L^* = L^*_{trial} - L^*_{standard} \tag{48.16}$$

$$\Delta a^* = a^*_{trial} - a^*_{standard} \tag{48.17}$$

$$\Delta b^* = b^*_{trial} - b^*_{standard} \tag{48.18}$$

$$\Delta E^*_{ab} = [(\Delta L^*)^2 + (\Delta a^*)^2 + (\Delta b^*)^2]^{1/2} \tag{48.19}$$

$$\Delta C^*_{ab} = C^*_{ab\ trail} - C^*_{ab\ standard} \tag{48.20}$$

$$\Delta H^*_{ab} = [(\Delta E^*_{ab})^2 - (\Delta L^*)^2 - (\Delta C^*_{ab})^2]^{1/2} \tag{48.21}$$

A negative value of ΔL^* means the trial is darker than the standard, and a negative value of ΔC^*_{ab} means the trial has a lower chroma than the standard. When the hue angle h_{ab} of the trial is greater than that of the standard, the sign of ΔH^*_{ab} is positive, and vice versa. The total color difference and its components can then be used in setting color tolerances [19,37].

Researchers have been making modifications to the CIELAB color difference equation in an attempt to have the color difference more closely correlate with visually observed color differences. The CMC(*l*:*c*) color difference equation [38–40] has gained great acceptance in the textile industry and is being tested in other areas. Starting with the CIELAB color differences, the CMC(*l*:c) color differences are calculated with Equations 48.22 through 48.28:

$$\Delta E = \left[\left(\frac{\Delta L^*}{l S_L} \right)^2 + \left(\frac{\Delta C^*_{ab}}{c S_C} \right)^2 + \left(\frac{\Delta H^*_{ab}}{S_H} \right)^2 \right]^{1/2} \tag{48.22}$$

$$S_L = \frac{0.040975 L^*}{1 + 0.01765 L^*} \tag{48.23}$$

unless $L^* < 16$, in which case $S_L = 0.511$,

$$S_C = \frac{0.0638 C^*_{ab}}{1 + 0.0131 C^*_{ab}} + 0.638 \tag{48.24}$$

$$S_H = (FT + 1 - F) S_C \tag{48.25}$$

$$F = \left(\frac{(C^*_{ab})^4}{(C^*_{ab})^4 + 1900} \right)^{1/2} \tag{48.26}$$

$$T = 0.36 + \text{abs}[0.4 \cos(35 + h_{ab})] \tag{48.27}$$

unless h is between 164° and 345° when

$$T = 0.56 + \text{abs}[0.2\cos(168 + h_{ab})] \tag{48.28}$$

in which the notation "abs" indicates the absolute (i.e., positive) value of the term inside the square brackets. When $l = c = 1$, the formula quantifies the perceptibility of color differences. Optimum values of l and c for quantifying the acceptability of a color match must be determined for the material being measured. The textile industry has found the optimum values to be $l = 2$ and $c = 1$ [39].

In 1994, the CIE recommended a new color difference equation, CIE94 [36], which is similar to the CMC equation. CIE94 color differences are calculated using Equations 48.29 through 48.33. The perceived color difference, ΔV, is related to the measured color difference through an overall sensitivity factor, k_E:

$$\Delta V = \left(\frac{1}{k_E}\right)\Delta E^*_{94} \tag{48.29}$$

$$\Delta E^*_{94} = \left[\left(\frac{\Delta L^*}{k_L S_L}\right)^2 + \left(\frac{\Delta C^*_{ab}}{k_C S_C}\right)^2 + \left(\frac{\Delta H^*_{ab}}{k_H S_H}\right)^2\right]^{1/2} \tag{48.30}$$

$$S_L = 1 \tag{48.31}$$

$$S_C = 1 + 0.045 C^*_{ab} \tag{48.32}$$

$$S_H = 1 + 0.015 C^*_{ab} \tag{48.33}$$

The overall sensitivity factor, k_E, is used to account for variation in the illuminating and viewing conditions. A person in the textile industry who is using CMC(2:1) and would like to compare the results with CIE94 would set $k_L = 2$ and $k_C = k_H = 1$, that is, CIE94(2:1:1).

The improvement in correlating with visual assessments of color difference could result in either the CMC(*l*:*c*) or the CIE94 replacing the CIELAB color difference equation. Hunter and Harold [30] detail many of the older color difference equations, many of which are still in use. A history of the development of color metrics was written by Richter [41].

48.8 Special Cases

48.8.1 Fluorescent Samples

Fluorescent materials not only reflect light but also emit light. Light absorbed at some wavelengths is emitted at longer wavelengths. The amount of light emitted depends on the intensity and the spectral power distribution of the source. Because of the emission of light, spectrophotometers that illuminate a fluorescent material with monochromatic light cannot be used, because the light emitted at the longer wavelengths will be measured as if it had been reflected from the material. Reflectance measurements of the material illuminated by polychromatic light will include the emitted light at the proper wavelengths. If the instrument's light source is a good representation of the illuminant, the measurement will be indicative of the observed color. Techniques have been recommended by the CIE for assessing the quality of daylight simulators [42]. Measured reflectance factors at the wavelengths of emittance may be greater than 1.0. Special fluorescent calibration standards must be used to accurately measure these materials [43]. The 45/0 or 0/45 bidirectional geometries are recommended for measuring fluorescent materials [44,45].

The complete analysis of a fluorescent material requires that the emittance be separated from the reflectance. Spectrofluorimeters were designed to analyze fluorescent samples. These instruments illuminate the sample with monochromatic light. Reflected and emitted rays pass through a second monochromator to isolate the receiver wavelengths. By viewing the sample at the same wavelength as it is illuminated, the true reflectance of the sample can be determined. Either the excitance spectra or the emittance spectra can be studied by setting each monochromator at different wavelengths. Techniques have also been developed to correct spectrophotometric measurements of fluorescent samples [45,46].

48.8.2 Metallic and Pearlescent Samples

Materials that contain metallic and/or pearlescent pigments are goniochromatic, that is, they change color with the illuminating and viewing geometry. Goniospectrophotometers are needed to measure these materials. A goniospectrophotometer illuminates (or views) the sample at a fixed angle, usually 45°, and views (or illuminates) the sample at three or more angles. The position of the receivers (or illuminators) is described by the specular angle, the viewing angle measured from the direction of the specular reflectance, which is equal and opposite the angle of illumination. In a goniospectrophotometer that illuminates the sample at 45° and views at three angles, one of the viewing angles would be near the specular reflection at about 25°, the second at the CIE recommended bidirectional angle of 0°, and the third would be far away from the specular reflectance at about 70°.

Goniospectrophotometry is still in its infancy and the CIE recommendations and ASTM standards for making these measurements are still under development.

48.8.3 Retroreflecting Samples

Highway signs and high-visibility clothing are examples of retroreflectors. Light shining on a retroreflector is returned in directions very close to the illumination angle. Most retroreflectance measurements are made in connection with highway safety. There are only a few specially built instruments for measuring retroreflection. A projector is usually used to illuminate the sample, and a teleradiometer or a radiometric telecolorimeter is used to view the sample. Tristimulus values can be calculated from the retroreflectance factors. Standard practices and test methods exist for specifying the illuminating and viewing geometries and making retroreflectance measurements [47–51].

48.8.4 Lamps, Light Sources, and Displays

Spectral radiometers and radiometric colorimeters were designed to measure lamps, light sources, and displays. These instruments are similar to spectrophotometers and colorimeters but do not need an illuminator, because the sample being measured emits light.

Lamps and light sources can either be measured directly or by measuring the reflectance of a stable white reflecting surface being illuminated by the lamp or light source. To measure televisions, computer monitors, and other similar devices, the emitted light must usually be imaged directly on the optics of the spectral radiometer or radiometric colorimeter [52,53].

48.8.5 Hazy and Translucent Materials

Hazy and translucent materials are measured by placing them in contact with an integrating sphere and measuring their diffuse transmittance. A haze index can be calculated from four diffuse transmittance measurements on a reflecting spectrophotometer [54]. Two of the measurements are made with a white material in the reflectance sample port, and two measurements are made with a light trap in the port. Special instruments called *hazemeters* were designed to make haze measurements.

48.9 Instrument Manufacturers

Costs of color-measuring instruments vary significantly. The more accurate instruments with the best repeatability and reproducibility can be expected to cost more. Table 48.1 lists the price ranges for various types of color-measuring instruments. There is a classification in the table called spectral analyzers. Although these instruments may provide information that makes them appear to be colorimeters or spectrophotometers, they use measurement techniques not traditionally associated with those instruments. For example, several use LEDs instead of more traditional light sources. Since the instruments vary so widely in capability, the purchaser must ensure that a particular instrument has the capability to make the measurements desired with sufficient accuracy, repeatability, and reproducibility.

Table 48.2 provides contact information for a number of manufacturers of color-measuring instruments. The manufacturers listed in this table design instruments specifically for color measurement. Thus, manufacturers of analytical spectrophotometers are excluded even if their instruments have color-measuring capabilities. The table is also limited to manufacturers with a major presence in the United States.

Defining Terms

For a more extensive collection of terms relating to color and appearance, the reader should refer to ASTM E 284 Standard Terminology of Appearance [55].

Chroma: Attribute of color used to indicate the degree of departure of the color from a gray of the same lightness.

CIE: The abbreviation for the French title of the International Commission on Illumination, Commission Internationale de l'Éclairage.

CIE standard observers: The ideal colorimetric observer data adopted by the CIE to represent the response of the average human eye, when light-adapted, to an equal-energy spectrum. The standard observer adopted in 1931 was developed from data obtained with a 2° field of vision and is commonly called the "2° standard observer." The standard observer adopted in 1964 was developed from data obtained with a 10° annular field of vision and is commonly called the "10° standard observer."

CIE tristimulus values: Amounts of the three mathematical lights necessary in a three-color additive mixture required for matching a color in the CIE System. They are designated *X*, *Y*, and *Z*. The illuminant and standard observer color-matching functions must be designated.

Colorimetry: The science of color measurement.

Hue: The attribute of color perception by means of which a color is judged to be red, orange, yellow, green, blue, purple, or intermediate between adjacent pairs of these, considered in a close ring (red and purple being an adjacent pair.) White, black, and grays possess no hue.

Illuminant: A mathematical description of the relative power emitted by a real or imaginary light source at each wavelength in its emission spectrum.

Lightness: (1) The attribute of color perception by which a nonself-luminous body is judged to reflect more or less light. (2) The attribute by which a perceived color is judged to be equivalent to one of a series of grays ranging from black to white.

Metamerism: Property of two specimens that match under a specified illuminator and to a specified observer and whose spectral reflectances or transmittances differ in the visible wavelengths.

Perfect reflecting diffuser: Ideal reflecting surface that neither absorbs nor transmits light, but reflects diffusely, with the radiance of the reflecting surface being the same for all reflecting angles, regardless of the angular distribution of the incident light.

Reflectance: Ratio of the reflected radiant or luminous flux to the incident flux in the given conditions. The term reflectance is often used in a general sense or as an abbreviation for reflectance factor. Such usage may be assumed unless the previous definition is specifically required by the context.

Reflectance factor: Ratio of the flux reflected from the specimen to the flux reflected from the perfect reflecting diffuser under the same geometric and spectral conditions of measurement.

Polarization Measurement

Soe-Mie F. Nee
U.S. Naval Air Warfare Center

49.1 Basic Concepts of Polarization

Polarization of light is a property of electromagnetic (EM) waves, which include heat, microwaves, radio waves, and x-rays. An EM wave has orthogonal electric and magnetic fields associated with it that vibrate in directions perpendicular to the direction of propagation. The *electric field* of a sinusoidal EM wave, in particular, can always be decomposed into two orthogonal components; each component has an *amplitude* and a *phase*. The amplitude is the maximum value of the field component, and the light *intensity* is proportional to the square of the amplitude. The phase, referred to a fixed position or time, tells what part of the cycle the electric field is vibrating in. G. G. Stokes pointed out in 1852 that these two orthogonal components do not interfere in amplitude but are additive according to vector algebra [1]. When the two orthogonal components are in phase, the EM wave is *linearly polarized*. When the two orthogonal components have the same amplitude and a relative phase of 90°, the EM wave is *circularly polarized*. In general, an EM wave has arbitrary amplitudes and phases for the two orthogonal fields and is elliptically polarized. The concept of polarization ellipse and the descriptions for the polarization of an EM wave in terms of Jones vectors and Stokes vectors are given in the subsection "Polarization of an EM Wave" and also in Refs. [1–9].

Light is composed of an ensemble of EM waves. A group of EM waves traveling in the same direction can have some linearly polarized waves, some circularly polarized waves, and some elliptically polarized waves. When they are combined, resulting light can be unpolarized, partially linearly polarized, or partially elliptically polarized. Unpolarized light occurs when there are no fixed directions of the electric field and also no fixed phase relations between the two orthogonal field components. In general, light is

partially polarized and can be decomposed into unpolarized light and elliptically polarized light. These concepts are described in terms of Stokes vector in the subsection "Polarization of Light" and also in Refs. [1–6].

Polarized light can be produced by passing light through a polarizer. An ideal polarizer transmits only light whose electric field is parallel to the transmission axis of the polarizer and rejects light with the orthogonal field. Polarization of light can be observed by stacking two polarizers together and turning one with respect to the other. The transmitted light intensity through these two polarizers will vary, and at some particular positions, it will vanish. In this case, light is linearly polarized after passing through the first polarizer. When the second polarizer is turned until its axis is perpendicular to the axis of the first polarizer, light cannot pass through the second polarizer. The transmitted intensity varies according to the square of the cosine of the angle between the two polarizers [5,9–12]. Real polarizers are not perfect and transmit light with minimum intensity $I_{\min}$ when the polarizer axis is perpendicular to the polarization of purely linearly polarized incident light. This is caused by the small depolarization of a polarizer [12]. Depolarization is a mechanism that turns polarized light into unpolarized light and is the opposite effect of polarization. The maximum transmitted intensity $I_{\max}$ occurs when the polarizer axis is parallel to the incident polarization direction. The extinction ratio of a polarizer is defined as $I_{\min}/I_{\max}$. Other relations for polarizers can be found in Refs. [9–12].

Besides the polarizer, another basic element in polarization measurements is the phase retarder or wave plate. A phase retarder changes the relative phase between the two orthogonal fields of an EM wave [4–11]. The change of relative phase between the two orthogonal components is called the *phase retardation* or *retardance*. The retardance of a quarter-wave retarder is 90°, and that of a half-wave retarder is 180°. Circularly polarized light can be generated by passing linearly polarized light through a quarter-wave plate whose axis is at 45° with respect to the incident linear polarization direction. A half-wave plate may change the polarization direction of linearly polarized light. In general, a phase retarder changes linearly polarized light into elliptically polarized light. Representations of the optical response of polarizers, retarders, and other materials in terms of the Müeller matrix and Jones matrix are given in the subsection "Polarization by the Response of a Medium" and also in Refs. [4–8,12–24].

Polarization is generated by the anisotropic response of materials and/or anisotropic geometry of systems. The mechanisms for producing polarization include preferential absorption in a dichroic material, reflection and transmission at oblique incidence, double refraction in a birefringent material, diffraction by grating or wires, and scattering by particles [2–11,13]. These properties can be utilized to make polarizers and phase retarders. For example, a wire-grid polarizer is made of parallel fine conducting wires. When light is incident on a wire-grid polarizer with the grid period smaller than the wavelength, the electric field parallel to the wires is shorted and absorbed so that only the electric field perpendicular to the wires passes through the polarizer. In a dichroic polarizer, anisotropic molecules are aligned in a preferential direction so that absorption is very different for the two orthogonal directions referred to the alignment direction. The nonpreferential field is absorbed by the molecules in the medium, while the preferential field passes through the medium [5,8]. In a prism polarizer, the two orthogonal fields are separated by double refraction in a birefringent crystal, and the unwanted polarization is deflected away by the special geometry of a prism. A material is birefringent when it has different refractive indices for different field directions. When a light beam passes through a birefringent slab, phase retardation is generated. Birefringent slabs can be used to make phase retarders or wave plates. Different kinds of polarizers and retarders are described in detail in Refs. [5,9–11].

When special arrangements of polarizers and phase retarders are combined with a light source and a detector, polarized light can be generated and analyzed. Such an optical system is called a *polarimeter* or an *ellipsometer*. The subsection "Principles of Polarimetry" discusses the generation and analysis of polarized light and the operational principles for polarizer–sample–analyzer (PSA) ellipsometry and polarizer–compensator–sample–analyzer (PCSA) ellipsometry using the intensity approach associated with Stokes vectors and Müeller matrices [4,17–23,25,26]. A phase retarder is also called a *compensator* because it was introduced into a polarimeter to compensate the phase change by a sample. The

intensity approach was chosen because intensity, but not electric field, is measured in most experiments and also because the electric field approach cannot treat depolarization. However, the electric field approach is convenient to use for highly polarized light when depolarization does not cause appreciable errors in the measurement. Discussion of ellipsometry using the electric field approach can be found in Refs. [4,15,16,27–33].

Polarization effects are widely applied in modern optical technologies. The electro-optic modulator and shutter are based on tunable birefringence by applying a high voltage across a birefringent crystal to modulate the phase of transmitted light and hence to achieve intensity modulation [4,7,9,34,35]. Liquid crystal displays use similar principles [36]. Birefringence can also be modulated by the photoelastic effect [37,38]. The magneto-optical readout for laser disks utilizes the magneto-optical Kerr effect that generates phase retardation upon reflection from magnetic materials [34,39]. Other applications of polarization are fiber optics, nonlinear optics, material characterization, medical optics, and many other fields. All of these applications utilize the anisotropic nature of materials or the anisotropic geometry of systems. This chapter is concerned with the application of polarization on material characterization. In this application, a polarimeter or ellipsometer is used to measure optical properties and surface properties of materials and thin films [40–48]. In the subsection "Polarization Instrumentation and Experiments," different components of polarimeters are discussed using an example of an automated reflection null ellipsometer (NE), and two sample experiments are described to measure birefringence of a birefringent slab and the optical constants of a material.

49.2 Polarization of an Electromagnetic Wave

The electric field $E(z, t)$ of a monochromatic EM wave propagating along the z-direction with a frequency ω and an angular wave number k can be decomposed into two orthogonal components E_x and E_y and represented by

$$\begin{aligned} E(z,t) &= \hat{x}E_x(z,t) + \hat{y}E_y(z,t) \\ E_x(z,t) &= a_x e^{i(\omega t - kz + \delta_x)} \\ E_y(z,t) &= a_y e^{i(\omega t - kz + \delta_y)} \end{aligned} \tag{49.1}$$

where a_x and δ_x are the amplitude and phase, respectively, for E_x, and a_y and δ_y are for E_y [1–4]. k is related to wavelength λ by $k = 2\pi/\lambda$. In vacuum, $k = \omega/c$. Let $\delta = \delta_y - \delta_x$ be the relative phase between E_y and E_x. Then Equation 49.1 can be simplified to

$$\mathbf{E}(z,t) = (\hat{x}a_x + \hat{y}a_y e^{i\delta}) e^{i(\omega t - kz + \delta_x)} \tag{49.2}$$

49.2.1 Polarization Ellipse

It is often convenient to express **E** in terms of a complex variable. The observed field is actually the real part of **E**. The projection of Re[**E**(z, t)] with $\delta_x = 0$ onto the xy-plane at $z = 0$ is given by

$$\mathbf{E}(0,t) = \hat{x}a_x \cos\omega t + \hat{y}a_y \cos(\omega t + \delta) \tag{49.3}$$

The loci of **E**$(0, t)$ with $a_x = 3$, $a_y = 2$, and different values of δ are shown in Figure 49.1. For $\delta = 0$, the locus of **E** is a line with a slope of a_y/a_x. The EM wave is linearly polarized when E_x and E_y are in phase with each other. In other cases, the loci are ellipses, which are called *polarization ellipses*, and the EM wave is elliptically polarized. The instantaneous electric field can be visualized by drawing an arrow from the origin to a point on an ellipse. The electric field direction rotates in the clockwise direction for $0 < \delta < 180°$, while in the counter clockwise direction for $-180 < \delta < 0°$. When $\delta = \pm 90°$, the axes of the ellipse correspond

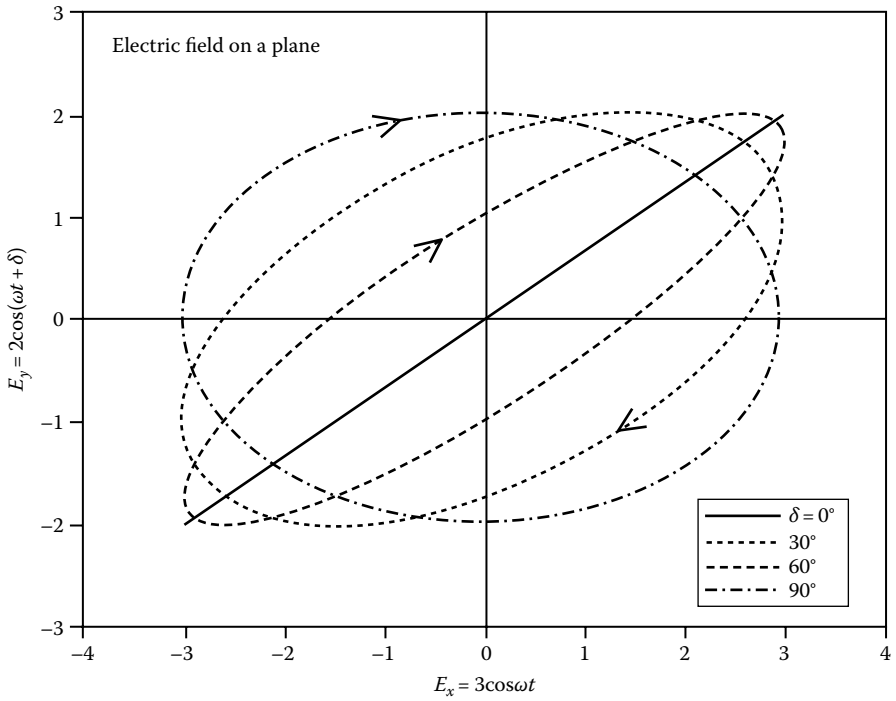

FIGURE 49.1 Projection of the electric field of an EM wave with amplitudes $a_x = 3$, $a_y = 2$ and different values of phase retardation δ onto the $z = 0$ plane. Most of these loci are ellipses and reduce to lines or circles in special cases. The electric field changes in the clockwise direction for δ between 0 and 180°.

to the x and y coordinate axes. If $a_x = a_y$, this ellipse then becomes a circle, and the EM wave is circularly polarized. The convention in ellipsometry defines the right-handed circularly polarized wave as the one whose field rotates in the clockwise direction with $\delta = 90°$ [4,5]. A left-handed circularly polarized wave thus corresponds to $\delta = -90°$ for a counterclockwise-rotating electric field.

In Figure 49.1, a polarization ellipse is specified by a set of three parameters: a_x, a_y, and δ. The ellipse can also be specified by the other set of three parameters: the major axis a, the minor axis b, and the orientation angle ϕ of the major axis measured from the x-axis. Figure 49.2 shows the geometry of an ellipse with these parameters. Parameters a and b can also be expressed in terms of the ellipticity e and ellipticity angle ε, defined by $e = b/a = \tan\varepsilon$. For linear polarization, $\delta = 0$, $b = 0 = e = \varepsilon$, and $\tan\phi = a_y/a_x$. For $\phi = 0$, the major and minor axes of the ellipse always correspond to the coordinate axes. For circular polarization, $a = b = a_x = a_y$ and $\delta = \pm 90°$. Right-handed circularly polarized light has a positive ellipticity with $e = 1$ and $\varepsilon = 45°$, and left-handed circularly polarized light has a negative ellipticity with $e = -1$ and $\varepsilon = -45°$. In general, ϕ represents the orientation of the ellipse and ε indicates the shape of the ellipse and the direction of field rotation. Refs. [2–7] give more details about this subject.

49.2.2 Jones Vector and Stokes Vector

The electric field expressed in vector form in Equation 49.1 can also be expressed as a column matrix. A polarization ellipse depends on a_x, a_y, δ_x, and δ_y, but not on k and ω. By neglecting the common factor of $e^{i(\omega t - kz)}$ in both E_x and E_y, the Jones vector is defined as [4,7,8]

$$\mathbf{E} = \begin{pmatrix} E_x \\ E_y \end{pmatrix} = \begin{pmatrix} a_x e^{i\delta_x} \\ a_y e^{i\delta_y} \end{pmatrix} \tag{49.4}$$

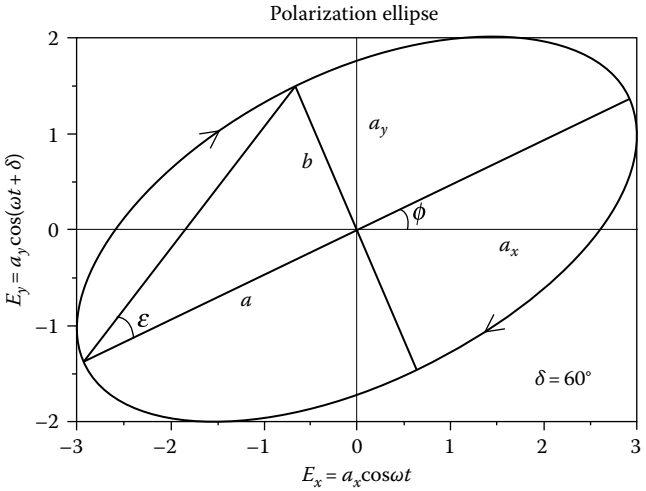

FIGURE 49.2 Characteristic parameters for a polarization ellipse. a_x and a_y are the field amplitudes in the x- and y-directions, and δ is the phase retardance; a and b are the major and minor axes of the ellipse, ϕ is the orientation of the major axis with respect to the x-axis, and ε is the ellipticity angle that is equal to $\tan^{-1}(b/a)$. A polarization ellipse can be characterized by (a_x, a_y, δ), (a, b, ϕ) or (I, ϕ, ε), where I is the intensity of the EM wave.

Both elements of a Jones vector are complex numbers. Jones algebra is convenient for describing perfectly polarized light. Since a light sensor measures only intensity but not electric field in most cases, the Stokes vector is more convenient to use in metrology. The Stokes parameters are four intensity-based parameters used to describe the polarization state of light, represented by S_0, S_1, S_2, S_3 or by I, Q, U, V [1–6,14]. The Stokes vector is the set of these Stokes parameters, defined as [4,14]

$$\mathbf{S} = \begin{pmatrix} S_0 \\ S_1 \\ S_2 \\ S_3 \end{pmatrix} = \begin{pmatrix} \langle E_x E_x^* \rangle + \langle E_y E_y^* \rangle \\ \langle E_x E_x^* \rangle - \langle E_y E_y^* \rangle \\ \langle E_x E_y^* \rangle + \langle E_y E_x^* \rangle \\ i\langle E_x E_y^* \rangle + i\langle E_y E_x^* \rangle \end{pmatrix} \tag{49.5}$$

For an EM wave, the average bracket in Equation 49.5 represents the time average. $\langle E_x E_x^* \rangle = I_x$ is the intensity of the component of light linearly polarized in the x-direction. Similarly, $\langle E_y E_y^* \rangle = I_y$. All of the Stokes parameters are real numbers and are measurable. For an ensemble of EM waves, the average brackets represent both time and ensemble averages.

49.2.3 Perfectly Polarized Light

Stokes vectors for different polarization states of light can be evaluated using Equation 49.5. Table 49.1 lists the Jones vectors and Stokes vectors for different states of perfectly polarized light. The Jones vector **E** and Stokes vector **S** expressed in terms of ellipticity angle ε and orientation angle ϕ are

$$\mathbf{E} = a \begin{pmatrix} \cos\varepsilon\cos\phi - i\sin\varepsilon\sin\phi \\ \cos\varepsilon\sin\phi + i\sin\varepsilon\cos\phi \end{pmatrix} \tag{49.6}$$

TABLE 49.1 Jones Vectors and Stokes Vectors for Different Polarization States for Perfectly Polarized Light

Polarization	Linear	Linear	Linear	Circular	Elliptical
Direction	0°	90°	±45°	Right/left	
Phase	0°	0°	0°	±90°	δ
Jones vector	$\begin{pmatrix}1\\0\end{pmatrix}$	$\begin{pmatrix}0\\1\end{pmatrix}$	$\frac{1}{\sqrt{2}}\begin{pmatrix}1\\\pm1\end{pmatrix}$	$\frac{1}{\sqrt{2}}\begin{pmatrix}1\\\pm\mathrm{i}\end{pmatrix}$	$\begin{pmatrix}a_x\\a_y e^{i\delta}\end{pmatrix}$
Stokes vector	$\begin{pmatrix}1\\1\\0\\0\end{pmatrix}$	$\begin{pmatrix}1\\-1\\0\\0\end{pmatrix}$	$\begin{pmatrix}1\\0\\\pm1\\0\end{pmatrix}$	$\begin{pmatrix}1\\0\\0\\\pm1\end{pmatrix}$	$\begin{pmatrix}a_x^2+a_y^2\\a_x^2-a_y^2\\2a_xa_y\cos\delta\\2a_xa_y\sin\delta\end{pmatrix}$

$$\mathbf{S} = I\begin{pmatrix}1\\\cos 2\varepsilon\cos 2\phi\\\cos 2\varepsilon\sin 2\phi\\\sin 2\varepsilon\end{pmatrix} \tag{49.7}$$

In Equations 49.6 and 49.7, the amplitude a and intensity I are totally separated from the angles ϕ and ε that determine the polarization state. The degrees of linear and circular polarization are $\cos 2\varepsilon$ and $\sin 2\varepsilon$, correspondingly. Stokes parameters for perfectly polarized light given in Equation 49.7 satisfy the identity

$$S_0^2 = S_1^2 + S_2^2 + S_3^2 \tag{49.8}$$

49.3 Polarization of Light

Light is composed of an ensemble of EM waves. A single EM wave has a certain electric field direction and phase. Unpolarized light can be visualized as an ensemble of EM waves with random field directions and phases. The field direction and phase for unpolarized light cannot be defined then. The description of light in terms of Jones vector is therefore inadequate to describe the polarization of unpolarized light. For an ensemble of many EM waves, the electric field components in the Stokes vector given by Equation 49.5 is the sum of the corresponding components for all waves. In particular, for an ensemble of incoherent EM waves, the Stokes vectors for individual waves are additive:

$$\mathbf{S} = \sum_{i=1}^{N} \mathbf{S_i} \tag{49.9}$$

For an ensemble of EM waves with identical $\phi_i = \phi$ and $\varepsilon_i = \varepsilon$, the resultant polarization is still the same as the individual wave, as indicated by Equations 49.6 and 49.7, regardless of whether these waves are coherent.

49.3.1 Unpolarized and Partially Polarized Light

If an ensemble consists of randomly oriented linearly polarized waves, all $\varepsilon_i = 0$ and ϕ_i are random, then $S_1 = S_2 = S_3 = 0$, according to Equations 49.7 and 49.9. Light is thus unpolarized, and $S = I(1, 0, 0, 0)$. If an ensemble consists of elliptically polarized waves with the same orientation $\phi_i = \phi$ or $\phi + \pi$ and perfectly

random ellipticity angle ε_i, then the Stokes vector is $I(1, 0, 0, 0)$, and light is also unpolarized. Thus, the Stokes vector **S** in Equation 49.9 already implies the sense of the ensemble average of polarization. The average brackets in Equation 49.5 can be considered as both the time average and ensemble average for incoherent waves.

For unpolarized light with $S_1 = S_2 = S_3 = 0$, Equation 49.8 does not hold. In general, light is partially polarized, that is, part of it is perfectly polarized and the rest is unpolarized [1–6]. Stokes parameters for arbitrary polarizations satisfy

$$S_0^2 \geq S_1^2 + S_2^2 + S_3^2 \tag{49.10}$$

The degree of polarization is given by

$$\mathcal{P} = \frac{\sqrt{S_1^2 + S_2^2 + S_3^2}}{S_0} \tag{49.11}$$

Perfectly polarized light has $\Pi = 1$, and unpolarized light has $\Pi = 0$. Partially polarized light has $0 < \Pi < 1$. The intensity of the polarized part is ΠI, and the intensity of the unpolarized part is $I(1 - \Pi)$. By the superposition concept, the Stokes vector for partially polarized light can be obtained from Equation 49.7 as

$$\mathbf{S} = I \begin{pmatrix} 1 \\ \mathcal{P}\cos 2\varepsilon \cos 2\phi \\ \mathcal{P}\cos 2\varepsilon \sin 2\phi \\ \mathcal{P}\sin 2\varepsilon \end{pmatrix} \tag{49.12}$$

The degree of linear polarization Π_L and circular polarization Π_C are

$$\begin{cases} \mathcal{P}_L = \mathcal{P}\cos 2\varepsilon = \dfrac{\sqrt{S_1^2 + S_2^2}}{S_0} \\ \mathcal{P}_C = \mathcal{P}\sin 2\varepsilon = \dfrac{S_3}{S_0} \end{cases} \tag{49.13}$$

49.3.2 Polarization by the Response of a Medium

49.3.2.1 Jones Matrix

To measure polarization, light must interact with a medium to give a response. The response of a polarizer is to pass one polarization and reject the orthogonal one. The response of a phase retarder is to change the relative phase between the two polarizations. A medium can be any optical component, a test sample, or any object under investigation. The response of a medium relates the state of output light to the state of incident light. The polarization state of light can be described by a complex vector EM field, a Jones vector, or a Stokes vector [4,5,7,8]. Let an incident EM wave be specified by a complex field or Jones vector (E_x, E_y) and the output field be (E_x', E_y'), the general relations between these two fields are

$$\mathbf{E}' = \begin{pmatrix} E_x' \\ E_y' \end{pmatrix} = \begin{pmatrix} r_{xx} & r_{xy} \\ r_{yx} & r_{yy} \end{pmatrix} \begin{pmatrix} E_x \\ E_y \end{pmatrix} = \mathbf{J}\mathbf{E} \tag{49.14}$$

J in Equation 49.14 is a 2 × 2 matrix that relates the input Jones vector **E** to the output Jones vector **E**′ and is called the Jones matrix. The response of a medium is characterized by the elements of the Jones matrix, r_{xx}, r_{xy}, r_{yx}, and r_{yy}, which are all complex numbers.

49.3.3 Principal Coordinate System

Since the directions of an electric field are different in different rotated coordinate systems, $\{r_{ij}\}$ are not unique. For many symmetric media, there exists a coordinate system in which r_{xy} and r_{yx} are zero and r_{xx} and r_{yy} are called the eigenvalues for $\{r_{ij}\}$. This is the principal coordinate system or principal frame whose x- and y-axes are the two principal axes. Finding the principal frame is an eigenvalue problem. If the incident polarization is along one of the principal axis $\hat{x}$, then the output polarization is still along $\hat{x}$. In the principal frame, $\{r_{ij}\}$ are called the coefficients of response. For example, $\{r_{ij}\}$ may represent the reflection coefficients for a reflection response or the scattering coefficients for a scattering response, etc. In the principal coordinate system, Equation 49.14 is simplified to

$$\mathbf{E}' = \begin{pmatrix} E_x' \\ \\ E_y' \end{pmatrix} = \begin{pmatrix} r_{xx} & 0 \\ 0 & r_{yy} \end{pmatrix} \begin{pmatrix} E_x \\ \\ E_y \end{pmatrix} = \mathbf{J}(0)\mathbf{E} \tag{49.15}$$

J(0) is the diagonalized Jones matrix in the principal frame. For a polarizer, the principal axes are the transmission and extinction axes. The former is assigned to the x-axis. For a phase retarder, the principal axes are the fast and slow axes. The phase change for the EM wave with its field along the fast axis is larger than the slow axis. The fast axis is usually assigned to the x-axis. The principal Jones matrices **P** for a perfect polarizer and **c** for a perfect wave plate with a retardance τ are [4,5,7,8]

$$\mathbf{p} = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} \quad \mathbf{c} = \begin{pmatrix} e^{i\tau/2} & 0 \\ 0 & e^{-i\tau/2} \end{pmatrix} \tag{49.16}$$

49.3.4 Ellipsometric Parameters

For reflection from a surface, the two principal axes are the s- and p-polarizations. The s-polarization field is along the y-axis, which is chosen to be perpendicular to the plane of incidence. The p-polarization field is along the x-axis, which is in the plane of incidence. The complex reflection coefficients for these two polarizations are designated as $r_p = r_{xx}$ and $r_s = r_{yy}$. The ellipsometric parameters ψ and Δ are defined by [4,15,16]

$$\frac{r_p}{r_s} = \frac{r_{xx}}{r_{yy}} = \tan\psi \exp(i\Delta) \tag{49.17}$$

Δ is the phase change between reflected and incident light. If the electric field direction of incident light is given by ϕ_0, then the field direction ϕ of reflected light can be obtained from $\tan\phi = \tan\phi_0 / \tan\psi$. At the Brewster angle, where $r_p = 0$ and $\psi = 0$, $\phi = 90°$, and reflected light is vertically polarized. Equation 49.17 can also be applied to transmissive systems. Since a vacuum does not change the polarization of light, the ellipsometric parameters are $\psi = 45°$ and $\Delta = 0°$. A perfect polarizer with the polarization along the x-axis has $\psi = 90°$ and $\Delta = 0°$, a perfect quarter-wave plate has $\psi = 45°$ and $\Delta = 90°$, and a perfect half-wave plate has $\psi = 45°$ and $\Delta = 180°$.

49.3.5 Müeller Matrix

The Jones calculus is convenient for perfectly polarized light and a nondepolarizing response [8]. If unpolarized light is incident on a sample, the Jones vector cannot describe the field direction and phase for unpolarized light. The Stokes vector and Müeller matrix are more convenient to use in treating polarization for general cases. A relation between the output Stokes vector $\mathbf{S}'$ and the input Stokes vector $\mathbf{S}$ is

$$\mathbf{S}' = \mathbf{MS} \tag{49.18}$$

The matrix $\mathbf{M}$ that relates the input and output Stokes vectors is called a Müeller matrix. $\mathbf{M}$ is a 4×4 matrix of real numbers.

For the general transformation of electric field given by Equation 49.14, the components M_{ij} of $\mathbf{M}$ can be derived from Equations 49.5, 49.14, and 49.18. The expressions for M_{ij} have been obtained by van de Hulst [13] and are also given as Equation 2.243) in Ref. [4]. In a measurement, the EM waves of output light may come from many different area or volume elements of a medium, so that statistical averages must be considered in the evaluation of M_{ij}. The ensemble average of $\mathbf{M}$ can still be expressed by the same expressions, with the ensemble average bracket applying to all M_{ij}. To make the Müeller matrix meaningful, the new subscripts of Equation 49.14 are reassigned as 1: *xx*, 2: *yy*, 3: *xy*, 4: *yx*. Subscripts 1 and 2 correspond to the copolarized response, and subscripts 3 and 4 correspond to the cross-polarized response. The ensemble average of any two of the response coefficients is called a *correlation function* for these coefficients. Let us define the self-correlation functions to be $2F_j$ and the cross-correlation functions to be $G_{jm} + i\,g_{jm}$ as follows:

$$\begin{cases} 2F_j \equiv \langle r_j r_j^* \rangle \\ G_{jm} + ig_{jm} \equiv \langle r_j r_m^* \rangle \end{cases} \quad j,m = 1, 2, 3, 4;\ j \neq m \tag{49.19}$$

The cross-correlation functions have the properties of $G_{jm} = G_{mj} = \text{Re}\ \langle r_j r_m^* \rangle$ and $g_{jm} = -g_{mj} = \text{Im}\ \langle r_j r_m^* \rangle$. All F_j, G_{jm}, and g_{jm} are real numbers. $\mathbf{M}$ is then

$$\mathbf{M} = \begin{pmatrix} F_1 + F_2 + F_3 + F_4 & F_1 - F_2 - F_3 + F_4 & G_{13} + G_{24} & g_{13} - g_{24} \\ F_1 - F_2 + F_3 - F_4 & F_1 + F_2 - F_3 - F_4 & G_{13} - G_{24} & g_{13} + g_{24} \\ G_{14} + G_{23} & G_{14} - G_{23} & G_{12} + G_{34} & g_{12} - g_{34} \\ -g_{14} + g_{23} & -g_{14} - g_{23} & -g_{12} - g_{34} & G_{12} - G_{34} \end{pmatrix} \tag{49.20}$$

The upper left quadrant of $\mathbf{M}$ corresponds to the self-correlation terms. The lower right quadrant corresponds to the cross-correlations between the two copolarized responses and between the two cross-polarized responses. The upper right and lower left quadrants correspond to the cross-correlations between the copolarized and cross-polarized responses.

49.3.6 Principal Müeller Matrix

For the Jones matrix in the principal frame given by Equation 49.15, the cross-polarized responses are zero, so that the M_{jm} in the upper right and lower left quadrants of Equation 49.20 are zero. $\mathbf{M}$ can be expressed in terms of ψ and Δ using Equations 49.17 and 49.20 as [4,17–19]

$$\mathbf{M} = R \begin{pmatrix} 1 & -\cos 2\psi & 0 & 0 \\ -\cos 2\psi & 1 & 0 & 0 \\ 0 & 0 & \sin 2\psi \cos\delta & \sin 2\psi \sin\Delta \\ 0 & 0 & -\sin 2\psi \sin\Delta & \sin 2\psi \cos\Delta \end{pmatrix} \tag{49.21}$$

where $R = (r_{xx}r_{xx}^{\star} + r_{yy}r_{yy}^{\star})/2$. For reflection, R is the average reflectance, and for transmission, R is the average transmittance. For a vacuum, $\psi = 45°$ and $\Delta = 0°$, **M** is a unit matrix. Using Equation 49.21 or Equations 49.16, 49.19, and 49.20 directly, matrix **P** for a perfect polarizer ($\psi = 90°$, $\Delta = 0°$) and matrix **C** for a perfect wave plate ($\psi = 45°$, $\Delta = \tau$) in the principal frame are obtained as [4,5,20]

$$\mathbf{P} = \frac{1}{2}\begin{pmatrix} 1 & 1 & 0 & 0 \\ 1 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix} \quad \mathbf{C} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & \cos\tau & \sin\tau \\ 0 & 0 & -\sin\tau & \cos\tau \end{pmatrix} \tag{49.22}$$

49.3.7 Depolarization

A very interesting example is the perfectly random response. Analogous to the conditions used for incoherent scattering [17–19], the random response coefficients δr_j have the properties that

$$\begin{cases} \langle \delta r_j \rangle = 0 \\ \langle \delta r_j \delta r_m^{\star} \rangle = \langle |\, \delta r_j \,|^2 \rangle \delta_{j,m} \quad j,m = 1,2,3,4 \\ \langle |\, \delta r_j \,|^2 \rangle = \text{constant} \end{cases} \tag{49.23}$$

The first line states that all δr_j are each averaged to zero, so that they would not appear in the average of Equation 49.14. By substitution of r_j of Equation 49.19 by δr_j and using the conditions for δr_j given by Equation 49.23, the correlation functions F_j and $G_{jm} + i\,g_{jm}$ can be evaluated. The second line of Equation 49.23 states that all δr_j are uncorrelated with one another, so that all G_{ij} and g_{ij} are zero. The third line states that δr_j are isotropic, so that all F_j are the same. Eventually, all $M_{jm} = 0$ except $M_{00} = 4\,F_1$. The depolarization matrix **D** for a perfectly random response is then

$$\mathbf{D} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix} \tag{49.24}$$

D is an ideal depolarizer as defined in Ref. [20]. The general Müeller matrix of Equation 49.20 satisfies the physical condition [14,24]:

$$\sum_{ij=0}^{3} M_{ij}^2 \le 4M_{00}^2 \tag{49.25}$$

The sum of all the squares of the elements of **D** is M_{00}^2. **D** satisfies the inequality of criterion in Equation 49.25. The matrix of Equation 49.21 is nondepolarizing such that output light is still perfectly polarized if incident light is perfectly polarized. The equality in Equation 49.25 holds for **M** of Equation 49.21. This section discusses optical components and samples that are nondepolarizing. Refs. [12,17–19] give more details about the Müeller matrices for samples that exhibit both polarization and depolarization properties.

49.3.8 Coordinate Transformation

In polarimetric measurements, polarizers and retarders are frequently rotated to desired positions. When a component is rotated, the incident field is not changed, but the representations of this field in the principal and laboratory coordinate systems are different. Transformations of the electric fields, Stokes vectors, Jones and Müeller matrices between these two coordinate systems or frames are basic exercises in polarimetry. Let the laboratory frame axes be x- and y-axes and the principal frame axes be x'- and y'-axes and the principal frame is rotated to an angle α with respect to the laboratory frame, as shown in Figure 49.3. The Jones vector (E'_x, E'_y) in the principal frame is related to (E_x, E_y) in the laboratory frame by

$$\mathbf{E}' = \begin{pmatrix} E'_x \\ E'_y \end{pmatrix} = \begin{pmatrix} \cos\alpha & \sin\alpha \\ -\sin\alpha & \cos\alpha \end{pmatrix} \begin{pmatrix} E_x \\ E_y \end{pmatrix} = r(\alpha)\mathbf{E} \tag{49.26}$$

The rotation matrix $\mathbf{r}(\alpha)$ is the 2×2 matrix in Equation 49.26 for transformation of Jones vectors. The inverse transform is given by $\mathbf{E} = \mathbf{r}^T(\alpha)\,\mathbf{E} = \mathbf{r}^T(\alpha)\mathbf{E}'$ where the superscript **T** denotes the transpose of a matrix. In Figure 49.3, $\mathbf{E}'$ appears to be turned by an angle of $-\alpha$, since the coordinate system is rotated by an angle α. The Faraday rotation matrix that rotates **E** by an angle of α is equivalent to $\mathbf{r}(\alpha)$.

One can substitute $r_1 = r_2 = \cos\alpha$ and $r_3 = -r_4 = \sin\alpha$ into Equations 49.19 and 49.20 to construct the rotation matrix $\mathbf{R}(\alpha)$ for transformation of a Stokes vector **S** to a coordinate system oriented at an angle α:

$$\mathbf{R}(\alpha) = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & \cos 2\alpha & \sin 2\alpha & 0 \\ 0 & -\sin 2\alpha & \cos 2\alpha & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} \tag{49.27}$$

The transformations between Stokes vector $\mathbf{S}'$ in the principal frame and **S** in the laboratory frame are

$$\begin{cases} \mathbf{S}' = \mathbf{R}\ \mathbf{S} \\ \mathbf{S} = \mathbf{R}^T\ \mathbf{S}' \end{cases} \tag{49.28}$$

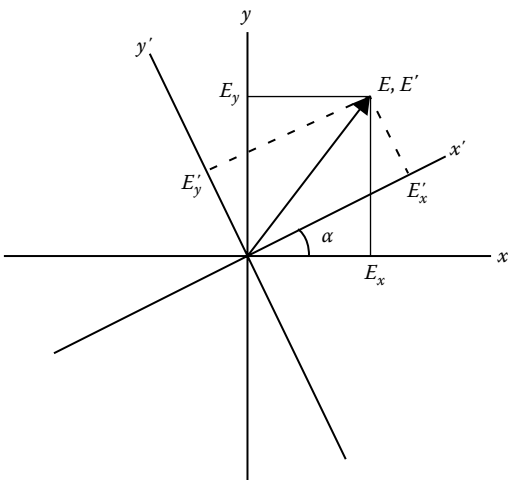

FIGURE 49.3 Coordinate transformation for the electric field components (E_x, E_y) in the laboratory system (x, y) and the components (E'_x, E'_y) in the principal coordinate system (x', y'). The principal frame is oriented at an angle a with respect to the laboratory frame.

The transformation of a Müeller matrix **M**(0) in the principal frame to **M**(α) in the laboratory frame can be obtained by a similarity transformation:

$$\mathbf{M}(\alpha) = \mathbf{R}^T(\alpha)\mathbf{M}(0)\mathbf{R}(\alpha) \tag{49.29}$$

Equation 49.29 can also be used for the transformation of Jones matrix **J**(0) in the principal coordinate frame to **J**(α) in the laboratory frame, provided that **M** is replaced by **J** and **R**(α) by **r**(α) in Equation 49.29.

The Jones matrix for a polarimetric component orientated at an angle α is

$$\mathbf{J}(\alpha) = \begin{pmatrix} r_{xx}\cos^2\alpha + r_{yy}\sin^2\alpha & \sin\alpha\cos\alpha(r_{xx} - r_{yy}) \\ \sin\alpha\cos\alpha(r_{xx} - r_{yy}) & r_{xx}\sin^2\alpha + r_{yy}\cos^2\alpha \end{pmatrix} \tag{49.30}$$

TABLE 49.2 Jones Matrices and Müeller Matrices for Perfect Polarizer and Wave Plates at Different Orientation Angles

Device	Angle	Jones Matrix	Müeller Matrix
Polarizer	0°	$\begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}$	$\frac{1}{2}\begin{pmatrix} 1 & 1 & 0 & 0 \\ 1 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}$
Polarizer	90°	$\begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix}$	$\frac{1}{2}\begin{pmatrix} 1 & -1 & 0 & 0 \\ -1 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}$
Polarizer	±45°	$\frac{1}{2}\begin{pmatrix} 1 & \pm 1 \\ \pm 1 & 1 \end{pmatrix}$	$\frac{1}{2}\begin{pmatrix} 1 & 0 & \pm 1 & 0 \\ 0 & 0 & 0 & 0 \\ \pm 1 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}$
$\lambda/4$ plate	0°	$\begin{pmatrix} e^{i\pi/4} & 0 \\ 0 & e^{-i\pi/4} \end{pmatrix}$	$\begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & -1 & 0 \end{pmatrix}$
$\lambda/4$ plate	±45°	$\frac{1}{\sqrt{2}}\begin{pmatrix} 1 & \pm i \\ \pm i & 1 \end{pmatrix}$	$\begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & \pm(-1) \\ 0 & 0 & 1 & 0 \\ 0 & \pm 1 & 0 & 0 \end{pmatrix}$
$\lambda/2$ plate	0°	$\begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}$	$\begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & -1 \end{pmatrix}$
$\lambda/2$ plate	±45°	$\begin{pmatrix} 0 & \pm 1 \\ \pm 1 & 0 \end{pmatrix}$	$\begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & -1 \end{pmatrix}$

The Müeller matrix $\mathbf{P}(P)$ for a perfect polarizer oriented at an angle P and $C(C)$ for a perfect compensator with a retardance τ at an angle C are [4,6,21]

$$\mathbf{P}(P) = \frac{1}{2}\begin{pmatrix} 1 & \cos 2P & \sin 2P & 0 \\ \cos 2P & \cos^2 2P & \sin 2P \cos 2P & 0 \\ \sin 2P & \sin 2P \cos 2P & \sin^2 2P & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix} \tag{49.31}$$

$$\mathbf{C}(C) = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & \cos^2 2C + \sin^2 2C \cos\tau & \sin 2C \cos 2C(1-\cos\tau) & -\sin 2C \sin\tau \\ 0 & \sin 2C \cos 2C(1-\cos\tau) & \sin^2 2C + \cos^2 2C \cos\tau & \cos 2C \sin\tau \\ 0 & \sin 2C \sin\tau & -\cos 2C \sin\tau & \cos\tau \end{pmatrix} \tag{49.32}$$

Equations 49.16, 49.22, and 49.30 through 49.32 can be used to calculate the Jones matrices and Müeller matrices for polarizers and wave plates at arbitrary orientations. Table 49.2 lists some of these matrices for the most frequently used devices.

For a light beam passing through successive components oriented at different angles, Müeller matrices or Jones matrices in the laboratory frame must be used for successive multiplications. According to Equation 49.18, the matrix $\mathbf{M}_1(\alpha_1)$ for the component that light first passes through should be placed at the extreme right, and the matrix $\mathbf{M}_n(\alpha_n)$ for the last component at the extreme left. The combined matrix $\mathbf{M}$ is

$$\mathbf{M} = \mathbf{M}_n(\alpha_n)\ldots\mathbf{M}_1(\alpha_1) \tag{49.33}$$

49.4 Principles of Polarimetry

Polarimetry is a method for measuring the polarization of light and the polarization response of materials. An optical system used for such purposes is called a polarimeter or an ellipsometer. To measure the polarization response of a sample, polarized light is generated and incident on the sample. By examining the polarization states of both incident and reflected or transmitted light, the characteristics of a sample can be determined. A schematic diagram of a polarimeter used to measure the polarization response of a sample is shown in Figure 49.4. The light source and polarizer are used to generate polarized light, and the analyzer and detector are used to analyze the polarization of light [4,20]. An analyzer is a polarizer used to analyze polarized light.

49.4.1 Analysis of Polarized Light

Measurement of polarization of light is essential in polarimetry, since polarized light to be examined is not limited to that generated in a laboratory. The instrument to measure the four Stokes parameters is called a photopolarimeter or a Stokesmeter. To measure linear polarization, pass the light beam through a linear analyzer oriented at angle A = 0°, 90°, and ±45° and measure the corresponding intensities I_x,

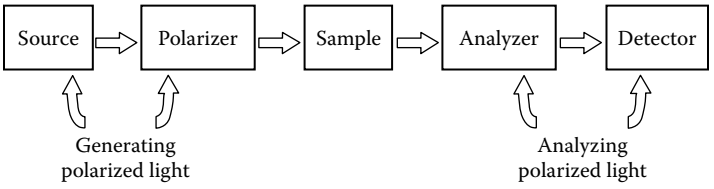

FIGURE 49.4 Schematic diagram of a polarimeter to measure polarization response. The light source and polarizer are used to generate polarized light, and the analyzer and detector are used to analyze the state of polarization of the light.

TABLE 49.3 Intensities I for a Light Beam with Stokes Parameters S_0, S_1, S_2, and S_3 Analyzed by Linear and Circular Analyzers

Analyzer	Linear	Linear	Circular
C (°)	NA	NA	0
A (°)	0, 90	45, −45	45, −45
Operation	0.5(1, ±1, 0, 0)	0.5(1, 0, ±1, 0)	0.5(1, 0, 0, ±1)
Intensity	I_x, I_y	I_+, I_-	I_R, I_L
I =	$(S_0 \pm S_1)/2$	$(S_0 \pm S_2)/2$	$(S_0 \pm S_3)/2$

A circular analyzer consists of a quarter-wave plate oriented at $C = 0°$, followed by an analyzer oriented at $A = \pm 45°$.

I_y, I_+, and I_-. To measure circular polarization, first pass the light beam through a quarter-wave retarder with $C = 0°$ then through an analyzer oriented at $A = \pm 45°$ and measure the intensities I_R and I_L. The pair of quarter-wave retarder and analyzer constitutes a circular analyzer. A detector measuring intensity corresponds to an operation given by a row vector $\mathbf{I} = (1, 0, 0, 0)$. The combined operation of a detector following an analyzer is $\mathbf{IA} = 0.5\,(1, \cos 2A, \sin 2A, 0)$. The operations for the linear and circular analyzers on a Stokes vector S and the intensities obtained are given in Table 49.3. The Stokes parameters can be obtained from the difference and sum of the intensities for these pair operations and are given by

$$\mathbf{S} = \begin{pmatrix} S_0 \\ S_1 \\ S_2 \\ S_3 \end{pmatrix} = \begin{pmatrix} I_x + I_y \\ I_x - I_y \\ I_+ - I_- \\ I_R - I_L \end{pmatrix} \tag{49.34}$$

Equation 49.34 is a general expression that is good for any polarization states and is also the operational principle for most Stokesmeters. The four-detector Stokesmeter designed by Azzam is an exception that contains no moving components and can measure the four Stokes parameters in real time [26].

49.4.2 Generation of Polarized Light

Characterization of polarization response of a sample requires incident polarized light whose polarization state is controllable. A convenient source is a laser, which may be constructed to emit polarized light directly without the help of extra devices. A half-wave plate may be used to rotate the laser polarization to a desired direction by placing the fast axis bisecting the new and old directions, as shown in Figure 49.5a. Light generated from a lamp and a monochromator is usually partially polarized [12]. To generate linearly polarized light at an angle P, a linear polarizer oriented at an angle P is placed behind the monochromator as shown in Figure 49.5b. To generate circularly polarized light, first generate linearly polarized light and then put a quarter-wave plate behind with the fast axis oriented at an angle of 45° or −45° with respect to the linear polarization as shown in Figure 49.5c. Such a combination of polarizer and quarter-wave plate is called a circular polarizer. When a phase retarder has an arbitrary retardance or is placed at an arbitrary angle relative to the polarizer, elliptically polarized light is then generated. Given an incident Stokes vector of (S_0, S_1, S_2, S_3), the Stokes vector $\mathbf{S}'$ for polarized light generated by the polarizers mentioned earlier can be obtained from Equations 49.18 and 49.31 through 49.33. The obtained $\mathbf{S}'$ are listed in Table 49.4. Note that $\mathbf{S}'$ is not directly proportional to S_0 unless incident light is unpolarized. Care must be taken in generating polarized light in an ellipsometer because incident light is rarely completely unpolarized.

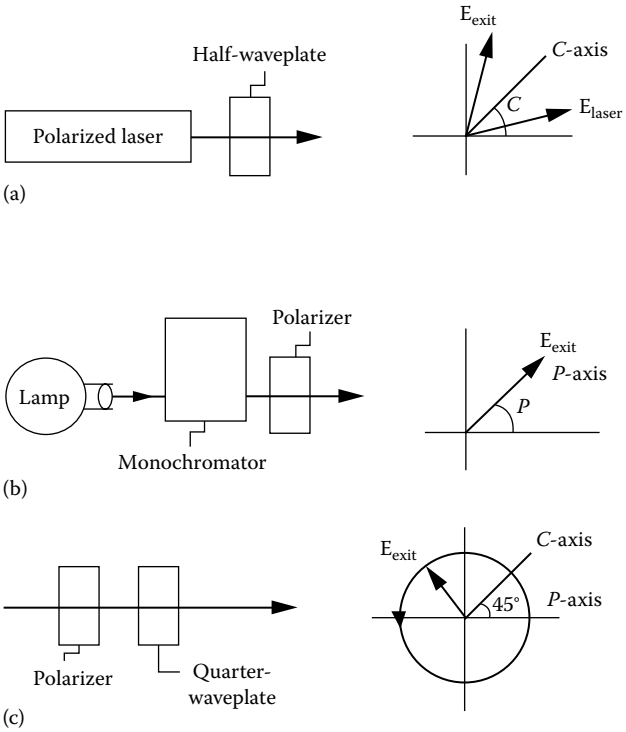

FIGURE 49.5 Generation of light linearly polarized at a desired direction using (a) a laser source and a half-wave plate and (b) a lamp, monochromator, and a polarizer, plus (c) generation of circularly polarized light using a polarizer and a quarter-wave plate.

TABLE 49.4 Stokes Vectors S' for Linearly and Circularly Polarized Light Generated by Specific Combinations of a Polarizer Oriented at an Angle *P* and a Quarter-Wave Retarder at an Angle *C*

Polarizer	Linear	Linear	Circular
P(°)	0, 90	45, −45	−45, 45
C(°)	NA	NA	0
Operation	**P**(P)**S**	**P**(P)**S**	**Q**(*C*) **P**(P) **S**
Stokes vector	$\mathbf{S}'_x, \mathbf{S}'_y$	$\mathbf{S}'_+, \mathbf{S}'_-$	$\mathbf{S}'_R, \mathbf{S}'_L$
S'	$\frac{S_0 \pm S_1}{2}\begin{pmatrix}1\\ \pm 1\\ 0\\ 0\end{pmatrix}$	$\frac{S_0 \pm S_2}{2}\begin{pmatrix}1\\ 0\\ \pm 1\\ 0\end{pmatrix}$	$\frac{S_0 \pm S_3}{2}\begin{pmatrix}1\\ 0\\ 0\\ \pm 1\end{pmatrix}$

The incident stokes vector is $S = (S_0, S_1, S_2, S_3)$.

49.4.3 Polarizer–Sample–Analyzer Ellipsometry

An ellipsometer is an instrument to measure the ellipsometric parameters ψ and Δ of a sample. It can be used for both reflection and transmission. An ellipsometer is usually referred to as the reflection system, and a polarimeter as the transmissive system [4]. Different ellipsometers are designed to measure different responses for different kinds of samples. It is important to know about the sample when

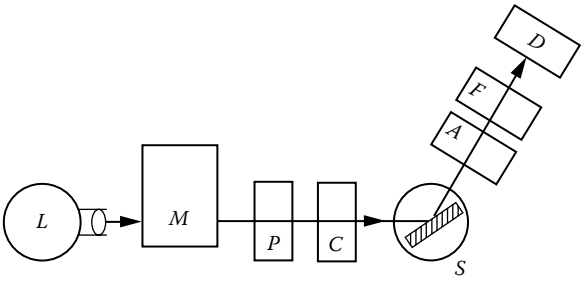

FIGURE 49.6 Schematic diagram of a PCSA ellipsometer.

designing an experiment. The simplest ellipsometer is a PSA ellipsometer. A more general one is a PCSA ellipsometer. Figure 49.6 shows a schematic diagram of a PCSA reflection ellipsometer. A PSA system can be visualized by removing the compensator *C* in Figure 49.6.

Let the oriented angles of the polarizer and analyzer be *P* and *A*, respectively, as measured from the plane of incidence. For unpolarized incident light and a sample matrix **M** given by Equation 49.21, the measured intensity *I* for a PSA ellipsometer is [22]

$$\begin{aligned} I(P,A) &= \mathbf{IA}(A)\,\mathbf{M}(R,\psi,\Delta)\mathbf{P}(P)\mathbf{S} \\ &= T_p T_a R I_0[1-\cos 2\psi(\cos 2P+\cos 2A)]+\cos 2P\cos 2A+\sin 2\psi\cos\Delta\sin 2P\sin 2A \end{aligned} \tag{49.35}$$

where

I_0 is the intensity of incident light

T_p and T_a are the transmittance of the polarizer and analyzer, respectively

If incident light is partially polarized with a Stokes vector (S_0, S_1, S_2, S_3), then the right-hand side of Equation 49.35 should be multiplied by the factor $(S_0 + S_1, \cos 2P + S_2 \sin 2P)/S_0$. In such a case, the dependence on *P* is more complicated. A good practice is to keep *P* fixed and vary only *A*. Many different ways can be devised to extract ψ and Δ from Equation 49.35, such as the Stokes polarimeter, null polarimeter, and rotating-analyzer ellipsometer (RAE).

For a Stokes polarimeter, *P* is set at 45° or −45°, and *A* at 0°, 90°, and ±45°. The ellipsometric parameters ψ and Δ can be solved from the four equations evaluated at these *P* and *A* positions via the relations

$$\begin{cases} \cos 2\psi = \dfrac{I_y - I_x}{I_y + I_x} \\ \sin 2\psi\cos\Delta = \dfrac{I_+ - I_-}{I_+ + I_-} \end{cases} \tag{49.36}$$

For a null polarimeter, set $P = \pm 45°$ and vary *A* to find the null positions. This method is excellent for reflection from transparent materials with Δ equal to 0 or π. The value of ψ is related to the null position $A_\pm$ as [22]

$$\tan 2A_\pm = \mp\tan 2\psi\cos\Delta \quad \text{for } P = \pm 45° \tag{49.37}$$

Average of $A_\pm$ at $P = \pm 45°$ can eliminate errors from the misalignment of analyzer and polarizer.

In a RAE, the analyzer is rotated at an angular frequency ω_r. Set $P = 45°$ or −45°, and $A = \omega_r t$. The measured intensity is

$$I = T_p R T_a I_0[1-\cos 2\psi\cos 2\omega_r t+\sin 2\psi\cos\Delta\sin 2\omega_r t] \tag{49.38}$$

The Fourier coefficients, being equal to $-\cos 2\psi$ and $\sin 2\psi \cos\Delta$, can be recovered from the demodulated signals or from a fast Fourier transform (FFT) technique [28,29]. However, the measured Δ cannot be distinguished from $-\Delta$. This system can be fully automated for real-time operation. With a white light source and monochromator, an RAE can serve as a spectroscopic ellipsometer [15,16,28,29].

49.4.4 Polarizer–Compensator–Sample–Analyzer Ellipsometry

In a PCSA or a PSCA ellipsometer, a compensator of retardance τ is inserted in front of or following the sample. Figure 49.6 shows a schematic diagram of a PCSA ellipsometer. For unpolarized incident light in a PCSA system, the measured intensity for general conditions of P, C, and A is given by [21]

$$\begin{aligned} I(P,C,A) &= \mathbf{I}\,\mathbf{A}(A)\,\mathbf{M}(R,\psi,\Delta)\,\mathbf{C}(C)\,\mathbf{P}(P)\,\mathbf{S} \\ &= T_p T_c R T_a I_0 [Y_0 + Y_1 \cos 2A + Y_2 \sin 2A] \end{aligned} \tag{49.39}$$

where

$$\begin{cases} Y_0 = \{1 - \cos 2\psi [\cos 2C \cos 2(P-C) - \cos\tau \sin 2C \sin 2(P-C)]\} \\ Y_1 = \{-\cos 2\psi + [\cos 2C \cos 2(P-C) - \cos\tau \sin 2(P-C)]\} \\ Y_2 = \sin 2\psi \{\cos\Delta [\sin 2C \cos 2(P-C) + \cos\tau \cos 2C \sin 2(P-C)]\} - \sin\tau \sin\Delta \sin 2(P-C) \end{cases} \tag{49.40}$$

If incident light is partially polarized, then I_0 in Equation 49.39 should be replaced by (S_0 + S_1 cos2P + S_2 sin2P). For a PSCA system, interchange P and A in Equations 49.39 and 49.40. These formulas can be used to design different kinds of PCSA ellipsometers by choosing different conditions and different types of modulation. For certain special conditions, Equations 49.40 can be greatly simplified.

49.4.5 Null Ellipsometry

Consider a PCSA NE in which the compensator is a perfect quarter-wave retarder ($\tau = 90°$) that is set at $C_{\pm} = \pm 45°$. The measured intensity is

$$I(P,C_{\pm},A) = T_p T_c R T_a I_0 [1 - \cos 2\psi \cos 2A \pm \sin 2\psi \sin 2A \cos\Delta \pm (2P - 90°)] \tag{49.41}$$

An NE is an instrument to find the null positions in order to determine ψ and Δ. The four zones that will null the intensity in Equation 49.41 and the null positions are listed in Table 49.5. The null positions of

TABLE 49.5 Null Positions of Polarizer Angle P and Analyzer Angle A for the Four Different Zones at $C = \pm 45°$ in a Null Ellipsometer

Zone	C(°)	P	A
1	−45	−45° + Δ/2	ψ
2	45	−45° − Δ/2	ψ
3	−45	45° + Δ/2	$-\psi$
4	45	45° − Δ/2	$-\psi$

Average $\psi = (A_1 + A_2 - A_3 - A_4)/4$, $\Delta = (P_1 - P_2 + P_3 - P_4)/2$.

A give ψ directly, and the null positions of P give Δ directly. Although ψ and Δ can be determined from measurements in only one zone, systematic errors caused by imperfect components, misalignment, and partially polarized incident light can be nonnegligible. By taking the average of four zones, many of these linear systematic errors can be cancelled [4,21,30,31]. To look for the null positions manually is a slow process; automation of the nulling process can speed up the measurements. Different methods can be used to automate the NE: (1) Both polarizer and analyzer are controlled by servomotors with the feedback from the detector to find the null intensity, (2) the intensity is digitized and fed into a computer that is used to find the null positions, and (3) Faraday rotators are used to rotate and modulate the polarization directions of light incident on and reflected from the sample to get the slopes of intensity versus angle until the slopes are zero at the null positions [4,27]. The advantage of NE is its simplicity in obtaining ψ and Δ. Also, its accuracy is unbeatable by other kinds of ellipsometry.

49.4.6 Phase-Modulated Ellipsometry

A phase-modulated ellipsometer (PME) uses a phase retarder whose retardance is modulative. For a PME, a good choice of P, C, and A in Equations 49.39 and 49.40 is $P = 0°$, $C = 45°$, and $A = 45°$. The intensity is then

$$I(\tau) = T_p T_c R T_a I_0 [1 - \cos 2\psi \cos\tau + \sin 2\psi \sin\Delta \sin\tau] \tag{49.42}$$

The retardance τ is modulated, and the modulated intensity is detected. If τ is modulated according to $\tau = \tau_o \cos\Omega_t$, then $I(\tau)$ can be expanded in a Fourier series with the Fourier coefficients, depending on $\cos 2\psi$, $\sin 2\psi \cos\Delta$, and the Bessel functions of τ_o. These coefficients can be recovered from the demodulated signals, and the values of ψ and Δ can then be solved. τ can be modulated by electro-optic modulation using the Pockels effect or piezoelectric modulation using the photoelastic effect [32,33]. These modulations are fast, and demodulation using a lock-in amplifier is convenient. The advantage of a PME is that it contains no moving components and offers real-time measurement.

49.5 Polarization Instrumentation and Experiments

Figure 49.7 shows a schematic diagram of a PCSA reflection null ellipsometer. The instrument is composed of five systems: the source system, polarimetric system, sample system, detection system, and computer system for automatic control, data acquisition, and processing.

The simplest source is a polarized laser. The monochromatic source system in Figure 49.7 is usually used in visible, ultraviolet, and infrared spectrometers. Light from a lamp source L is focused by a lens system or a spherical mirror system onto the entrance slit of a grating monochromator M. Light leaving the exit slit of M is collimated by another lens system and a set of iris apertures. The longpass filter F in the detector arm is used with a grating monochromator to remove undesired short-wavelength radiation. Choices of monochromators include a grating monochromator, prism monochromator, or Fourier transform spectrometer. A spectrometer is a necessary component for a spectroscopic ellipsometer. Synchrotron radiation is also a continuum source and is used to replace the lamp in the vacuum ultraviolet region [25]. The synchrotron radiation beam is intense and polarized. Grazing incidence reflection optics is usually used to avoid absorption in the components.

The polarimetric system shown in Figure 49.7 is a PCSA ellipsometer. For a PSA ellipsometer, remove the compensator C. For a PCSCA system, add another compensator in the detector arm [20]. It is better to mount the polarizers and phase retarders on automatic rotators so that their orientations can be easily aligned and read. For simple experiments, manual rotators can also do the job. Refs. [10,11] give detailed descriptions and references for different kinds of polarizers and phase retarders. Many of the well-known optical companies sell polarizers and wave plates (retarders) for use in the visible, ultraviolet, and near-infrared spectral regions. *The Buyers Guide of Laser Focus World* [49] and the *Photonics Buyers' Guide* [50] list companies that manufacture and sell polarizers, phase retarders, and polarimeters. Tables 49.6 and 49.7 list some companies that make these products. Commonly

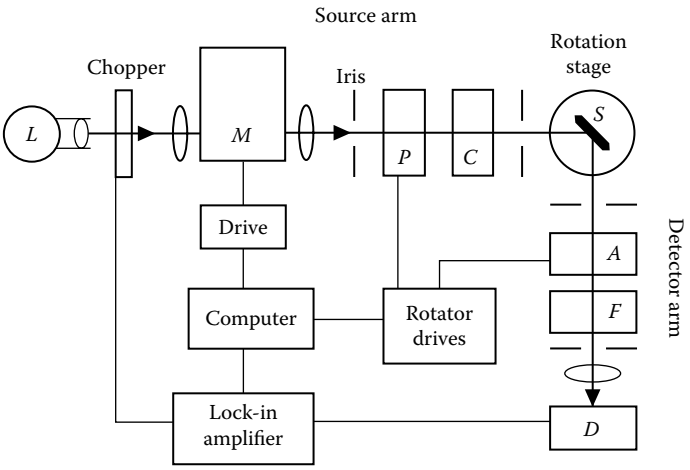

FIGURE 49.7 Schematic diagram of a PCSA reflection null ellipsometer, which is composed of five systems: the source system, polarimetric system, sample system, detection system, and computer system. The symbols are as follows: *L*, light source; *M*, monochromator; *F*, wavelength filter; *D*, detector. The symbols *P*, *C*, *S*, and *A* have their customary meanings.

used polarizers in the visible are Glan prisms and dichroic sheets or plates. The best polarizer in the visible is the calcite Glan–Thompson prism, which has a very small extinction ratio and a large acceptance angle. It is more difficult to find a good broadband polarizer in the midinfrared spectral region (λ: 3 to 5 μm). Wire-grid polarizers are good in the long-wave infrared region ($\lambda > 8$ μm). For a broadband phase retarder, a Babinet–Soleil compensator is convenient, since it can be set to any retardance value using a micrometer adjustment. Inexpensive wave plates are good for laser sources. Phase modulation can be achieved by modulation of the birefringence of electro-optic or photoelastic retarders.

The sample system depends on the type of experiment to be performed. Components on the detector side of Figure 49.7 are normally mounted on a rail that is rotatable about the axis of the rotation stage. The sample holder *S* on the rotation stage should have enough degrees of freedom for easy alignment. In a reflection ellipsometer, the *x*-axes for *P*, *C*, and *A* should be well aligned to lie in the plane of incidence. A transmission polarimeter is much simpler to align.

The detection system consists of a detector and a noise suppression system. Diode detectors for use in the visible and near-infrared spectral regions are inexpensive. Photomultipliers for the visible and near-infrared regions have high sensitivity, and cooled semiconductor detectors give good performance in the midinfrared to far-infrared regions. In Figure 49.7, the noise suppression system includes a chopper and a lock-in amplifier. The chopper modulates incident light intensity, and the intensity detected by detector *D* is demodulated by a lock-in amplifier. This combination eliminates most broadband noise and greatly improves the signal-to-noise ratio. RAE and PME have their own modulations and do not need a chopper.

A computer system provides the automatic functions to control the polarizers, retarder, and monochromator and to acquire and process data. A computer system is essential for making accurate and rapid measurements. In Figure 49.7, the computer records the polarizer angle *P*, the analyzer angle *A*, the intensity *I* from the detector, and the wavelength λ of the monochromator. The data of $I(P)$ and $I(A)$ can be used to find the null positions of *P* and *A*. Then the computer controls the drivers to move *P* or *A* to the null positions. In a spectroscopic RAE, data of $I(t)$ are recorded as the analyzer is rotating. The computer uses the FFT program to find the Fourier coefficients, solves for ψ and Δ, records the results, and then drives the monochromator to a new wavelength and repeats the process. A spectroscopic PME uses similar computer process as RAE, besides the different modulation and demodulation.

49.5.1 Measurement of Birefringence

Retardance can be measured using a transmission PSA ellipsometer. A wave plate is a good sample for this experiment. The retardance δ for a birefringent slab of thickness d and principal refractive indices n_e and n_o is

$$\delta = \frac{2\pi d(n_e - n_o)}{\lambda} \tag{49.43}$$

in the absence of multiple reflections. For a wave plate, the value of ψ is close to 45°, and the Δ value is equal to δ. Use a lamp source with a monochromator to scan the wavelength. Put a polarizer at 45° and an analyzer at −45° with respect to the fast axis of the wave plate [40]. When λ is scanned, the transmitted intensity I through the PSA ellipsometer will vary, in proportion to $(1 + \cos\delta)$ according to Equation 49.35. I is a maximum when δ is 0° and is a minimum when $\delta = 180°$. From the wavelengths at which a maximum or a minimum intensity occurs, the birefringence $n_e - n_o$ can be determined.

49.5.2 Measurement of Optical Constants

A reflection ellipsometer can be used to measure optical constants n and k of materials. Light is incident obliquely on a sample at an angle of θ. The refractive index n and the extinction coefficient k can be calculated from the measured ψ and Δ values using the following formula [2,4,16,22]:

$$(n + ik)^2 = \sin^2\theta\left\{1 + \tan^2\theta\left[\frac{1 - \tan\psi\exp(i\Delta)}{1 + \tan\psi\exp(i\Delta)}\right]^2\right\} \tag{49.44}$$

If an automated system is not available, try an NE to obtain ψ and Δ manually. Automated systems such as an RAE or a PME can take data much faster. For transparent materials, Δ is either 0 or π; the simple null polarimeter with a PSA system offers satisfactory results [22]. The method is effective near the Brewster angle region. At the Brewster angle θ_B, $\psi = 0$, $n = \tan\theta_B$ according to Equation 49.44. For metals whose ψ is large when $\Delta = -90°$, the principal angle ellipsometry (PAE) can be used [2]. At the principal angle θ_p, $\cos\Delta = 0$, Equation 49.44 can be simplified to

$$(n + \mathrm{i}k)^2 = \sin^2\theta_P[1 + \tan^2\theta_P(\cos 4\psi + i\sin 4\psi)] \tag{49.45}$$

In PAE, the principal angle θ_P is searched and then ψ is measured. The Stokes polarimeter with a PSA system is suitable to search θ_P and measure ψ for PAE.

Determination of optical constants using reflection ellipsometry is subject to errors caused by surface roughness, natural oxides, and surface contamination [15,16,41–48]. These effects can be corrected by assuming that there is an effective layer on the surface and then using a least-square regression method to fit the ellipsometric data to the appropriate model [16,43–48]. Ellipsometry is also used to measure refractive index and thickness of a thin film on a bulk substrate whose optical constants are known [4,15,16,27]. Other applications of polarimetry and ellipsometry can be found in recent proceedings about polarization [51–53].

Acknowledgments

The author would like to thank Dr. J. M. Bennett for her review of the original manuscript and her suggestions especially for the introduction. This work was supported partially by the "Polarizer Standard and Metrology Program" funded by the US Naval Warfare Assessment Division.

Refractive Index Measurement

Gerry H. Meeten
Schlumberger
Gould Research

50.1 Introduction

Light is electromagnetic radiation of wavelength about 450–700 nm, in which region the human eye is sensitive and refractive index measurements are commonly made. The refractive index or indices of a substance describe an important part of its interaction with electromagnetic radiation. Refractive index is a dimensionless quantity, real for transparent materials and complex if there is absorption. It generally depends on the direction of light relative to axes of the material; such substances, for example, many crystals, are anisotropic and possess more than one refractive index. In general, the index is a tensor (3×3 matrix) with up to nine components. Many substances are isotropic, for example, liquids, glasses, and other noncrystalline materials, and one refractive index is sufficient. Some substances are optically inhomogeneous and possess refractive index fluctuations over distances comparable in size with a wavelength. They scatter light and appear milky or turbid. Many foodstuffs and drinks are optically heterogeneous. Refractometry is, fortunately, a robust technique in the face of material complexities. It has widespread application to many industries and materials. This chapter treats the refractive index as the principal measurand; the complications of real materials may require extra attention. Excluded ones are those strongly absorbing materials such as metals in which absorption are more important than refraction. The appropriate measurement technique is then ellipsometry, in which the amplitude and phase of the reflected light are measured, as the polarization and the angle of incidence is varied. Some refractometric methods are essentially ellipsometric, but for transparent samples transmission methods are also important. Refractive index measurements of high precision, for example, 10^{-4}–10^{-5}, are possible with relatively simple techniques. Although ocular instruments remain popular, semiconductor technology has been applied to refractive index measurement in recent years, improving the measurement speed and precision. One of the limits to improvement in precision is the sample's absorption or heterogeneity, a factor considered herein. Several online instruments exist, and the application of refractive index measurements to complex industrial fluids has been recently described [1]. Fiber-optic methods do not yet possess the precision of conventional methods but offer the possibility of remote sensing.

Refractive index is measured for many reasons. It is clearly important to know the refractive index of materials used for their clarity, such as glasses and solid plastics. In complex fluids such as drinks or foods, the refractive index is a measure of dissolved or submicronic material. The Brix scale relates refractive index to sugar concentration. Common industrial applications are to microemulsions to measure their oil/water ratio, to antifreeze to check the glycol/water ratio, and to inaccessible liquids such as the electrolyte of rechargeable cells [2]. The clinical applications of light have stimulated interest in biotissue refractometry [3], and refractometry is useful for the analysis of small samples of biofluids.

50.2 Physical Principles

The electromagnetic nature of light and the atomic origin of refraction are described herein only in enough detail to be useful to refractometry; detailed descriptions of them are readily found in optics textbooks [4].

Monochromatic light can be described as an electromagnetic radiation of frequency ν (Hz) and free-space wavelength λ_0. In free space (vacuum), the phase velocity c_0 is given by $c_0 = \nu\lambda_0$. In a medium or material substance, the phase velocity changes to $c = \nu\lambda$, the refractive index n of that substance then being defined as $n = c_0/c$. As the frequency is unchanged by entering the medium, $n = \lambda_0/\lambda$. In an electromagnetic wave, the vibration directions of the electric and the magnetic fields are 90° apart, and both fields vibrate at 90° to the wave's direction of propagation. In transparent and nonmagnetic materials, refractive index is determined primarily by the interaction of the electric field of the wave with the permittivity e of the medium. This quantity is written as $\varepsilon = \varepsilon_r\varepsilon_0$, where ε_r is the relative permittivity of the medium and ε_0 is the permittivity of free space being $10^7/(4\pi c_0^2)$F m^{-1}, or about 8.854 pF m^{-1}. In the wave theory of light, ε_r is determined by the strength of elastic interaction between the wave's electric field and the bound charges (electrons and protons) in the atoms and molecules of the medium. For nonmagnetic transparent materials, $n = \sqrt{\varepsilon_r}$ can be shown if both quantities are measured at the same frequency, and this relation is also closely true if the absorption is weak. Absorption can be ascribed to the inelasticity of the interaction of the wave's electric field with the bound charges, some of the wave's energy being turned to heat during propagation.

The time (t) and distance dependence of the electric field £ of a wave propagating in the z direction can be written as

$$E = E_0 \exp i(\omega t - k_0 z) \tag{50.1}$$

where

$\omega = 2\pi\nu$ is the pulsatance or angular frequency
$k_0 = 2\pi/\lambda_0$ is the free-space wave number
$i = \sqrt{-1}$

The field E in Equation 50.1 is complex, and the physical field is understood to be the real part of the complex one, that is, $E = E_0\cos(\omega t - k_0 z)$. The wave amplitude E_0 is the maximum excursion of E, both quantities being coparallel and normal to the direction of propagation z. The optical power per unit area (radiance) conveyed by the wave is proportional to $|E|^2$, or also $|E_0|^2$. The phase velocity c is given by ω/k, which the aforementioned relations show to be c_0/n. Waves in absorbing media are attenuated as z increases. This is described by a complex refractive index in Equation 50.1, that is, writing $n = n' - in''$ so that the field oscillates in space and time as before but decays exponentially with propagation distance z as $(-k_0 n'' z)$. The cause of the index n'' may be absorption, scattering, or both. It will be clear from context whether n refers to the real part of the complex quantity or to the complex quantity itself. For the most part, this chapter deals with transparent or only slightly absorbing materials, where n'' is very small.

Equation 50.1 shows that n determines the phase of a wave, and this is the basis of the interferometric methods of refractometry, most used for either highly precise measurements on liquids or solids or for gases where the refractive index is close to 1. Other common refractometric methods rely on the reflection or transmission of light at the interface between the sample and a material of known refractive index. Reflection and refraction of light at optically smooth interfaces are treated (Fresnel relations) in optics textbooks. A description follows that it should be sufficient for the experimental refractometrist.

Simple laws apply to the incident, reflected, and transmitted beams at a planar interface between two transparent media. For brevity, we consider only isotropic media. A parallel–collimated incident light beam produces a parallel–collimated reflected and transmitted beam. All beams are coplanar and define a plane of incidence, which is orthogonal to the planar interface. The interface normal also lies in the plane of incidence. Figure 50.1 shows the incident, reflected, and transmitted beams in the plane of incidence. In the first medium, the angle of incidence and reflection made to the interface normal are equal, both θ_1. The angle of transmission θ_2 into the second medium is given by Snell's law:

$$n_1 \sin \theta_1 = n_2 \sin \theta_2 \tag{50.2}$$

where the subscripts refer to the first and second medium. If n_1 is known and the angles are measured, n_2 can be obtained. Equation 50.2 is the basis of deviation refractometry, $q \cdot v$.

If $n_1 > n_2$, Equation 50.2 shows that real angles of transmission do not exist for $\theta_1 > \arcsin(n_2/n_1)$; that is, θ_2 is imaginary. The incident and reflected beams are then of equal power, transmitted light is absent, and the reflection is said to be total. However, although in the second medium no wave propagates, there is an evanescent wave close to the interface, which is nonpropagating and therefore transmits no power. The critical angle is given by

$$\theta_c = \text{arc sin}\left(\frac{n_1}{n_2}\right) \tag{50.3}$$

(See Figure 50.2.) Reversing the light direction, Figure 50.3 shows that a beam traveling parallel to the interface in the least refractive index medium enters the second medium at a transmission angle also given by θ_c. A full analysis (Fresnel's equations) shows that in the region of the critical angle, the reflected or transmitted optical power changes very rapidly with angle of incidence. If there is no absorption, there is actually a discontinuity of reflected or transmitted radiance at θ_c. This makes θ_c easy to measure accurately and gives the critical angle or Abbe method of refractometry used by most commercial refractometers.

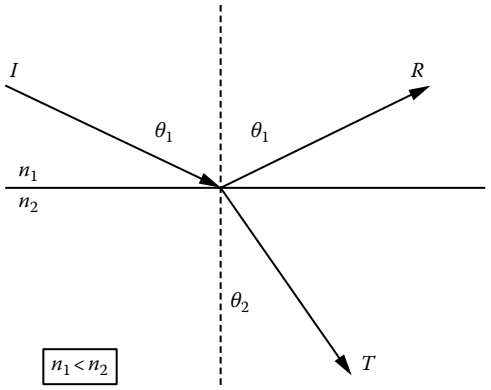

FIGURE 50.1 Light beams reflected (R) and transmitted or refracted (T) at the interface between two refractive indices, n_1 and n_2, the second being greater than the first.

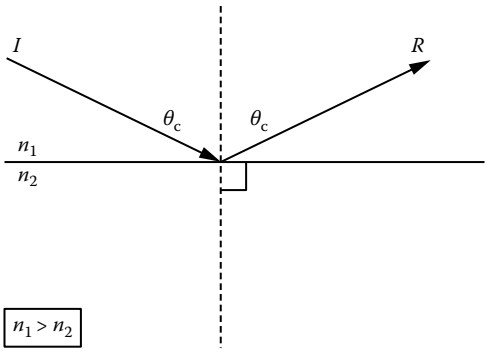

FIGURE 50.2 Total reflection at the critical angle of the incident beam (I) in the first medium of greater refractive index than the second. No light is transmitted into the second medium for angles exceeding the critical angle.

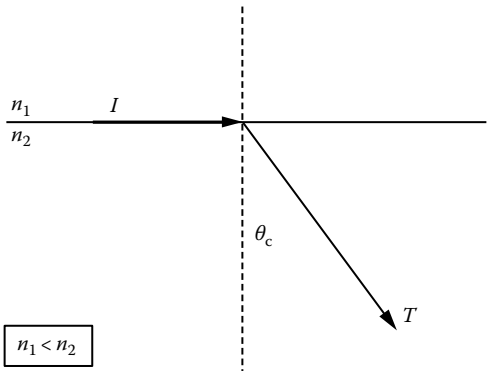

FIGURE 50.3 Total refraction of incident beam (I) transmitted as beam T into the medium of lesser refractive index at the critical angle. No light exists for angles in the second medium bigger than the critical angle.

The Fresnel laws of reflection at a plane interface between two media show that if the incident light is linearly polarized with its electric field in the plane of incidence, then there is no reflected light at the Brewster angle θ_B given by

$$\theta_B = \arctan\left(\frac{n_2}{n_1}\right) \tag{50.4}$$

(see Figure 50.4.) Measurements of θ_B usually in air (n_1 close to 1) will give n_2. The reflected optical power is zero at θ_B and it increases approximately quadratically for angles below and above θ_B. Consequently, the Brewster angle method is regarded to be of lower precision than the critical angle method and so is relatively less used. However, unlike the critical angle method, it does not require a reference medium of higher refractive index than the sample.

If the sample is a finely divided solid or has an irregular interface, none of the preceding methods is useful. Fresnel's equations show the reflectance of any shape of interface to be zero if the refractive index difference across the interface is also zero. In the method of refractive index match, the turbidity or scattering from a cloud of particles suspended in a liquid is measured, and the refractive index of the liquid is found, which gives minimum turbidity or scattering. The liquid should not swell or interact with the interior of the solid.

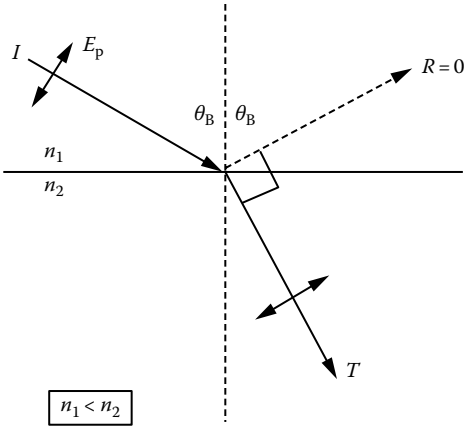

FIGURE 50.4 Light incident in the first medium at the Brewster angle, and polarized with its electric vector parallel to the plane of incidence, is transmitted (*T*) wholly into the second medium with zero reflection *R*.

50.3 Techniques

50.3.1 Interferometry

The sample, with parallel input and output faces, is put in the sample beam of a two-beam interferometer (e.g., Rayleigh, Michelson, or Jamin). From Equation 50.1, a sample of length z and refractive index n causes a phase lag of $2\pi nz/\lambda_0$, compared with $2\pi n_{air}z/\lambda_0$ for the reference beam in air. The phase difference between the two beams is thus

$$\delta = \frac{2\pi z(n - n_{air})}{\lambda_0} \tag{50.5}$$

The refractive index of air is 1 for approximate purposes or is known more precisely [5]. Sample insertion causes a step increment of δ in the phase difference, which is measured by adjusting a calibrated phase compensator in the reference beam to regain the zero-order fringe of white-light fringes. Equation 50.5 enables n to be calculated. For gaseous samples, use of the compensator may be avoided by allowing the gas to enter an initially evacuated tube with rigid and parallel window faces placed in the sample beam. As the gas enters slowly, the interference fringes passing a fiducial mark may be counted. Each whole fringe corresponds to a change in δ of π radian. The refractive index of a gas depends, through its density, on pressure and temperature. The number of fringes between a vacuum ($n = 1$) and the gas at a given pressure and temperature will then give the gas refractive index.

In interferometry, the effect of optical attenuation (via absorption or scattering) by a sample of complex refractive index decreases the fringe brightness but does not affect the phase. Thus, only the real part of the complex refractive index is measured.

About 0.1 of a fringe can be judged by eye; electro-optic methods can measure 10^{-6} of a fringe. The method's potential precision is very high. However, an interferometer is delicate and expensive, and good sample quality (homogeneity, face parallelism) is necessary. A difference in dispersion (wavelength dependence) of the sample and compensator refractive index can be a problem. For a sufficiently large number of fringes, the dispersion difference between the sample and compensator can make the white-light fringe pattern and zero-order fringe invisible [6]. One solution is to use a compensator more closely matched to the sample dispersion. A cheaper option is to reduce the sample length, with some loss of precision. A major use of the interference method is for gases, where $n - 1$ is about 1000 times less than $n - 1$ of solids and liquids. It is also used in solution differential refractometry, for example, to measure

the concentration in the eluted solvent relative to the pure solvent. A stable folded Jamin interferometer for refractive index measurements is described by Moosmüller and Arnott [7]. Liquid refractive index measurements using a Michelson interferometer are described by Richerzhagen [8].

50.3.2 Deviation Methods

Lateral and angular deviation methods make use of Snell's law (Equation 50.2). The incident beam is usually in air, of refractive index n_{air}.

Lateral deviation l occurs for a beam of light transmitted through a parallel-sided sample of thickness L (see Figure 50.5). If the incident angle is θ_{air}, Snell's law (Equation 50.2) gives

$$\frac{n}{n_{air}} = \left[1 + \left(\frac{\cos\theta_{air}}{\sin\theta_{air} - (l/L)}\right)^2\right]^{1/2} \sin\theta_{air} \tag{50.6}$$

If θ_{air} and L can be measured the most accurately, the precision of the method depends on the accuracy of measuring l. Modern electro-optic beam-displacement detection devices permit a precision of a few micrometers in l, giving a typical precision in n of about 0.001. The lateral deviation method is suitable for samples in sufficiently thick sheet form.

In the angular deviation method, parallel–collimated light is incident on one face of the sample of refractive index n in triangular prism form with vertex angle A, the vertex line of the prism being normal to the plane of incidence (see Figure 50.6). The exit beam deviates angularly from the direction of the incident beam. At the angle of minimum deviation D, the analysis is simplest, Equation 50.1, showing that

$$\frac{n}{n_{air}} = \frac{\sin((A+D)/2)}{\sin(A/2)} \tag{50.7}$$

For $A = 60°$, a 1 min (1′) uncertainty in D gives 0.0003 for the corresponding precision in n. Angular deviation requires the sample to be a less convenient shape than the parallel-sided sheet of the lateral deviation method. However, measurements of D and A can be made by simply using an ocular goniometer.

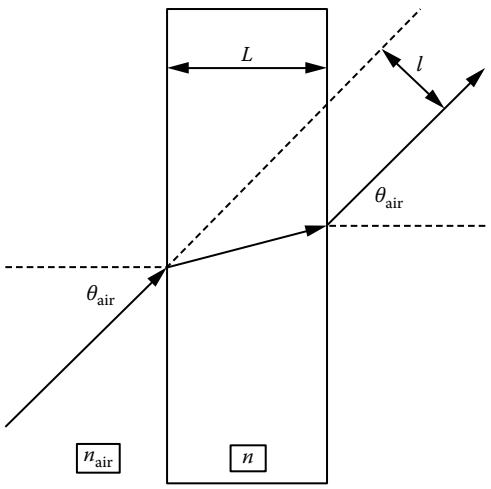

FIGURE 50.5 Lateral deviation l of a light beam on passage through a parallel-sided refractile sample slab of thickness L.

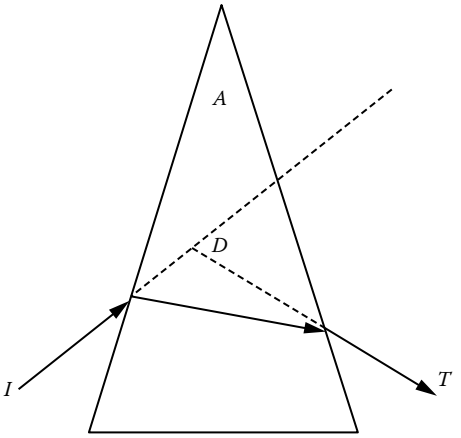

FIGURE 50.6 Angular deviation, D, of a light beam on passage through a prism of vertex angle A. If the interior beam forms an isosceles triangle with A at the vertex, then D is the angle of minimum deviation.

Lateral or angular deviation methods can be applied to liquid samples in a suitable cell with walls having parallel sides. Such cell walls will, however, give some lateral deviation but not cause angular deviation if used to make a hollow prism to contain a liquid sample. In the Hilger–Chance angular deviation refractometer [9], the liquid sample is contained in a glass 90° V-block of refractive index n_{glass}, with parallel outer faces. A parallel–collimated light beam incident normally on one outer face of the block suffers angular deviation D (not minimum), Equation 50.2, giving

$$n^2 = n_{glass}^2 + (n_{glass}^2 - \sin^2 D)^{1/2} \sin D \tag{50.8}$$

For a 1′ uncertainty in D, the precision in n is about 10^{-5}. Solid samples can be measured by coupling a prism of the sample into the V-block using a thin film of liquid of refractive index intermediate between that of the sample and the prism.

50.3.3 Critical Angle Method

In the region of the critical angle, Fresnel's equations show that the transmitted or reflected optical power varies discontinuously with angle. Thus, θ_c is accurately measurable and a refractive index precision of about 10^{-4}–10^{-5} is obtained. Liquid samples are placed directly onto one face of the refractometer prism of known refractive index. Solid samples need only one face to be flat and optically polished, which is coupled to face of the refractometer prism using a liquid film of intermediate refractive index. For a transparent sample, either the transmission or the reflection mode can be used, as θ_c is the same for both (see Figures 50.2 and 50.3). In the transmission mode, the sample–prism interface is illuminated diffusely through the sample, the critical angle then being the largest angle of transmission in the prism. In the reflection mode, useful for highly scattering or absorbing samples, the prism–sample interface is illuminated diffusely from within the prism. The critical angle is then where the reflectance changes discontinuously with angle of reflection within the prism, being total for $\theta \geq \theta_c$. In the transmission mode, the transmittance from the sample into the prism is zero for $\theta \geq \theta_c$ and finite for $\theta \leq \theta_c$, whereas in the reflection mode, typically a few percent of the light is reflected for $\theta \leq \theta_c$ and 100% is reflected for $\theta \geq \theta_c$. If the interface is illuminated with diffuse light, the transmission mode gives a dark–bright contrast at the critical angle, with a dim–bright contrast for the reflection mode. For ocular observation, this difference can make the transmission method preferable. Automatic instruments invariably use the reflection mode, this being necessary for samples that attenuate by absorption or scattering. For such samples, however, the discontinuity of reflectance is replaced by a continuous function with a maximum gradient

at an angle θ_{max} that differs increasingly from θ_c as the sample becomes more absorbing [10–12]. A separate measurement of the absorption index is required before θ_c can be obtained from θ_{max}. Attempts to improve the precision of critical angle refractometry of nontransparent samples are expected to become increasingly limited by this effect.

The critical angle method, however, is robust and simple to use. Despite the problems associated with optically attenuating samples, it is likely to persist as the preferred method in commercial refractometers.

50.3.4 Brewster Angle Method

Here, the angle of reflection θ_B is measured for which there is no linearly polarized light reflected from the sample surface. Equation 50.4 then gives the sample refractive index, where n_1 is the refractive index of the medium containing the incident and reflected light, usually air. The light is polarized such that its electric field vector vibrates parallel to the plane of incidence (see Figure 50.4). A linearly polarized laser is a suitable source of monochromatic light. Nonpolarized sources require polarizing with a Glan–Thomson prism or a quality dichroic polarizer. With a 1 mW HeNe laser and ocular judgment of the minimum reflectance, a precision in θ_B of about 0.1° can be obtained, giving a precision in the sample refractive index of about 0.005. Precision improvement by factors of 10–100 can be expected if photometric analysis replaces the eye. The Brewster angle method is then comparable in precision to the critical angle method. Unlike the critical angle method, however, it does not require a reference material of higher refractive index than the sample. If the sample is absorbing, the reflectance zero at θ_B is replaced by a reflectance minimum at an angle θ_{min}. It can be shown that a given absorption produces less error in the Brewster angle method than in the critical angle method [6,12]. Despite these good features of the Brewster angle method, a commercial Brewster angle refractometer is not known to this author.

50.3.5 Index Match Method

The refractive index match method does not require the sample to be in any special shape or form. Thus, it might be finely divided, that is, a powder. Assuming the particles to be isotropic and homogeneous, then the reflected radiance, the angular or lateral deviation, and the relative phase shift of transmitted light all become zero at refractive index match. If the sample is absorbing, the refractive index of the surrounding liquid that gives the minimum visibility still gives closely the real part of the sample's refractive index. Similarly, if the sample is heterogeneous or anisotropic, the method gives the average refractive index of the sample. The liquid should not dissolve, permeate, or react in any way with the solid sample.

For macroscopic samples, a precision of about 0.005 in n has been estimated [6] from the index match method, where a simple ocular estimation of match is employed. For a matching liquid of refractive index n_{liq}, the reflectance from an interface varies approximately as $(n - n_{liq})^2$. This quadratic dependence makes the sensitivity of the method decrease as the match is approached and makes it difficult in practice to judge whether n_{liq} should be increased or decreased to improve the match.

50.3.6 Microscopy and Scattering Methods

The refractive index of individual particles large enough to image in a microscope can also be measured by the index match method. Central or oblique illumination modes can be used corresponding to the Becke and Schroeder van der Kolk methods, respectively, which utilize null deviation at refractive index match. A precision of 0.0002 in n is quoted [13] for the Becke line method. Whether n_{liq} is lesser or greater than the sample's refractive index n is shown by the appearance of the image.

The phase difference between light transmitted through and around the particle is proportional to $n - n_{liq}$, so that the phase changes sign each side of match. This is used in measurement of refractive index of particles by phase-contrast or interference microscopy, in which the image is brighter or darker than the background according to whether $n > n_{liq}$ or $n < n_{liq}$. These methods can measure the refractive

index of particles below the conventional resolving limit, as the details of an object need not be fully resolved in order to discern match or otherwise. Users of microscopy in refractometry should refer to texts on phase-contrast and interference microscopy. Newer forms of optical microscopy (e.g., scanning confocal) have greater resolving power and can be used for refractive index matching of finer particles.

For a suspension of particles smaller than about 1 μm, the optical turbidity and light scattering are zero at refractive index match, leading to turbidimetric or nephelometric methods of measuring the particle refractive index. For particles of colloidal size, it is important to avoid aggregation or flocculation and suspension destabilization. Thus, chemical restrictions can preclude the attainment of match, particularly if the particle's refractive index is large compared with n_{liq}. In such cases, the turbidity E is measured for changes in n_{liq} that do not destabilize the suspension, and the value of n_{liq} is found by extrapolation to $E = 0$. Extrapolation to obtain this value of n_{liq} is difficult unless the experimental parameters can be arranged to have a linear relation. Theory and experiments described by Griffin and Griffin [14] showed that linearity is obtained if $n_{liq}\sqrt{E}$ is plotted versus n_{liq}.

50.3.7 Anisotropic and Heterogeneous Materials

If a plane face is made from a general optically anisotropic sample, and this face is then offered to the prism of a critical angle refractometer, two critical angles can be simultaneously observed. One can be enhanced over the other through the use of a linear polarizer rotated in the incident or refracted light path. The interpretation of these critical angles, in the general case, is not simple, and the reader is referred to analyses [15–17]. Similar complexity is visited upon the Brewster angle method if the sample is anisotropic, and again the reader is referred to Ref. [6] for works on ellipsometry.

Highly turbid samples, such as polymer latexes and other concentrated colloidal fluids, have been investigated using the critical angle method [1,18–20]. It appears that if the particle size is less than about half a wavelength, the critical angle method remains successful for volume fractions up to at least 0.5. For high concentrations of larger particles, there is a rapid degradation of the reflectance or transmittance discontinuity at the critical angle. This angle is replaced by a region where the reflectance or transmittance may vary in an unexpected way as the particle size and concentration increase.

The effect of heterogeneity on the reflection of polarized light, and on the Brewster angle, is also affected by sample heterogeneity [21,22]. Whereas for a homogeneous sample the parallel-polarized reflectance at the Brewster angle is zero, the effect of sample heterogeneity on the wavelength scale is to cause finite reflectance. Comparison of the Brewster angle and the critical angle methods for heterogeneous materials awaits investigation.

Gate and coworkers have measured the refractive index of emulsion paint films [23] and coated paper [24] by a non-Brewster angle reflection method. Both materials were strongly heterogeneous on the wavelength scale and so (in air) had a strong nonspecular or diffuse reflectance. Some specular reflection remained, however, and the method derives the refractive index of the surface of the film from the ratio of the specular reflectances at a non-Brewster angle for polarizations parallel and normal to the plane of incidence.

The application of refractometry to heterogeneous and absorbing samples is clearly a developing art, and although it is clear that refractometry offers valuable information, the refractometrist should use existing instruments critically.

50.4 Review of Refractometers

The author's initial review of refractometer manufacturers revealed about 30 companies, and the true number may be more than 50. A very large number of general- and special-purpose instruments are offered by each company. It is clearly not possible to review, compare, and advise on individual models. The aspiring refractometrist should do this according to needs and budget. The generalities that follow should assist.

Most instruments use the critical angle (or Abbe) method. They thus have a prism of known refractive index with a face to which the sample is offered. The larger manufacturers offer three types of critical angle instrument:

1. The portable handheld models, which require no power or battery and are customized and calibrated for Brix (sugar), urine, antifreeze, cutting oil, etc. Their refractive index precision is typically between 10^{-3} and 10^{-4}, but their range is small owing to their particular application. The user looks into an eyepiece and reads a scale on which is superposed the dark–light boundary caused by transmission or reflection in the region of angle each side of the critical angle, often termed the critical edge. The price varies greatly between models and manufacturers, typically U.S. $400. Some manufacturers offer digital readout portable models, of similar weight (less than 1 kg) and precision, and battery powered. These cost about U.S. $2000.
2. The laboratory (Abbe) refractometer, which has a refractive index precision of typically 10^{-4}–10^{-5} and covers a wide range of refractive index, typically 1.3–1.75 in a low refractive index instrument and 1.4–1.85 in a high refractive index model. Such instruments are calibrated so that the temperature can be varied using an external liquid bath, and the wavelength can be varied using external light sources. Very roughly, their weight, cost, and precision are about 10 times that of the portable instruments in (1) earlier. They require the user to estimate the position of the critical edge on a graduated scale viewed through an eyepiece.
3. The digital refractometer. Compared with those in (2) earlier, these have similar precision and general facilities, a cost typically a few times greater, but with the advantage of a digital or electronic readout of the data. The upper refractive index offered by several manufacturers appears to be restricted to about 1.6.
4. The process refractometer is a version of those described in (3) earlier, but where the prism is mounted to contact a fluid in a reactor or a pipe and viewed via a fiber-optic cable. Thus, high pressures and temperatures can be accommodated. The prism is usually of sapphire to avoid wear of the optical face, and the precision generally tends to be somewhat lower than those described in (2) and (3) earlier.

Turbidity Measurement

Daniel Harrison
John Carroll University

Michael Fisch
John Carroll University

51.1 Introduction

For nearly 50 years, turbidity measurements have been used to perform a wide variety of physical measurements. These include the determination of particle concentration per unit volume when the scattering cross section per particle is known, the determination of particle size (scattering cross section) when the concentration of particles is known [1–4], and the determination of some of the critical exponents associated with second-order and nearly second-order phase transitions [5–9].

The basic ideas necessary to understand turbidity measurements are fairly simple. In the absence of reflection losses, when a weak beam of light passes through a dielectric sample, the two processes most responsible for reducing the intensity of the transmitted beam are absorption and scattering. The reduction in transmitted light intensity due to scattering is called the sample's turbidity. Extinction includes the effects of both absorption and scattering. The Beer–Lambert or Lambert law describes the effects of both absorption and turbidity on the transmitted intensity. This law is written as

$$I_T = I_0 \exp -(\alpha + \tau)l \tag{51.1}$$

where
I_T is the intensity of the light transmitted through the sample
I_0 is the intensity of the light incident on the sample
α is the absorption coefficient per unit length
τ is the turbidity per unit length
l is the length of the light path in the sample

As discussed later, it is more correct to use powers rather than intensities; thus, this equation should be written as

$$P_T = P_0 \exp -(\alpha + \tau)l \tag{51.2}$$

The most general situation is to have an absorbing medium with absorbing and scattering particles embedded within it; however, here the focus is on the simpler case of nonabsorbing medium and consider the two most common cases: nonabsorbing particles in medium and scattering caused by fluctuations in the medium itself.

Instruments generally fall into two categories: commercial and laboratory constructed. The commercial units are of two general types: (1) attachments to spectrophotometers and (2) white-light turbidity meters, which operate under ambient conditions. Anyone interested in the former should consult the catalog of accessories for the instrument in question. Those interested in the latter should check under "nephelometers" or "turbidimeters" in scientific supply catalogs or on the web [10]. Units of this type perform their designed function admirably and are sufficient for routine work. However, they may need modification for the more specialized measurements performed in many research laboratories. For this reason, it is common to construct special laboratory instruments. These come in at least two types, most commonly either single-beam or dual-beam instruments. The single-beam instrument usually has an intensity-stabilized light source, whereas the dual-beam instrument corrects for drift in the light source and reflection losses by either electronically or mathematically taking the ratio of the transmitted light power and a reference beam power.

The balance of this chapter is divided into three parts. The first part briefly discusses the physical basis of turbidity measurements and demonstrates how such measurements may be used to infer the scattering cross section of the particles in the solution or the concentration of the scatters in the solution. The second section discusses turbidity of pure fluids and shows how certain critical exponents may be determined from such measurements. The last section discusses laboratory instruments and the relative trade-offs involved in such instruments.

51.2 Extinction and Turbidity: Particles in a Nonabsorbing Medium

Suppose that electromagnetic radiation is incident upon a slab of medium consisting of randomly positioned particles and that the transmitted radiation is detected as shown in Figure 51.1. For the present discussion, assume that the source and detector are in the medium. The radiation that is received by the detector will be less than that incident on the slab because of the presence of the particles in the medium—the particles have caused extinction (or attenuation) of the beam. The extinction of the radiation depends on two physical processes, scattering and absorption, whereas the turbidity depends only on scattering. In scattering, there is no change in the total energy of the radiation; rather, some of the

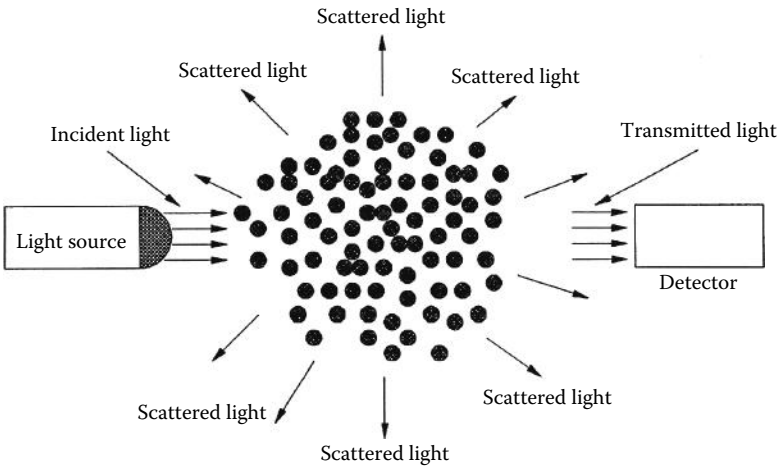

FIGURE 51.1 An idealized experiment indicating the physical basis of turbidity.

incident radiation is redistributed away from the incident direction. In absorption, some of the energy of the incident beam is transformed into other energy forms. This extinction of the beam is rather complicated; it will, in general, depend on the chemical composition, size, shape, number, and orientation of the particles; the chemical composition of the medium; and the frequency and polarization of the incident radiation [2,3].

In discussions of scattering, one often focuses on the *cross sections*, C_i, of the particles. On the basis of conservation of energy, one must write

$$C_{ext} = C_{scatt} + C_{abs} \tag{51.3}$$

where C_{ext}, C_{scatt}, and C_{abs} are the cross sections for extinction, scattering, and absorption, respectively. These cross sections all have the dimension of area, and in all cases a larger cross section (area) indicates a larger effect, and a smaller cross section a smaller effect. In general the cross section will depend on all the intensive quantities that describe the extinction. Finally, note that for nonabsorbing media, $C_{abs} = 0$.

To see how this relates to the measured turbidity, assume now that the medium is nonabsorbing, that all the particles are nonabsorbing and have the same scattering cross section (C), and that there are n of these particles per unit volume. Then, one obtains the following expression for the transmitted light power:

$$P_T = P_0 \exp -(nCl) \tag{51.4}$$

where

P_T is the transmitted power

P_0 is the incident power

We have switched from intensity to power because power is the quantity detected, and power is independent of the details of the spatial distribution of electromagnetic radiation. Upon noting this change and comparing this to Equation 51.2, when $\alpha = 0$, it is clear that the turbidity can be expressed as

$$\tau = nC \tag{51.5}$$

Thus, a measured turbidity can be related to C_{scatt} if n is known, or n may be determined if C_{scatt} is known. The difficulty is then in determining C_{scatt}. There are a number of approaches that can be used. For well-characterized particles, theoretical expressions may be determined [2]. In the absence of such theory, measurements may be made as a function of concentration and then, since $\tau = nC$, C may be determined. The generalizations to account for nonmonochromatic beams and extinction by a collection of noninteracting particles of the same type but different sizes are straightforward. The simplest generalization to include different sizes assumes that there is one parameter, ζ, that describes the distribution of particle size and the corresponding C_{scatt} [1]. That is, let $C_{scatt}(\zeta)$ be the scattering cross section for a particle characterized by the parameter (for instance, radius) ζ, and let the number per unit volume with parameter between ζ and $\zeta + d\zeta$ be $N(\zeta)d\zeta$, such that

$$n = \int_0^\infty N(\zeta)d\zeta$$

then

$$\tau = \int_0^\infty C_{scatt}(\zeta)N(\zeta)d\zeta \tag{51.6}$$

A similar integral exists when the incident radiation is not monochromatic, but, in this case, the average is over the wavelength variation of the incident radiation.

51.3 Turbidity Due to Density Fluctuations in Pure Fluids

It is well known that even in very pure and well-filtered liquids, in which there are essentially no particles, there is still some reduction in the detected power due to scattering [3]. The explanation is that there are always thermal fluctuations in the dielectric constant of the media, ε, and it is these fluctuations from the mean dielectric constant that lead to the scattering of light. Through application of thermodynamic and statistical mechanical principles [3], the following expression for the turbidity results:

$$\tau = \frac{8\pi^3}{2\lambda^4}\left[\rho\left(\frac{\partial\varepsilon}{\partial\rho}\right)_T\right]^2 kT\beta_T \tag{51.7}$$

where

ρ is the density
ε is the dielectric constant
k is Boltzmann's constant
T is the absolute temperature
λ is the wavelength of the incident light
β_T is the isothermal compressibility

Near a second-order phase transition, the fluctuations become correlated over larger distances, and this expression must be generalized to include the effects of this increase in the *correlation length*, ξ. In this case, the turbidity is given by [6]

$$\tau = A\pi\beta_T\left[\frac{2\alpha^2+2\alpha+1}{\alpha^3}\ln(1+2\alpha) - \frac{2(1+\alpha)}{\alpha^2}\right] \tag{51.8}$$

where

$$A = \frac{\pi^2}{\lambda^4}\left[\rho\left(\frac{\partial\varepsilon}{\partial\rho}\right)_T\right]^2 kT \quad \text{and} \quad \alpha \equiv 2\left(\frac{2\pi n}{\lambda}\xi\right)^2$$

where n is the (mean) index of refraction of the fluid. Both the isothermal compressibility and the correlation length exhibit approximate power-law behavior of the form

$$\beta_T, \xi \sim \left(\frac{|T_c - T|}{T_c}\right)^{-x_i} \tag{51.9}$$

near these phase transitions. Thus, a measurement of $\tau(T)$ allows the determination of the critical exponents, x_i, and the values of β_T and ξ far from the phase transition. This technique has been generalized to binary liquid mixtures, liquid crystals, and other systems. In these cases, the isothermal compressibility is replaced by the appropriate generalized susceptibility. There are also, in some cases, small corrections to the aforementioned expressions. These can also be found in Refs. [11–13].

51.4 Design of Laboratory Instruments

When more exact measurements are required than can be obtained using commercial instruments, and other enhancements such as mK temperature and/or pressure controlled sample chamber are required, it is common to construct a turbidity instrument. There are basically two types of instruments (single beam and dual beam). With both types of instruments, both ac and dc detection

schemes are possible. Generally, the long-term time stability of synchronous ac detection techniques is superior to dc techniques. This section discusses all of these techniques.

51.4.1 Single-Beam Instruments: Optics

The basic optical design of a single-beam instrument is shown in Figure 51.2. The light source is a low-power (1–5 mW) vertically polarized He–Ne laser. It is important to use a polarized laser. The polarization direction of an unpolarized laser wanders, and this can lead to time-dependent reflection coefficients from the various surfaces in this instrument and hence reduced performance. The beam passes through a laser intensity stabilizer. This device reduces long-term drift in the laser power to ≤0.1%, thus allowing single-beam operation. Table 51.1 shows several commercial intensity stabilizers.

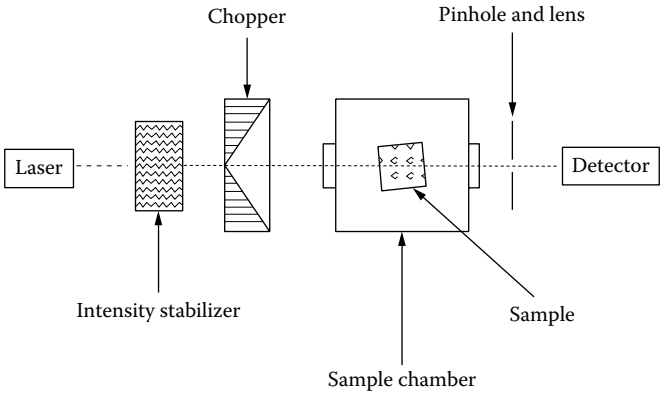

FIGURE 51.2 Block diagram of the optics for a single-beam turbidity apparatus.

To reduce any possible heating of the sample due to absorption, the beam is then passed through a neutral density filter, which attenuates the beam further to a level of 50–100 μW. The next item in the beam line depends on the detection scheme. For ac operation, a light chopper is inserted into the beam line, while for dc detection, nothing else is required before the sample. An output from the chopper is used for synchronous detection. The sample chamber then follows. This chamber requires an input and an output port and a design that precludes interference of any beam with other reflected beams. Other design details are determined by the materials to be studied and any required external factors that are to be controlled. After the beam has been transmitted through the sample, it passes through either a pinhole or a lens–pinhole combination [14,15]. This results in a small angle of acceptance for the detector that, in turn, reduces the scattered light at small angles from the transmitted beam that reaches the detector. A detector then completes the optical train. For most applications, a *pin* photodiode is an excellent, inexpensive detector; however, in some applications, other types of detectors may be superior.

51.4.2 Single-Beam Systems: Electronics

For both synchronous and dc detection, the output of the photodiode, which is a current device, must be transformed into a voltage using a current-to-voltage converter (CVC). It is important not to use just a resistor for this function. The simplest workable CVC uses an FET-input operation amplifier such as an LM-11 and one resistor. The circuit, also known as a transimpedance amplifier, is common and can be found in many sources [16].

When dc detection is used, the output voltage from the CVC is read on a voltmeter. The relationship between this voltage and the turbidity will be discussed later. The stability of dc operation is greatly improved by maintaining the photodiode and the electronics at a stable temperature. The drifts in detector efficiency and in component values associated with temperature changes can limit the accuracy of the instrument. Furthermore, the detector must be shielded from stray light, which means the instrument must be operated in a darkened room or under a light-tight cover. Such covers may cause excessive heating of the laser and the system. A "spike" filter that passes the wavelength of the laser may also assist in solving this problem.

When synchronous ac detection is used, the output from the CVC is the input to a lock-in amplifier that is synchronized to the chopper. Commercial units are available and can be used. One can also construct a simple lock-in using an Analog Devices AD-630 balanced modulator/demodulator, a phase shifter to ensure that the reference signal and the transmitted signal are in phase, and an *RC* filter. The output voltage from the RC filter is then read with a dc voltmeter. The necessary wiring diagrams are available from Analog Devices [17]. Synchronous detection has the advantage of having lower $1/f$ noise than dc circuits. Also, synchronous detection can discriminate against signals not synchronized with the reference and hence offers much greater immunity to room lights and other stray light sources. The advantages of such detection are discussed extensively in the literature [16,18].

Single-beam techniques are most useful for measuring changes in turbidity. To see this, note that the voltage output from the CVC or the lock-in, V_t, is given by $V_t = AP_T$, where A is an instrument constant that includes factors such as current-to-voltage gain, light power level to current conversion in the photodiode, reflection losses from the various interfaces, incident light power, and gain of the lock-in. Now, P_T is given by Equation 51.2; hence V_{dc}, the measured dc voltage, may be written as

$$V_{dc} = B\exp -(\alpha + \tau) \tag{51.10}$$

where $B = AP_0$ is another constant, and we have included absorption. B may be determined by putting a solution of known extinction in the instrument and solving Equation 51.10 for B. Then, knowing l, α, B, and V_{dc}, the turbidity may be found by solving Equation 51.10 for τ, that is

$$\tau = \frac{1}{l}\ln\left(\frac{V_{dc}}{B}\right) - \alpha \tag{51.11}$$

This technique is rather limited if a large number of different samples must be compared. For a given sample, the change in turbidity is easily measured as a function of externally controlled parameters. However, putting samples into and taking them out of the instrument usually produces small random errors that slightly change the instrumental constant A and degrade performance. In some cases, the difference in turbidity between two samples may be small and result in a situation in which one must deal with a small difference of large numbers. This situation may be rectified using dual-beam instruments.

For simple measurements, a turbidimeter device is available for GE. It is described as follows: "GE Sensing/NovaSensor Turbidity Sensors measure the amount of suspended particles, or turbidity, in the wash water of washing machines and dishwashers." There are devices with both turbidity and temperature sensors and only turbidity. It has the potential to be of use in simple one-beam instruments that have some special characteristic such as low battery drain or flow through water conditions. These devices require 5 V dc, although less appears to be acceptable, and draw 30 mA max. To operate, one needs a voltage source, two resistors, and a voltmeter [19].

51.4.3 Dual-Beam Instruments: Optics

The optical design of a dual-beam, two-detector instrument is shown in Figure 51.3. The first several parts of the optical train are the same as for the single-beam instrument, and the same comments apply in this case. The first real difference is that there need not be an intensity stabilizer in the dual-beam system. However, inclusion of the intensity stabilizer may improve system performance. The second difference is the inclusion of a beam splitter that splits the laser beam into two parts. We have found that a microscope slide works well as a beam splitter [20]. One of these beams (usually the reflected beam) becomes a reference beam that passes through a reference sample. The other passes through the sample as in the single-beam instrument. The beams from these two paths go through lens–pinhole combinations and fall on detectors. All of the comments that apply to the single-beam instrument also apply here. The associated electronics are also identical. Once more, both dc and ac detection may be used. Experience in our laboratory shows that the best results are obtained when the sample signal is simultaneously divided by the reference signal using an integrated circuit divider. A modification that uses two beams and one detector is shown in Figure 51.4. This modified design eliminates the need for absolute stability of two separate detectors but requires somewhat more complex optics.

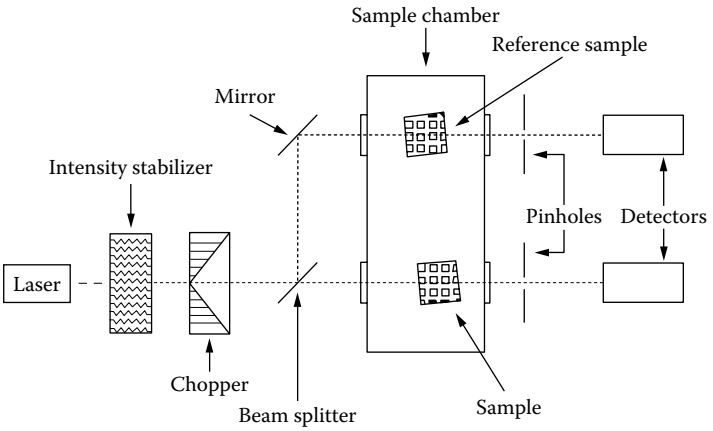

FIGURE 51.3 Block diagram of the optics for a dual-beam, two-detector turbidity apparatus.

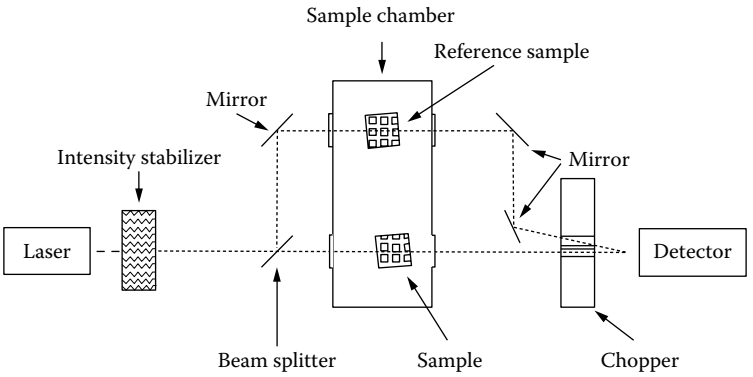

FIGURE 51.4 Block diagram of the optics for a dual-beam, one-detector turbidity apparatus.

The following analysis assumes that the measured output is the ratio of the sample signal voltage to the reference signal voltage. Let the voltage output from the detector's CVC be V_{sig} and the voltage output of the reference signal detector's CVC be V_{ref}. Then

$$V_{sig} = AP_T \tag{51.12}$$

and

$$V_{ref} = CP_R \tag{51.13}$$

where

A and C are the instrumental constants totally analogous to the instrumental constant A earlier
P_R is the power of the reference beam at the detector

It is important to realize that A and C are constant, but they need not be identical. The output voltage ratio, V_{out}, is given by

$$V_{out} = \frac{V_{sig}}{V_{ref}} = \frac{AP_T}{CP_R} = D\frac{P_T}{P_R} \tag{51.14}$$

where $D = A/C$ is a constant. Note that in this arrangement, common multiplicative noise on the two voltages will tend to cancel out. Now P_T can be replaced by Equation 51.1, and P_R is given as

$$P_R = f^{\star} P_0 \exp -(\alpha_R + \tau_R) l_R \tag{51.15}$$

where

α_R is the absorption
τ_R is the turbidity of the sample in the reference beam
l_R is the thickness of the sample in the reference beam
f is a constant determined by the beam splitter

Then, assuming that l_R is the same as l, the following expression results:

$$V_{out} = D\frac{P_0 \exp -(\alpha + \tau) l}{f^{\star} P_0 \exp -(\alpha_R + \tau_R) l} \tag{51.16}$$

and thus,

$$\tau = -\frac{1}{l}\ln\left(\frac{V_{\text{out}}}{D'}\right) + \tau_{\text{R}} - \alpha + \alpha_{\text{R}} \tag{51.17}$$

where $D' = D/f$. Often, this can be considerably simplified when the reference sample is a pure liquid because then τ_{R} is of order 10^{-5} and α_{R} is totally negligible. Normally, the reference sample is chosen so that its optical properties approach those of the sample in the case where the concentration of particles is low or the system is far from a phase transition. The constant D' may be determined by using the same sample in both the reference and the signal arms of the instrument—in this case, $V_{\text{out}} = D'$.

51.4.4 Dual-Beam Instruments: Electronics

The electronics for dc detection consist of two CVC converters, one for each detector. The voltage outputs from these may be read directly. However, experiments indicate that greater stability is achieved by simultaneously dividing these two signal outputs as discussed earlier. In our laboratory, this is accomplished using an Analog Devices AD-532 internally trimmed integrated circuit divider. These can be purchased with different accuracies. In the present application, they typically perform slightly better than the factory specifications indicate. The circuit details are available from Analog Devices [21].

The electronics for ac detection generally consist of two synchronous detectors followed by division of the sample signal by the reference signal. Once more, this may be accomplished using two Analog Devices AD-630 balanced modulator/demodulators or two commercial lock-in amplifiers. Division can be accomplished in the same way as in the dc technique section.

51.5 Limitations

Highly turbid samples, which transmit very little light, may be difficult to measure using a photodiode. In such cases, the photodiode in the sample arm may be replaced with a photomultiplier (PM). In this case, a chopper can be used to reduce the effects of the dark signal from the PM. The outputs, when the signal is present and when it is blocked, are both measured and averaged (preferably digitally), and the difference is computed. By counting for a fixed number of reference counts (requiring another PM), drift in the source may be eliminated. A Stanford Research Instruments photon counter [22] may be configured in this mode. Furthermore, unless extreme precautions are taken in this situation, erroneous results may occur because the scattered power is as large or larger the transmitted beam power.

Laser Output Measurement

Haiyin Sun
Coherent Auburn Group

52.1 Introduction

A laser is a device that emits an optical beam. A laser beam carries a certain amount of optical power. Lasers emit beams in two different ways: continuous wave (CW) or pulsed. A CW laser emits a steady power as shown in Figure 52.1. CW laser power is measured in terms of watts. The power of commonly used CW lasers ranges from a fraction of milliwatts for a small helium–neon (He–Ne) laser to tens of kilowatts for a carbon dioxide (CO_2) laser. A pulsed laser emits a pulsed power as shown in Figure 52.2. The pulse can be repeated. The pulse duration and repetition rate vary for lasers of different types and are adjustable for some types of lasers. Pulsed laser power is more easily measured in terms of energy per pulse such as joules per pulse. The term "per pulse" is usually omitted. The energy of commonly used pulsed lasers ranges from a few picojoules for a semiconductor laser to tens of megajoules for a semiconductor laser array. The pulse repetition rate ranges from a single pulse for an excimer laser or an x-ray laser to hundreds of megahertz for a neodymium/YLF laser. The pulse duration ranges from tens of femtoseconds for a Ti/sapphire laser up to CW for a CO_2 or He–Ne laser.

A laser beam may contain more than one wavelength (monochromatic) component. One wavelength component may have an optical intensity different from that of another wavelength component. Optical spectral intensity is defined as power per unit wavelength. The optical intensity–wavelength profile of a laser beam is known as the "spectrum." Spectrum measurement usually means measuring the spectral profile. The absolute value of the optical spectral intensity is in fact not important. Figure 52.3 shows a typical spectrum of a multimode semiconductor laser. The wavelength components are inside several bands. Each band may be a "longitudinal mode," and the width of a band is known as the "mode linewidth." Figure 52.4 shows a typical spectrum of a single-mode He–Ne laser. There is only one longitudinal mode with a very narrow linewidth. The power of a laser beam can be calculated by integrating over the laser spectrum.

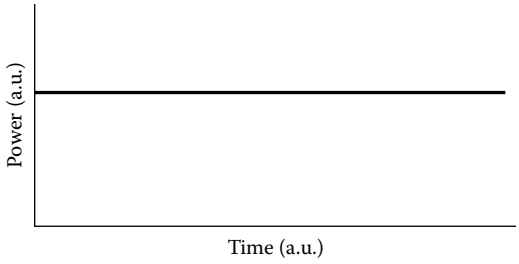

FIGURE 52.1 A CW laser emits a steady power.

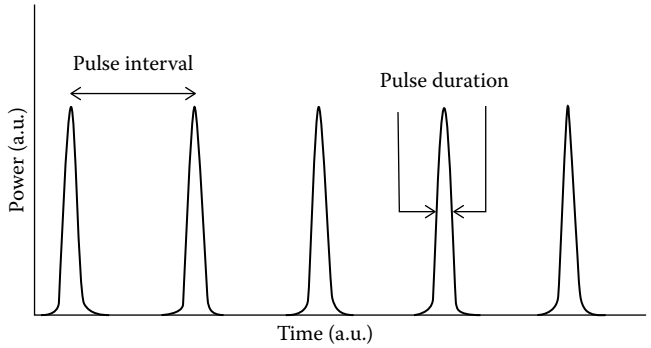

FIGURE 52.2 A pulsed laser emits a pulsed power.

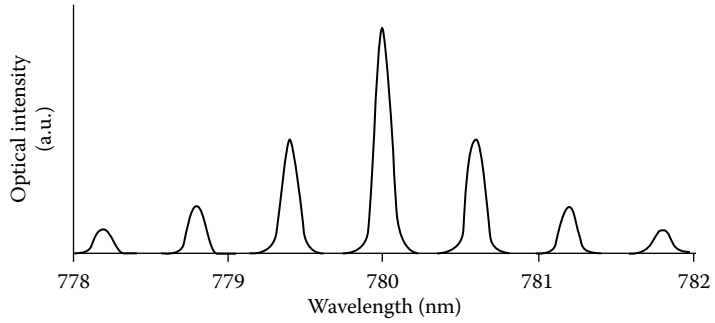

FIGURE 52.3 Spectrum of a multimode semiconductor laser.

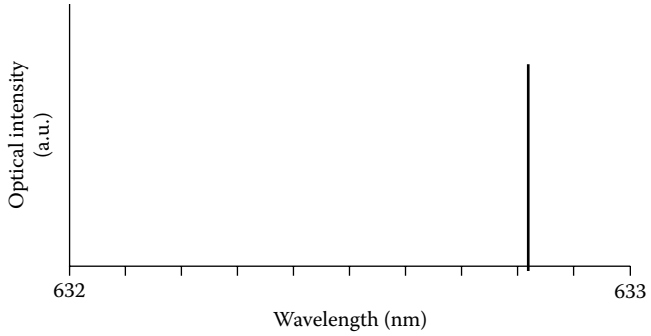

FIGURE 52.4 Spectrum of a single-mode helium–neon laser.

The wavelength of a laser is referred to as the *central wavelength* of the spectrum. But the term "central" is usually omitted. For example, the wavelength is 780 nm for the semiconductor laser shown in Figure 52.3 and is about 632.8 nm for the He–Ne laser shown in Figure 52.4. The wavelength of commonly used lasers ranges from 270 nm in ultraviolet for a neodymium/YAG laser, or even lower for an x-ray laser, to 10.6 μm in infrared for a CO_2 laser. Many lasers have a beam with single longitudinal mode and very narrow linewidth like that shown in Figure 52.4. The spectrum measurement for these lasers then virtually reduces to wavelength measurement.

Power, spectrum, and wavelength are the three most important parameters describing a laser. Laser manufacturers should provide information about these three parameters of their lasers. Some lasers have adjustable power, spectrum, or wavelength. Users often need to measure these parameters to ensure appropriate use of these lasers. This chapter discusses the principles and techniques involved in the measurement of laser power, spectrum, and wavelength.

Readers interested in knowing more about laser working principles and characteristics can read laser textbooks such as Ref. [1], available in many libraries.

52.2 Measurement of Laser Power

A laser power meter can measure laser power or energy. Figure 52.5 shows the scheme of a laser power meter. The three basic components of a laser power meter are a photodetector, an electronic conditioner, and a display device. The photodetector detects the laser beam under measurement and outputs an electrical response proportional to the laser power. The electronic conditioner processes the response and provides a digital or analog signal for displaying. The display device displays the measurement result in terms of watts or joules. To a large extent, the characteristics of the photodetector used determines the performance of a laser power meter. When selecting or using a laser power meter, the following issues are of primary concern:

1. *Spectral response range*: A photodetector has a certain spectral response range that limits the spectral range of a laser power meter. Some photodetectors have a wavelength-dependent spectral response. Calibration is necessary when using a laser power meter with such a photodetector to measure the power at different wavelengths.
2. *Power range*: The detection threshold and damage threshold of a photodetector usually determine the power range of a laser power meter. Incident laser power lower than the detection threshold can cause measurement error, while incident power higher than the damage threshold can cause permanent damage to the photodetector. Specifically, power range includes CW power range, peak power range, spatial power density range, single-pulse energy range, and spatial energy density range. An optical attenuator put in front of the photodetector can raise the damage threshold to as high as megawatt. However, an attenuator will also raise the detection threshold.

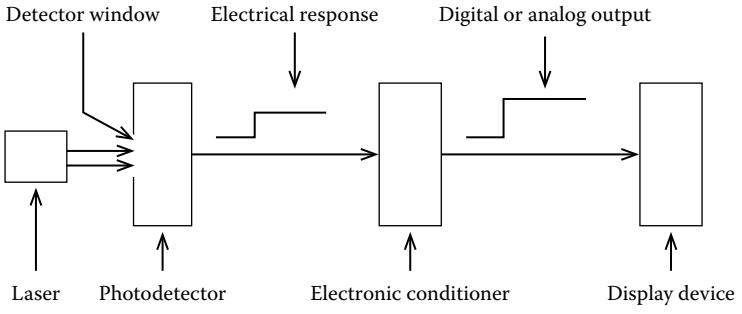

FIGURE 52.5 Scheme of a laser power meter.

3. *Response time*: A photodetector needs a certain time to respond to an incident laser beam. In order to determine the shape of a laser pulse, the detector response time must be shorter than the width of the pulse.
4. *Detector window size*: The input window size of commonly used photodetectors are from a few to tens of millimeters. When the size of a laser beam under measurement is larger than the detector window size, focusing optics must be used to reduce the beam size. Power loss caused by the focusing optics must be excluded to avoid measurement error.

52.2.1 Photodetectors

Three photodetectors are commonly used in laser power meters. They are thermopiles, photodiodes, and pyroelectric probes.

52.2.1.1 Thermopiles

A thermopile is usually a light absorber disk onto which a ring of thermocouples has been deposited. The absorber converts the laser power incident on it into heat and generates between the absorber and a heat sink a temperature difference proportional to the incident laser power. The thermocouples generate and output an electrical response proportional to the temperature difference. Thermopiles usually have a long response time of a few seconds, a broad and fiat spectral response range from 200 nm to 20.0 μm, and a power range of 1 mW–5 kW for CW lasers or 0.01–300 J for pulsed lasers. Because of the flat spectral response, calibration is independent of wavelength. Thermopiles are primarily used to measure moderate to high power output of CW lasers, moderate to high energy output of single-shot pulsed lasers, and the energy output of pulsed lasers with a repetition rate higher than 10 Hz.

52.2.1.2 Photodiodes

Silicon and germanium photodiodes are widely used as photodetectors. A photodiode absorbs the photons (laser beam) incident on it and utilizes the photon energy to create free-carrier pairs (electrons and holes). These free carriers form a response current in an external circuit. The responsivity of a photodiode in amps/watt is given by

$$R\left(\frac{A}{W}\right) = \eta_D \frac{e}{hv} \tag{52.1}$$

where

R is the current produced by the photodiode for per watt of incident power
η_D is the detection efficiency
e is the electron charge (1.6×10^{-19} C)
hv is the photon energy

Since a typical photon energy is 2 eV ≈ 3×10^{-19} J, e/hv is of the order of 0.5 A/W. Normal detection efficiencies η_D exceed 0.5 at optical wavelengths (500–800 nm), leading to typical responsivities of 0.25 A/W. Silicon photodiodes have a narrow spectral response range (400 nm–1.1 μm). The response peak is at about 800 nm. Germanium photodiodes also have a narrow spectral response range (800 nm–1.8 μm). The response peak is at about 1.5 μm. Photodiodes usually have a power range of 1 nW–50 mW for CW lasers or 1 pJ–1 μJ for pulsed lasers and a short response time of about 100 ms. Photodiodes are best for measuring low power output of CW lasers or low energy output of pulsed lasers. Because their spectral response is wavelength dependent, calibration is always required when measuring the power of lasers with different wavelengths. Manufacturers should attach a calibration data sheet to their laser power meters that use a photodiode as the detector. Several other semiconductor photodetectors with different spectral response ranges are available commercially. For example, the spectral response ranges are from

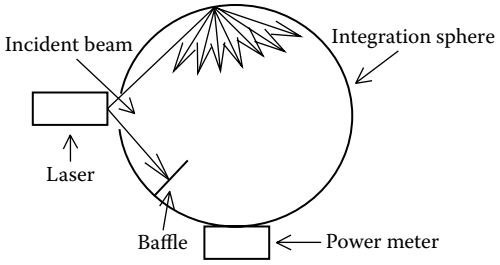

FIGURE 52.6 Scheme of an integration sphere.

1.0 to 3.6 μm, 1.0 to 5.5 μm, and 2 to 22 μm for indium arsenide photodetectors, indium antimonide photodetectors, and mercury cadmium telluride photodetectors, respectively.

52.2.1.3 Pyroelectric Probes

A pyroelectric probe uses a ferroelectric material that is electrically polarized at a certain temperature. The material is placed between two electrodes. Any change in temperature of the material caused by the absorption of laser power produces a response electric current in the external circuit. Pyroelectric probes are primarily used to measure the energy of pulsed lasers because they only respond to the rate of temperature change. Pyroelectric probes usually have a spectral response range from 100 nm to 100 μm, a response time as short as a few picoseconds, and a pulsed energy range from 10 nJ to 20 J.

52.2.2 Integration Spheres

Integration spheres are designed to collect the power of highly divergent laser beams, such as semiconductor laser beams, since these beams can overfill the input window of a photodetector and cause considerable measurement error. Figure 52.6 shows the scheme of an integration sphere. The hollow spherical cavity has a diffusive internal wall and at least two windows. The reflectivity of the internal wall is high and slightly wavelength dependent. The highly divergent laser beam under measurement is incident into the sphere from one window. The photodetector of a laser power meter is mounted on another window. A baffle is used to prevent the photodetector being directly hit by the incident beam. The sphere can collect all the incident laser power and convert the power into a diffusive radiation proportional to the power. The laser power meter measures the radiation and displays the laser power under measurement based on the calibration data of the integration sphere.

Readers interested in knowing more about laser power meters can read Refs. [2–4] or contact manufacturers. Chapters 43 and 44 provide more information about photodetectors.

52.3 Measurement of Laser Spectrum

An instrument that can measure a laser spectrum is known as an optical spectrum analyzer. An optical spectrum analyzer consists of two basic components: an optical device and a laser power meter. The optical device can select and output a certain wavelength band of a polychromatic laser beam incident on the device. The central wavelength of the output wavelength band can be scanned over a certain range by the scan of the optical device. The laser power meter measures the power of the optical device output. The width of the output wavelength band usually does not change. Therefore, the power measured by the power meter is proportional to the optical spectral intensity. Since the absolute value of the optical spectral intensity is not important in the measurement of spectrum, the laser power meter sometimes can be as simple as a photodiode combined with a voltmeter. As the optical device is scanned, the power meter outputs the power (optical spectral intensity) as a function of the wavelength and thereby measures the spectrum. Diffraction gratings and scanning Fabry–Perot interferometers (SFPIs) are two widely used optical devices for spectrum analysis.

52.3.1 Light Interference

Most optical spectrum analyzers make measurements utilizing light interference. The wave theory of light can explain interference. A single-mode, narrow-linewidth laser beam can be described by its electric field $E(z)$:

$$E(z) = A\exp[-i\phi(z) + i\alpha(t)] \tag{52.2}$$

where

A is the amplitude

$\phi(z) = 2\pi z/\lambda$ is the phase, λ is the laser wavelength, z is the coordinate in the direction of beam propagation

$\alpha(t)$ is a phase factor that varies fast with time t

The intensity of the laser beam is given by

$$I = |E(z)|^2 = A^2 \tag{52.3}$$

52.3.1.1 Two-Beam Interference

A beam splitter such as a partially transparent plate can split a laser beam into two described by

$$E_1(z) = A_1\exp[-i\phi(z) + i\alpha(t)] \tag{52.4}$$

$$E_2(z) = A_2\exp[-i\phi(z) + i\alpha(t)] \tag{52.5}$$

where A_1 and A_2 are the amplitudes. Let the two beams propagate through two different distances, z_1 and z_2, respectively, and then be recombined into one. The intensity of the recombined beam is

$$I = |E_1(z_1) + E_2(z_2)|^2 = A_1^2 + A_2^2 + 2A_1A_2\cos\frac{2\pi(z_2 - z_1)}{\lambda} \tag{52.6}$$

Equation 52.6 shows that I varies sinusoidally as $|z_2 - z_1|$ is varied. Such a phenomenon is known as *two-beam interference*. When $|z_2 - z_1| = m\lambda$ (m is any integer), I takes the maximum value of $(A_1 + A_2)^2$ and the situation is called "constructive interference." When $|z_2 - z_1| = (m + 1/2)\lambda$, I takes the minimum value of $(A_1 - A_2)^2$, and the situation is called *destructive interference*. Combining two beams with the same wavelengths but from two different lasers results in

$$I = A_1^2 + A_2^2 + 2A_1A_2\cos\left[\frac{2\pi(z_2 - z_1)}{\lambda} + \alpha_2(t) - \alpha_1(t)\right] \tag{52.7}$$

where $\alpha_1(t)$ and $\alpha_2(t)$ are the two different phase factors of the two lasers, respectively. For broadband lasers, $\alpha_1(t)$ and $\alpha_2(t)$ are uncorrelated, and they vary rapidly and randomly. The last term at the right-hand side of Equation 52.7 can contribute to I only in a time-averaged way, and the time average of this term is zero. For narrowband lasers, a beat is obtained at the differential frequency of the two lasers, and I varies sinusoidally in time for any fixed $z_2 - z_1$. The time average of the last term in Equation 52.7 is also zero. Thus, I always equals a constant of $A_1^2 + A_2^2$, no matter how $|z_2 - z_1|$ is varied.

52.3.1.2 Multibeam Interference

Interference can occur among any number of beams obtained by splitting one laser beam. Let a laser beam with unit amplitude be split into $N(N > 1)$ beams, the amplitudes of these N beams fall off progressively, and the phase difference between two successive beams be a constant $\Delta\phi$. These beams can be described by $E_k(z) = \rho^k\exp[-i\phi(z) - ik\Delta\phi + i\alpha(t)]$, where $k = 0, 1, \ldots, N - 1$ and $\rho < 1$. Then, these N beams

are recombined. Multibeam interference occurs among these beams. The intensity of the recombination of these beams is given by

$$I = \left| \exp[-i\phi(z) + i\alpha(t)] \sum_{k=0}^{N-1} \rho^k \exp(-ik\Delta\phi) \right|^2 = \frac{1 + \rho^{2N} - 2\rho^N \cos(N\Delta\phi)}{1 + \rho^2 - 2\rho\cos(\Delta\phi)} \tag{52.8}$$

Equation 52.8 shows that I is a function of ρ and N and is a periodic function of $\Delta\phi$. More information about the wave theory of light and light interference can be found in many advanced optics textbooks such as Ref. [5].

52.3.2 Diffraction Gratings

A diffraction grating can spatially disperse a polychromatic laser beam into its monochromatic components and is the most widely used optical device for analyzing optical spectrum covering a relatively wide range. Several different types of diffraction gratings are available. A planar reflective diffraction grating is a collection of many small, identical, and slit-shaped grooves ruled on a planar high reflective surface; Figure 52.7 shows two grooves of such a grating, an incident laser beam with three wavelength components $\lambda_1 < \lambda_2 < \lambda_3$ and three diffraction beams marked by $m = 0$, 1, and 2, respectively. The beams are in the plane defined by the grating normal and the groove normal. The grooves illuminated by the incident beam generate diffraction beams with the same amplitude since the grooves are identical. Multibeam interference occurs among the diffraction beams. The phase difference $\Delta\phi$ between two adjacent diffraction beams of a grating is given by

$$\Delta\phi = \frac{2\pi}{\lambda} d[\sin(\theta_1) + \sin(\theta_2)] \tag{52.9}$$

where

d is the groove period

θ_1 is the angle between the incident beam and the grating normal

θ_2 is the angle between the diffraction beams and the grating normal (θ_2 is not marked in Figure 52.7)

$d[\sin(\theta_1) + \sin(\theta_2)]$ is the path difference between two adjacent diffraction beams. Constructive interference among the diffraction beams occurs at

$$\Delta\phi = 2m\pi \tag{52.10}$$

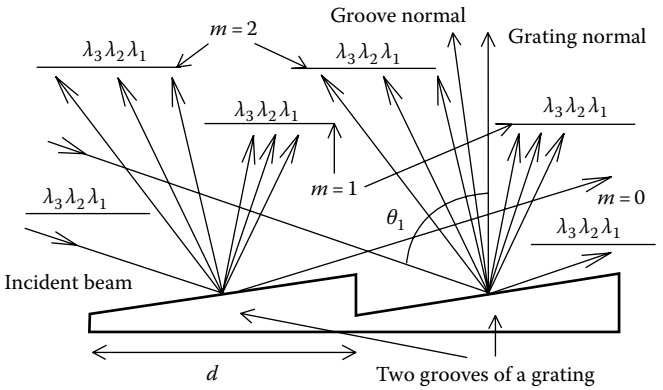

FIGURE 52.7 Two grooves of a planar reflective diffraction grating. The grating disperses an incident beam containing three wavelengths, $\lambda_1 < \lambda_2 < \lambda_3$. There are three diffraction beams with diffraction order $m = 0$, 1, 2.

where m is an integer known as the *diffraction order*. Combining Equations 52.9 and 52.10 results in

$$d[\sin(\theta_1) + \sin(\theta_2)] = m\lambda \tag{52.11}$$

Equation 52.11 is known as the *grating equation* and shows that for a given θ_1 and m, θ_2 is a function of λ. θ_2 gives the diffraction beams a propagation direction in which I has the maximum value. The angular dispersion resolution of a grating is defined by $d\theta_2/d\lambda$ and can be obtained by differentiating Equation 52.11. The result is

$$\frac{d\theta_2}{d\lambda} = \frac{m}{d\cos(\theta_2)} \tag{52.12}$$

where θ_1 is assumed to be a constant. Large $d\theta_2/d\lambda$ is often desired and can be obtained by the use of a small d, a large θ_2 close to 90°, and a large m. Usually, θ_2 must be smaller than 80° to maintain the proper functioning of the grating and $d \approx \lambda$; Equation 52.11 shows that the largest possible value of m is 2. Equations 52.11 and 52.12 also show that $m = 0$ leads to $\theta_2 = -\theta_1$ and $d\theta_2/d\lambda = 0$. That means that in the zero diffraction order, the grating does not disperse the incident beam, and all the diffraction beams propagate in the same direction, $\theta_2 = -\theta_1$. Commonly used diffraction gratings have a groove density from 300/mm ($d \approx 3.33$ μm) to 2400/mm ($d \approx 420$ nm). The corresponding dispersion resolution for $m = 1$ is from $d\theta_2/d\lambda = 4 \times 10^{-4}$ rad/nm to $d\theta_2/d\lambda = 3.4 \times 10^{-3}$ rad/nm. The intensity of the diffraction beams of a grating can also be described by Equation 52.8 with $\rho = 1$. That is,

$$I = \frac{\sin^2(N\Delta\phi/2)}{\sin^2(\Delta\phi/2)} \tag{52.13}$$

Equation 52.13 is plotted in Figure 52.8 for $N = 5$ and 20, respectively. Equation 52.13 shows that I is a periodic function of $\Delta\phi$. I reaches maximum of N^2 at $\Delta\phi = 2\,m\pi$ and zero at $\Delta\phi = 2k\pi/N$ (k is any integer, but $k \neq mN$). The fringe width $\Delta\phi_w$ of I is given by

$$\Delta\phi_w = 2\left[2m\pi - \frac{-2(mN-1)\pi}{N}\right] = \frac{4\pi}{N} \tag{52.14}$$

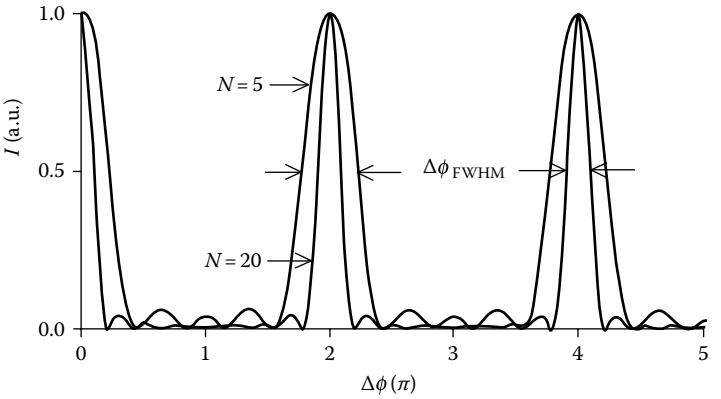

FIGURE 52.8 Multibeam interference intensity I is a periodic function of the phase difference $\Delta\phi$ between two adjacent beams. I is plotted for beam number $N = 5$ and 20, respectively. The full fringe width at half maximum power $\Delta\phi_{FWHM}$ of I decreases as N is increased.

Equation 52.14 shows that the resolution of a grating is proportional to N, since the resolution can be defined as $1/\Delta\phi_w$.

Most advanced optics textbooks (e.g., Ref. [5]) study gratings, and manufacturers' catalogs (e.g., Ref. [6]) give a product-oriented description of gratings.

52.3.3 Monochromators

Monochromators are instruments widely used for optical spectrum analysis. Various types of monochromators have been developed. Figure 52.9 shows the scheme of a simple monochromator. The laser beam under measurement is incident through the entrance slit, two concave spherical mirrors collimate the beam, the grating disperses the beam, then one concave spherical mirror focuses the beam on the exit slit, and a laser power meter measures the power of the beam passing through the exit slit. The grating is mounted on a rotator. The position of the two slits is fixed. For any given grating orientation, θ_1 and θ_2 are known. The wavelength λ of the diffraction beams passing through the exit slit can be calculated using Equation 52.11. By rotating the grating and recording the power measured as a function of the corresponding λ, we can measure the spectrum. The widths of the two slits are Δs_1 and Δs_2, respectively, and are adjustable. The three mirrors image the entrance slit on the exit plane. The image width $\Delta s_1'$ of the entrance slit is proportional to Δs_1; Equation 52.15 gives the measurement resolution of a monochromator:

$$\Delta s \frac{d\lambda}{ds} = \frac{\Delta s\, d\lambda}{f\, d\theta_2} \tag{52.15}$$

where

$d\lambda/ds$ is the linear dispersion resolution
Δs equals the larger of $\Delta s_1'$ and Δs_2
$d\lambda/d\theta_2$ is the inverse of the angular resolution of the grating used
f is the focal length of the focusing mirror

Equation 52.15 shows that reducing the widths of the two slits can increase the measurement resolution. However, the slits must be wide enough to allow enough laser power passing through for measurement. The grating rotation angular resolution also affects the measurement resolution of a monochromator. The resolution of commonly used monochromators is from 0.1 to 1 nm. Monochromators usually have a moderate price and measurement resolution. A product-oriented description of monochromators can be found in manufacturers' catalogs such as Ref. [7].

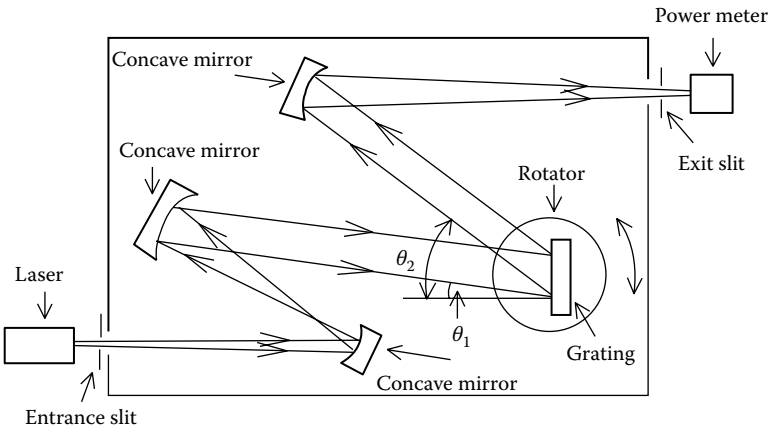

FIGURE 52.9 Scheme of a simple monochromator.

52.3.4 Scanning Fabry–Perot Interferometer

Another widely used optical spectrum analyzer is an SFPI. An SFPI consists of two slightly wedged transparent plates with flat surfaces as shown in Figure 52.10. The two inner surfaces of the plates are set parallel to each other and are high-reflecting coated. The distance D between the two inner surfaces can be adjusted by a piezoelectric device. The two outer surfaces have a small angle between them, so that reflections of the two outer surfaces cannot interfere with the reflections of the two inner surfaces. The medium between the two plates is usually air with a unit refractive index. The laser beam under measurement is collimated by a lens and incident on the SFPI. The beam transmitted through the SFPI is focused by another lens onto the photodetector of a laser power meter. When a beam with unit amplitude is incident at angle θ on the inner surface of an SFPI, multiple reflections take place at the two inner surfaces and produce a series of transmitted beams whose amplitudes fall off progressively. In Figure 52.10, only three incident rays with a few reflections are plotted. The phase difference between two successive transmitted beams is

$$\Delta\phi = \frac{4\pi D}{\lambda \cos(\theta)} \tag{52.16}$$

Interference occurs among the amplitude of the transmitted beams. The intensity of the combination of the transmitted beam is given by

$$I = \left| T \sum_{k=0}^{\infty} R^k \exp(-ik\Delta\phi) \right|^2 \tag{52.17}$$

where R and $T = 1 - R$ are the power reflectivity and transmission coefficient of the inner surfaces of the SFPI, respectively, and the reflectivity of the outer surfaces of the SFPI is neglected. The laser power meter measures the power of the transmitted beams. Note that Equation 52.8 can be reduced to Equation 52.17 by letting the amplitude $\rightarrow T$, $\rho \rightarrow R < 1$, and $N \rightarrow \infty$. Therefore, the I obtained in Equation 52.17 can also be described by the curve shown in Figure 52.8. The full width at half the maximum (FWHM) power of I can be found by solving Equation 52.17. The result is

$$\Delta\phi_{\text{FWHM}} = 4\sin^{-1}\left(\frac{1-R}{2R^{1/2}}\right) \tag{52.18}$$

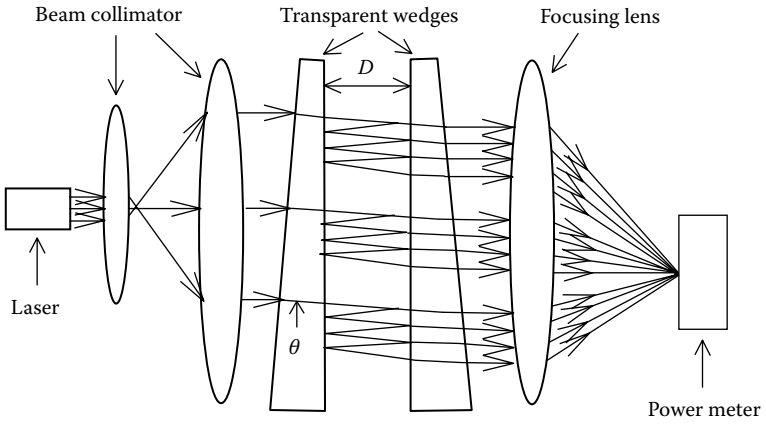

FIGURE 52.10 Scheme of an SFPI. Only three incident rays and a few reflections are plotted.

When R is close to 1, the right-hand side of Equation 52.18 is close to zero. We have

$$\Delta\phi_{\text{FWHM}} = \frac{2(1-R)}{2R^{1/2}} \tag{52.19}$$

Equation 52.19 shows that the fringe width of I reduces as R is increased, because larger R results in more reflections between the two inner surfaces of the SFPI. In an SFPI, the beam is usually arranged to incident at normal on the inner surface. θ becomes zero. Combining Equations 52.10 and 52.16 results in

$$\lambda = \frac{2D}{m} \tag{52.20}$$

where λ is the wavelength at which the peak of I appears. Figure 52.8 shows that an SFPI functions like a multibandpass filter. The central wavelengths of the bands (fringes) are given by Equation 52.20 and can be adjusted by adjusting D. The FWHM of the bands is given by Equation 52.19. The spacing between two adjacent bands in terms of wavelength can be obtained by differentiating Equation 52.20 with respect to m, eliminating m, and letting $\Delta m = 1$. The result is

$$\Delta\lambda = \frac{\lambda^2}{2D} \tag{52.21}$$

$\Delta\lambda$ is known as the free spectral range (FSR) of an SFPI. The laser beam under measurement must have a wavelength bandwidth smaller than the FSR to ensure that the beam can transmit only through one band. When D is scanned, the transmitted wavelength is scanned, and the laser power meter measures and outputs the beam spectrum. The measurement resolution of an SFPI is limited by $\Delta\phi_{\text{FWHM}}$. Most SFPIs have an $R > 0.95$ to reduce the $\Delta\phi_{\text{FWHM}}$. The characteristics of an SFPI can be described by the fringe finesse F, defined as

$$F = \frac{2\pi}{\Delta\phi_{\text{FWHM}}} = \frac{\pi R^{1/2}}{1-R} \tag{52.22}$$

where 2π is the period of the fringes given by Equation 52.10 in terms of phase. An SFPI usually has a resolution of FSR/100. For λ = 500 nm and D = 5 mm, the FSR is 0.025 nm, and the resolution is 0.00025 nm. Compared with monochromators, SFPIs are more expensive, and they have much higher resolution and a much smaller wavelength range.

More information about SFPIs can be found in many advanced optics textbooks such as Ref. [5]. A product-orientated description of Fabry–Perot interferometers can be found in manufacturers' catalogs such as Ref. [8].

52.4 Measurement of Laser Wavelength

For single-mode and narrow-linewidth lasers, the spectrum measurement reduces to wavelength measurement. Laser wavelength can be measured to a higher accuracy by the use of techniques that are not much different from those used to measure the spectrum. A laser wavemeter is an instrument designed to measure the wavelength without knowing the details of the spectrum.

52.4.1 Michelson CW Laser Wavemeter

Figure 52.11 shows the scheme of a widely used Michelson CW laser wavemeter that consists of a Michelson interferometer (MI), a laser power meter, and a computer system for data processing. The MI has two optical arms formed by a beam splitter and two mirrors, respectively. Mirror M_1 can be moved by a stepper motor driving system, and thereby the arm length z_1 can be changed. The position of mirror M_2 is fixed, and

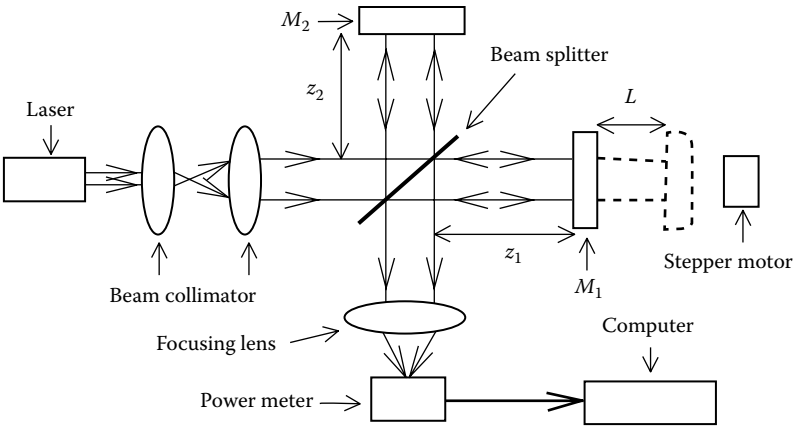

FIGURE 52.11 Scheme of a Michelson CW laser wavemeter.

the arm length z_2 cannot be changed. Two lenses collimate the laser beam under measurement. The beam splitter splits the collimated beam into two. The two beams propagate in the two arms and are reflected by the two mirrors back to the beam splitter, respectively. Then the beam splitter recombines the two beams. Interference occurs between these two beams. Another lens focuses the combined beams onto the photodetector of a laser power meter. The computer system processes the output data of the laser power meter. The intensity I of the two combined beams can be described by Equation 52.6. As M_1 is moved, z_1 is changed, the path difference $|z_2 - z_1|$ between the two optical arms varies, and I varies periodically. The computer counts the number of the varying period of I, known as *counting the fringes*. Equation 52.23 relates the wavelength λ under measurement, M_1 moving distance L, and the counted fringe number $m + \Delta m$ by

$$(m + \Delta m)\lambda = 2L \tag{52.23}$$

where
- m is an integer
- Δm is a fraction
- the factor of 2 is introduced because the beam round-trip distance is considered

A He–Ne laser with accurately known wavelength λ_H is used as a calibration source. For the He–Ne laser, there is the relation

$$(m_H + \Delta m_H) = 2L \tag{52.24}$$

where
- m_H is another integer
- Δm_H is another fraction

Combining Equations 52.23 and 52.24 results in

$$\lambda = \frac{m_H + \Delta m_H}{m + \Delta m}\lambda_H \tag{52.25}$$

For $L = 500$ mm and $\lambda \approx 500$ nm, Equations 52.23 and 52.24 give $m \approx 2 \times 10^6$ and $m_H \approx 2 \times 10^6$. If Δm and Δm_H can be counted to an accuracy of 0.1, Equation 52.25 can provide six significant digits. Thus, λ can be calculated to a relative accuracy of about 10^{-6}. The commonly used commercial Michelson CW laser wavemeters have a relative measurement accuracy from 10^{-4} to 10^{-7}. The measurement range is usually from 400 nm to 1.1 μm, limited by the spectral range of the silicon photodetector used.

Steadily moving M_1 over a distance of 500 mm or so can take several seconds, and the computer is counting fringes during the entire moving period of M_1. Several seconds is much longer than the pulse duration of most pulsed lasers. Thus, the computer will miss fringes in the period of time between two successive pulses when measuring the wavelength of a pulsed laser, and the measurement result will be erroneous. To measure the wavelength of pulsed lasers, the laser wavemeter must not have any moving parts and must be capable of taking data instantaneously.

More information about MIs can be found in many advanced optics textbooks such as Ref. [5]. Reference [9] presents a comprehensive study about the design and development of a MI CW laser wavemeter that achieves an accuracy of a few parts in 10^9.

52.4.2 Pulsed Laser Wavemeter

Figure 52.12 shows the scheme of a Fizeau pulsed laser wavemeter, which consists of a Fizeau wedge, a charge-coupled device (CCD) linear sensing array with 1024 pixels, a computer system for data processing, and an optical collimation system. The Fizeau wedge is made of a transparent material such as glass. The wedge has two flat surfaces. The angle α between the two surfaces is a few milliradians. The optical thickness $l(x)$ of the wedge is about 2 mm and varies linearly along the wedge. The optical system collimates the laser beam under measurement. The collimated beam is incident on the wedge. Both surfaces of the wedge reflect the incident beam. The two reflected beams form tens of spatial interference fringes on the CCD array. The CCD array detects the interference fringes and sends the data to the computer for processing. A Fizeau wavemeter does not have any moving parts and can measure the wavelength of pulsed lasers. It can be shown that the fringe period p is proportional to the wavelength λ under measurement by

$$p = F_1(\alpha)\lambda \tag{52.26}$$

where $F_1(\alpha)$ is a function of α. A He–Ne laser with accurately known wavelength λ_H is used separately as a calibration source. The He–Ne laser also forms spatial interference fringes on the CCD array with a fringe period p_H proportional to λ_H by

$$p_H = F_1(\alpha)\lambda_H \tag{52.27}$$

The data processing algorithm used in Fizeau wavemeters has two steps. λ is first calculated by combining Equations 52.26 and 52.27:

$$\lambda_1 = p\frac{\lambda_H}{p_H} \tag{52.28}$$

In Equation 52.28, the symbol λ_1 denotes the wavelength calculated in the first step because λ_1 is still not accurate enough. The data processing algorithm can calculate the fringe period p and p_H to an accuracy of

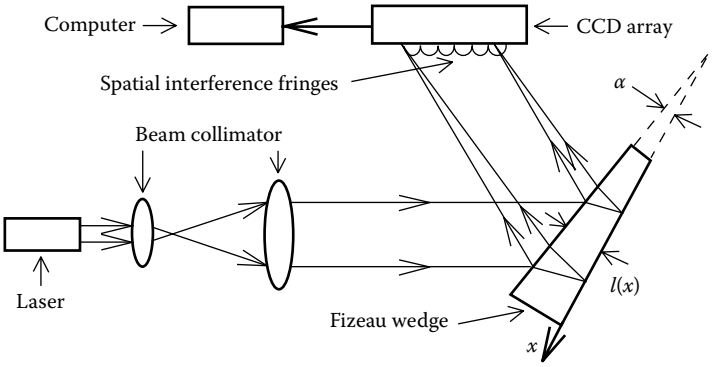

FIGURE 52.12 Scheme of a Fizeau pulsed laser wavemeter.

higher than $10^{-4}p$ and $10^{-4}p_H$ utilizing the 1024 sensing data provided by the CCD array. Thus, Equation 52.28 can provide λ_1 to an accuracy higher than $10^{-4}\lambda_1$, and λ must fall somewhere inside the range

$$\lambda_1 - 10^{-4}\lambda_1 < \lambda < \lambda_1 + 10^{-4}\lambda_1 \tag{52.29}$$

Any point on the CCD array corresponds to a point on the wedge with a certain optical thickness $l(x)$. It can be shown that at a given point on the CCD array, there is such a relation for λ and λ_H that

$$(m + \Delta m)\lambda = F_2[l(x)] \tag{52.30}$$

$$(m_H + \Delta m_H)\lambda_H = F_2[l(x)] \tag{52.31}$$

where

m and m_H are two integers and are unknown
Δm and Δm_H are two fraction orders at this point on the CCD array and can be measured
$F_2[l(x)]$ is a function of $l(x)$
$l(x)$ is the thickness of the wedge at the point corresponding to the point on the CCD array

In the second step of the data processing, λ is calculated by combining Equations 52.30 and 52.31. The result is

$$\lambda_2 = \frac{m_H + \Delta m_H}{m + \Delta m}\lambda_H \tag{52.32}$$

In Equation 52.32, we use the symbol λ_2 to denote the wavelength calculated, because λ_2 is still not necessarily equal to λ. A number of test m and m_H values are inserted into Equation 52.32 and result in a number of different λ_2 values. It can be shown that only one combination of m and m_H can result in a λ_2 that falls inside the range of Equation 52.29. This λ_2 is accepted as λ. m and m_H are of the order of 10^5, and Δm and Δm_H can be measured to an accuracy of 0.01. Therefore, Equation 52.32 can provide Δ to an accuracy of 10^{-6}. The commercial Fizeau pulsed wavemeters have a measurement accuracy of $10^{-5}\,\lambda$. The measurement spectral range is from 400 nm to 1.1 μm, limited by the CCD array, which is made of silicon material. More information about Fizeau wedges can be found in many advanced optics textbooks such as Ref. [5]. Readers interested in learning more about the design and development of Fizeau pulsed wavemeters will find Ref. [10] to be a good starting point.

52.5 Instrumentation and Components

Table 52.1 lists a few companies manufacturing photodetectors, laser power meters, diffraction gratings, monochromators, SFPIs, Michelson CW laser wavemeters, and Fizeau pulsed laser wavemeters. The price ranges of these instruments and components are also listed in Table 52.1. Table 52.2 lists the

TABLE 52.1 Manufacturers, Components and Instruments, and Price Ranges

Product Description	Manufacturer
Thermopile for laser power meters	Coherent, Newport
Photodiode head for laser power meters	Coherent, Newport
Pyroelectric probe head for laser power meters	Coherent, Newport
Laser power meter (including one detector head)	Coherent, Newport
Integration sphere	Newport, Oriel

address of these companies. These two tables are far from exhaustive. Interested readers could consult two excellent books, *Laser Focus World Buyers Guide* [11] and *Photonics Buyers' Guide* [12]. These two books are published annually and contain up-to-date information about most optical and laser manufacturers in the United States and their products.

Defining Terms

Continuous-wave (CW) laser power: Laser power that does not vary with time.

Laser spectrum: Laser power–wavelength profile.

Laser wavelength: The spatial period of a laser electric field.

Pulsed laser power: Laser power that lasts only a short period of time.

Martin Maier
Institut National de la Recherche Scientifique

53.1 Introduction

Fiber optics is a fundamental part of most computer and communications networks and devices. This chapter focuses on the principle of fiber-optics for a variety of applications mainly in telecommunications and fiber-optic sensors. Starting from the very basic concepts of optics and photonic systems, the principles of the loss mechanism in fibers are explained in detail including extrinsic (bending, connector, and launching) losses and intrinsic (absorption and scattering) losses. The loss mechanisms of fiber-optics are explained in detail for sensor applications and traditional optical time domain reflectometry (OTDR) methods. Standard attenuation test techniques are also explained. Finally, this chapter provides useful references and list of the manufacturers (Table 53.1) for fiber-optics equipment and devices.

53.2 Basic Concepts

53.2.1 Light and Optics

Light or visible light is the portion of electromagnetic spectrum that is visible to the human eye. Visible light corresponds to the wavelength range from 390 to 750 nm. However, in physics, the term light often comprises the two adjacent regions of infrared (higher wavelengths) and ultraviolet (lower wavelengths), not visible to the human eye. Primary properties of light are intensity, propagation direction, wavelength (frequency), polarization, and phase. The light speed in vacuum is however one of the fundamental constants of nature and is about 300,000 km/s.

The branch of physics, which involves the behavior and properties of light, is known as optics. The science of optics studies the interaction of light with matter and explores the construction of instruments that use or detect the related phenomena. The aforementioned properties of light are manipulated and detected using the measurement and instruments for a particular purpose. Applications vary from photographic imaging to high-speed data transmission via fibers. Depending on the application, a different optical signal processing scheme may be utilized to expand, condense, collimate, reflect, polarize, filter, diffuse, absorb, refract, or scatter the generated light. The desired information modulated on the light is detected by the appropriate instrument. Practical applications of optics are found in a variety of technologies including mirrors, lenses, telescopes, microscopes, lasers, fiber optics (telecommunication and sensors), and medicine.

53.2.2 Fiber Optics

During the past three decades, fiber optics has attracted considerable attention as the light transmission media. They are now widely used in telecommunication applications and enable us to transmit at longer distances and with higher bandwidth (data rates) compared to other forms of telecommunication. Fibers are also used for a variety of other applications, including sensors and fiber lasers.

In principle, an optical fiber acts as a waveguide or "light pipe" for the light propagating between the two ends of the fiber. In fact, a fiber-optic system is similar to the copper wire system that fiber optics is replacing. The difference is that fiber optics uses light pulses to transmit information down fiber lines instead of using electronic pulses inside the copper lines. It is a circular dielectric glass* waveguide, which consists of a core (central glass) surrounded by a concentric cladding material with a slightly lower (≈1%) refractive index. Because of *total internal reflection,* the light is confined to the core if the angular condition of total internal reflection is met. For this to happen, not leaking out, the light must strike the boundary with an angle greater than the critical angle $\theta_{c,}$ which occurs only when light enters the fiber within a certain range of angles $\phi_{max.}$ Hence, the acceptance and transmission of light depends greatly on the angle at which the light enters the fiber. The angle must be less than the *critical acceptance angle* of the particular fiber being used, as shown in Figure 53.1. This angle depends on the difference of the refractive index of the core and cladding. Light then travels along the fiber bouncing back and forth of the boundary.

* Some other polymers are also used.

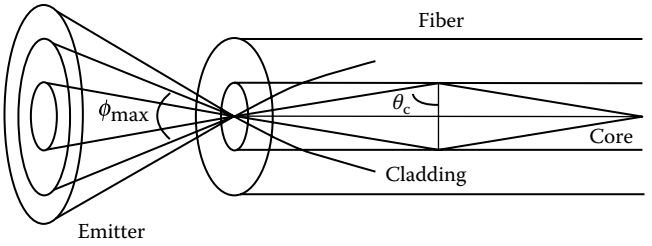

FIGURE 53.1 An optical fiber is a circular dielectric glass waveguide that can efficiently transport optical energy. It consists of a central glass core surrounded by a concentric cladding material. An important requirement for the connection of a light source is that sufficient amount of useful light must be coupled into the fiber. The core has a higher index of refraction than the cladding. Therefore, light is confined to the core only if the angular condition of total internal reflection is met. The acceptance and transmission of light depends greatly upon the angle at which the light rays enter the fiber, and it must be less than the *critical acceptance angle* of a particular fiber.

Theoretically, light propagation in fibers can be treated in a number of ways. For example, in treating propagation by modes, the fibers are viewed as optical waveguides (such as single-mode fibers), whereas treatment by rays is an approximate description of fibers with diameters much greater than the wavelength (such as multimode fibers).

There are three basic types of fibers: single-mode step index, multimode graded index, and multimode step index, as shown in Figure 53.2a through c, respectively. The characteristics of optical losses in these three types of fibers vary slightly due to differences in construction and the nature of propagation of light. For example, in the case of multimode step-index fibers, light striking the core-cladding junction at an angle greater than the angle of internal reflection passes through and becomes absorbed by the opaque jacket. This represents a significant source of attenuation, limiting the injection efficiency at the transmitting end.

Single-mode fibers, shown in Figure 53.2a, are used in transmitting broadband signals over large distances. By choosing a very small core diameter, these fibers allow only one mode of propagation through the fiber. Their attenuation is generally very small and their transmission band is large. Owing to material properties, low attenuations (~0.25 dB/km) can be expected for wavelengths around 1.3–1.6 μm. Additional attenuation arises from splices and fiber bending. The most common type of single-mode fiber has a core diameter of 8–10 μm and is designed for use in the near infrared (1.5 μm). The mode structure depends on the wavelength of the light used, so that this type of fiber actually supports a small number of additional modes at visible wavelengths. Single-mode fiber provides a higher transmission rate and up to 50 times more distance than multimode, but it also costs more. Single-mode fiber has a much smaller core than multimode fiber and virtually eliminates any distortion that could result from overlapping light pulses, thus providing the least signal attenuation and the highest transmission speeds of any fiber cable type. Single-mode fiber is used in many applications where data are sent at multifrequency (wavelength division multiplexing [WDM]), so only one cable is needed (single-mode on one single fiber).

Multimode graded-index fibers have medium size cores (50–100 μm) and refractive indices that decrease radially outward. The two optical materials with different refractive indices are mixed together in such a way that the index of refraction decreases smoothly with distance from the fiber axis. The graded index causes the light to gradually bend back and forth across the axis in sinusoidal manner when very small injection angles are used. Hence, no abrupt reflection from the core-cladding boundary occurs. This greatly reduces the light losses from the fiber and results in better bandwidth and power efficiency. Indeed, the index profile is chosen to minimize the difference in axial propagation speeds of the various rays in the fiber. Therefore, the graded-index fibers reduce the total dispersion experienced by light wave signals compared to step-index versions. They also allow the use of simpler splicing techniques. Light waves are dispersed into numerous paths, or modes, as they travel through the cable's core typically at 850 or 1300 nm. Typical multimode fiber core diameters are 50, 62.5, and 100 μm. In the United States, the most common size is 62.5 μm.

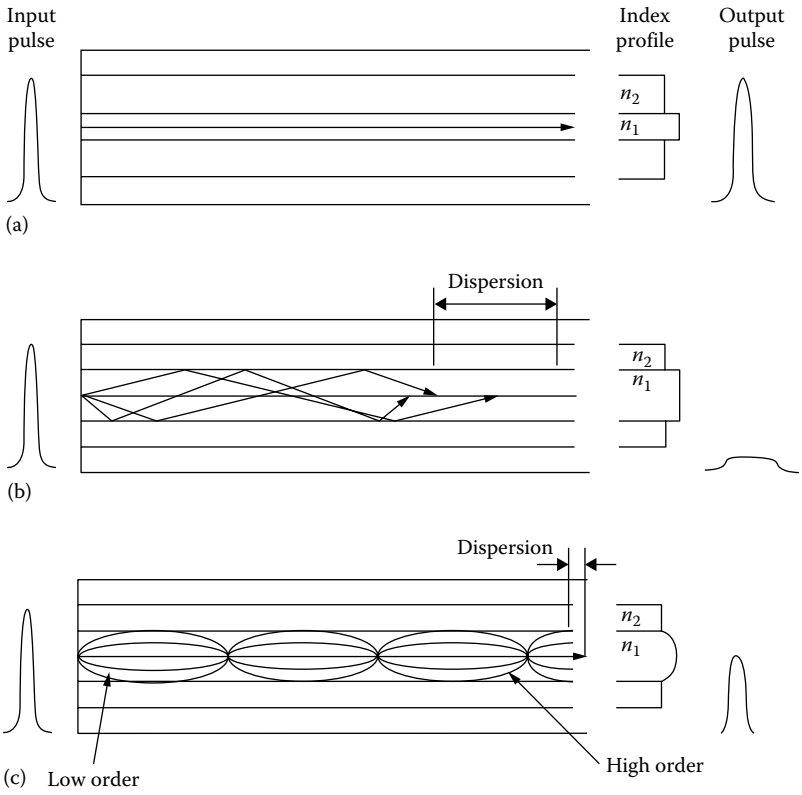

FIGURE 53.2 Three basic types of fibers: (a) single-mode step index that is used in transmitting broadband signals over large distances, (b) multimode step index in which refractive index changes between fiber and cladding and rays striking the core-cladding junction reflect back in the glass, and (c) multimode graded index, obtained by mixing two optical materials with different refractive indices together in such a way that the index of refraction decreases smoothly with distance from the fiber axis.

Special purpose fibers are another type of fibers usually made for a specific application. They are usually fabricated with noncylindrical core and/or cladding layer, usually with an elliptical or rectangular cross section. The most important examples of these fibers are polarization maintaining fibers, photonic crystal fibers, and plastic optical fibers (POFs).

There are two basic cable designs for fiber optics called loose-tube cables and tight-buffered cables. While the former is used in the majority of outside-plant installation such as in aerial, duct, and direct-buried applications, the latter is utilized for inside buildings. The modular buffer-tube design permits easy drop-off of groups of fibers at intermediate points, without interfering with other protected buffer tubes being routed to other locations. The loose-tube design also helps in the identification and administration of fibers in the system. Both single- and multifiber tight-buffered cables are available. Single-fiber tight-buffered cables are used as pigtails, patch cords, and jumpers to terminate loose-tube cables directly into optoelectronic transmitters, receivers, and other active and passive components. Multifiber tight-buffered cables are also available and are used primarily for alternative routing and handling flexibility and ease within buildings. There are a variety of fiber cable types such as distribution cable, indoor/outdoor tight buffer, indoor/outdoor breakout, aerial cables, hybrid and composite cables, armored cables, low-smoke zero halogen (LSZH), corning cable systems, freedom LTS cables, and Kron indoor/outdoor dry loose-tube cables. Depending on the application and the role of the fiber, different types of fibers are employed in an optical system.

Glass optical fibers are usually made from silica. Silica exhibits good transmission over a wide wavelength range and has extremely low loss near the infrared regime (~1.5 μm). In addition, for silica fibers

cleaving and fusion splicing is relatively effective. They also have high mechanical strength against pulling and bending. Notwithstanding that, other materials such as fluorozirconate, fluoroaluminate, and chalcogenide glasses and crystalline materials like sapphire are sometimes used for longer-wavelength infrared or other specialized applications. While bandwidth is the primary consideration in the use of fiber optics in communication applications, light attenuation characteristics are equally important. The overall quality of a fiber-optic light guide is determined by its light transmissivity, defined as the ratio of the output light to that put into the fiber.

53.2.3 Light Sources for Fiber Optics

The most commonly used optical transmitters are semiconductor devices such as light-emitting diodes (LEDs) and laser diodes. The difference between LEDs and laser diodes is that LEDs produce incoherent light, while laser diodes produce coherent light. The emitted light is incoherent with a relatively wide spectral width of 30–60 nm. LED light transmission is also inefficient, with only about 1% of input power, or about 100 μW, eventually converted into launched power, which has been coupled into the optical fiber. However, due to their relatively simple design, LEDs are very useful for low-cost applications. LEDs are suitable primarily for local-area-network applications with bit rates of 10–100 Mbit/s and transmission distances of a few kilometers. They are currently in use for local-area WDM networks.

A semiconductor laser emits light through stimulated emission rather than spontaneous emission, which results in high output power (~100 mW) as well as other benefits related to the nature of coherent light. The output of a laser is relatively directional, allowing high coupling efficiency (~50%) into single-mode fiber. The narrow spectral width also allows for high bit rates since it reduces the effect of chromatic dispersion. Furthermore, semiconductor lasers can be modulated directly at high frequencies. Laser diodes are often directly modulated, that is, the light output is controlled by a current applied directly to the device. For very high data rates or very long-distance links, a laser source may be operated continuous wave in an external modulation scheme. The choice of wavelength is also determined by the transmission characteristics of optical fibers.

53.3 Losses in Fiber Optics

Attenuation in fiber optics, also known as transmission loss, is the reduction in intensity of the light with respect to distance as a result of propagation through the fiber optic. By definition, signal attenuation is defined as the ratio of optical input power to the optical output power. Attenuation coefficients in fiber optics expressed in units of dB/km are an important factor, which limits the data transmission across large distances. It was shown that attenuation in optical fiber is caused primarily by both scattering and absorption. Scattering, also known as diffuse reflection, is a consequence of the reflection of light ray in random directions due to the total internal reflection at molecular level in the glass structure of the fiber core. These sources of fiber loss, also known as intrinsic fiber loss, are discussed in more detail in the next section.

The interpretation and treatment of "optical loss" is different for each individual instrumentation and measurement activity. It entirely depends on the purpose and method of measurements. For example, scattering of the light (radiation) from clouds is a useful property for determining atmospheric characteristics, whereas scattering of light in optical fibers may not be desirable due to resulting losses in power and decrease in efficiency. While many instrumentation systems (e.g., imaging) make use of scattering, absorption, refraction, and reflection as useful properties, in others mainly telecommunications, these are considered to be mere losses that cause undesirable attenuation.

This chapter concentrates on losses in fiber optics to clearly demonstrate the fundamental principles. Nevertheless, it is important to recognize that the same losses in fiber optics may not be regarded as losses in other applications. It will be shown here that losses in fiber optics have useful properties in determining the optical fiber characteristics.

53.3.1 Loss Mechanisms in Optical Fibers

Although due to the total internal reflection principle an optical signal is confined into the fiber core (i.e., no loss exists for the core-cladding interface), the light experiences attenuation as it travels through the fiber. This attenuation mechanism in fiber can be categorized into extrinsic and intrinsic losses. Intrinsic loss is related to the attenuation mechanisms occurring within the fiber core material only, whereas extrinsic attenuation is due to nonideal modifications of the fiber or external damages, which consequently change the behavior of the fiber-optic media. These mechanisms are explained in detail in the following subsections.

53.3.2 Extrinsic Fiber Losses

Extrinsic fiber losses are generated from sources outside the optical fiber core, which finally affect the transmission of light down the fiber. These losses are not functions of the fiber core materials; they are specific to geometry and handling problems. There are three basic types of extrinsic losses, namely, bending losses, launching losses, and connector losses.

53.3.2.1 Bending Losses

Bending losses are the result of distortion of the fiber cable from the ideal configuration and are classified according to the radius of curvature of the bending: microbend loss versus macrobend loss. The bending loss depends on the radius of the curvature; the smaller the radius of the curvature is, the greater is the bending loss. For instance, kinks or microbends are an important source of attenuation and generally impose higher bending loss compared to macrobends.

Microbends are generated by microscopic discontinuities and imperfections as a result of deformation or damage in the fiber structure. As exemplified in Figure 53.3, irregularly distributed undulations in the fiber with radius of curvature of a few millimeters and deviations from the mean line of a few micrometers can cause microbends. Imperfect coating and improper cabling procedures increase the loss of microbends. Light wave signals experience higher losses because low-order modes become coupled with high-order modes that are naturally more lossy. Microbending is usually distributed along the fiber.

Microbending is a critical feature of a fiber and can cause significant transmission loss. External forces (such as mechanical forces, stress, or crushing forces) or environmental factors (like temperature and pressure) can damage the smooth cylindrical surface of fiber or the cable jacket surrounding the fiber, hence affecting the quality of the fiber as a transmission medium. These damages can be caused by

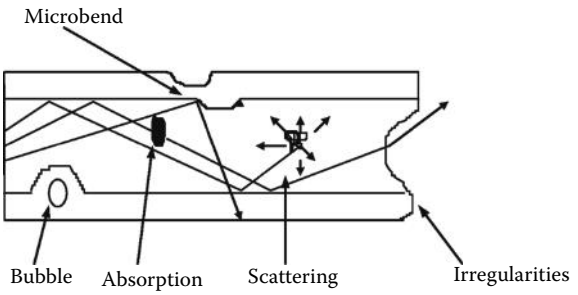

FIGURE 53.3 An important cause of attenuation is due to microbending of the fiber. This is due to irregularly distributed undulations in the fiber and from mechanical tensile forces when fiber is pressed against a rough surface. Absorption losses are caused by the presence of impurities such as traces of metal ions (e.g., Cu^{2+}, Fe^{3+}) and hydroxyl (OH^-) ions. Despite the careful manufacturing techniques, fibers may have inhomogeneous, disordered, amorphous structures. Power losses due to scattering are caused by such imperfections in the core material and irregularities between the junction and cladding.

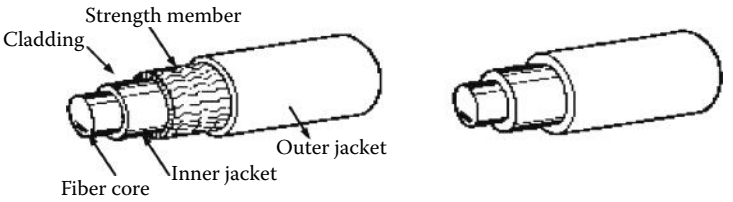

FIGURE 53.4 Some of the fiber losses may be avoided by careful cable constructions, eliminating excessive mechanical forces, and controlling the temperature variations of the cable assembly. This is achieved by a loose encasing of the fiber in a plastic sheath or by covering of the fiber with soft flexible materials. Most optical fibers constructed for communication purposes have inner and outer jackets for protection and strength.

poor or incorrect fiber processing during cabling, low temperature, and high pressure. It is interesting to mention that while the fiber may appear normal under standard conditions, improper handling and incorrect installation can severely cause microbending losses throughout the fiber. These losses may be avoided by careful cable constructions, protecting from excessive mechanical forces, and controlling the temperature variations of the fiber. Often this is achieved by a loose encasing of the fiber in a plastic sheath or by covering the fiber with soft flexible material, as shown in Figure 53.4.

Macrobend losses are observed when a fiber bend's radius of curvature is large compared to the fiber diameter. These bends become a great source of loss when the radius of curvature is less than several centimeters. In this situation, the optical path traveled by light is shorter at the inner side of the bend than the outer side. Thus, light can be lost when the angle of incidence (equivalently the fiber bend radius) exceeds the critical angle. In other words, part of the light is transformed to higher-order modes that are more lossy and radiates out of the fiber. This is more problematic for fibers with low numerical apertures, that is, larger critical angles. Usually improper cable handling, such as poor reeling and poor rolling, creates macrobending losses during network installation. Rather than microbending, macrobending is localized and the bend might not be simply identified on troubleshooting.

The fiber sensitivity to macrobending losses can be reduced by increasing the refractive index of the fiber core and/or increasing the overall fiber diameter. However, increases in the fiber core diameter increase the number of propagating modes in the fiber, which are more lossy leading to more sensitive fibers. Generally, extrinsic losses are less important for fibers with high numerical apertures. Bending losses also depend on the wavelength of light and generally are higher for longer wavelength; therefore, longer wavelengths in U band (1625–1675 nm) have been recommended by ITU-T for the fiber link monitoring application.

53.3.2.2 Launching Losses

Since the maximum transmission power is limited due to practical constraints (laser peak power and nonlinearities), it is generally desirable to maximize the power utilization generated by the light source connected to a fiber. In practice, more than half of the generated power by light sources may be lost at the interface between a laser diode and a single-mode optical fiber.

The term *launching loss* refers to an optical fiber not being able to propagate all the incoming light rays from an optical source. These occur during the process of coupling light into the fiber (e.g., losses at the interface stages). Rays launched outside the angle of acceptance excite only dissipative radiation modes in the fiber. In general, elaborate techniques have been developed to realize efficient coupling between the light source and the fiber, mainly achieved by means of condensers and focusing lenses. The focused input light beam needs to be carefully matched to the fiber for an efficient coupling.

Similarly, once the light is transmitted through the fiber, output fiber characteristics must also match the output target characteristics to be able to couple the largest proportion of the transmitted light. This can be done by suitably focusing lens arrangements at the output. There are also initial face (Fresnel)

losses due to reflections at the entrance aperture. The Fresnel losses are greater if the fiber/source is air coupled. Hence, most optical couplings to a fiber utilize index-matching materials to substantially reduce coupling loss.

53.3.2.3 Connector Losses

A fiber-optic cable may be terminated with connectors creating a temporary connection between two fibers and/or a fiber with a network component. However, splicing creates a permanent joint between the two fibers. Fiber terminations are of great importance because of their insertion loss; hence, they should be correctly installed and be protected against dirt and damage for a correctly selected connector. Ever since the introduction of fiber optics, more than 80 types of connector have been manufactured and tens of installation schemes have been proposed. A fiber-optic connector is basically a rigid cylindrical barrel surrounded by a sleeve that holds the barrel in its mating socket.

Significant insertion loss may arise in fiber connectors and splices of the cores of the joined fibers having unequal diameters or misaligned centers, or if their axes are tilted. As shown in Figure 53.5, mismatching of fiber diameters causes losses that can be approximated by $-10 \log(d/D)$. There are other connection losses such as offsets or tilts or air gaps between fibers and poor surface finishes. Some of these are illustrated in Figure 53.5. However, to take full advantage of fiber characteristics in transmission systems, the contribution of losses from other sources must be minimized. The attenuation $a_s(d)$ due to coupling efficiency may be expressed as

$$a_s(d) = -10 \text{ dB} \log \eta(d) \tag{53.1}$$

where $\eta(d)$ is the coupling coefficient.

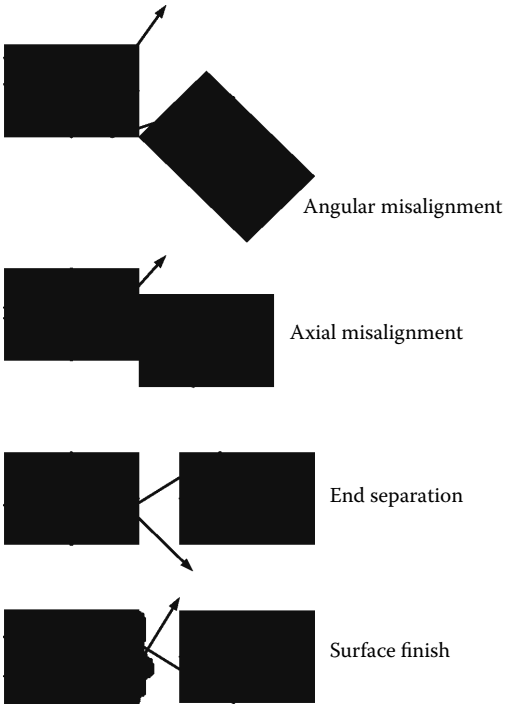

FIGURE 53.5 Some of the fiber losses may be avoided by careful cable constructions, eliminating excessive mechanical forces, and controlling the temperature variations of the cable assembly. This is achieved by a loose encasing of the fiber in a plastic sheath or by covering the fiber with soft flexible materials. Most optical fibers constructed for communication purposes have inner and outer jackets for protection and strength.

Different mating schemes such as "push and click," "turn and latch" ("bayonet"), or screw-in (threaded) can be used for connector implementation. Also depending on the type of fiber and application, various polishing profiles are used. For instance, for single-mode fiber, fiber ends are polished with a slight curvature, which is known as "physical contact" (PC) connection. However, polishing at an angle is called "angled physical contact" (APC) and has higher insertion loss compared to PC connections but suffers less from back reflection problems. Consequently, various connector different have been developed in different standard forms such as ferrule connector (or fiber channel [FC]), subscriber connector (square connector or standard connector [SC], straight tip [ST], lucent connector [LC]), or mechanical transfer registered jack (or media termination recommended jack [MTRJ]).

The loss leaking out of the angled surface is also known as gap loss. End gaps cause both insertion loss and return loss. The light emerging out of the connector spills over the receiving fiber core and is partially lost. In addition, the air gap between the fibers causes a reflection when the light faces the refractive index difference from the glass fiber to the air in the gap. This reflection (also known as the Fresnel reflection or back reflection) accounts for about 5% in typical flat polished connectors. In other words, no connector with an air gap can have less than 0.3 dB loss. Back reflection or simply optical return loss might be problematic in laser-based systems. To mitigate this problem, connectors use a number of polishing techniques to insure PC of the fiber ends and minimize back reflection. On mechanical splices, it is possible to reduce back reflection by using nonperpendicular cleaves, which cause back reflections to be absorbed in the cladding of the fiber.

Gap losses can also be viewed as a type of Fresnel loss as the fiber–air interface introduces Fresnel reflection losses. In this case, there are two major losses to be considered. The first takes place in the inner surface of the transmitting fiber, and the second occurs due to reflections from the surface of the second fiber. One way of eliminating these losses is by introducing a coupler that matches the optical impedances of the two materials. This arrangement results in matched reflection coefficients, which is analogous to matching of impedances.

In general, the positions and shapes of the fiber cores are controlled to tight manufacturing tolerances. Fibers having an attenuation of greater than 1 dB/km are rarely used in communication networks. Nevertheless, the attenuation of badly matched fibers may exceed 1 dB/km per connector or splice if they are badly handled during installation stages. Good coupling efficiency requires precise positioning of the fibers to center the cores. The simplest way to avoid connector losses is by splicing the two ends of the fibers permanently, either by gluing or by fusing them at high temperatures.

Splicing joins two fibers together and forms a continuous optical waveguide. Generally, splicing is realized by employing the arc fusion splicing method. In this technique, an electric arc is used to melt the fiber ends together. Mechanical fiber splices are additionally designed to be quicker and easier to install. Good splicing requires appropriate stripping, careful cleaning, and precision cleaving. A splice loss under 0.1 dB is typical. The complexity of this process makes fiber splicing much more difficult than splicing copper wire. All splicing techniques involve the use of an enclosure for protection afterward.

Similar to connector loss, splice loss is minimized when the two fiber cores are identical and perfectly aligned. The fiber ends must also be properly polished; a rough surface will scatter light and dirt can scatter and absorb light. Due to the small size of optical fibers, typical airborne dirt can be a major source of loss. Therefore, whenever connectors are not terminated, they should be covered to protect the ends from dirt. More importantly, one should never even touch the fiber end, since the oils on one's skin cause the fiber to attract dirt. It is also highly recommended to clean connectors with lint-free wipes moistened with isopropyl alcohol before connection and/or testing operations.

Usually fiber mismatches occur for two reasons: First, we occasionally need to interconnect dissimilar fibers, which produce difference in fiber index of the same nominal dimensions. Second, it is possible to have dissimilar fiber connections in optical systems designed for single- or multimode fibers. However, some system manufacturers provide guidelines on using various fibers, and some don't. For example, by connecting a smaller fiber (in diameter) to a larger one, the coupling loss will be minimal, limited only by the Fresnel loss. However, connecting larger fibers to smaller ones results in substantial losses.

53.3.3 Intrinsic Fiber Losses

Intrinsic fiber losses are those associated with the fiber-optic material itself and are considered the primary source of attenuation. There is no way to eliminate all impurities in fiber optics even with a precise manufacturing process. The total loss is proportional to the fiber length L and the attenuation coefficient α is expressed in decibels per kilometer of fiber. Intrinsic fiber losses are mainly caused by absorption and scattering because scattering and absorption occur when light wave signals interact with impurities in the fiber.

53.3.3.1 Material Absorption Losses

Absorption is the main source of intrinsic loss in optical fibers, which causes attenuation by converting optical power into vibration energy or other energy forms such as heat. Unlike scattering, absorption can be limited by controlling the amount of impurities during the manufacturing process. Note that as fiber is almost pure, it does not heat up because of absorption. In principle, absorption occurs when a light particle (i.e., photon) interacts with an electron and excites it to a higher energy level. In other words, it is caused by the material properties of the optical fiber and is usually explained by three important factors listed as follows:

- Imperfections in the atomic structure of the fiber material
- Intrinsic or basic fiber material properties
- Extrinsic fiber material properties (presence of impurities)

Intrinsic and extrinsic material properties are the main cause of absorption. Intrinsic absorption is caused by basic material properties of the fiber itself (i.e., imperfection, impurities, and undulation) and sets a minimal attenuation level due to total absorption loss. For this reason, silica (pure glass) is predominantly used in fiber optics because of its very low intrinsic absorption in the operational wavelength window of 700–1600 nm. Similar to most transmissive systems, the absorption loss depends on the fiber length with an exponential function of length. In silica glass, absorption is caused by the vibration of silicon–oxygen (Si–O) bonds. The interaction between the vibrating bond and the electromagnetic field of the optical signal causes intrinsic absorption. Hence, energy is transferred from the electromagnetic field to the bond. Absorption is also induced by the diffusion of hydrogen molecules into the glass fiber.

Extrinsic absorption is caused by impurities in the fiber such as iron, nickel, and chromium during fabrication. In this case, the ion transitions between energy levels cause absorption. Extrinsic absorption also occurs when hydroxyl ions (OH^-) are introduced into the fiber. Optical power is absorbed in the excitation of molecular vibrations of such impurities in the glass, as illustrated in Figure 53.6. One characteristic of absorption is that it occurs only in the vicinity of wavelengths corresponding to the natural oscillation frequencies or their harmonics of the particular material. In modern fibers, absorption losses are almost entirely due to OH^- ions. The fundamental vibration mode of these ions corresponds to $\lambda = 2.73$ μm and the harmonics at 1.37 and 0.95 μm. Dehydration techniques can be employed during the manufacturing process to reduce the presence of OH^- ions. As illustrated in Figure 53.6, absorption losses due to each type of impurity act like a band suppression filter, showing peak absorption at well-defined wavelengths. Absorption accounts for 3%–5% of fiber attenuation. In addition, the amount of water (OH^-) impurities in a fiber should be less than a few parts per billion as extrinsic absorption is only affected by the level of impurities present in the fiber.

53.3.3.2 Scattering Losses

The light traveling down the fiber core interacts with the silica molecules. Rayleigh scattering is the result of these elastic collisions between the light wave and the silica molecules in the fiber. Rayleigh scattering accounts for about 96% of attenuation in optical fiber. However, no attenuation occurs if the scattered light maintains an angle that only supports traveling in the forward direction within the core.

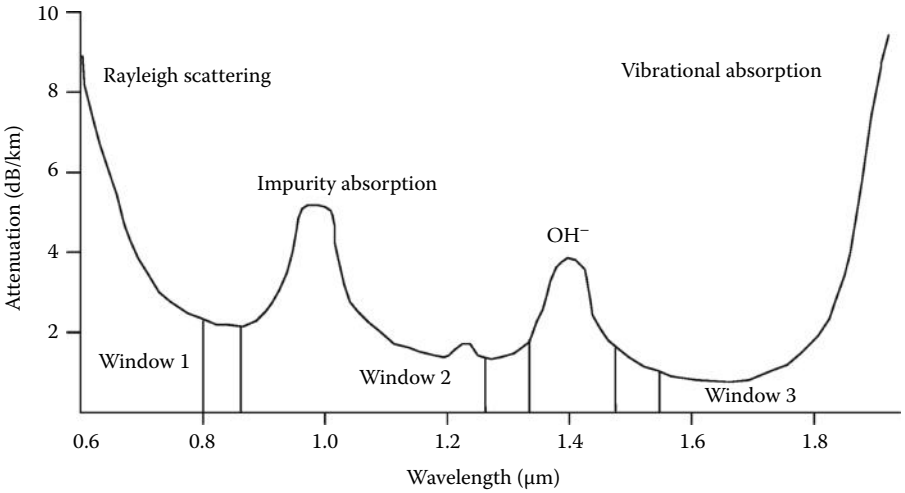

FIGURE 53.6 Attenuation characteristics of a typical optical fiber. The attenuation coefficient α varies against wavelength for all low-loss fused silica fiber due to Rayleigh scattering and impurity absorptions. The optical losses for wavelengths below 1 μm are mainly due to scattering. At longer wavelengths absorption losses are important, notably at 1.4 μm through absorption by OH^- ions. Above 1.6 μm, absorption due to impurities becomes dominant.

Otherwise, the light is diverted out of the core and attenuation occurs. In other words, depending on the incident angle, portion of the light propagates forward and the remaining portion deviates out and escapes from the fiber core. Some scattered light is reflected back toward the light source, which can be used in an optical time domain reflectometer for testing live (data carrying) fibers. The same principle applies to analyzing loss associated with localized events in the fiber such as splices, connectors, and bending.

Despite careful manufacturing techniques, most fibers are inhomogeneous and have disordered, amorphous structures, which cause power losses due to scattering caused by imperfections in the core material and irregularities between the junction and cladding. Generally, shorter wavelengths are scattered more than longer wavelengths. More precisely, wavelengths below 800 nm are useless for optical communication due to very high Rayleigh scattering attenuation. At the same time, propagation above 1700 nm is not possible due to high losses resulting from infrared absorption.

Inhomogeneities can be either structural or compositional in nature. In structural inhomogeneities, the basic molecular structure has random components, whereas in compositional inhomogeneity the chemical composition of the material varies. The net effect from either inhomogeneity is a fluctuation in the refractive index. As a rule of thumb, if the scale of these fluctuations is on the order of $\lambda/10$ or less, each irregularity acts as a scattering center. This is a form of Rayleigh scattering and is characterized by an effective absorption coefficient that is proportional to λ^{-4}. Rayleigh scattering can be caused by the existence of tiny dielectric inconsistencies in the glass. Because these perturbations are small with respect to the waves being propagated, light striking a Rayleigh imperfection scatters in all directions. Scattering losses are less at longer wavelengths, where the majority of the transmission losses are due to absorption from impurities such as ions. Rayleigh scattering losses are not localized, and they follow a distribution law throughout the fiber. However, they can be minimized by having low thermodynamic density fluctuations.

A small part of the scattered light propagates in the opposite direction. This backscattering has important characteristics and may be used for measuring fiber properties. Usually, the inhomogeneities in the glass are smaller than the wavelength λ of the light. The scattering losses in glass fibers approximately follow the Rayleigh scattering law; that is, they are very high for small wavelengths and decrease with increasing wavelength.

In general, optical losses in the glass cause the optical power in a fiber to fall off exponentially with the length L of the fiber:

$$P(L) = P(0)\ 10^{(-\alpha L/10\ \mathrm{dB})} \tag{53.2}$$

where

$P(0)$ denotes the optical power that couples to the fiber
$P(L)$ denotes the power remaining after length L
α is the attenuation coefficient indicating the rate of loss of optical power in dB/km

The product αL is called the *attenuation of the fiber*. An attenuation of 10 dB means that the optical power $P(L)$ at the end of the fiber is only 10% of the initial power $P(0)$. For instance, a 3 dB attenuation is equivalent to 50% and 1 dB to about 80% of $P(0)$. A typical attenuation coefficient α against wavelength λ is shown in Figure 53.6 for common low-loss fused silica fiber. The optical losses for wavelengths below 1 μm are mainly due to Rayleigh scattering. At longer wavelengths, absorption losses are important, notably at 1.4 μm through absorption by OH^- ions. Above 1.6 μm, absorption due to impurities becomes dominant. Because of attenuation, only limited wavelength ranges are appropriate for optical data transmission.

Although intrinsic fiber losses can be associated with the core index n_f, the core index plays an important role in determining the propagation time delay of optical signals. The propagation time delay t_p may be expressed by

$$t_p = n_f \frac{L}{c} \tag{53.3}$$

where

c denotes the velocity of light in the fiber
L denotes the fiber length

Another type of loss in optical fibers occurs due to the propagation of light at different angles.* For a given length of fiber, the high-order modes reflect more often and cover longer distances than the low-order modes. Therefore, high-order modes suffer from more losses, thus causing modal dispersion. Modal dispersion is one of the primary causes of rise time degradation for increasing fiber wavelengths. In addition, the propagation time varies with the index of refraction so that different wavelength components of the source spectrum have different travel times, thus causing chromatic dispersion.

53.4 Application of Fiber Loss Properties in Fiber Sensors

As mentioned earlier in this chapter, while fiber loss characteristics are undesirable for data transmission in telecommunication applications, the loss properties may be employed to develop high-accuracy sensing devices for a variety of applications. Fiber-optic-based sensors have significant advantages compared to conventional electric counterparts. They are highly sensitive (more than other technologies), configuration versatile (i.e., provide both localized and distributed sensing), chemically and physically passive, free of electromagnetic interference, and remotely powered. They also have a wide dynamic range and bandwidth, are available in extremely small size, are immune to electromagnetic interference and radio frequencies, and provide environmental ruggedness.

* Light propagating at shallow angles is called low-order mode, while light propagating at larger angles is called high-order mode.

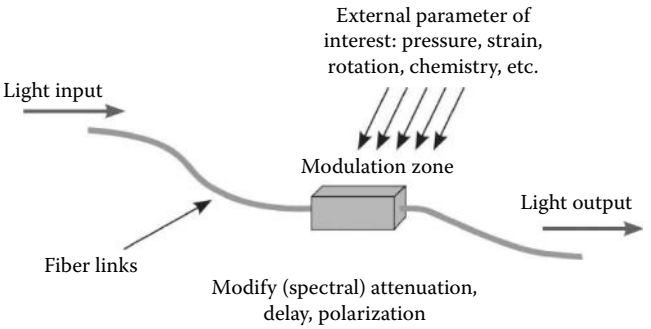

FIGURE 53.7 Operation principle of fiber sensors. In extrinsic fiber-optic sensors, the fiber mainly acts as a transmission medium for the modulated light beam by an environmental effect. In intrinsic fiber-optic sensors, the propagating light beam is modulated either directly or indirectly by the environmental effects.

The operation principle of fiber-optic sensors is depicted in Figure 53.7. As illustrated, in principle, any physical or chemical phenomenon, which can directly/indirectly change the loss properties of fiber transmission media, can be measured and controlled by monitoring the corresponding variations in the transmitted light wave power and/or rate. These include temperature, pressure, acoustics, linear and angular position, strain, voltage, current, liquid level, viscosity, torque, twisting, rotation, acceleration, and particle velocity. In these applications, the desired variable quantity to be monitored modulates the intensity, phase, polarization, wavelength, or transit time of light in the fiber.

Depending on the role of the fiber, fiber-optic sensors can generally be classified into two groups: intrinsic (or hybrid) fiber sensors and extrinsic fiber sensors (or all-fiber sensors). In intrinsic fiber sensors, fiber is utilized as the sensing element, where the propagating light is modulated by the environmental effects, whereas in extrinsic fiber sensors, the signals are relayed via fiber from a remote sensor (can also be fiber optics) to the optoelectronics, which process the signals. In its simplest form, a fiber-optic sensor is an intrinsic type, whose operation is based on intensity modulation. Spectral, interferometric, and distributed (multiplexing) mechanisms may also be employed for sensing application. Fluorescent-based fiber sensors are used in medical application and chemical sensing; fiber-optic gyros are used in navigation systems (most types of vehicles such as Boeing 777), pointing and tracking of satellite antennas.

Distributed sensing over very large distances is provided by intrinsic fiber-optic sensors. Figure 53.8 illustrates the general scheme of distributed sensing techniques based on backscattering of the launched optical signals to the fiber. Reflected and backscattered signals coming from different points in the fiber provide a continuous profile of temperature (external parameter of interest) versus distance. The spatial and temperature resolution as well as the reach length* of the system varies, depending on the application and technology. Some examples are provided in Figure 53.8.

In general, both OTDR and optical frequency domain reflectometry (OFDR) techniques may be employed for this purpose. For instance, distributed temperature sensing (DTS) is available by using a fiber that has an evanescent loss that varies with temperature or by analyzing the Raman scattering of the optical fiber. A continuous profile of temperature versus distance with special resolution of 1 m over very large distances such as 30 km within ±1 °C at a resolution of 0.01 °C with measurement times in order of minutes can be obtained. These so-called distributed sensor techniques are unique to fiber-optic technology. OTDR is addressed in greater detail in the next section.

Brillouin scattering (i.e., OFDR in fibers) is due to the interaction of light wave signals in a medium (such as crystal) with time-dependent optical density variations. From a quantum point of view, an incident light beam (photon) can be converted into a scattered light (photon) of slightly lower frequency (energy), usually propagating in the backward direction. Indeed, similar to sound waves, the backward propagating

* The longest distance for which the results are valid with acceptable accuracy.

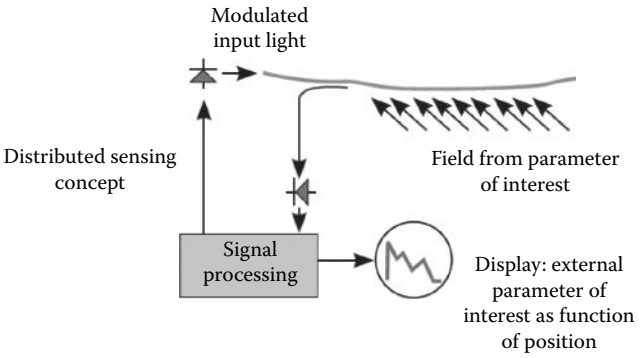

FIGURE 53.8 Distributed sensing using fiber-optic technology. Backscattering from different points of the fiber reflected back to the launch point at one fiber end can be measured. A continuous profile of temperature versus distance is obtained with special resolution of 1 m over very large distances such as 30 km within ±1 °C at a resolution of 0.01 °C with measurement times in order of minutes.

light experiences a Doppler shift, that is, frequency change. This frequency shift in the reflected light is known as *Brillouin frequency shift* (BFS) and can be measured by Brillouin spectrometers. The BFS for the reflected light is slightly lower than that of the launched light. BFS in fibers can be calculated from the effective refractive index n, the acoustic velocity v_a, and the vacuum wavelength λ as follows:

$$\nu_B = \frac{2nv_a}{\lambda} \tag{53.4}$$

In general, BFS depends on the material composition inside the fiber core, temperature, and pressure of the medium, which are exploited in fiber sensors.

53.5 Optical Time Domain Reflectometry

Time domain reflectometry, initially developed for conventional copper wires, is a well-known solution for infield monitoring of installed fiber links. OTDR is used to test fibers during fabrication, cabling, and warehousing; it is also used for troubleshooting deployed fiber infrastructures. The very first OTDR equipment has been implemented for optical carriers in long-distance transmission systems.

53.5.1 OTDR Principle

The principle of OTDR is based on the fact that as the optical pulse propagates through the fiber, both reflection and scattering result in a fraction of the optical signal being reflected back in the opposite direction. Rayleigh scattering and Fresnel reflections are physical causes of this behavior. Generally, the magnitude of the backscattered light depends on the Rayleigh scattering, fiber attenuation and imperfections, splices, and the launched light wave signal specifications (power and pulse width).

The OTDR equipment launches a series of short light pulses into the fiber and measures the backscattered light. A general schematic of an OTDR device is presented in Figure 53.9. The reflected signal arrives at the transmitter with a delay proportional to the corresponding relative distance with respect to the transmitter. The backreflected signals are decoupled from the fiber by means of a beam splitter and circulators installed inside the OTDR. The OTDR trace then gives the impulse response of the link under the test, that is, a plot of the power versus distance. OTDR is an optoelectronic device, which provides a full characterization of the fiber link under test.

Figure 53.10 presents a typical OTDR trace. Using this trace, an impulse response of the fiber link is provided by the OTDR device. For instance, the jumps in Figure 53.10 correspond to the insertion loss

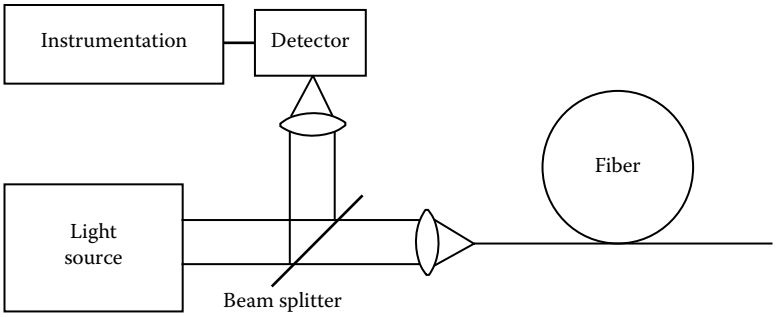

FIGURE 53.9 OTDR is used in link tests. The optical power is launched into the fiber, and the reflected power associated with Rayleigh scattering is measured from the same sending end. OTDR is usually offered with customized analysis software and optical modules to be integrated into a computer. OTDR complements attenuation measurements by measuring backscattering. This permits not only the attenuation of the complete fiber to be measured but also different attenuation coefficients of fiber segments as well as optical losses in connectors and splices.

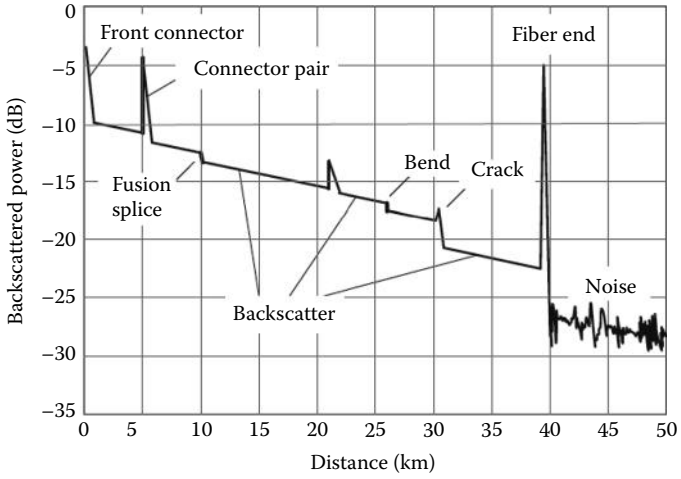

FIGURE 53.10 A typical OTDR trace, which provides full fiber link characterization. The jumps correspond to the insertion loss of network components as illustrated, whereas the power reflection peak at 40 km signifies the Fresnel reflections at the fiber–air interface (e.g., fiber cut). No backscattering is detected after the fiber end and the trace drops to the receiver noise. The power level decreases linearly from left to right (in logarithmic scale). From the location and height of the events, the positions and magnitudes of the local losses can easily be identified.

of network components as illustrated, whereas the power reflection peak at 40 km signifies the Fresnel reflections at the fiber–air interface. After the fiber end no backscattering is detected and the trace drops to the receiver noise, which is usually dominated by the thermal noise of the electronic circuit.

Generally, the OTDR trace can be used to extract information about link faults, including fiber misalignment, fiber mismatch, angular faults, dirt on connectors, macrobends, and/or breaks. These faults are usually referred to as events on the OTDR trace. An OTDR device is a distributed fiber sensing instrument and can be effectively employed for fiber link troubleshooting and fault root cause analysis. OTDR is also useful to reduce the operational cost of fiber repair while reducing the network downtime.

The backscattering factor depends on scattering and numerical aperture. This factor is usually very small in the range of 50–70 dB and is reduced proportionally by decreasing the transmitted pulse width. Despite of its low level, the reflected power is still detectable for several kilometers depending on the application. In many cases, light pulses with high-energy content are used along with sensitive receivers based on avalanche photodiodes (APDs), which provide both detection and amplification.

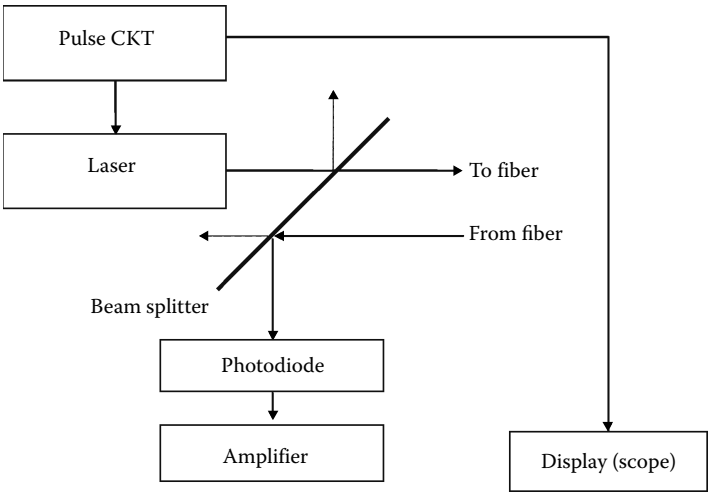

FIGURE 53.11 OTDR products usually come with a laser source and modules that allow for wavelength selection. The short, intense laser pulses with high peak power are coupled into the fiber. Backscattering echoes are detected from different regions of the fiber. The returned signal is decoupled from the fiber by means of a beam splitter to be further processed for analysis.

Assuming a constant attenuation coefficient throughout the fiber, in the OTDR trace the power level decreases exponentially (or linearly in logarithmic scale, i.e., decibel) from left to right. In practice, local events due to imperfect connectors, splices, etc. impose some discontinuities in the OTDR trace. These localized jumps (discontinuities) provide information about both the physical location and insertion loss of the corresponding events. A practical advantage of this technique is that it involves only one of the fiber ends. The reference trace acquired under normal conditions is very useful to determine where changes have occurred. Some companies keep the reference OTDR test results in case of future fiber failure for warranty claims.

Manufacturers usually provide OTDR products with customized software analysis to be integrated into a computer and optical modules, as illustrated in Figure 53.11. Therefore, OTDR products usually have significant computing ability with graphical display. Notwithstanding that, the proper operation and interpretation of the OTDR trace require technical training and experience.

53.5.2 OTDR Design and Considerations

Generally, OTDR is available for a variety of fiber types and wavelengths for different applications. Longer wavelengths, such as 1625 nm (U band), are highly recommended for troubleshooting as splice or connector losses impose higher losses and hence are more visible on OTDR traces. U band probe signals also provide a transparent scheme, where monitoring systems do not interfere with other data communication bands such as C and L bands. The dynamic range of an OTDR is limited by a combination of optical output power, transmitted pulse width, processing time at the receiver (or equivalently the electrical bandwidth), and receiver sensitivity. Higher launched power and better sensitivity are usually combined to improve the measurement range and are often fixed features of a particular instrument. The pulse width adjustment, however, implies certain trade-offs, depending on the desired application. A longer laser pulse width provides a better dynamic range and attenuation measurement resolution at the expense of higher distance resolution (i.e., spatial resolution). For example, using a long pulse width, it may be possible to measure attenuation over a distance of more than 100 km; however, for this application, only events physically located farther than 1 km (for 1 μs pulse width) are distinguishable in the OTDR trace. This scenario is useful for overall characterization of a link, but is useless for fault localization.

Similarly, for a short pulse width, we have a better distance resolution of events, while suffering from a smaller measuring range and attenuation measurement resolution. The "apparent measurement length" of an event is known as the "dead zone" on the OTDR trace. The dead zone is the minimum distinguishable distance between any two events in the OTDR trace, which in turn is a function of the transmitted pulse width, light wave speed in the fiber medium, and size of the event. Therefore, events physically located closer than the "dead zone" of an OTDR are not separable. As mentioned earlier, for the attenuation zone, where no reflecting event exists, the power level drops linearly (in dB) with the slope of fiber attenuation.

Most OTDR solutions employ averaging techniques to improve both the sensitivity and dynamic range. The sensitivity of an OTDR increases with the square root of the total integration time (i.e., averaging time). For instance, a 16-time increase in averaging time results in a sensitivity increased by a factor of four. However, the integration time is practically limited to few minutes. Advanced digital signal processing techniques may also be employed for further improvement in the OTDR trace quality and analysis.

While OTDR is able to identify events such as unacceptable losses, it is merely used for accurate end-to-end loss or return loss measurements. A separate end-to-end loss test with a light source and power meter is required for this purpose. In some applications, the OTDR capability to localize a fault may be improved via augmented (sometimes localized) modules such as red laser fault locator, clip-on identifier, or "cold clamp" optical cable marker.

Multiple joined fibers of different types and lengths can also cause an incorrect interpretation of the events on an OTDR trace. A well-known example is where a fiber joint shows an abnormal gain (jump) in the OTDR trace instead of loss. This is because connected (adjacent) fibers may have different properties such as backscatter coefficients and core diameters. Consequently, more light is reflected right after the fiber junction while the same light is propagating down the fiber. Placing the OTDR equipment on the other side of the same fiber will illustrate an abnormally high loss at that joint. In these cases, the combination of the two directional tests (taken from both ends of the link) should be utilized for proper interpretation of the OTDR data. For this reason, it is common OTDR practice to measure and combine the traces from both ends for a more accurate characterization of the fiber link.

53.5.3 OTDR for Branched Optical Networks

While providing an automatic monitoring system and full characterization of the fiber link, OTDR is ineffective for a point-to-multipoint (PMP) network (i.e., branched network) such as a passive optical network (PON). This is because the backscattering signal of each branch in a PMP network is partially masked by the others. In this case, the total power measured via OTDR is a linear sum of all powers coming from different branches. Useful information can nevertheless be extracted from the global backscattering trace. Actually, the OTDR trace does not take into account the fact that there are different paths because it only measures the total accumulated backscattered light coming from all the branches. The desired information about the network, however, is in the OTDR trace itself, which needs to be decoded and extracted. Extracting the desired information from the OTDR trace might require considerable off-line signal processing and detailed knowledge of the fiber network infrastructure.

The key point for analyzing an OTDR trace in the case of a branched network is to compare the current backscattering trace with a reference acquired from the PMP network under standard conditions. A network simulator is then required to obtain more significant data from the measured trace. The software developed for this purpose needs a self-learning module to develop and continuously update a database containing the reference patterns and an event table. During the in-service monitoring of the network, if any deviation in the measured trace (with respect to the standard trace) is observed, an alarm is sent to the service provider and the software starts to analyze the measured data. The simulator in the software then generates a variety of virtual network configurations to achieve the measured trace by using the information of the standard trace.

The accuracy of such software is strongly dependent on the accuracy of the simulator developed for the network and the uncertainties of both the training and measured data. Deviation in the backscattered coefficient of different fiber branches is another source of error. The situation is problematic when two or more branches are located at the same distance. In such cases, OTDR cannot distinguish different events and branches. The test system then should take separate end-to-end measures for each branch to differentiate them among individual branches in the overall OTDR trace. Recall that as the number of branches (i.e., network size) increases, the complexity of the analysis increases dramatically leading to a less reliable network analysis by the OTDR device.

Neglecting the complexity in the analysis of the OTDR trace in a PMP network, the huge loss incurred usually by passive splitters, located at the remote node (RN), leads to a significant drop in the measured power. For example, if there is a 1:32 splitter at the RN, the total backscattered light from each branch suffers 15 dB loss, as shown in Figure 53.12. The RN is then recognized as the fiber end and no useful information can be extracted for distances farther than the RN. In traditional OTDR, losses higher than 3–7 dB are usually identified as end-of-fiber. By simply modifying the OTDR analysis, testing can be performed through splitters with losses up to 20 dB. This kind of OTDR is usually referred to as PON-tuned OTDR.

In order to further reduce the complexity in the analysis of OTDR trace in a PMP networks, a variety of solutions have been proposed to distinguish individual fiber branches, among which the most well-known techniques are reference reflectors, fiber selectors, wavelength routers, chained branches, and dark fibers. In each of these techniques, a unique signature is assigned to each fiber branch to make it distinguishable from the others.

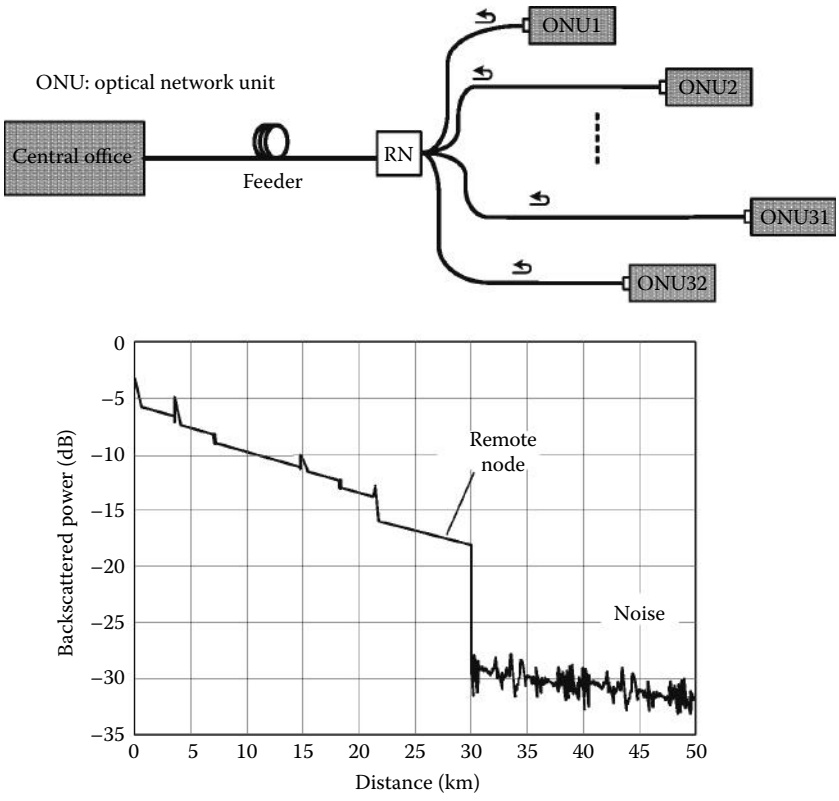

FIGURE 53.12 OTDR for a typical PMP network with a 1 × 32 splitter at the RN. The RN imposes 15 dB additional loss on the data measured via OTDR. The figure shows the corresponding OTDR trace of the network. It is observed that the power falls to the receiver noise level, and therefore, no useful information is extracted after the passive splitter.

53.5.4 OTDR Challenges for Branched Networks

The most critical components for OTDR-based monitoring technologies are optical selectors, filters, reflectors, and WDM devices. These devices should be cost- and dimension-effective (i.e., low cost and high density) to be able to manage a large amount of fibers in future access networks. Recall that while the ITU-2 recommendations propose the U band, 1625–1675 nm, for monitoring applications, the behavior of passive components is not very well investigated for this wavelength regime. The OTDR itself is the basic equipment for the automatic test system and needs to have suitable technical characteristics. These include spatial resolution, dynamic range, dead zone, wavelength stability and compatibility, launched power, and sensitivity.

These requirements should be met for OTDR to be an effective monitoring solution for future access networks. As the field of OTDR techniques and the corresponding key components are continuously advancing, these techniques are expected to be more reliable in the future. Recall that the cost is an important issue, but as OTDR is shared among many branches (customers) in the network, it is not the most critical one. Also note that the OTDR trace analysis in a PON is still challenging, especially for a large number of individual branches.

53.6 Standard Field Fiber-Optic Attenuation Test

In practical applications of optical fibers, it is necessary to have quantitative knowledge about the whole range of properties. The most important properties are length, attenuation, and bandwidth of the fibers, along with external diameter, core diameter, numerical aperture, and refractive index profile. The actual performance of installed links may be different from the desired performance. Therefore, it is important that both individual components and the entire assembled system undergo testing to verify compliance with the required operations. Additional testing may be conducted over the lifetime of the system to ensure continued functional operation over long periods of time.

There are two basic standard fiber-optic attenuation tests: the component acceptance test and the link test. The component acceptance test is performed prior to installation to verify the power and performance acceptance levels of each fiber. The acceptance testing of a functional module begins with power testing of the transmitter. The testing is done by attaching the module set into a reference link and verifying the data rates and bit error rates taken at the other end of the fiber, as shown in Figure 53.13.

Fiber acceptance testing also requires power testing, which can be done by launching a known power from a reference source, as explained in the OTDR section. The functional testing verifies power budget of coupling attenuation effects as well as bandwidth for the fiber. The attenuation and power transmission depend on the mode distribution within the fiber. In short fibers, higher modes dominate, whereas in long fibers, power is more concentrated in lower-order modes. Mode stripping is often used by introducing small bends into the fiber to correlate the performance of tested fiber to actual in-service performance.

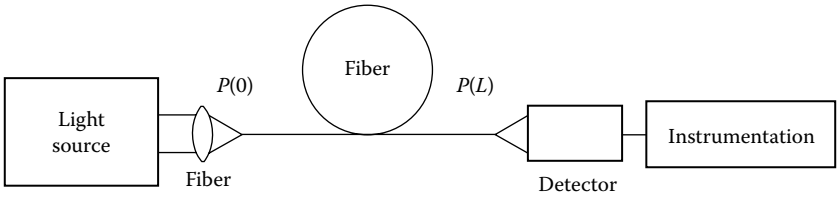

FIGURE 53.13 The measurement of transmission properties of laid optical fibers is obtained by end-to-end tests. The testing is done by attaching the module to a reference link and verifying the data rates and bit error rates taken at the other end of the fiber.

In addition to acceptance tests, fibers undergo other tests such as pull strength, breaking, humidity resistance, prolonged tension, and bend tests. Connectors, splitters, combiners, and fiber amplifiers need to be tested frequently to minimize power transmission losses.

In almost all fiber optics, low noise and very sensitive photodetectors are used in measurements. Semiconductor photodiodes made from silicon are suitable for measurements with wavelengths below 1 μm. For larger wavelengths, other detectors are used, such as those made of germanium. Semiconductor photodiodes work via the internal photoelectric effect; that is, they absorb photons of energy $h\nu$ containing the incoming light beam power P and emit a number of electrons proportional to the number of photons, creating a current given by

$$i_P = \frac{P\eta e}{h\nu} \tag{53.5}$$

where

h denotes Planck's constant
ν denotes the frequency of the absorbed light ($\nu = c/\lambda$)
η is a constant of proportionality or quantum efficiency ($\eta < 1$)
e denotes the charge of an electron

Photodetectors are used to measure the attenuation in fibers by measuring the optical power at the input $P(0)$ and power $P(L)$ at the end of the fiber. From Equation 53.2, the attenuation of the fiber can be calculated as

$$a_0 = \alpha L = \frac{-10 \log P(L)}{P(0)} \tag{53.6}$$

When photodetectors are used, Equation 53.6, can be written as

$$a_0 = \frac{-10 \log i_P(L)}{i_P(0)} \tag{53.7}$$

It is worth noting that optical power is proportional to current i_p, not to i_p^2.

LEDs or incandescent halogen lamps are suitable for use as light sources for attenuation measurements. If LEDs are used, several interchangeable ones are needed, suitable to different wavelengths to make measurements. On the other hand, halogen lamps yield a wide spectrum of radiation, from which light of various wavelengths can be filtered with a monochromator that uses optical filters, prisms, or diffraction gratings. With an arrangement of this kind, the attenuation of the fiber can be measured as a function of the wavelength of the light.

To measure small optical powers precisely for the purpose of determining attenuation, the photodetector is usually connected to a selective amplifier, and the light source is modulated at a low frequency (e.g., 400 Hz) using a rotating disk called a *chopper*. The selective amplifier amplifies only the similarly modulated components of the photocurrent so that detector noise and the influence of background light are suppressed. For this purpose, frequency-selective level meters or lock-in amplifiers are often used. In both cases, the frequency and phase of the modulation are fed back in the form of a reference voltage.

53.7 Out-of-Plane Scattering and Polarization Methods

The art of scatter measurements has long been evolved to established forms within the optics industry. Scatter methods provide extremely sensitive measurements in many diverse applications. There are two basic instruments developed for this purpose: the scatterometer and the polarimeter.

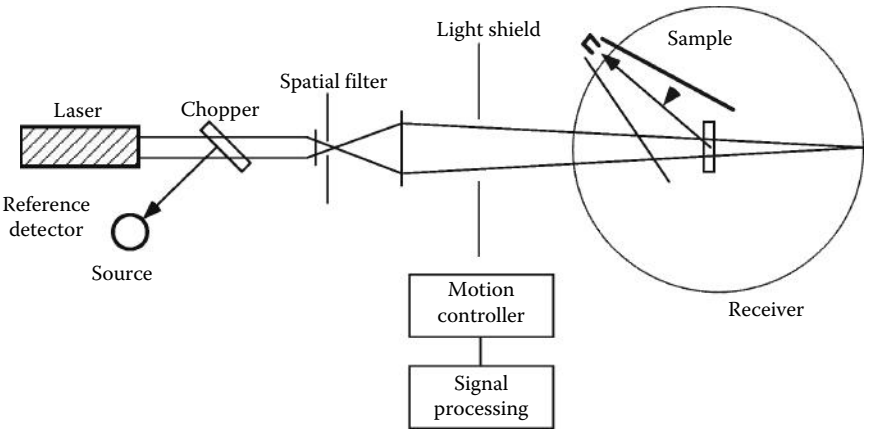

FIGURE 53.14 A typical scatterometer. In this particular type, the source is fixed in position and the sample is rotated to the required incident angle. The receiver is rotated about the sample in the plane of incidence. In other types, source and receiver may be fixed and the sample is rotated so that the scatter pattern moves past the receiver. Scatterometers are offered with full supporting software for analysis and appropriate software.

The basic setup for a scatterometer is shown in Figure 53.14. Measured scatter is a good indicator of surface quality as well as discrete defects. However, the scattered signals are generally small compared to the specular beams, and they can vary by several orders of magnitude for just a few degrees. Therefore, scatter measurements need sophisticated instrumentation and the signal processing is more complex than many other optical techniques. For successful applications, the system specifications and measurements must be given in terms of accepted, well-defined quantities. Scatter methods are used routinely as a quality check of optical components in fiber-optic applications. Conversion of surface scatter data to other required formats, such as surface roughness, is common practice. Out-of-plane measurements and polarization-sensitive measurements are areas currently experiencing rapid advancements.

Another instrument in common use is the polarimeter, which senses the polarization of scattered light. The scattering characteristics of a sample are generally described by its bidirectional reflectance distribution function. The reflectance distribution function is the ratio of scattered flux in a particular direction to the flux of an incident beam. The scattered light is often a sensitive indicator of surface conditions. A small amount of surface roughness may reduce the specular power by less than 1% while increasing the scattered power by orders of magnitude. Similarly, the retardance, attenuation, and depolarization of scattered light provide sensitive indicators of conditions, such as uniformity of refractive index, orientation of surface defects, texture, strain, subsurface damage, coating microstructure, and the degree of multiscattering. Among many other methods, the use of prisms helps realize polarization and depolarization of the scattered light.

Chemical Variables

54

Interference and Selectivity in Portable Chemical Sensors

Denise Wilson
University of Washington

54.1 Introduction

Chemical sensors can be loosely classified into those that use light to extract information about chemical concentration (optical sensors) and those that do not (nonoptical sensors). Optical chemical sensors tend to use multiple stages of transduction and require large amounts of system and signal processing overhead to convert target analyte information into a useful output. These sensors often become complex systems or entire pieces of equipment in their final, commercialized form. For this reason, optical chemical sensors are not frequently found in portable, handheld, or field-monitoring units. Nonoptical chemical sensors, on the other hand, especially those that are integrated into an electronic device, are much better suited to portable and related applications. In the interests of evaluating chemical "sensors," where the bulk of the complete system is the sensor itself, this chapter focuses on nonoptical chemical sensors. While compact, low-cost, small in size, and suitable for field or portable monitoring applications compared to other types of chemical sensors, nonoptical sensors are often hampered by (a) insufficient selectivity or chemical interference where a sensor responds to nuisance analytes in addition to target analytes and (b) nonchemical interference (from both physical/environmental and electronic influences). Advances in materials, sensor design, and signal measurement have made a significant impact on interference and selectivity barriers; however, barriers to commercialization remain. This chapter explains the basic issues associated with selectivity and interference and highlights some of the most promising advances in enhancing selectivity and reducing interference that support continued commercialization of chemical sensor products.

54.2 Fundamentals of Selectivity

Most nonoptical chemical sensors rely on a direct interaction between an analyte and the active sensor area. For purposes of a discussion that focuses on improving selectivity (and thereby reducing chemical interference), these types of interactions can be loosely classified into three different categories:

- Chemical: The analyte binds chemically to a portion of the active sensor area. These reactions can be (1) lock and key, where the active sensor area reacts with only one analyte and is insensitive to all others; (2) semiselective, where the active sensor area reacts with a particular class of chemicals (e.g., aldehydes or alcohols); and (3) broadly selective, where the active sensor area reacts to a group of unrelated chemicals with a common property (e.g., reducing gases).
- Catalytic: The analyte binds chemically to a portion of the sensor area, but the reaction is made faster by the use of a catalyst or is otherwise assisted by the use of an enzyme. In the process of speeding up the reaction rate with one analyte (the target) as opposed to others (the interferents), the net response to the target analyte increases, thereby increasing selectivity.
- Electrochemical: A semiselective sensor area is made more selective by the use of electrochemistry where an applied potential in amperometric modes of operation limits the number of analytes that will bind with the active sensor area.

54.3 Chemical Interactions

Chemical sensors can respond with selectivity ranging from one-to-one (lock-and-key) to broadly selective (reducing gases) interactions with analytes of interest. Although most chemical sensors are developed to detect single, known analytes of interest, some chemical sensors are developed to differentiate one mixture from another; for example, it may be more relevant to distinguish the quality of one manufactured olive oil from the next rather than to discern specific chemical concentrations in the oil itself. The following discussion focuses on single analytes rather than on mixtures and, in so doing, evaluates different levels of interaction between sensor material and target analyte(s) that determine quality and selectivity of the final sensor system.

54.3.1 Lock-and-Key Chemical Interactions

In many commercial sensor applications, it is highly desirable to sense one analyte with one sensor. The ideal sensor has 100% specificity, responding to no other analytes aside from the molecule of interest. Lock-and-key chemical interactions provide this one-to-one specificity and are surprisingly common among many analytes of interest, paving the way for a wide range of highly specific chemical sensors. Affinity-based recognition elements involved in lock-and-key sensing specifically bind to individual analytes of interest or small groups of structurally related analytes.

Antibodies are by far the most common affinity-based recognition elements. They are both highly sensitive and highly selective. Polyclonal antibodies are cheap but require animals to be immunized to obtain them and are vulnerable to nonspecific binding (interference from undesirable analytes). Monoclonal antibodies do not have these specificity problems but are costly and time consuming (Van Dorst et al., 2010). Used as chemical sensors in nonclinical applications, sensors based on the use of both polyclonal and monoclonal antibodies are highly vulnerable to losing their highly specific binding affinities under changing environmental conditions (Van Dorst et al., 2010). Thus, while antibodies have the potential for a variety of lock-and-key chemical interactions, their use as chemical sensors outside clinical applications is impractical.

Phages provide similar levels of specificity to antibodies but with fewer limitations. Bacteriophages infect bacteria, using the host bacterial cell to replicate themselves. They indicate recognition of specific

bacteria by displaying specific peptides or proteins on their surface. Phages can be selected and genetically modified to obtain high specificity to specific bacterial agents. They are also inexpensive, do not require animal hosts to produce, and are stable in a wide range of environmental conditions. They have been used in amperometric (electrochemical sensor) designs to detect such important biological agents as *Escherichia coli* (Neufeld et al., 2005) and *Listeria monocytogenes* (Benhar et al., 2001) with detection limits of 1 cfu/mL and 500 cells/mL, respectively. In order to work properly as sensors, however, the target bacteria in these types of sensors must be immobilized, which make their use in portable sensor systems limited.

Nucleic acids provide similar specificity to phages, exploiting the complementary nature of DNA strands to obtain high affinity for specific types of bacteria. These sensors have some sensitivity limitations but have been integrated into electrochemical systems using voltammetry to detect chemicals such as oxytetracycline (Kim et al., 2009) and trinitrotoluene TNT (Ehrentreich-Forster et al., 2008) as well as biological toxins such as botulinum neurotoxin (Fang and Ho, 2009) and *Trichoderma harzianum* (Shafiquzzaman et al., 2012).

Antibodies, phages, and nucleic acids are, in principle, ideally suited to lock-and-key sensors but have limitations that often make them impractical for portable or field-monitoring applications. For these types of applications, the molecular imprintable polymers (MIPs) are often a good choice. MIPs essentially mimic the biological activity of antibodies but do so in a way that can be engineered to make them highly specific to a wide range of chemical analytes. A MIP is made by binding a monomer to a template molecule and then removing the template molecule, thereby leaving a "space" for recognition of target analytes of the same morphology (shape and size) as the template molecule (Figure 54.1). MIPs can be made using covalent or noncovalent bonds to create a binding site for a specific analyte. The noncovalent bonds (where a target molecule physically links to the MIP sensor) are most common because it provides the most flexibility in creating target sites (and thereby provides the widest range of sensors). Unlike antibodies, MIPs are highly stable, both thermally and chemically, producing shelf lives of up to 8 years (Van Dorst et al., 2010). To date, MIPs have been used to bind to such diverse analytes as uranium (Metilda et al., 2007), ephedrine (Mazzota et al., 2008), TNT (Riskin et al., 2008),

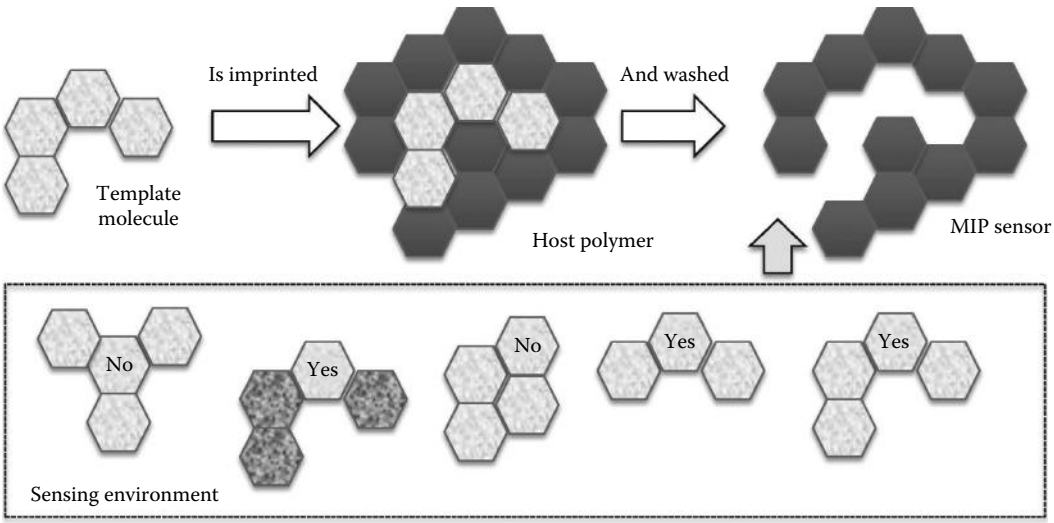

FIGURE 54.1 Molecular imprinted polymers as sensors. A monomer is bound to a template molecule, creating the sensor space (characterized by its shape). The template molecule is then removed via washing or similar process, leaving a space by which molecules of appropriate size and shape in the sensing environment can bond strongly (covalently) or weakly (physisorption) to the MIP sensor, creating a highly selective interaction between the sensor and the shape/size of target molecules.

phenols (Sergeyeva et al., 2010), atrazine (Pardieu et al., 2009), caffeine (Alizadeh et al., 2010), glucose (Fang et al., 2009), and melamine (Liang et al., 2009) using either voltammetry or other potentiometric electrochemical transduction mechanisms.

While the research on highly specific, lock-and-key chemical interactions for use in chemical sensing remains extremely active (see Van Dorst et al., 2010 for an excellent review of activity in phage, nucleic acid, and MIP-based interactions), a significant barrier to their use in commercialized sensors (especially portable or field based) is the difficulty in transducing the interaction into an electrical signal. Optical means to transduction predominate and often require complex systems overhead that lead to high-cost systems that can only be used in a laboratory. Even sensors based on electronic devices using electrochemical transduction often involve complex voltage sweeps (voltammetry) that keep system overhead high and portable or field deployment out of reach. Thus, sensors with less specificity remain popular for portable sensors. These sensors rely on semiselective or broadly selective chemical interactions that are described next.

54.3.2 Broadly Selective Chemical Interactions

On the other end of the spectrum to lock-and-key chemical interactions lie those chemical sensors that respond broadly to a range of chemicals. By far the most common types of nonoptical chemical sensor that uses broadly selective chemical interactions are those based on metal–oxide–semiconductors. Metal–oxides can be used as chemical sensors in pure form, doped, or modified by the addition of a catalyst as described in the next section. A metal–oxide sensor whose resistance changes as a function of analyte concentration (a chemiresistor) works as an n-type semiconductor with an excess of electrons in the conduction band to conduct current. The surface of a bulk metal–oxide chemical sensor contains oxygen molecules that have not bonded with the metal in the semiconductor, creating dangling bonds that are then free to interact with analytes or molecules in the surrounding air (Figure 54.2). As these

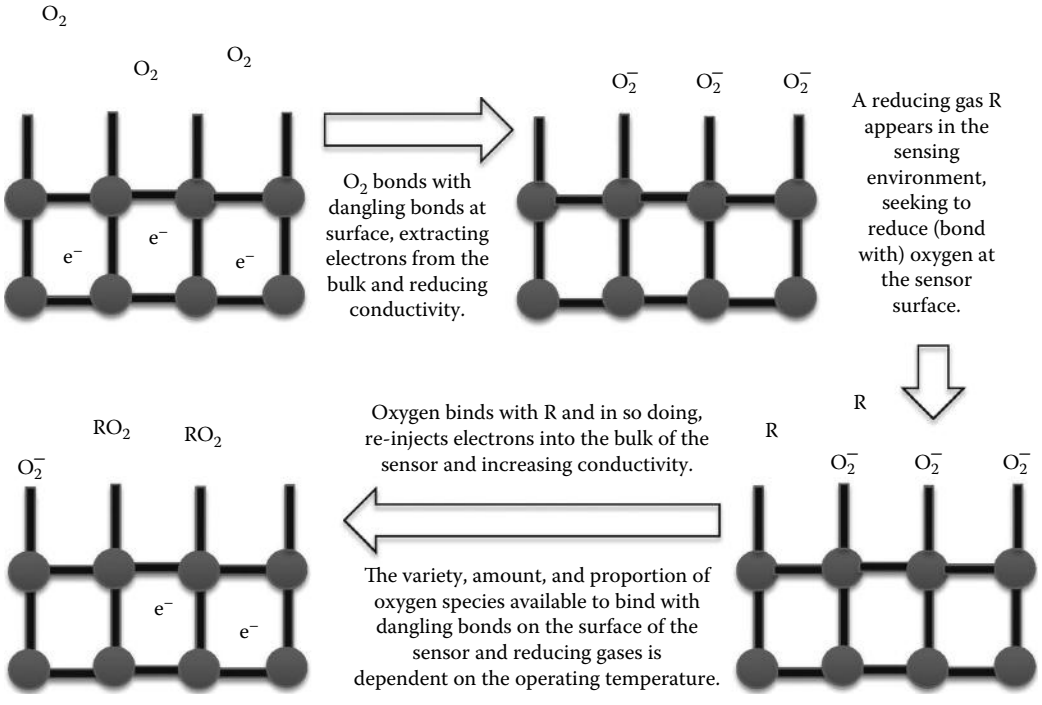

FIGURE 54.2 Basic operation of metal–oxide sensors.

oxygen molecules seek to fill their outer shells to enhance stability, they will extract electrons from the bulk of the semiconductor to fill that outer shell:

$$\left(\frac{m}{2}\right)O_2 + [\text{vacant site}] + e^- \rightarrow (O_{m^-})_{site} \tag{54.1}$$

For each dangling bond, an electron is extracted from the bulk of the semiconductor, decreasing conductivity accordingly. When a reducing gas C is present in the ambient environment, these reducing molecules will bind with the oxygen molecules, completing the outer shell of oxygen molecules which in turn will return electrons back to the bulk of the semiconductor and increase conductivity:

$$C + (O_{m^-})_{site} \rightarrow (CO_{m^-})_{site} + e^- \tag{54.2}$$

The rate K2 at which reaction in (54.1) proceeds relative to the rate K3 at which reaction in (54.2) proceeds influences the proportionality constant r that impacts the input/output relationship of the metal–oxide sensor:

$$\sigma = \mu q(n + [C]^r) \tag{54.3}$$

where

[*C*] is the concentration of the analyte of interest
σ is the conductivity of the sensor
μ is the mobility of electrons in the metal–oxide
q is the electronic charge (1.6×10^{19} C)

Clearly, the metal–oxide sensor responds to any reducing gases that react with oxygen at the surface of the sensor but it does so to varying degrees, as expressed by r in Equation 54.3. Tin oxide is, by far, the most popular material used for broadly selective metal–oxide chemiresistors and similar sensors. However, zinc oxide, tungsten oxide, titanium oxide, and tungsten oxide have also proven popular for a wide variety of gas sensing applications (Table 54.1). Palladium, platinum, zinc, silver, copper oxide, fluorine, lanthanum oxide, and cobalt oxide are popular dopants used to increase the sensitivity of these baseline metal–oxide films (Bochenkov and Sergeev, 2010).

54.3.3 Semiselective Chemical Interactions

Selectivity of many broadly selective, chemically sensitive materials and chemical sensors can be adjusted through a range of parameters. For example, the broadly selective metal–oxide materials highlighted in the previous section can be modified to improve selectivity via the following approaches:

Choice of material: Although metal–oxides react, in general, to gases that reduce the sensor surface, the rates of reaction and the equilibrium established at the sensor surface can vary between materials and certain classes of materials. Common examples of metal–oxides preferred for different classes of reducing chemicals are summarized in Table 54.1.

Operating temperature: The charge of oxygen species that is adsorbed at the metal–oxide sensor's surface is highly dependent on temperature (Iwamoto, 1992). Oxidation rates also increase with temperature and patterns of adsorption, desorption, and diffusion are dependent on temperature (Wlodek et al., 1991a,b). Thus, as a first cut to improving selectivity, the operating temperature of a metal–oxide sensor, regardless of material, can be optimized to an analyte of interest. Further improvements in selectivity can be achieved by modulating operating temperature to obtain a signature or pattern that is indicative

TABLE 54.1 Snapshot of Metal–Oxide Chemical Sensors and Affinity to Specific Analytes

Class of Chemicals	Analyte	Metal–Oxide	Dopant	Approximate LOD (ppm)
Ammonia		Tin oxide	Palladium	100
		Zinc oxide	None	10
		Tungsten oxide	Titanium	5
Alcohols	Ethanol	Tin oxide	Palladium	4000
		Zinc oxide	Aluminum	400
		Zinc oxide	None	30
		Zinc oxide	Indium	2
Carbon oxides	CO	Zinc oxide	None	300
		Tin oxide	Gold	10
		Tin oxide	None	5
Hydrocarbons	Butane	Zinc oxide	None	1000
		Zinc oxide	Gold	1000
	Methane	Zinc oxide	None	5000
		Tin oxide	None	500
Hydrogen		Tin oxide	Palladium	1000
		Zinc oxide	None	600
		Tin oxide	Fluorine	100
Nitrogen oxides	NO_2	Zinc oxide	None	1000
		Zinc oxide	Indium	5
		Tin oxide	Tungsten oxide	500
Volatile organic compounds	Acetone	Tin oxide	Palladium	200
		Zinc oxide	None	10
	Hydrogen sulfide	Tin oxide	Copper oxide	10
		Tin oxide	Silver	1
		Zinc oxide	None	0.01
	Propane	Zinc oxide	None	4000
		Tin oxide	Nickel	600
		Tin oxide	Strontium	10

LOD, limit of detection.

of particular analytes present in a mixture. Complex features of output patterns generated by varying operating temperature have been used to improve the selectivity of tin oxide sensors in a range of research efforts (Huang et al., 2007; Vergara et al., 2007).

Arrays: Variations in the speed and degree of reaction among different materials and different operating temperatures (for metal–oxide sensors) and similar variables with other classes of materials can be used to create patterns that advance sensors from being broadly selective to being semiselective. A wide variety of arrays have been used to create both electronic noses and electronic tongues capable of distinguishing one mixture from another as well as one analyte from another in both liquid- and gas-phase environments.

Like metal–oxide sensors, many polymers are also inherently sensitive to reduction and oxidation, albeit through the conjugated backbone of the polymer rather than the dangling bonds of the metal–oxide sensor surface. However, conducting polymers have almost no conductivity (in the neutral state) until they are oxidized (p-doping) or reduced (n-doping). The baseline conductivity of the polymer can

be adjusted via chemical doping (similar to semiconductor doping) but this process is not reproducible. Alternatively, electrochemical doping enables fine-tuning of the doping level (and therefore the baseline conductivity of the polymer). Once the baseline is established through appropriate doping, conducting polymers can be further selected or modified to be broadly selective or semiselective.

Used in solution as broadly selective sensors, several conducting polymers make good pH sensors. Polyaniline (PANI), polypyrrole (PPY), polyimide (PI), polycarbazole, and polyazines are readily protonated or deprotonated making them appropriate for pH sensing. Protonation increases conductivity, while deprotonation decreases conductivity. As semiselective sensors, PI and polycarbazoles respond to copper ions in solution, while poly-3-octylthiophene (P3OTH) responds to silver ions. Complementing the sensitivity of these polymers to these inorganic ions are some conducting polymers that respond to classes of organic ions in solution. PANI and PPY respond electrically to classes of organic analytes in solution such as dicarboxylates and amino acids. In solution, however, it is far more common for these conducting polymers to demonstrate measurable responses in optical properties rather than nonoptical or electrical properties.

In air, the situation is different. A wide range of gases can both react chemically and adsorb physically onto conducting polymers, thereby making them semiselective by choice of specific polymers. Chemical reactions with electron acceptors such as NO_2, I_2, O_3, and O_2 partially oxidize many conducting polymers, thereby increasing the doping level and decreasing the resistance of these polymers. On the other end of the spectrum, electron donors such as H_2S, NH_3, and N_2H_4 reduce conducting polymers, thus leading to an increase in resistance. In addition to chemical reactivity, physical adsorption of certain classes of molecules leads to semiselectivity of these polymers to nonreactive organic compounds including chloroform, acetone, aliphatic alcohols, benzene, toluene, and similar (Lange et al., 2008).

Thus, just like metal–oxide chemical sensors, conducting polymers are used to make sensors ranging from broadly selective to semiselective. An excellent review of the use of conducting polymers as nonoptical sensors can be found in Lange et al., 2008.

54.3.4 Catalytic Interactions

Additional selectivity can be incorporated into chemical sensors via the addition of catalysts to the sensor material. Ion-selective electrodes (and electrochemical sensors that use them) are often modified with enzymes for chemical sensing in biological systems. For example, urease has commonly been used as an enzyme catalyst to detect urea. Urease reacts with urea to produce ammonia that is then sensed with an ammonium-selective electrode (Singh et al., 2008). Similar catalysts can be used in nonbiological systems to preferentially increase reaction rates to target chemicals or analytes, thereby increasing selectivity to those analytes. For example, platinum and palladium can be added to tin oxide sensors to detect carbon monoxide in the presence of interfering C_3H_8 and NO_2 as demonstrated in a variety of efforts, but most recently with nanoparticle-based tin oxide sensors (Aruna et al., 2009). These catalysts improve sensor performance via the spillover effect (Sharma and Madou. 2012). The catalyst dissociates a gas molecule, causing the dissociated atoms to spill over onto the surface of the sensor where they then react with the reactive oxygen species on the metal–oxide surface. The better the dispersion of catalyst near the reactive sensor surface, the less catalyst is needed to achieve the desired sensor response (Cukrov et al., 2001; Rothschild and Komem, 2004). The most popular catalyst for metal–oxide materials is palladium Pd (Bochenkov and Sergeev, 2010).

54.3.5 Electrochemical Interactions

Electrochemical sensors are the one of the most popular commercially available chemical sensors. Commonly termed "ion-selective electrodes," a complete electrochemical cell consists of at least two electrodes (Figure 54.3) interacting with ions in solution. This pair of electrodes acts according to similar (but reverse) behavior to a battery; in certain operating modes, a third electrode may be

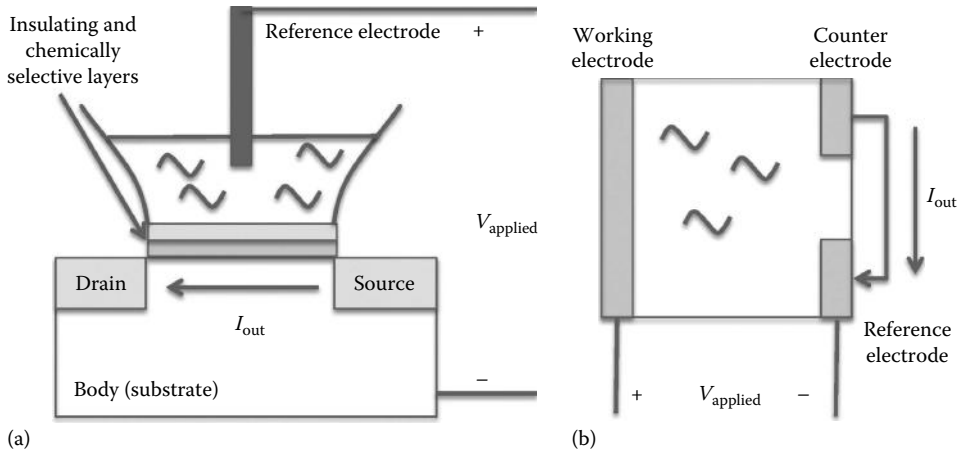

FIGURE 54.3 Electrochemical sensor operation: (a) Potentiometric operation is commonly configured using a field effect transistor (FET). A voltage is applied from the reference electrode to the body of the transistor and the analyte of interest interacts with the insulator layers, creating a charge on those layers. The charge enhances or detracts from the net field effect, either increasing or decreasing the resulting transistor current respectively (I_{out}). No current flows from the solution to the transistor, thereby ensuring Nernstian operation. In (b) amperometric mode, a voltage is applied between the working electrode and reference electrode and the resulting current from working to counter electrode is measured as a function of analyte concentration.

used, but the basic operation of the electrochemical cell remains the same. One of the electrodes in the electrochemical cell has a stable and constant interaction with a known concentration of ion in solution; this electrode is the reference electrode and plays a critical role in the resulting stability, drift, and accuracy of the electrochemical sensor. The other "working" electrode is chosen to interact with the ion of interest in solution. Selectivity of this working electrode can be enhanced in two primary ways.

First, the electrode can be modified to prefer the ion of interest more than other ions that inherently exchange electrons with the working electrode, thereby transitioning the electrode from broadly selective to semiselective. If the voltage (potential) across the two electrodes is then measured as a function of ion concentration without drawing a current, the well-known Nernst equation applies:

$$V_{sensor} = K + \left(\frac{RT}{nF}\right) \ln [C] \tag{54.4}$$

where

V_{sensor} is the voltage across the two electrodes
R, K, and F are constants
n is the number of electrons exchanged between solution and working electrode
$[C]$ is the concentration of the analyte of interest in solution

This Nernst relationship provides the electrochemical sensor the stable, predictable operation inherent to potentiometric operation. Potentiometric mode of operation (Figure 54.3a) is more stable than other modes of operation because electrode material is not typically consumed during sensor operation and it is more predictable than other modes of operation because it is governed by a well-known theory (Nernst behavior) rather than empirical relationships. Potentiometric operation is also largely considered more scalable than other modes of operation, meaning that no penalty in limit of detection or sensitivity is inherent in miniaturizing these sensors. However, sensor selectivity in potentiometric

mode of operation is largely limited by the types of ions the working electrode will exchange electrons with, thereby making these sensors vulnerable to interference from competing ions.

Second, in amperometric operation, the selectivity can be enhanced electrochemically by controlling the voltage applied to the electrode pair (Figure 54.3b). In amperometric mode, if the redox potential (voltage) of a particular molecule and the working electrode is greater than the applied voltage, that molecule will not react with the working electrode. Only molecules whose redox potential is lower than the applied voltage will react with the working electrode, hence improving selectivity well beyond that enabled by the material selectivity of the working electrode. Although amperometric sensors are more selective, have higher signal-to-noise ratio, and lower detection limits than potentiometric sensors, they suffer from the drawbacks of electrode consumption during operation (limited lifetime) and restricted scalability (miniaturization hurts detection limit and signal-to-noise ratio). They are also governed by empirical relationships rather than being grounded in theory:

$$I_{\text{peak}} = (2.68 \times 10^5) n^{3/2} A D^{1/2} [C] v^{1/2} \tag{54.5}$$

where

I_{peak} is the maximum current flowing between the electrodes
v is the sweep rate (of the voltage across the electrodes)
D is the diffusion constant of the analyte in solution
A is the cross-sectional area of the electrode
n is the number of electrons exchanged between solution and working electrode

These input/output relationships derived from data rather than theory can limit the predictability of their behavior (and resulting accuracy) in unknown sensing environments. Nevertheless, the redox potential adds another dimension to selectivity for amperometric sensors that in principle can enhance overall sensor performance. Moreover, advances in nanomaterials have reduced or eliminated the scale penalty of amperometric sensors, further increasing their competitiveness with potentiometric sensors.

54.4 Interference

Any deviation from lock-and-key selectivity is essentially chemical interference. A chemical or analyte that is not of interest in an application (oxygen to a carbon monoxide sensor, for example) is a chemical interferent. However, other sources of interference extend beyond a nondesirable analyte binding with an active chemical surface. Two primary sources of additional interference in chemical sensor operation are (1) physical interference from nonchemical interactions between the sensing environment and the active chemical sensor area and (2) electrical interference where electronic noise underlying the fundamental operation of the transduction mechanism in a chemical sensor limits overall performance. These two forms of interference are discussed next.

54.4.1 Physical Interference

Physical interference is loosely used to describe any (undesirable) interaction between a chemical sensor and the sensing environment that does not involve a strong interaction (covalent bonding) between molecule and sensor material, whether through adsorption or absorption into the sensor surface or bulk, respectively. For example, water vapor may adsorb onto the surface of a metal–oxide sensor, thus blocking reaction sites and reducing chemisorption of oxygen onto the surface. A reduction in oxygen species available for interaction with reducing gases in the environment results in an overall decrease in sensor surface area and resulting sensitivity of the sensor. Likewise, water vapor may absorb into composite polymer structures, thus inducing swelling and generating a misleading

decline in conductivity that can be falsely interpreted as a shift in concentration of the analyte(s) of interest. Similar interference can be caused by fluctuations in pH in liquid solution as fluctuations in humidity in gaseous environments. In addition to water vapor and protons/hydroxide ions, a wide range of analytes can block binding sites in chemical sensors, creating physical interference at multiple levels, both reversible and irreversible.

54.4.2 Electrical Interference

Most electrical interference associated with chemical sensor behavior and performance is noise, loosely defined as "any unwanted disturbance that obscures or interferes with a desired signal" (Motchenbacher and Connelly, 1993). Although noise can come from a variety of sources both internal and external to a sensor, most of the electronic noise that occurs in chemical sensors is directly related to the type of transduction mechanism required to convert the chemical signal to an electrical signal. Common sources of electronic noise (interference) and their impact on sensor performance are briefly discussed here. A full discussion of electronic noise is outside the scope of this chapter but an excellent text on the subject is by Motchenbacher and Connelly (1993).

Resistors: All electronic devices have some resistance associated with them and all resistors operating above temperatures of absolute zero are affected by thermal noise. Thermal or Johnson–Nyquist noise is generated by thermal fluctuations of electrons inside an electrical conductor at equilibrium. Thermal noise is independent of both frequency and applied voltage and can be expressed by an RMS voltage as follows:

$$V_{\mathrm{RMS}} = (4kTR \times \mathrm{Bandwidth})^{0.5} \tag{54.6}$$

where

k is Boltzmann's constant = 1.38×10^{23} m^2 kg s^{-2} K^{-1}
T is the temperature in degrees kelvin
R is the resistance in ohms and Bandwidth is the frequency band over which the resistor is operated (in Hz)

In a simple circuit, where a resistance is being measured directly, the bandwidth is the high frequency limit of operation of the measurement instrument. For example, consider a resistor of value 20,000 Ω, operating at 20 °C (293 K) operating in a circuit whose output voltage is measured by an operational amplifier with a maximum operating frequency of 1 MHz. The RMS noise of the resistor is then

$$V_{\mathrm{RMS}} = (4 \times 1.38 \times 10^{-23}\ \mathrm{m^2\ kg\ s^{-2}\ K^{-1}} \times 293\ \mathrm{K} \times 20{,}000\ \Omega \times 1 \times 10^{6}\ \mathrm{s^{-1}})^{0.5} = 18\ \mu\mathrm{V} \tag{54.7}$$

which simply means that the smallest voltage that can be measured across the 20,000 Ω resistor under these operating conditions is 18 μV. Conductivity in many materials, including metal–oxides and conducting polymers, can be used to directly transduce a chemical signal or analyte concentration into an electrical output (as a resistance). Unfortunately, these devices tend to have high baseline resistances on the order of 10–100 kΩ, which generates significant thermal noise and makes the small changes in resistance generated by chemical concentration even more difficult to measure. One way to reduce electrical noise (interference) in resistors is to use the fact that noise is constant across frequency to an advantage in measurement circuits. Since thermal noise increases as the square root of the bandwidth, reducing the bandwidth over which the measurement of resistance is made can significantly reduce noise. One way to do this is to use a lock-in amplifier, which can measure resistance over a very narrow range of frequencies, thus reducing noise by several orders of magnitude over standard measurement techniques.

Transistors: When chemical sensors are operated in potentiometric mode, a field effect transistor (FET) can be used to convert the electrochemical signal into an electrical output without drawing current, thus guaranteeing Nernstian operation. To do this, the interaction of the analyte of interest with the working electrode of the electrochemical cell generates all or part of the gate voltage of the transistor. As the gate voltage changes, the underlying channel current between the drain and source of the transistor changes, yet no current from gate to channel flows (as is characteristic of the fundamental behavior of a FET). However, unlike chemiresistors or conductivity-based chemical sensors, multiple types of noise are generated in the FET channel. The first is thermal noise, a characteristic of the inherent resistance of the channel. The second component of the noise is the flicker noise, which is shown as the second term in the following equation, after the thermal noise:

$$I_{\mathrm{RMS}} = \left[\left(\frac{4kT}{R_{\mathrm{channel}}} \right) \times \mathrm{Bandwidth} + [I_{\mathrm{channel}} \times K] \times \ln(f_2/f_1) \right]^{0.5} \tag{54.8}$$

where

e is an empirical constant

K is a combination of constants and geometry-dependent terms

Note that the noise in this potentiometric (FET-based) sensor is given in terms of current rather than voltage because the fundamental output of the FET-based transduction mechanism is current rather than voltage; I_{RMS} represents the minimum amount of current that can be detected by the transistor. Flicker ($1/f$) noise clearly dominates at lower frequencies. Thus, one way to reduce noise in chemFET (potentiometric) operation is to operate the sensor at high frequencies and narrow bandwidth thus reducing both $1/f$ noise and thermal noise, respectively.

Other sources of noise exist in electronic devices, yet for standard operation (defined as low to moderate frequencies of operation under room temperature conditions or above), thermal and $1/f$ noise are often the strongest source of electronic interference. Electronic noise is a key player in determining the limit of detection (lowest detectable concentration) in chemical sensors and sensor arrays; hence, careful design of measurement circuits is important to optimizing sensor performance.

54.5 Advances in Selectivity and Interference of Chemical Sensors

An immense amount of research has been dedicated over the last three to four decades to developing materials and functionalizing sensor platforms for specificity to analytes of interest. As important to sensor operation as the material, however, is the transduction mechanism and sensor platform that ultimately determine sensitivity, resolution, and detection limit. Because so many sensing applications, especially in the field, rely on ultralow limits of detection and accuracy (immunity from false alarms) at these limits, we focus this section on two promising advances in chemical sensor technology: (1) developments in nanomaterials that substantially expand usable surface area for chemical sensor response and (2) signal measurement approaches that lower the noise floor of these sensors in the interests of improving limits of detection and resolution at low concentration levels.

54.5.1 Importance of Surface Area

Whether it is of interest to a chemical sensing application or undesirable (an interferent), a chemical analyte impacts the signal produced by an electronic device involved in its transduction via (1) the electronic signal responsible for transducing the chemical signal into a usable, readable output;

(2) the interference associated with the chemical signal (selectivity and physical interference as discussed in previous sections); and (3) the interference associated with the electrical signal (various forms of noise). Reducing the interference involved in creating a chemical signal (binding a target analyte to the active sensor area) is one way to reduce interference (improving selectivity). Reducing electronic interference is another way. However, yet another approach to reducing interference in a chemical sensor is to increase the chemical signal relative to the electrical interference. The most common way of increasing chemical signal while maintaining electrical interference relatively constant is to increase the surface area of the sensor without increasing the overall sensor volume, thus increasing the ratio of chemically active area/electronically active area. In bulk sensors, however, increases in surface area are highly limited because they involve a corresponding increase in overall sensor volume. Nanoscale particles or structures embedded in a chemical sensor, however, can increase active sensor area considerably more than corresponding increases in active electronic volume. When these nanomaterials are integrated into a sensor, they create little microcosms of active sensing area within the larger sensor electronic structure, substantially increasing surface area-to-volume ratio. Nanomaterials cover a wide range of structures from nanoparticles that lack any definite shape to those with distinct shape, including nanospheres, nanowires, and nanotubes. One of the first substantial efforts at incorporating nanomaterials into sensors was by Labeau et al. (1993) involving a simple chemiresistor made of tin oxide nanoparticles, undoped or doped with palladium to increase sensitivity. The sensor delivered an 8 × increase in conductance when exposed to 300 ppm of carbon monoxide.

Since these early efforts in the use of nanomaterials for chemical sensors, the advantage of greater surface area (alongside greater surface area-to-volume ratio) has contributed to a wide range of effort in this area. A brief snapshot of the different kinds of nanomaterials used as chemical sensors and their enhancements over bulk sensor performance is provided in Table 54.2. An excellent review of chemical sensors using gold nanoparticles as the foundation of both nonoptical and optical sensors can be found in Saha et al. (2011) and a similar review for other nanostructures in Huang and Choi (2007). Advances in and theory of operation associated with reducing metal–oxide materials and sensors to nanoscale are explored by Sharma and Madou (2012). Development of carbon nanotubes (CNTs) for electrochemical sensors and the detection of molecules/analytes in biological systems are surveyed by Gao et al. (2012) and Jacobs et al. (2010), respectively. These reviews cover an enormous amount of ground with respect to the development of nanomaterials specifically for chemical sensing. Nanoscale materials for chemical sensing, in addition to providing a lower limit of detection, can also operate faster, use less power, operate at lower temperatures (as in the case of metal–oxide sensors), and sometimes have less need for expensive catalysts. However, nanomaterials may also be susceptible to instability, thermal degradation, and higher drift rates (Korotcenkov and Cho, 2010).

Of the nanomaterials, CNTs (Figure 54.4) have particular promise for use as chemical sensors. CNTs not only have the advantage of high surface area-to-volume ratio but are also chemically and mechanically stable and possess superior electronic characteristics including electronic mobilities up to 100,000 $cm^2/V\ s$ (Fam et al., 2011). Thus, they can offer high sensitivity, lower operating temperatures, and faster response times over their bulk sensor counterparts. CNTs are in a fairly unique position to provide both superior chemical sensor and superior transduction properties for use in complete chemical sensors. CNTs come in two basic forms. Single-walled carbon nanotubes (SWCNTs) are shaped as armchair, zigzag, or chiral depending on how the central axis of the tube is oriented relative to the hexagonal lattice (Figure 54.4a). Multiwall carbon nanotubes (MWCNTs) are typically concentric cylinders of carbon (Figure 54.4b). The presence of a chemical of interest typically changes the Fermi energy of the CNT (similar to doping a semiconductor) or changes the band structure of the tube, leading to a change in conductance. Both SWCNTs and MWCNTs can be used in two fundamentally different ways as chemical sensors. They can be used in their pristine form where a property of the nanotube itself changes directly with chemical concentration or alternatively, as functionalized nanotubes where metals or molecular groups are attached to the tip or sides of the nanotube to react with chemicals of

TABLE 54.2 Snapshot of Nanostructure Use in Chemical Sensors and Systems

			Performance	
Type	Material	Target Analyte	Nanoscale[a]	Bulk[a]

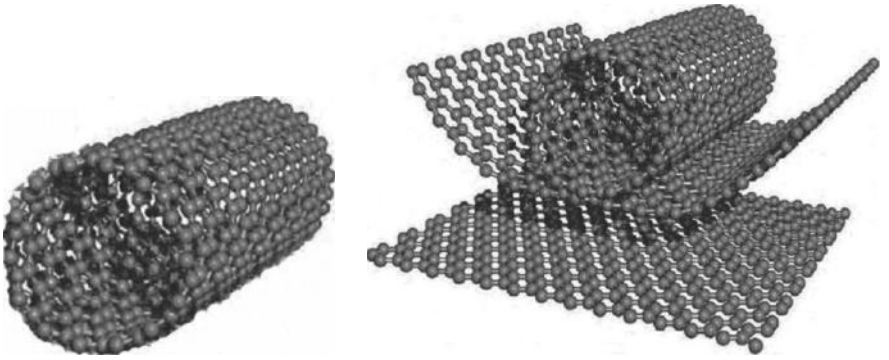
interest (Goldoni et al., 2010). Pristine CNTs have been used to detect oxygen, NO_2, ammonia, sulfur dioxide, and NO (as reviewed by Goldoni et al., 2010). These materials, as they are inherently part of the underlying CNT, make for simpler manufacturing and sensor design yet continue to suffer from the same selectivity limitations as their bulk sensor counterparts. To overcome these limitations inherent in broadly selective sensor materials, the CNT can be functionalized to provide selectivity much closer to the lock-and-key ideal. For example, CNTs functionalized in a wide variety of ways to detect



(a) Unfunctionalized SWCNT (b) Unfunctionalized MWCNT

FIGURE 54.4 CNTs used as chemical sensors: (a) A "pristine" SWCNT sensor consists of a single, unprocessed or bare CNT cylinder structurally configured in armchair, zigzag, or chiral patterns, and (b) single-wall nanotubes wrapped concentrically around each other are MWCNTs. Greater specificity (higher selectivity) can be added to the CNT sensor by adding molecules to the sides or tip of the CNT. (Images courtesy of what-when-how, www.what-when-how.com.)

chemicals of interest. A snapshot of advances in the chemical sensing capability of CNTs is provided in Table 54.3. More complete reviews of the use of CNTs to detect molecules in biological systems and in natural world environments can be found in Jacobs et al. (2010) and Goldoni et al. (2010)/Bondavalli et al. (2009), respectively.

54.5.2 New Approaches to Signal Measurement

Research and product development for portable chemical and biological sensors tend to favor a single form of signal measurement. A single measurement is often simpler, more compact, and least expensive to implement. However, additions to or adjustments to single dc measurements of chemical sensor

outputs can often be made without significant compromise to cost, size, weight, or power of chemical sensor systems while achieving valuable improvements in performance, especially resolution and limit of detection. We describe one such approach in detail here and its relevance both to conducting polymers where it was originally demonstrated as well as to other chemiresistors. Other creative approaches to signal measurement, transduction, and sensor arrays are also described briefly to convey the largely unrealized contribution that smart design of signal measurement and transduction can make to overall chemical sensor performance.

Multiple simultaneous approaches to capturing conductivity (resistance) changes as a function of a changing concentration of chemical analyte can creatively overcome some of the limitations involved in any single measurement. One such example of the benefits that can be achieved with creative signal measurement schemes without significant compromise to cost, size, or weight of a portable system is demonstrated by Lange et al. (2011). In this heterogeneous signal measurement scheme, the advantages of three ways of extracting conductivity changes resulting from chemical concentration are combined. The two-point measurement scheme used in the traditional chemiresistor consists of two electrodes (Figure 54.5a) over which a voltage (ac or dc) is applied and the resulting current is measured using a simple measurement circuit such as a voltage divider or Wheatstone bridge. Since it involves measuring a current over the same interface at which a voltage is applied, this measurement includes both channel resistance and polymer/electrode contact resistance in the resulting sensor output. Both polymer/electrode contact properties and polymer channel conductivity often change in response to biological or chemical stimulation, in different ways. A four-point measurement (Figure 54.5b) applies a fixed current between one pair of (outer) electrodes and measures the voltage across the remaining (inner) pair of electrodes. This approach, because it does not involve drawing any current at the inner pair of electrodes to make a measurement (of voltage), is insensitive to contact resistance. Using both two- and four-point

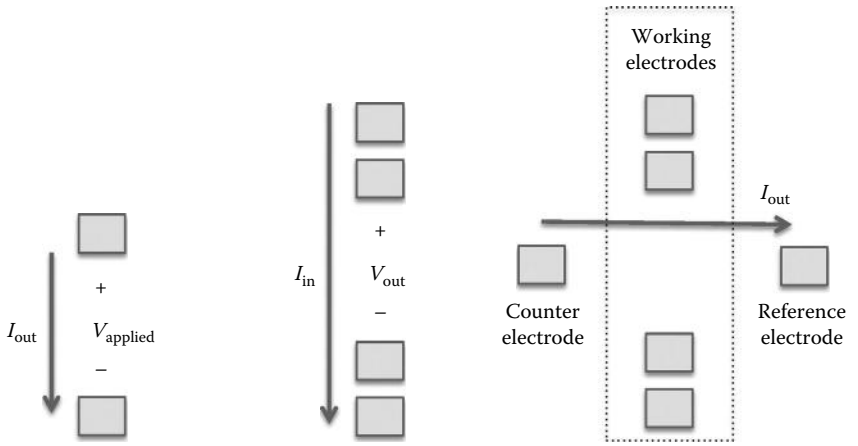

FIGURE 54.5 Multiple measurements of polymer-based chemical sensors: (a) In the standard two-point configuration (Measurement #1), a voltage is applied across two electrodes and the output current measured (usually as a voltage) using a voltage divider or Wheatstone bridge; (b) in the four-point configuration (Measurement #2), current is applied between the two outer electrodes and voltage measured on the inner electrodes (thus eliminating the contact resistance from the output); (c) in the six-point configuration (Measurement #3), the electrochemistry is measured amperometrically by the current between counter and reference electrodes.

measurements simultaneously can allow contact resistance and conductivity changes in the main polymer to be individually extracted from the sensor signal. Bulk measurements (captured by two-point and four-point signals) and contact resistance (captured by only two-point measurements) can change differently with analyte concentration due to delays in the diffusion of analyte through the conducting polymer. Thus, combining two- and four-point measurements provides information about analyte concentration both through bulk resistance and the ratio of bulk to contact resistance. This improves both detection limit and sensitivity of the device by improving signal-to-noise ratio through multiple distinct measurements of the same reaction between sensor and analyte. Successful combination of two- and four-point measurements was reported by Krondak et al. (2006) for the detection of gaseous HCL using polydialkoxybipyrroles (chemiresistor layer) combined with interdigitated gold electrodes.

This approach to signal measurement can be further enhanced by adding at third six-electrode measurement to the overall sensor. A six-electrode measurement (Figure 54.5c) is essentially a chemFET measurement, allowing the redox state of the polymer to be controlled so that only certain analytes will react with the conducting polymer surface. Lange et al. (2011) demonstrated the compact nature and the advantage of this three simultaneous measurement configuration using the conductive polymer polythiophene to detect nitrogen dioxide in a compact footprint, demonstrating faster regeneration time than single measurement configurations. Using this approach with other chemiresistive materials, including metal–oxides, can achieve similar performance benefits.

Multiple measurements of conductivity can improve the limit of detection and other performance outcomes of chemiresistors but are by no means the only signal measurement or transduction approach available for improving chemical sensor performance. Arrays, discussed previously, are another approach to improving performance and detection capability. According to basic statistics, identical sensors in an array (same material, same manufacturing technique) provide output whose resolution and detection limit improves as the square root of the number of sensors. In addition, nonidentical sensors placed in heterogeneous arrays are commonly used to increase selectivity and specificity of chemical performance. As long as the noise added by each sensor in the array does not exceed the information provided, higher density arrays can continue to make contributions to system performance when materials availability, manufacturing technique, and cost/size/weight/power constraints permit.

A wide range of other techniques have also been explored at the signal measurement and transduction level to improve chemical sensor performance. To reduce the size of chemFETs, which are essentially miniaturized potentiometric sensors, light can be used to amplify carrier levels in a much smaller capacitive structure in order to achieve comparable performance to chemFETs; these light-addressable potentiometric sensors (LAPSs) have been successfully used to detect oxygen, pH, and glucose in solution in a much smaller footprint than other electrochemical approaches to chemical sensing (Yotter and Wilson, 2004). LAPSs have been commercialized by molecular devices and have the potential to resolve events at a cell-by-cell level. Modulation of operating temperature for metal–oxide sensors has also proven useful for improving specificity, selectivity, and accuracy of these sensors (Gutierrez-Osuna et al., 2011; Rogers and Semancik, 2012). Careful signal measurement circuit design, including lock-in amplification, can substantially reduce electronic noise (Moe et al., 2004). Likewise, elimination of baseline resistance (McKennoch et al., 2001) from a conductive chemical sensor allows measurement circuit resolution to be focused on capturing chemical signal information rather than irrelevant baseline information. These and additional techniques enable signal measurement, transduction, and sensor interface design to improve overall performance for chemical sensor systems.

54.6 Conclusions

For decades, the primary emphasis on reducing interference and enhancing selectivity and specificity in chemical sensors has been on developing new or modified materials to this purpose. These efforts continue today with a focus on nanomaterials, ranging from nanoparticles to CNTs. Relative to materials development efforts, work that focuses on improving chemical sensor performance by manipulating sensor

arrays, measurement schemes, transduction mechanisms, and interface circuits has been relatively scant. However, these nonmaterial approaches to improving sensor performance can have comparable impact to advances in materials, especially when integrated into a system approach to design. Thus, future efforts in chemical sensors should place a high priority on commercialization and should take a balanced and integrated look at both materials and supporting components that make up a full chemical sensor system.

Electrochemical analysis in liquid solutions is concerned with the measurement of electrical quantities, such as potential, current, and charge, to gain information about the composition of the solution and the reaction kinetics of its components. The main techniques are based on the quantitative determination of reagents needed to complete a reaction or the reaction products themselves. Four traditional methods of electrochemistry are described here (Figure 55.1): potentiometry, voltammetry, coulometry, and conductometry. Potentiometry implies the measurement of an electrode potential in a system in which the electrode and the solution are in electrochemical equilibrium. Voltammetry is a technique in which the potential is controlled according to some prescribed function while the current is measured. Coulometry involves the measurement of charge needed to completely convert an analyte, and conductometry determines the electrical conductivity of the investigated test solution. The practical applications of these measurement techniques for analytical purposes range from industrial process control and environmental monitoring to food analysis and biomedical diagnostics. The analytical methods and their instrumentation as well as recent trends, such as electrochemical sensors, are discussed.

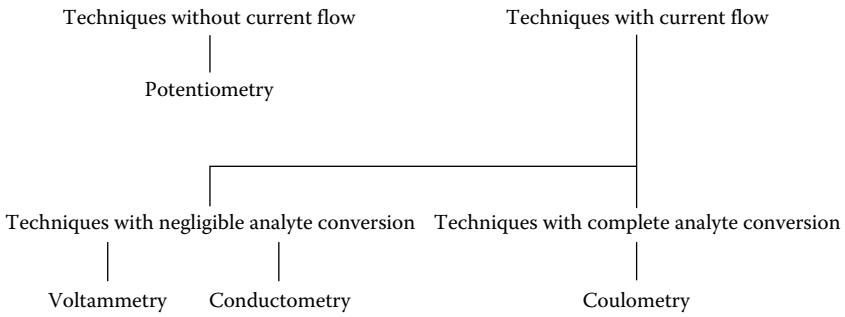

FIGURE 55.1 Electrochemical methods described in this section.

55.1 Basic Concepts and Definitions

55.1.1 Electrodes and the Electrical Double Layer

In electrochemistry, *electrodes* are devices for the detection of charge transfer and charge separation at phase boundaries or for the generation and variation of the charge transfer and separation with an impressed current across the phase boundary. One important feature of electrodes is a potential difference across the electrode/electrolyte phase boundary. At this interface, the conduction mechanism changes since electrode materials conduct the current via electrons, whereas electrolytes conduct via ions. To understand the processes that lead to the formation of the potential difference, it is helpful to consider first an atomistic model, which was given by Helmholtz. It leads to the idea of an *electrical double layer*.

If an electrode is immersed in an electrolyte solution, the bulk regions of the two homogeneous phases—the electrode material and the electrolyte—are in equilibrium. This means that far away from the phase boundary (>1 μm), the sum of the forces on the particles is zero and charges are distributed homogeneously. Since the cohesion forces that bind the individual particles together in the bulk are significantly reduced at the surface of the electrode, particles in this region will have less neighbors or neighbors from the other phase. Thus, close to the phase boundary, the equilibrium conditions are drastically different from the equilibrium conditions in the bulk of the electrolyte. This change in the equilibrium of forces on particles at the interface can lead to an *interfacial tension*. In addition, the surface of a condensed phase usually has different electrical properties than the bulk phase, for example, due to the accumulation of free charge on the surface of an electrically charged solid. Besides, the orientation of dipoles in the surface region and adsorption of ions and dipoles from the electrolyte can lead to a change in the electrical properties. This excess charge from ions, electrons, and dipoles produces an electric field that is accompanied by a potential difference across the phase boundary. The region in which these charges are present is termed the electrical double layer (Hamann et al. 2007). The formation of an electrical double layer at interfaces is a general phenomenon but only the electrode/electrolyte interface will be considered here in more detail.

According to the hypothesis of Helmholtz, the electrical double layer has the character of a plate capacitor, whose plates consist of a homogeneously distributed charge in the metal electrode and ions of opposite charge lying in a parallel plane in the solution at a minimal distance from the surface of the electrode (Rieger 1987). Modern conceptions are based on the assumption that the electron cloud in the metal extends to a certain degree into a thin layer of solvent molecules in the immediate vicinity of the electrode surface. In this layer, the dipoles of the solvent molecules (e.g., H_2O) are oriented to various degrees toward the electrode surface. Ions can accumulate in it due to electrostatic forces or be adsorbed specifically on the electrode through van der Waals and chemical forces. These substances are called *surface-active substances* or *surfactants*. The sum of oriented solvent molecules and surfactants

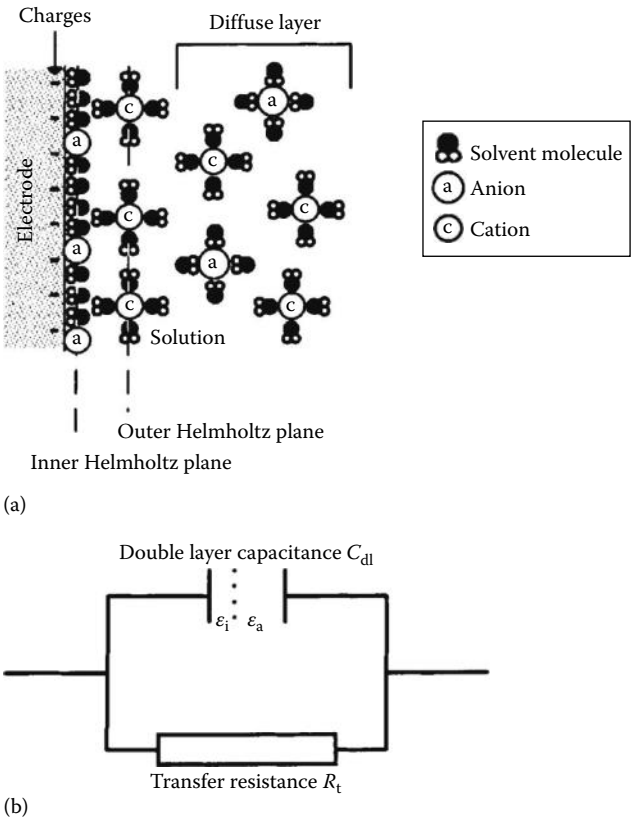

FIGURE 55.2 Helmholtz model describes the electrical double layer as a plate capacitor: (a) capacitor representation with inner and outer planes, and (b) the equivalent circuit representation.

in the immediate vicinity of the electrode is considered as one layer. The plane through the centers of these molecules and ions parallel to the electrode surface is termed *inner Helmholtz plane* (Figure 55.2).

If only electrostatic attraction is taken into account, ions from the solution can approach the surface to a distance given by their primary solvation sheaths. This means that at least a monomolecular solvent layer remains between the electrode and the solvated ion. The plane through the centers of these ions is called *outer Helmholtz plane*, and the solution region between the electrode surface and this outer Helmholtz plane is called *Helmholtz* or *compact layer*. In reality, electrostatic forces cannot retain ions at a minimal distance from the electrode surface. Due to thermal motion, the excess charge is smeared out in the direction of the electrolyte bulk to form a *diffuse layer*, also termed the *Gouy–Chapman layer*. It describes the region between the outer Helmholtz plane and the bulk of the solution. In concentrated electrolyte solutions (approx. 1 mol L^{-1}), the diffuse layer is as thin as the inner Helmholtz plane and may be considered as rigid. In highly dilute solutions, its thickness can be as large as 100 nm. As in the early model of Helmholtz, the double layer acts as a capacitor (Wang 2006). Here, two different dielectric layers with permittivities ε_i and ε_o represent the region between the electrode surface and the inner Helmholtz plane and the region between the inner and the outer Helmholtz plane, respectively (Figure 55.2).

In addition to these ideal electrostatic processes that lead to the formation of the electrical double layer, one has also to consider the transition of charge, ions, and/or electrons from the electrode phase into the electrolyte phase or vice versa. In the equivalent circuit representation, such a charge transport through the double layer is symbolized as a transfer resistance R_t connected in parallel with the capacitor. If any charge transport through the double layer is excluded, the transfer resistance is nearly infinite. According to Ohm's law, any current impressed across the electrode surface leads to a high polarization

voltage determining the electrode as *ideally polarizable*. One example of a polarizable electrode is the dropping mercury electrode (DME), which is frequently used in polarography. In the opposite case with a nearly vanishing transfer resistance, the electrode is termed *ideally unpolarizable*. In the equivalent circuit representation, this corresponds to short circuit of the capacitor. The current flow then does not influence the voltage drop across the phase boundary. *Reference electrodes*, whose voltage has to be constant when immersed in an electrolyte, are nearly unpolarizable electrodes. Since every voltage measurement is accompanied by a small current flow, the difference between polarizable and unpolarizable electrodes is very important in measurement technique.

55.1.2 Nernst Equation

If the electrode phase and the electrolyte phase contain a common ion, the potential difference across the phase boundary is determined by the effective concentration (activity) of this ion in the solution. This fact is described quantitatively by the *Nernst equation* and will be derived in the following. If one mole of ions of a species *i* has to be transferred from a given reference state outside into the bulk of an electrically charged phase, work must be expended to overcome the chemical bonding forces and the electric forces. This work is given by the electrochemical potential $\bar{\mu}_i$. Since the chemical interactions of a species with its environment always possess electric components, generally the electrochemical potential cannot be separated into chemical and electrical parts. Nonetheless, the electrochemical potential is frequently given formally as a sum of the chemical potential μ_i and an electrostatic work $zF\phi$:

$$\bar{\mu}_i = \bar{\mu}_i + zF\phi \tag{55.1}$$

The chemical potential μ_i of an uncharged component of a system is the amount of Gibbs energy G inherent in 1 mol of that component (Koryta and Stulik 2009):

$$\mu_i = \left(\frac{\partial G}{\partial n_i} \right)_{p,T} \tag{55.2}$$

Here, n_i is the number of moles of the given component. In the case of a dilute solution, the chemical potential of a component *i* is

$$\mu_i = \mu_i^0 + RT \ln c_i \tag{55.3}$$

where

$\bar{\mu}_i^0$ denotes the standard chemical potential
c_i denotes the concentration of the species *i*
R is the gas constant
T is the absolute temperature

The values of standard chemical potentials can be found in standard textbooks of thermodynamics and in tables of physicochemical constants under the name standard molar Gibbs energies. μ_i^0 is independent of the concentration c_i. In concentrated electrolytes, the concentration c_i has to be replaced by the respective activity a_i. The activity a_i is given by the relationship $a_i = \gamma c_i$, where γ is the activity coefficient that is a correction factor for nonideal behavior. In the second term of Equation 55.1, z denotes the charge number of the ion *i*, F is the Faraday constant, and ϕ is the *inner electric potential*, which is, in general, the electric work necessary for the transfer of a unit charge: for example, 1 C, from infinity to a given site.

The inner electric potential may consist of two components: an *outer electric potential* ψ and a *surface electric potential* χ. Whereas the outer electric potential of a phase is produced by excess electric charge

supplied from outside, the surface electric potential is an effect of electric forces at the interface that leads to the electrical double layer introduced earlier. The difference of the outer potentials of the electrode (e) and the solution (s)

$$\psi_e - \psi_s = \Delta\psi \tag{55.4}$$

is termed *Volta potential difference* and is the only measurable quantity. Neither the difference of the surface potentials of the appropriate phases $\Delta\chi$ nor the difference of the inner electric potentials

$$\Delta\phi = \Delta\psi + \Delta\chi \tag{55.5}$$

defined as the *Galvani potential difference* can be measured directly. Strictly speaking, even the Volta potential difference between the solution and the electrode is a not measurable quantity since only the Volta potential difference between two electrodes can be measured. To determine the potential of the solution phase, one has to dip an electrode in the solution. This, however, creates a new electrode/solution interphase, and consequently, one measures the sum of two potential differences. This is the reason for the lack of absolute potentials in electrochemistry. Therefore, one uses a reference electrode that has a known potential relative to a standard electrode.

In thermodynamic equilibrium, the electrochemical potentials of the considered species are equal in both phases. For a charged particle *i* that may cross the phase boundary solution/electrode, this means

$$\mu_{i,s}^0 + RT\ln a_{i,s} + z_i F\phi_s = \mu_{i,e}^0 + RT\ln a_{i,e} + z_i F\phi_e \tag{55.6}$$

and therefore, in equilibrium the Galvani potential difference is given by

$$\Delta\phi = \phi_e - \phi_s = \frac{\mu_{i,s}^0 - \mu_{i,e}^0}{z_i F} + \frac{RT}{z_i F}\ln\frac{a_{i,s}}{a_{i,e}} \tag{55.7}$$

Since the chemical standard potentials of the respective phases are constants, the first term in Equation 55.7 can be expressed as a standard Galvani potential difference $\Delta\phi^0$:

$$\Delta\phi = \Delta\phi^0 + \frac{RT}{z_i F}\ln\frac{a_{i,s}}{a_{i,e}} \tag{55.8}$$

For metal electrodes, the activity of the metal atoms M and that of the electrons in the electrode phase equals unity per definition. Thus, for an electrode reaction of type

$$M_s^{z+} + ze^- \leftrightarrow M_e \tag{55.9}$$

Equation 55.8 becomes the *Nernst equation*

$$\Delta\phi = \Delta\phi^0 + \frac{RT}{zF}\ln a_s \tag{55.10}$$

which gives the relation between the activity of the potential determining ion a_s and the Galvani potential difference $\Delta\phi$. Using base 10 logarithms, the Nernst equation is given as

$$\Delta\phi = \Delta\phi^0 + \frac{RT\cdot 2.3}{zF}\log a_s = \Delta\phi^0 + k\cdot\log a_s \tag{55.11}$$

where *k* is called the *Nernst constant*.

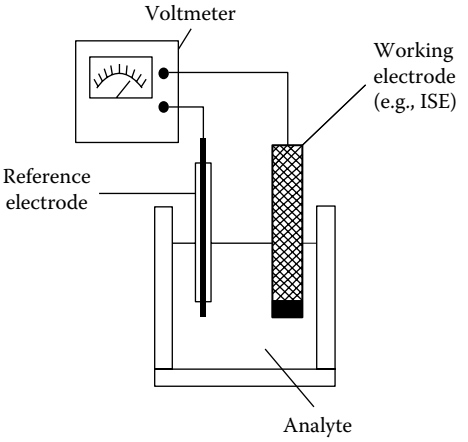

FIGURE 55.3 Schematic of an electrochemical cell with a working electrode and a reference electrode immersed in the test solution (electrolyte).

The classical form of the Nernst equation (Equation 55.10) can be formulated more generally for a redox reaction. If a_{ox} and a_{red} are the activities of the oxidized and reduced form of the considered ion, the Galvani potential difference is given as

$$\Delta\phi = \Delta\phi^0 + \frac{RT}{zF}\ln\frac{a_{ox}}{a_{red}} \tag{55.12}$$

In *potentiometry*, the activity of a certain ion can be determined directly by the measurement of the equilibrium Galvani potential difference of a suitable electrode (*direct potentiometry*). On the other hand, changes of the activity of the detected ion and equivalence points (EPs) can be detected in titration reactions (*potentiometric endpoint titration*).

After this rather theoretical definition of the Galvani potential difference, the question arises on how to measure this potential difference between the bulk of the electrode and the solution. Since a potential difference cannot be measured with only one electrode, a second one must be immersed in the solution. Both are connected to a voltmeter, to complete the *electrochemical cell* (Figure 55.3). An electrochemical cell generally consists of two (or more) electrodes immersed in an analyte. Thus, in some of the old literature, a single electrode is often referred to as a *half-cell* and its potential is called *half-cell potential*. In modern electrochemistry, usually the term *electrode potential* is used. An electrochemical cell is in a current-free state during potentiometric measurements (e.g., with an *ion-selective electrode* [ISE]), but may also supply electric energy (a galvanic cell) or accept electric energy from an external source (an electrolytic cell). Since a second electrode potential arises at the phase boundary second electrode/electrolyte, only the sum of at least two Galvani potential differences can be measured. A separation into the two individual parts is impossible. Hence, the function of the second electrode, named reference electrode, is to act as an electrode of constant potential against which variations in the potential of the measuring electrode in various samples can be measured. In the Nernst equation, the Galvani potential ϕ is then replaced by E, the symbol for measurable voltages.

55.1.3 Classification of Electrodes

Electrodes are termed *reversible electrodes* if they transfer electrons and ions with negligible impedance. Therefore, under current, the electrochemical potential of electrons, ions, and neutral species does not change across the different interfaces that may exist in an electrode. Otherwise, the electrode is not suitable to measure thermodynamic (equilibrium) quantities such as ion activity. Since distribution

equilibrium of charged species is considered here, the electrode and the solution phase must have at least one charged species in common. Depending on the number of equilibria being involved in the forming of the electrode potential, reversible electrodes can be divided into different groups:

1. *Electrodes of the first kind*. These may be cationic or anionic electrodes at which equilibrium is established between the atoms or molecules in the electrode material and the respective cations or anions in the solution. According to the Nernst equation, the equilibrium Galvani potential difference is here determined by the activity of the considered ion in the solution. Examples for electrodes of the first kind are ISEs including metal and amalgam electrodes and the hydrogen electrode.
2. *Electrodes of the second kind*. These electrodes consist of three phases. A metal wire is covered by a layer of its sparingly soluble salt that usually has the character of a solid electrolyte (e.g., Ag and AgCl). This wire is immersed in a solution containing a soluble salt of the anions of this solid electrolyte (e.g., KCl). Here, the equilibrium between the Ag atoms in the metal and the anions in the solution is established through two equilibria: the first one is given between the metal and the cation in its sparingly soluble salt, for example,

$$\mathrm{Ag} \leftrightarrow \mathrm{Ag}^{+} + \mathrm{e}^{-} \tag{55.13}$$

   and the second one between the anion in the sparingly soluble salt and the anion in the solution, for example,

$$\mathrm{AgCl} \leftrightarrow \mathrm{Ag}^{+} + \mathrm{Cl}^{-} \tag{55.14}$$

   The electrode potential of electrodes of the second kind is rather insensitive to small current flows. Thus, they are often used as reference electrodes.
3. *Electrodes of the third kind*. In this electrode, the sparingly soluble salt contains a second cation that also forms a sparingly soluble compound with the common anion but with a higher solubility product than the electrode metal compound (e.g., Ag_2S and PbS). Here, the electrode potential depends on the activity of this cation in the solution.
4. *Oxidation–reduction (redox) electrodes*. They consist of an inert metal such as Pt, Au, or Hg that is immersed in a solution of two soluble oxidation forms of a single substance (e.g., Fe^{3+} and Fe^{2+}). Thus, for the electrode reaction

$$\mathrm{Fe}^{3+} + \mathrm{e}^{-} \leftrightarrow \mathrm{Fe}^{2+} \tag{55.15}$$

   the Nernst equation is

$$E_{\mathrm{Fe}^{3+}/\mathrm{Fe}^{2+}} = E^{0}_{\mathrm{Fe}^{3+}/\mathrm{Fe}^{2+}} + \frac{RT}{F} \ln \frac{a_{\mathrm{Fe}^{3+}}}{a_{\mathrm{Fe}^{2+}}} \tag{55.16}$$

   according to Equation 55.10. Here, E is termed the *electrode potential* and E^0 is designated the *standard electrode* (or *redox*) *potential* of the electrode reaction if it is measured versus the *standard hydrogen electrode* (SHE). The subscripts of E and E^0 denote the redox couple of the considered electrode reaction. The standard redox potential is a measure of the reducing or oxidizing ability of a substance. If one considers, for example, two systems 1 and 2 with their respective standard redox potentials E_1^0 and E_2^0, system 1 is a stronger oxidant than system 2 if $E_1^0 > E_2^0$. This means that in a mixture of the solutions of these two systems where originally the activities of the reduced forms equal that of the oxidized forms ($a^1_{\mathrm{red}} = a^1_{\mathrm{ox}}$ and $a^2_{\mathrm{red}} = a^2_{\mathrm{ox}}$), an equilibrium will be

TABLE 55.1 Some Standard Electrode Potentials and Redox Potentials

Electrode or Half-Cell Reaction	E^0 (V)
$Li^+ + e^- \leftrightarrow Li$	−3.0403
$K^+ + e^- \leftrightarrow K$	−2.931
$Ca^{2+} + 2e^- \leftrightarrow Ca$	−2.868
$Mg^{2+} + 2e^- \leftrightarrow Mg$	−2.372
$Al^{3+} + 3e^- \leftrightarrow Al$	−1.662
$Zn^{2+} 2e^- \leftrightarrow Zn$	−0.762
$Fe^{2+} + 2e^- \leftrightarrow Fe$	−0.447
$Pb^{2+} + 2e^- \leftrightarrow Pb$	−0.1264
$AgCl + e^- \leftrightarrow Ag + Cl^-$	0.22216
$Hg_2Cl_2 + 2e^- \leftrightarrow 2Hg + 2Cl^-$	0.26791
$Cu^{2+} + 2e^- \leftrightarrow Cu$	0.3417
$I_2 + 2e^- \leftrightarrow 2I^-$	0.5353
$Fe^{3+} + e^- \leftrightarrow Fe^{2+}$	0.771
$Ag^+ + e^- \leftrightarrow Ag$	0.7994
$Tl^{3+} + 2e^- \leftrightarrow Tl^+$	1.2152
$2Cl^- \leftrightarrow Cl_2 + 2e^-$	1.35793
$Ce^{4+} + e^- \leftrightarrow Ce^{3+}$	1.610

established with $a^2_{ox} > a^2_{red}$ and $a^1_{red} > a^1_{ox}$. The experimentally determined standard potentials of well-known redox systems are listed in (Haynes 2011). Table 55.1 gives some examples. In redox electrodes, the metal acts as a medium for the electron transfer between the two forms. In contrast to electrodes of the first kind, the solution should not contain ions of the electrode metal in order to avoid an additional Galvani potential difference at the electrode determined by the activity of the electrode metal ions in the solution. This disturbing ion activity is negligible if the standard potential of the electrode metal is a few 100 mV higher than the redox potential to be measured. Thus, mainly platinum electrodes ($E^0_{Pt^{2+}/Pt} = 1.20$ V) and gold electrodes ($E^0_{Au^+/Au} = 1.42$ V) are used as redox electrodes.

55.1.4 Reference Electrodes

The potential of an ISE is always measured with respect to a reference electrode. Ideally, the reference electrode should not cause chemical changes in the sample solution, or vice versa. It should maintain a constant potential relative to the sample solution, regardless of its composition. In practice, any changes of its potential with composition should be at least as small as possible and reproducible. Reference electrodes with liquid junctions, strictly speaking reference electrode *assemblies*, consist of a reference element immersed in a filling solution (often called bridge solution) contained within the electrode. This reference element should possess a fixed activity of the ion defining the potential of the element with respect to the filling solution. The electric contact between the electrode and the sample solution is made by the liquid junction consisting of a porous plug or a flow restriction that permits the filling solution to flow very slowly into the sample.

At the junction between the two electrolyte solutions, ions from both solutions diffuse into each other. Since different ions have different mobilities, they will diffuse at different rates. Thus, a charge separation will occur related in size to the difference in mobilities of the anions and cations in the two solutions. This charge separation produces a potential difference across the junction called the *liquid junction potential* (Morf 1981). In reference electrodes, usually the bridge solution is given a slightly higher pressure than the sample so that the solution, often concentrated potassium chloride, flows out

relatively rapidly into the sample and diffusion of the sample back into the salt bridge is impeded. If the bridge solution is concentrated enough, it is assumed that variations in the liquid junction potential due to the varying composition of the sample are suppressed. This is the basis on which the reference electrode assembly is used. Since the potential of the whole assembly E_{ref} is the sum of the potential of the reference element E_r in the bridge solution and the liquid junction potential E_j

$$E_{ref} = E_r + E_j \tag{55.17}$$

any change in the liquid junction potential appears as a change in the potential of the assembly. An extra liquid junction potential must be included if a *double-junction* reference electrode is considered. When an analysis using a cell with an IES is carried out, standard solutions are used to calibrate the ISE. A change in the liquid junction potential that occurs when the standard solutions are replaced by the sample is termed the *residual liquid junction potential* and constitutes an error in the analytical measurement. The needed constancy of the potential can be approached by a suitable choice of standards and/or sample pretreatment and by the use of a proper bridge solution and the best physical form of the liquid junction.

Several types of liquid junctions exist from which the best ones with regard to stability and reproducibility are complicated to realize in practice and the worst ones are easy to use but much less stable and reproducible. Most of the commercial reference electrodes with adequate properties possess *restrained diffusion junctions* where the most common junctions available are the ceramic plug, the asbestos wick or fiber, two types of ground sleeve junction, and the palladium annulus junction (Figure 55.4). For a very large majority of applications with IESs, a ceramic plug will perform adequately. The flow rate of the bridge solution into the sample solution is sometimes called leak rate and is given in mL per 5 cm head of

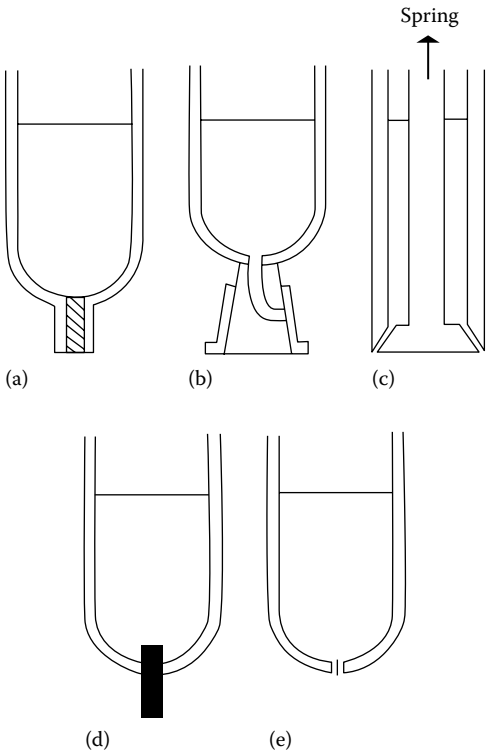

FIGURE 55.4 Different types of liquid junctions: (a) ceramic plug, (b) ground glass sleeve (type 1), (c) ground glass sleeve (type 2), (d) asbestos wick, and (e) palladium annulus.

bridge solution per day. The head of bridge solution is measured as the height of the surface of the bridge solution above the surface of the sample. In order to work satisfactorily, the surface of the bridge solution of all these restricted junction devices has to be at least 1 cm above the sample solution. Otherwise, if the bridge solution falls too low, the junction and the bridge will become contaminated by species diffusing from the sample. The bridge solution has then to be replaced. For the same reason, reference electrodes should be stored, when not in use, with the junction immersed in bridge solution.

Whereas the ceramic plug and the asbestos wick and fiber (Figure 55.4a and d) have relatively slow flow rates of about 0.01–0.1 mL per 5 cm head of bridge solution per day, ground sleeve junctions of type (b) have a flow rate of 1–2 mL. On the other hand, the flow rates of different asbestos wick junctions may vary by a factor up to 100, and the liquid junction potential may have a day-to-day (in) stability of ±2 mV under the favorable conditions of a junction between strong potassium chloride solution and an intermediate pH buffer. Under the same conditions, ground glass sleeve junctions of type (b) and the little-used palladium annulus junction show stabilities of ±0.06 and ±0.2 mV, respectively. It is worth mentioning that palladium annulus junctions may partly respond as a redox electrode in strong oxidants (e.g., 0.2 M $KMnO_4$ in 0.05 M H_2SO_4) and mild or strong reductants (e.g., 0.5 M $SnCl_2$ in 1 M HCl). In such samples, reference electrodes with palladium or platinum annulus junctions should not be used. Although ground glass sleeve junctions have inconveniently high flow rates and the bridge solution needs to be replenished frequently, these junction types have found particular use in applications where the junction has the tendency to clog, such as measurements in protein solutions. However, the stability of the liquid junction potential appears to be relatively poor in fast-flowing sample solutions and may be very sensitive to sample flow rate. Asbestos wick junctions are particularly liable to blockage and should consequently be used in clear solutions only.

In *double-junction reference electrodes*, the filling solution in which the reference element is immersed (reference solution) makes contact with another solution, the bridge solution, by means of a liquid junction. A second liquid junction enables contact to be made between the bridge solution and the sample. Such electrodes are useful when it is essential that contamination of the sample by the inner filling solution must be kept at a very low level. The outer bridge solution can be selected to be compatible with the sample. In order to minimize the liquid junction potentials that can drift and cause instability, the bridge solution should be equitransferent; that is, the transport numbers of its anion and cation should be nearly equal. However, the complication of a second liquid junction in the cell should be avoided if possible.

55.1.4.1 Standard Hydrogen Electrode

Aqueous solutions are of major concern in electrochemistry because of their hydrogen ion content. Thus, it is advantageous to use a reference electrode where a reaction occurs that involves the participation of hydrogen ions. One of these reactions is

$$\frac{1}{2}H_2 + H_2O \leftrightarrow H_3O^+ + e^- \tag{55.18}$$

Figure 55.5 shows a hydrogen electrode. A hydrogen electrode usually consists of a platinum sheet covered by a thin layer of spongelike structured platinum, so-called platinum black that has a high specific surface area. This electrode is rinsed with pure gaseous hydrogen in order to form a complete layer of adsorbed H_2 molecules at the surface. If this electrode is immersed in an electrolyte, it acts as an electrode consisting of hydrogen at which the gaseous hydrogen is oxidized to hydronium ions or the hydronium ions are reduced to hydrogen, respectively, according to Equation 55.18. The real mechanism of this electrode process is rather complicated because the platinum electrode is in contact with the hydronium ions in the solution as well as with the gaseous hydrogen that is bubbled through it. Thus, the final equilibrium between the gaseous hydrogen, the dissolved hydronium ions, and the electrode phase consists of several successive equilibrium steps that can be found in Koryta (1991).

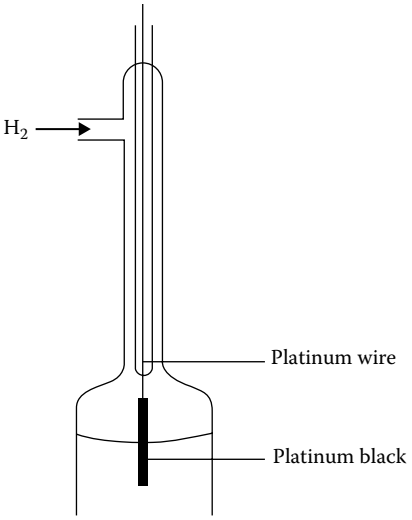

FIGURE 55.5 Schematic of a hydrogen electrode.

To calculate the potential of a hydrogen electrode, which is strictly speaking the difference between the potential of the electrode and that of the solution, one has to consider the electrochemical potentials of the respective phases. The chemical potential of gases is usually expressed in terms of the pressure p instead of the molar concentration c. Due to the elementary relationship $pV = nRT$ for ideal gases, where V is the volume of the gas and n is the amount of moles the pressure, p is proportional to the molar concentration $c = n/V$. Thus, according to Equation 55.3

$$\mu_{H_2} = \mu^0_{H_2} + RT \ln \frac{P_{H_2}}{P^0_{H_2}} \tag{55.19}$$

where μ_{H_2} and $\mu^0_{H_2}$ are the pressure and standard pressure of hydrogen, respectively. In the case of moderate ion concentrations, the chemical potential of the solvent water is equal to its standard chemical potential. Hence, the potential difference between the electrode and the solution is, according to Equation 55.7,

$$\Delta\phi = \frac{\mu^0_{H_3O^+} - \frac{1}{2}\mu^0_{H_2} - \mu^0_{H_2O}}{F} + \frac{RT}{F} \ln c_{H_3O^+} - \frac{RT}{2F} \ln \frac{P_{H_2}}{P^0_{H_2}} \tag{55.20}$$

This equation is generally valid for hydrogen electrodes. The electrode is called SHE if the molar concentration is such that the activity of the hydronium ions is unity ($a_{H_3O} = 1$) and the pressure of hydrogen is equal to its standard pressure. Hence, for an SHE, the second and third terms in Equation 55.20 vanish. The combination of standard chemical potentials in the first term of Equation 55.20 is defined as zero. Consequently, the total potential difference across the interface SHE/electrolyte is equal to zero *by definition* at any temperature. Since SHEs are very difficult to prepare, they are not used as reference electrodes in practice. However, electrode potentials are usually standardized with respect to the SHE, and their values are thus called "on the hydrogen scale."

55.1.4.2 Calomel Electrode

The calomel electrode is the most common of all reference electrodes. It consists of a pool of mercury that is covered by a layer of mercurous chloride (calomel, Hg_2Cl_2). The calomel is in contact with a

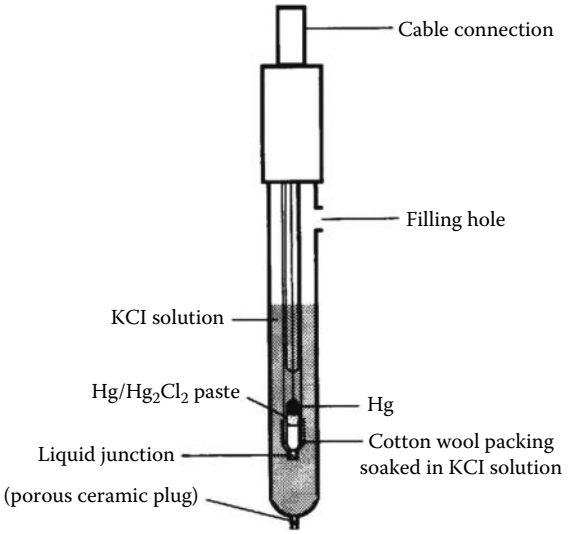

FIGURE 55.6 Schematic of a calomel reference electrode.

reference solution that is nearly always a solution of potassium chloride, saturated with mercurous chloride. Thus, the calomel electrode is a typical electrode of the second kind. Figure 55.6 shows a typical arrangement of a commercial calomel electrode assembly where the electrode is inverted, with the mercury uppermost, and packed into a narrow tube. Depending on the strength of the potassium chloride solution used, the electrode is called saturated calomel electrode (SCE), 3.8 or 3.5 M calomel electrode, respectively. Potassium chloride is used as reference solution because it gives rise to a small liquid junction potential at the outer liquid junction of the electrode, that is, the liquid junction with the sample. Hence, potassium chloride is a suitable reference solution as well as a good bridge solution. Furthermore, mercurous chloride has a very low solubility in potassium chloride solutions, regardless of concentration. The electrode reaction of a calomel electrode is

$$Hg + Cl^- \leftrightarrow \frac{1}{2}Hg_2Cl_2 + e^- \tag{55.21}$$

Its standard potential, including the liquid junction, is 0.2444 V versus SHE at 25 °C for the SCE and 0.2501 V for the 3.5 M calomel electrode (Bailey 1980; Koryta et al. 1993).

The components of a calomel electrode are chemically stable except for the mercurous chloride, which significantly disproportionates at temperatures above 70 °C according to the following equation:

$$Hg_2Cl_2 \leftrightarrow Hg + HgCl_2 \tag{55.22}$$

Hence, potential drift occurs and lifetime decreases with increasing working temperature. On the other hand, calomel electrodes can be used at temperatures down to −30 °C if 50% glycerol is added to the potassium chloride solution.

Impurities in the potassium chloride solution, such as bromide and sulfide ions as well as redox agents and complexants, cause a small shift in the electrode potential. Nevertheless, the measurement of potential differences is not affected. However, the most unsatisfactory feature of the performance of the calomel electrode is its thermal hysteresis that occurs if the electrode filling material is not in thermal equilibrium or if the electrode and the sample have different temperatures. Thus, temperature stability

during the storage and measurements is very important. In any cases where the temperature of the reference electrode or the sample has to be varied, it is thus usually better to use a silver/silver chloride electrode instead of a calomel electrode.

55.1.4.3 Silver/Silver Chloride Electrode

The silver/silver chloride electrode consists of a silver wire or plate that is coated with silver chloride. For the same reasons as with the calomel electrode, this phase is in contact with a strong potassium chloride solution, here saturated with silver chloride. Figure 55.7 shows the diagram of a typical Ag/AgCl reference electrode. Since this kind of reference electrode is the simplest and for many applications the most satisfactory one, it is commonly used as internal reference electrode of pH electrodes and other IESs. Besides, Ag/AgCl electrodes can be easily prepared in the laboratory. In contrast to mercury-based electrodes, the Ag/AgCl electrode does not contain toxic chemicals and is therefore recommendable for measurements in food.

The major problem with the Ag/AgCl electrode is the considerably high solubility of AgCl in concentrated potassium chloride solution. Thus, especially for the use at high temperatures, a sufficient excess of solid silver chloride must be present in the reference solution. This can be achieved, for example, through the addition of a few drops of diluted silver nitrate solution. Otherwise, silver chloride will dissolve off the electrode until saturation is reached. As a consequence, the electrode potential will drift and the lifetime of the electrode will be shortened. However, in contrast to the calomel electrode, the Ag/AgCl electrode can be used successfully up to 125 °C. Its electrode potential is very stable in the long term in pure potassium chloride solutions, but is affected by impurities like redox reagents and species that react with the silver chloride, as with the calomel electrode. Unlike the calomel electrode, in the Ag/AgCl electrode, the concentration of the electrode coating in the bridge solution is rather high. Thus, a greater amount of reaction products (e.g., solid silver sulfide) may arise in the reference solution and block the liquid junction causing drift and instability of the electrode potential. In contrast to the calomel electrode, the silver/silver chloride electrode shows only very small thermal hysteresis effects that are usually negligible. Hence, this kind of electrode is suitable for measurements in samples with varying temperatures. Ag/AgCl electrodes are relatively insensitive to polarization. The standard potentials, including the liquid junction potentials of saturated and 3.5 M silver/silver chloride electrodes, at 25°C are 0.1989 and 0.2046 V, respectively (Bailey 1980). As with the calomel electrode, the nomenclature of the electrodes is derived from the potassium chloride concentration of the respective reference solution.

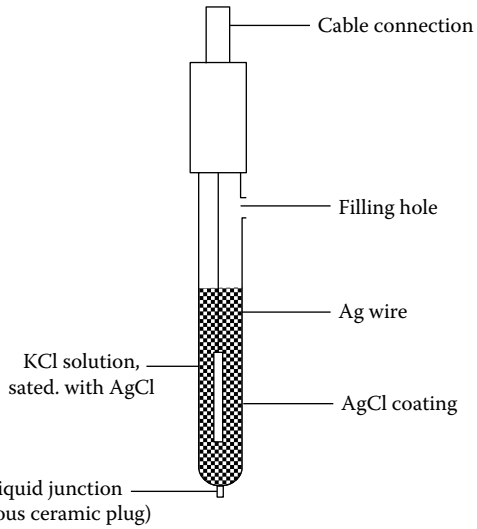

FIGURE 55.7 Schematic of a Ag/AgCl reference electrode.

55.2 Volumetry

The basic concept of *voltammetry* is the measurement of the current *i* at a redox electrode as a function of the electrode potential *E* (Bard and Faulkner 2001). During the experiment, the electrode is immersed in a solution that contains an electroactive species, that is, a species that can undergo an electrode reaction (standard redox potential E^0). The electrode potential is changed from a value $E_1 < E^0$ to a value $E_2 > E^0$ or vice versa in a manner that is predetermined by the operator. Thus, during the measurement, the electrochemical equilibrium shifts from the oxidized (reduced) form of the analyte to the reduced (oxidized) form. The resulting charge transfer across the interface electrode/solution can be observed as a current flow, which is termed *faradaic*.

55.2.1 Instrumentation

Voltammetric measurements are usually performed with a cell arrangement of three electrodes (Figure 55.8). The redox electrode at which the electrode processes occurs is called *working electrode*. Its potential is measured against a suitable reference electrode, often Ag/AgCl or calomel. To adjust the potential difference between the working and the reference electrode to a certain value, a current is forced through the working electrode. Because the current and the electrode potential are related functionally, this current is unique. However, the current through the reference electrode must be kept as small as possible. Therefore, a third electrode called *auxiliary electrode* or *counter electrode* is usually employed to close the current circuit. It should be emphasized that there are two circuits: one in which the current flows and which contains the working and the auxiliary electrode and another, a current-free one, in which the potential difference between the working and the reference electrode is measured. Since almost no current flows through the reference electrode, its potential can be regarded as constant and the measured change in potential equals the potential change of the working electrode. The current through the working electrode, and thus its potential, can be adjusted by controlling the voltage between the working and the auxiliary electrode. This task is performed by an instrument called a *potentiostat*, which basically consists of a voltage source and a high-impedance feedback loop. With a function generator that may be integrated into the potentiostat, the potential time course can be predetermined. Modern potentiostats are controlled by a PC and offer the possibility to program many different potential time courses. Thus, they allow the performance of several voltammetric techniques, as are discussed later. The measured current can be displayed as a function of the electrode potential or of time using a strip-chart or *xy* recorder or a PC.

There are two possibilities to operate an electrochemical cell: in so-called *batch cells*, the electrolyte solution rests stationary during the measurement, whereas in *flow-through cells*, it flows across the electrode. Between two measurements with different solutions, the cell must be cleaned in order to remove

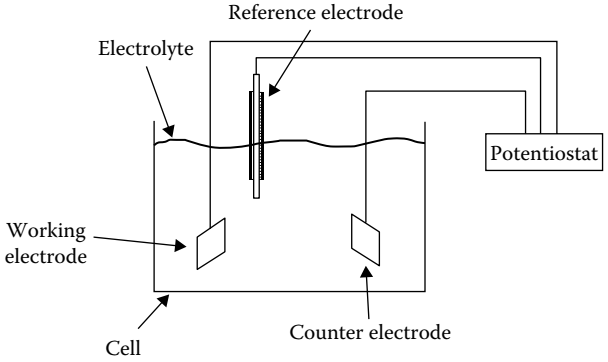

FIGURE 55.8 For voltammetric measurements a three-electrode arrangement is usually employed.

residues of the preceding measurement's solution that could disturb the new measurement. The electrochemical cell is usually built of glass or Teflon because of these materials' chemical inertness.

The chemical inertness is also important for the choice of the working electrode because the electrode must not change during the measurement. Common materials are gold, platinum, and mercury. Several kinds of carbon electrodes (e.g., glassy carbon) are also used but are often covered with gold or mercury. An advantage of the solid-state electrodes is their easy handling. They can be employed as planar or as wire electrodes. Further, with the noble metal electrodes, substances having a more positive redox potential than mercury can be investigated. However, the use of mercury electrodes offers distinct advantages and the voltammetric techniques using mercury electrodes are extremely well developed. These techniques play a major role in electroanalytical methods and are summarized under the term *polarography*.

In polarography, mercury is used either as a *thin mercury film electrode* (TMFE) or as a *hanging mercury drop electrode* (HMDE). The HMDE can be a *stationary mercury drop electrode* (SMDE) or a DME. The drop is produced from a thin capillary with an inner diameter that can range from several ten to a few hundred micrometers. The size of an SMDE is held constant during the measurement, whereas a DME constantly grows during its lifetime until it falls from the capillary due to its weight.

The main advantages of mercury drop electrodes are their good reproducibility and their high *overpotential* for the hydrogen evolution, that is, the fact that hydrogen evolution is inhibited and thus occurs at much higher potentials than would be expected from the standard potential. The good reproducibility is achieved because a new drop can easily and rapidly be produced from the capillary for each measurement. Hence, the contamination of the electrode with substances from a preceding measurement and from impurities in the solution is near zero. However, a drawback of HMDEs is their relative mechanical instability, which can be a problem in flow-through cells, in field measurements, and if the solution is stirred.

Stirring of the solution is often applied during the measurement if the supply of reactive species at the electrode should be enhanced. However, this forced convection affects the electrode current. Moreover, the electrolyte is often stirred and bubbled with an inert gas like nitrogen or argon before voltammetric measurements are carried out to remove dissolved oxygen. This is usually necessary to reduce background currents from oxygen reduction and to prevent undesirable oxidation or precipitation of solution components. Because the electrode currents, especially in trace and ultratrace analysis, can be quite small, it is common to place the cell in a faradaic cage to shield it from electromagnetic stray fields. Coaxial cables are then used for the electric connections from the cell to the instruments.

55.2.2 Principles of Voltammetry

Actually, the electrode current measured in voltammetry is a sum of two currents that arise due to different processes. Besides the faradaic current i_f, a capacitive current i_c results from changes in the *double-layer charging*. Although the faradaic current is a direct measure for the rate of the electrode reaction, several effects usually occur that have to be considered.

55.2.2.1 Diffusion Limitation of the Faradaic Current

The decrease of the analyte concentration at the electrode surface due to an electrode reaction must be balanced by the diffusion of species from the bulk solution. In most measurements, the consumption of reactive species is faster than the supply by diffusion, and the effect of *diffusion limitation* of the faradaic electrode current is observed. To understand this important point, the time-dependent concentration profile of the analyte has to be calculated using *Fick's laws*. The electrode current can then be derived as a function of time. According to Fick's first law, the flux j of the analyte at the point r and at the time f is proportional to the gradient of the analyte concentration c:

$$j(r,t) = -D\nabla c(r,t) \tag{55.23}$$

The proportionality factor D is called the *diffusion coefficient*. At the electrode surface, the flux must be equal to the number of moles N converted per unit of time and surface area by the electrode reaction:

$$j(0,t) = \frac{\mathrm{d}N}{\mathrm{d}t} \tag{55.24}$$

The faradaic current i_f is related to dN/dt according to

$$i_f = \frac{nFA\mathrm{d}N}{\mathrm{d}t} \tag{55.25}$$

where

n is the number of electrons involved in the reaction of a single analyte particle
F is the Faraday constant and
A is the surface area of the working electrode

The *Nernst diffusion layer* model assumes that within a layer of thickness δ, the analyte concentration depends linearly on the distance from the electrode surface until it reaches the bulk concentration c_0. For simplicity, the diffusion problem is often considered to be 1D as it is the case for a planar working electrode in a cylindrical cell. The combination of Equations 55.23 through 55.25 then gives

$$i_f = nFAD\left(\frac{(c_0 - c_e)}{\delta}\right) \tag{55.26}$$

where c_e is the concentration at the electrode surface. For a sufficiently large difference between the applied potential and the standard potential of the analyte's redox couple, all species reaching the electrode surface by diffusion are immediately converted, and the faradaic current reaches a maximum. In this case, the analyte concentration c_e at the electrode surface can be regarded as zero.

The diffusion profile and thus the dependence of δ from time can be obtained by solving the differential equation that is known as Fick's second law:

$$\frac{\partial c(r,t)}{\partial t} = D\nabla^2 c(r,t) \tag{55.27}$$

where ∇^2 is the Laplacian operator. For *linear diffusion*—that is, 1D diffusion as it was considered in Equation 55.26—the solution of Equation 55.27 with the appropriate boundary conditions ($c_e(t = 0) = c_0$; $c_e\ (t > 0) = 0$; $c(x > \delta = c_0)$) yields

$$\delta = \mathrm{sqrt}(\pi Dt) \tag{55.28}$$

Combination with Equation 55.26 leads to the *Cottrell equation*:

$$i_f(t) = nFAc_0\mathrm{sqrt}\left(\frac{D}{\pi t}\right) \tag{55.29}$$

After reaching a maximum value, the current decreases with $t^{-1/2}$ and is proportional to c_0, whereas the diffusion layer thickness increases with $t^{1/2}$ (Figure 55.9).

For a spherical electrode of radius r_0, as it is the case for HMDEs, one has to change to spherical coordinates and Fick's second law becomes

$$\frac{\mathrm{d}c(r,t)}{\mathrm{d}t} = D\left[\frac{\mathrm{d}^2 c(r,t)}{\mathrm{d}r^2} + \frac{r\ \mathrm{d}c(r,t)}{\mathrm{d}r}\right] \tag{55.30}$$

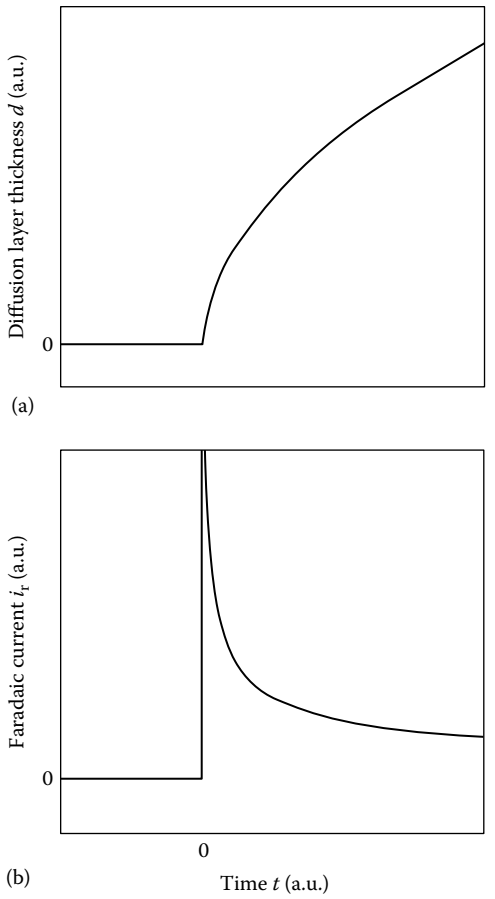

FIGURE 55.9 At a planar electrode, the diffusion layer thickness increases with $t^{1/2}$ (a), whereas the diffusion-limited current decreases with $t^{-1/2}$ (b).

where $r > r_0$ is the radial distance from the electrode center. The solution of Equation 55.30 with the appropriate boundary conditions $c(r, 0) = c_0$, $\lim(r \to \infty)\, c(r, t) = c_0$, $c(r_0, t > 0) = 0$ yields the current–time relation

$$i_f(t) = n\mathrm{FAD}c_0\left[\frac{1}{(\pi Dt)^{1/2}} + \frac{1}{r_0}\right] \tag{55.31}$$

The first term in brackets equals that for the linear case; the second, constant term reflects the fact that the surface of the spherical diffusion layer grows and thus can draw an increasing number of reactive species.

The situation is even more complicated for DMEs because in addition to the surface of the diffusion layer, the surface and the radius of the drop are growing during the drop's lifetime. At any time, the growing electrode surface forces the depletion layer to stretch over a still larger sphere, which makes the layer thinner than it otherwise would be. A rigorous mathematical approach to this is rather difficult because the relative convective movement between the solution and the electrode during drop growth must be considered (Bard and Faulkner 2001). However, a simplified approach that is valid when the second term in Equation 55.31 is negligible and the diffusion problem can be regarded as linear yields the *Ilkovic equation*

$$i_f(t) = 708nDcm^{2/3}t^{1/6} \tag{55.32}$$

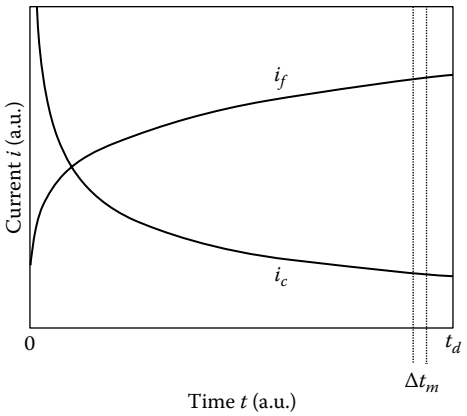

FIGURE 55.10 At a DME the measurement is performed during a time interval Δt_m at the end of the drop's lifetime when the ratio i_f/i_c is very large.

where m is the mercury flow rate (mass/time) from the capillary. Consequently, the current increases during the lifetime t_d of the drop (*drop time*), whereas it decreases with time in the other arrangements that have been described. Figure 55.10 depicts this current–time relation of a DME with the characteristic current plateau at the end of the drop's lifetime.

In the considerations that have been made previously, analyte transport by convection and migration in the electric field have been neglected. Convection can be regarded as absent if the solution is unstirred and if the working electrode rests motionless. However, in longer-lasting measurements, convective mass transport can play a role due to arising inhomogeneities in the density of the solution. Furthermore, if a DME is employed, the growth of the drop may cause a considerable convection of the solution. When the drop falls off, it stirs the surrounding solution and the depletion effect almost vanishes. Consequently, every drop is born in an almost homogeneous environment. The migration of electrically charged analyte particles due to the electric field in the solution can easily be suppressed using an inert supporting electrolyte with a concentration that is much larger than the analyte concentration. Since all charged species contribute to the migration current, the migration of the analyte species can then be neglected.

55.2.2.2 Double-Layer Charging Current

A process that affects all kinds of voltammetric measurements is the flow of *capacitive current*. The accumulation of charge on one side of the electrode/solution interface causes the necessity of a mirror charge on the other side. Hence, a change of the electrode potential (i.e., in the electrode charging) causes a corresponding flux of charged particles between the double layer and the bulk solution. Therefore, the interface has a certain capacitance that is called the double-layer capacitance. The resulting *double-layer charging current* i_c is superimposed on the faradaic current and often perturbs its measurement. In analytical techniques, one is often concerned with the reduction of the capacitive/faradaic current ratio. However, the actual measurement of the double-layer capacitance is demanding and requires the technique of *impedance spectroscopy*, as described, for example, in Gileadi (1993) and Bard and Faulkner (2001).

55.2.2.3 Irreversible Electrode Processes

Another assumption that has been made implicitly is that the rate of the electrode reaction is very fast in comparison to the supply of analyte by diffusion (*reversible electrode process*). Under this condition, all analyte species reaching the electrode are immediately converted. However, if the reaction rate is too slow, the consumption of reactive species is compensated by the diffusion of the analyte (*irreversible electrode process*), and thus, the concentration at the electrode surface never drops to zero. The electrode current is then determined by the reaction rate, and the previous calculations do not hold. In practice,

the situation is sometimes complicated if so-called *quasi-reversible* electrode processes with intermediate reaction rates occur. Although this concept of electrochemical *reversibility* is a simplification, it is a suitable working basis and can be summarized in the following statement: in a given electrochemical experiment, an electrode process that follows the *Nernst equation* at *any time* is called *reversible*.

55.2.2.4 Influence of Adsorption, Catalysts, and Chemical Reactions

Besides the diffusion and reaction rate, some other processes can influence the electrode current. *Adsorption* of the analyte or its reaction product on the electrode changes the double-layer capacitance or can passivate the electrode surface and thus lower the current. Moreover, if a species serves as a *catalyst*, it may shift the equilibrium potential. In the case that the catalyst returns the product of the electrode reaction back into the initial form of the analyte, the analyte concentration at the electrode surface will always be large and thus increases the limiting current and shifts the equilibrium. All these *catalytic currents* are subject to analytical studies. Besides adsorption and catalysis, complicated scenarios occur if the electrode reaction is followed by a chemical reaction whose product itself undergoes an electrode reaction within the observed potential range.

55.2.3 Techniques

The several voltammetric (i.e., *potential-controlled*) techniques differ just in the manner in which the electrode potential is varied with time. The potential can be changed in distinct steps, in a continuous sweep, or it can be pulsed or superimposed with an ac signal. In addition, the rate of potential change can be varied. The characteristics, advantages, and drawbacks of the most important techniques will be discussed in the following sections. Special attention will be given to polarography due to its practical importance in electroanalysis. Besides, the emphasis will be on reversible electrode processes because only they allow the realization of *analytical* investigations, on which this chapter is focused.

55.2.3.1 Amperometry

If in a *potential step* experiment the working electrode potential is abruptly changed from a constant value E_1 where faradaic processes do not occur to another constant value E_2 where the electrochemical equilibrium is on the side of the oxidized or reduced form of the analyte, then a faradaic current begins to flow (Figure 55.11a). In the case that the difference between the applied potential and the standard potential E^0 of the analyte's redox couple is sufficiently large, the effect of *diffusion limitation* sets in and a further increase of the potential difference yields no increase in the electrode current. The current is then called *limiting current*. The current–time relationship follows the Cottrell equation (Equation 55.29), with the current decreasing while the diffusion layer thickness increases.

If the diffusion layer thickness could be held constant, then from Equation 55.26, it follows that the current would not decrease with time but remain at a constant value. This can be accomplished if the solution is stirred or flows across the electrode in a proper way. According to Equation 55.26 (with $c_e = 0$), the current then is proportional to the analyte concentration in the solution.

The described method corresponds to the electroanalytical technique called *amperometry* (Oehme 1991), with the exception that in this the potential step is omitted and the electrode current is measured at a fixed potential E at which the analyte undergoes an electrode reaction and the faradaic current is in the limited region. The solution usually crosses the electrode in a laminar flow, keeping the diffusion layer thickness constant.

Because the electrode current is proportional to the concentration of the analyte, only two measurements are needed for calibration. The base current is measured in an analyte-free solution, and a second measurement is performed at a known analyte concentration. It should be mentioned that amperometry cannot only be used to determine liquid and ionic components of a solution but also to measure the amount of dissolved gas in a liquid. Moreover, with modified electrochemical cells, even gas analysis can be accomplished.

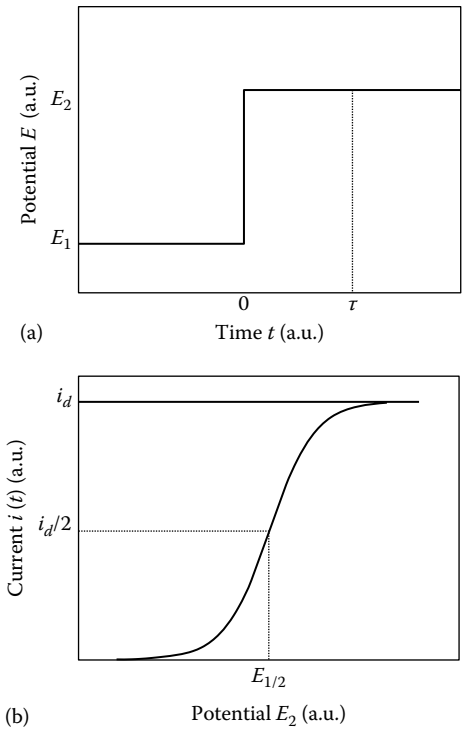

FIGURE 55.11 In potential step techniques, the current is measured a fixed time τ after the potential step (a). The measurement of $i(\tau)$ for different potential steps ΔE yields a wave-shaped current–potential relation with a half-wave potential $E_{1/2} \approx E^0$ (b). The maximum current is proportional to the analyte's bulk concentration c_0.

The main disadvantage of amperometry is its poor selectivity. Given a certain analyte and operating at a higher potential than the corresponding standard potential E^0, all components of the solution with a standard potential smaller than E also contribute to the faradaic current. Operating at a potential $E < E^0$, the same problem occurs if substances with a standard potential larger than E are present in the solution. For this reason, amperometry is preferably carried out in solutions containing only one electroactive substance or, if possible, at a potential at which only one substance is involved in an electrode reaction. If this is impossible, the selectivity can often be enhanced by covering the working electrode with a membrane that, in comparison to the diffusion rate of the analyte through the membrane, is virtually impermeable for the interfering substances.

In addition to analytical purposes, amperometric methods can also be used to investigate reaction constants of chemical reactions. In *reversed potential step techniques*, the first potential step is followed by a second one in the opposite direction, often back to the initial value. The reaction product B of the first step is then reconverted into the original analyte A. However, if the first electrode reaction is followed by an additional chemical reaction, a certain part of B is converted into a product C before the reversed step is applied. Therefore, the current during the reversed step is reduced. The ratio of the electrode currents during the forward and reversed steps depends on the reaction constant of the chemical reaction. Because the reconversion of B into A is required, batch arrangements without convection of the electrolyte are used for reversed step methods. Otherwise, a large part of B would be flushed away from the electrode surface and could not be reconverted.

55.2.3.2 Amperometric Titration

In *amperometric titration techniques* (Willard et al. 1988; Settle et al. 2011), a titrant that reacts with the analyte is added to the analyte solution. During the titration, the limiting current is measured

as a function of the volume of titrant added. The titrant has to be chosen such that the reaction product is not reducible or oxidizable at the applied potential and, hence, does not contribute to the current.

If the analyte and the titrant are electroactive at the applied potential, then the current flow will be large at the beginning of the measurement and decreases linearly with the volume of the titrant added, because both, the analyte and the titrant, are consumed by the reaction. The concentration of electroactive species then diminishes until the analyte is totally consumed. Further addition of titrant leads to a linearly increasing current because the titrant is no longer consumed. In the plot of the current versus the volume of titrant added, the point where the slope changes is called *endpoint* of the titration. From the corresponding amount of titrant added and the stoichiometry of the reaction, the original volume of analyte can be computed. If only the analyte is electroactive, then from the endpoint the current will not increase but remain zero. If only the titrant undergoes an electrode reaction, the current will be zero until all analyte is consumed and then will linearly increase from the endpoint. In practical operation, the slope of the current does not change abruptly due to background currents, and the endpoint has to be determined by extrapolation of the two linear regions.

In contrast to the majority of other electrochemical techniques, amperometric titration offers the advantage that even analytes that are not reducible or oxidizable can be determined using the oxidation–reduction characteristics of the titrant. Moreover, it is possible to analyze systems that have no measurable standard potential but can be electrolyzed.

55.2.3.3 Sampled-Current Voltammetry

Consider a *potential step* experiment like the one in the section next to the previous one. If the potential difference between E_2 and E^0 is too small, the electrode reaction is not so efficient that the analyte concentration at the electrode surface becomes zero (i.e., $c_e > 0$ in Equation 55.26). Within this region, the current depends on the applied potential. However, even in this situation, a depletion effect occurs so that the current always decreases with time. Recording the current i for different values of E_2 at a fixed time τ after switching the potential (*sampled-current voltammetry*), a sigmoidal (wave-shaped) curve is obtained (Figure 55.11b).

The shape of this curve can also be calculated by exactly solving the diffusion problem. A wave rising from a baseline to the diffusion-limited current i_d is obtained. The diffusion coefficients of the analyte and its redox partner are nearly equal to the *half-wave potential* $E_{1/2}$, where $i = i_d/2$ is almost identical with the standard potential E^0. Therefore, $E_{1/2}$ is often used in qualitative analysis to determine the analyte. Quantitative information about the analyte concentration is obtained from the maximum current (Cottrell current), which according to Equation 55.29 is proportional to c_0.

The influence of the double-layer charging current has been neglected thus far, but is worth considering. It obeys the equation:

$$i_c = \frac{\Delta E}{R_s} \exp\left(\frac{-t}{(R_s C_{dl})}\right) \tag{55.33}$$

where

ΔE is the potential step width
R_s the solution resistance
C_{dl} is the double-layer capacitance

Although the measurement of R_s and C_{dl} is not trivial, one can obtain qualitative information from this formula. Comparison of Equations 55.33 and 55.29 yields that the capacitive current decreases exponentially, while the faradaic current decreases according to $t^{-1/2}$. Consequently, the electrode current is measured a sufficiently long time after the potential step when the capacitive current has largely decayed,

whereas the faradaic current is still significant. In polarography with DMEs, the growth of the electrode surface alters the temporal decrease of the double-layer charging current according to

$$i_c \sim m^{2/3} t^{-1/3} \tag{55.34}$$

whereas the faradaic current increases according to $t^{1/6}$ (Equation 55.32). The current is measured shortly before the drop falls off (Figure 55.10).

The lower detection limit (LDL) amounts to 10^{-5}–10^{-6} mol L^{-1} for the determination of organic and inorganic analytes. The half-wave potential of different substances should be at least 100 mV apart for a simultaneous determination.

55.2.3.4 Linear Sweep and Cyclic Voltammetry

In *linear sweep voltammetry* (LSV), the electrode potential is changed *continuously* from an initial to a final value at a constant rate $\nu = dE/dt$, such that $E(t) = E_1 \pm \nu t$. Starting at a potential E_1 where no faradaic process occurs, a current begins to flow when the electrode potential comes into the vicinity of E^0. The current rises to a maximum and then decreases due to the depletion effect (Figure 55.12). The solution of the diffusion equations, which yields the shape of the *i*–*E* wave, can only be found numerically. For the electrode process to always follow the Nernst equation and thus be reversible, the sweep rate must not be too high (e.g., $\nu < 100$ mV s^{-1}). The peak potential E_p can then be calculated to be

$$E_p = E_{1/2} \pm 1.1 \cdot \left(\frac{RT}{nF}\right) = E_{1/2} \pm \left(\frac{28.0}{n}\right) \text{mV (at 25 °C)} \tag{55.35}$$

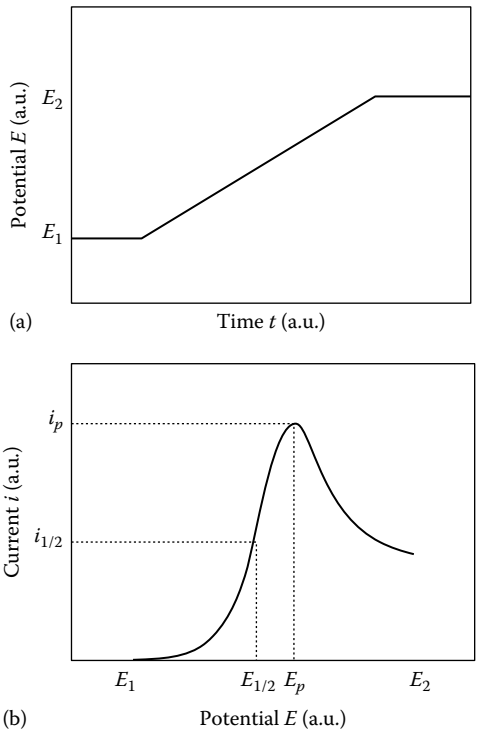

FIGURE 55.12 In LSV the potential varies linearly with time (a). The current–potential relation yields a peak-shaped curve with a half-wave potential $E_{1/2} \approx E^0$ (b). The peak current is proportional to the analyte's bulk concentration c_0.

The positive sign in Equation 55.35 applies to an anodic sweep (from negative to positive potential with $v > 0$) and the negative sign to a cathodic one (from positive to negative potentials with $v < 0$). The peak current is given by

$$i_p = 0.446nFA\left(\frac{nF}{RT}\right)^{1/2} D^{1/2} c_0 v^{1/2} \tag{55.36}$$

Thus, the peak current is proportional to the bulk concentration c_0 of the analyte and depends on the sweep rate according to $v^{1/2}$.

Another contribution to the measured current is the capacitive double-layer-charging current i_c, which always flows in LSV due to the continuous change of potential. It can be calculated using the following equation:

$$i_c = C\left(\frac{dE}{dt}\right) = Cv \tag{55.37}$$

which yields a proportionality to v while the faradaic peak current is proportional to $v^{1/2}$. Thus, for the faradaic current to dominate the measurement, the sweep rate should not be chosen too large. A sweep rate of 100 mV s^{-1} can be regarded as an upper limit. Moreover, the surface area of the working electrode must be taken into consideration. Rough electrodes have a much larger active than geometric surface area and thus a very large capacitance. Therefore, small, very smooth electrodes should be chosen.

A variation of LSV is a technique called *cyclic voltammetry* (CV). Here, the electrode potential is swept forth and back between two potentials E_1 and E_2 (Figure 55.13a). Although the bulk concentration of the reaction product is essentially zero, its concentration at the electrode surface after the first sweep is quite large. In the backward sweep, the reaction product of the analyte is converted into the analyte again. The current flows in the opposite direction and using an *xy* recorder, an *i*–*E* curve is obtained (Figure 55.13b). From Equation 55.35, it follows that for reversible processes, the peak potentials of the forward and backward sweep have a distance of (56/*n*) mV at room temperature. Therefore, CV is a favorable method for the investigation of the reversibility of a system. If the electrode current totally decays in the forward sweep, the analyte concentration has dropped to zero and the product concentration at the electrode surface is about c_0. Ideally, the peak current during the reverse scan should be equal (with reversed sign) to the peak current of the forward sweep.

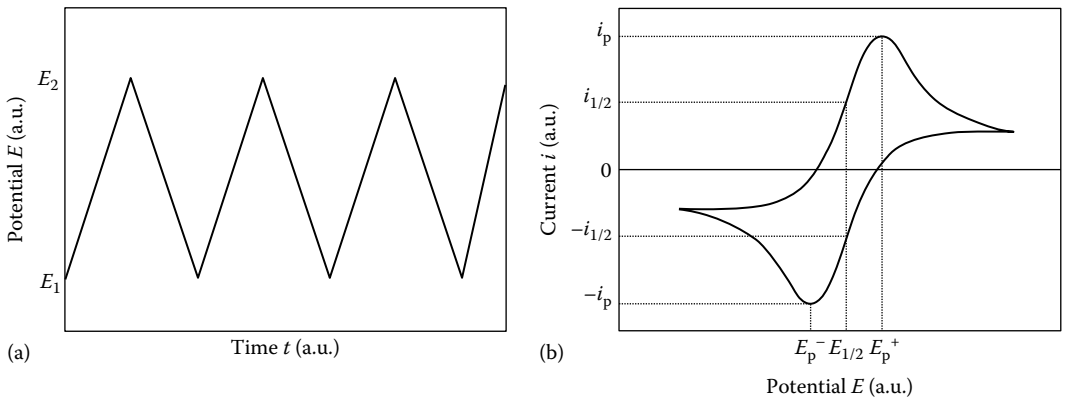

FIGURE 55.13 In CV, the potential is swept forth and back between two fixed values (a). The current–potential relation yields a peak-shaped curve with a half-wave potential $E_{1/2} \approx E^0$ (b). The peak current is proportional to the analyte's bulk concentration c_0. For totally reversible systems, the peak currents of the forward and the backward sweep are equal in magnitude but of opposite sign.

Although the theory of LSV and CV measurements is very promising, the methods have several practical limitations. One is the frequently insufficient stability of the *i*–*E* characteristic during the first cycles in CV. However, after 5–10 cycles, it tends to become highly reproducible. Yet, one must be careful deriving quantitative information from these later cycles because the initial and boundary conditions of the diffusion problem have changed and convective mass transport may already play a role. Thus, the equations developed for LSV cannot be used. Another problem that concerns both LSV and CV is the potential drop that occurs in the solution between the working and the reference electrode and that leads to a distortion of the shape of the *i*–*E* wave. This error increases with increasing current flow. Thus, the rate of change v of the electrode potential is not really constant, as has been assumed in the boundary conditions for solving the diffusion equations. Furthermore, the quantitative information is usually obtained from the position E_p and the height i_p of the current peak where the error is maximum. Finally, the determination of the peak height itself is sometimes problematic due to difficulties in the extrapolation of the baseline. For all these reasons, it may be advisable to verify the results of quantitative analysis with additional methods. Nevertheless, on easy terms, the LDL of LSV and CV in quantitative analysis can amount to 10^{-7} mol L^{-1} with a resolution of about 50 mV.

Besides the analysis of faradaic processes, LSV and CV are favorable techniques for the investigation of the adsorption of species on the electrode surface (Bard and Faulkner 2001). In such adsorption processes, the current is called *pseudocapacitive current*. Although it is a charge transfer across the interface, it exhibits many of the properties of a pure capacitive current. The current–potential wave has a very similar shape as for faradaic processes. If Θ denotes the coverage ($0 \leq \Theta \leq 1$) and q_1 the charge that is required to form a monolayer of a species, the pseudocapacitive current i_a can be expressed as

$$i_a = q_1\left(\frac{d\Theta}{dt}\right) = q_1\left(\frac{d\Theta}{dE}\right)\left(\frac{dE}{dt}\right) = C_a v \tag{55.38}$$

where C_a is called the *adsorption pseudocapacitance*. The calculation of C_a yields that the pseudocapacitance does not depend on v. Therefore, at any potential the current is proportional to the sweep rate ($i \sim v$). The peak potential gives information about the adsorption kinetics. In contrast to faradaic CV, it has the same value for the forward and the backward sweep.

55.2.3.5 Pulse Techniques

Voltammetric pulse techniques are derived from potential step experiments to suppress the capacitive currents during the measurement. A potential step that can vary in amplitude and sign is periodically repeated and superimposed with a potential ramp. The current is measured at the end of the step when the double-layer charging current has largely decayed.

Normal Pulse Voltammetry: In *normal pulse techniques*, periodic voltage pulses with an increasing amplitude from pulse to pulse are superimposed on a constant potential. Typical pulse duration is about 50 ms and the current is measured during a time interval Δt_m of about 10–15 ms at the end of each pulse. Between two pulses there is a waiting period of a few seconds (Figure 55.14). In polarography with a DME, each drop is dislodged directly after the pulse and thus used for just one measurement.

Because normal pulse voltammetry equals a series of potential step measurements with increasing step widths, the current obeys to Equation 55.29 and the evaluation of the measured current values can be carried out using the sampled-current method. In comparison with the step technique, the LDL is enhanced for one to two orders of magnitude up to 10^{-6} and 10^{-7} mol L^{-1} (Henze 2008). The peak resolution is about 100 mV.

Square-Wave Voltammetry: In *square-wave* techniques, a periodic rectangular voltage is superimposed on a linearly rising potential ramp. The measuring interval lies at the end of a pulse when the capacitive current can be neglected (Figure 55.15a). Typical pulses have frequencies between 200 and 250 Hz and an amplitude of ΔE_p = 5–30 mV (Henze 2008). The capacitive current is suppressed even more effectively if the pulse is tilted to decrease during the pulse period. No pulse tilt is required

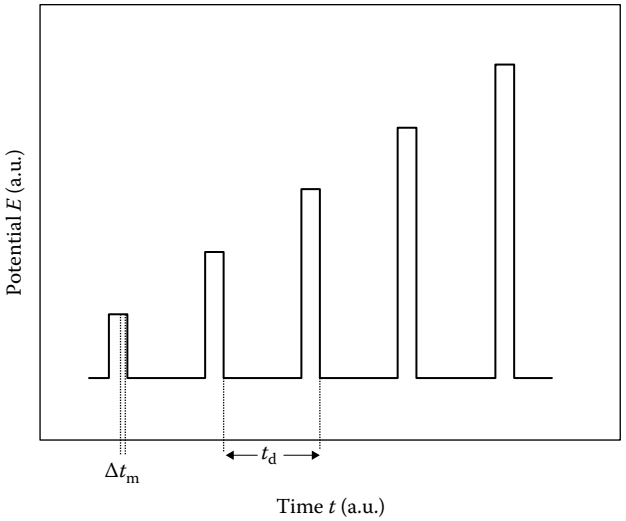

FIGURE 55.14 Normal pulse voltammetry equals a series of potential step measurements with increasing step widths. The current is measured during a time interval t_m near the end of the pulse. In polarography with a DME, the drop is dislodged after each measurement. The drop's lifetime is denoted by t_d.

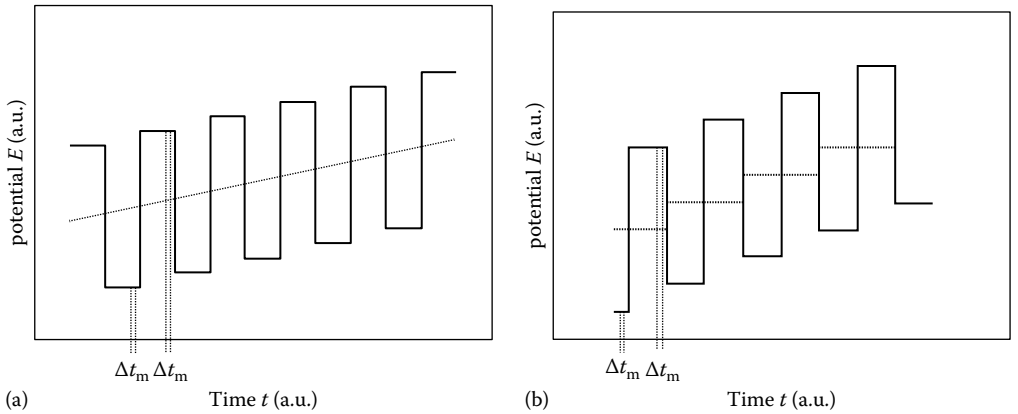

FIGURE 55.15 In square-wave voltammetry, a periodic rectangular voltage pulse is superimposed on (a) a linearly changing potential ramp (dotted line) or (b) on a stepped ramp (dashed curve). The current is measured during a time interval Δt_m at the end of each pulse.

if the potential ramp is stepped (staircase ramp) instead of a linear ramp. The voltage pulse is then applied on the plateau of the stepped ramp (Figure 55.15b).

After rectification of the measured current values, one obtains peak-shaped i–E curves. The peak potential corresponds to the half-wave potential of LSV and, thus, to the standard potential of the analyte's redox couple. The peak current i_p depends on the frequency and amplitude ΔE of the voltage pulses and obeys

$$i_p \sim n^2 D \Delta E c_0 \tag{55.39}$$

where the frequency dependence is included in the proportionality constant. The LDL is in the range of 10^{-8} mol L^{-1} and the peak resolution amounts to 40–50 mV.

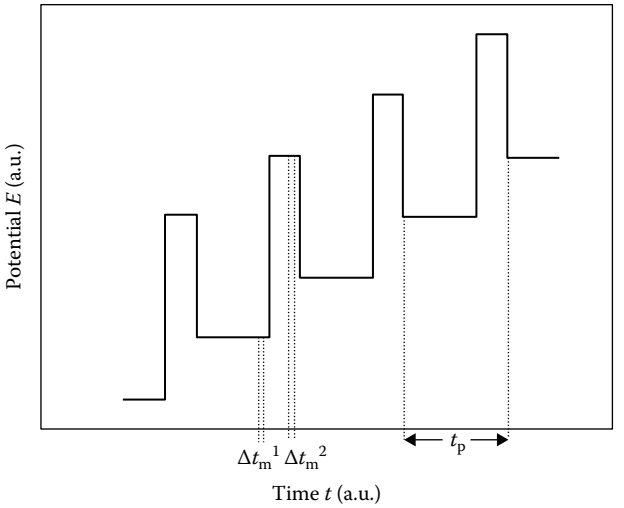

FIGURE 55.16 In differential pulse voltammetry, periodic rectangular pulses are superimposed on a stepped potential ramp. The difference between the current measured in a time interval Δt_m^1 directly before each pulse and during a time interval Δt_m^2 at the end of each pulse is plotted against the base potential. In polarography with a DME, the drop is dislodged after each pulse. The drop's lifetime is denoted by t_d.

Shorter analysis times are achieved if very short and relatively large rectangular pulses with a duration t_p = 5–10 ms and an amplitude of ΔE = 50 mV are superimposed on a stepped potential ramp with the same duration but smaller potential steps of about 10 mV. The potential can then be scanned at extremely high rates of up to 1200 mV s^{-1}. However, the sensitivity decreases because the ratio of faradaic to capacitive currents is lowered by the short pulse times.

Differential Pulse Voltammetry: Differential pulse methods are the most important ones in analytical voltammetry. Periodically repeated rectangular voltage pulses with a constant amplitude ΔE of several 10 mV are superimposed on a stepped potential ramp (Figure 55.16). The pulse duration Δt_p is about 5–100 ms (Henze 2008). Between two pulses, the potential is held constant for a few seconds. The current is measured in a short time interval ($\Delta t_m \approx$ 1–20 ms) directly before a pulse is applied and for the same duration near the pulse end. If a DME is used, the drop is knocked off mechanically between two pulses and each drop serves for just one measurement.

For the evaluation, the difference between the two measured current values Δi that corresponds to one pulse is recorded as a function of the base potential. A peak-shaped curve is obtained with a maximum very close to the half-wave potential $E_{1/2}$. The peak height is proportional to the analyte concentration in the bulk:

$$\Delta i_p \sim nFA\left(\frac{D}{\pi t_p}\right)^{1/2} c_0 \tag{55.40}$$

With differential pulse measurements, a LDL of 10^{-8} mol L^{-1} and a resolution of 50–100 mV can be achieved.

55.2.3.6 Alternating Current Voltammetry

Alternating current techniques are similar to differential pulse methods. A linear potential ramp is modulated with a low-frequency ($f \sim$ 50 Hz) sinusoidal alternating voltage of small amplitude ($\Delta E \sim$ 50 mV) (Henze 2008). The amplitude of the resulting alternating current is plotted against

the base potential. A peak-shaped curve is obtained with a maximum that is proportional to the bulk concentration of the analyte:

$$i_p \sim \Delta F f^{1/2} c_0 \tag{55.41}$$

The LDL is 10^{-5} mol L^{-1} due to the large capacitive currents. It can be enhanced by phase-selective rectification because the capacitive and the faradaic currents have a phase shift of 90° and 45°, respectively. The peak resolution amounts to 50–100 mV.

55.2.3.7 Stripping Voltammetry

Stripping techniques can be performed with analytes whose reaction products adsorb on the electrode surface. For accumulation, the electrode potential is held at a value at which the electrochemical equilibrium is on the product's side. Accumulation times usually amount up to several minutes. During this period, the solution is stirred to prevent the depletion of the analyte at the electrode surface. The accumulation is followed by a rest period of 2–30 s, during which the solution remains unstirred and the current falls to a small residual value. In the subsequent *stripping step*, the electrode potential is shifted to a value at which the adsorbed product is reconverted into the analyte by oxidation or reduction. Depending on whether an oxidation or reduction process occurs, the method is called *anodic stripping voltammetry* (ASV) or *cathodic stripping voltammetry* (CSV), respectively. The stripping step can be performed in various manners (Wang 1998) of which the linear sweep method shall be exemplary discussed here. It yields a peak-shaped *i*–*E* curve with a maximum at

$$E_p = E_{1/2} - \frac{1.1\,RT}{nF} \tag{55.42}$$

and a peak height that is proportional to the bulk analyte concentration according to

$$i_p \sim n^{3/2} v^{1/2} c_0 \tag{55.43}$$

Different substances can be determined in successive experiments with an adequate choice of the accumulation potentials. For the first measurement, the accumulation potential is chosen to allow adsorption of only one species; in the next experiment, the first and one further analyte adsorb, and so on. For the simultaneous determination of two or more substances, their peak potentials should be at least 150 mV apart.

A special case of the stripping techniques is *adsorptive stripping voltammetry* (AdSV). Here, the analyte is deposited in the form of metal chelates or organic molecules. For the formation of metal chelates, a complexing agent is added to the electrolyte or the surface of a solid-state electrode is modified with it. The stripping current is then due to the oxidation or reduction of the central atom or the ligand of the metal chelate complex. With this method, organic and organometallic compounds can be determined in the ultratrace range.

A crucial point in stripping analysis is the reproducibility. All experimental parameters have to be selected very carefully. In particular, the electrode surface must not be changed significantly by the adsorption and dissolution processes. Therefore, HMDEs are frequently employed for stripping analysis. A new drop is produced for each measurement. Another advantage of mercury electrodes is the fact that not only their surface but rather the hole bulk is used for the accumulation of analyte species. Consequently, more material can be collected. This leads to an enhanced lower determination limit that can be below 10^{-8} mol L^{-1}. Comprehensive monographs about stripping techniques are given in Brainina et al. (1993) and Wang (1998).

55.2.4 Applications

Analytical applications of voltammetry concern the determination of (heavy) metal cations, typical anions (halides, pseudohalides), organometallic, and organic compounds in the 10^{-4}–10^{-9} mol L^{-1} concentration range. Therefore, they are established in several fields like environmental, medical, food, and water analysis. A disadvantage is the usually labor-intensive sample preparation necessary, for example, to disintegrate ions from complexes, to adjust the pH of the solution, or to remove interfering species like oxygen and organic molecules. Principally, the preparation of the electrode (surface) is also crucial. However, commercially available equipment is well developed not only to enhance determination limits, sensitivity, selectivity, and reproducibility but also to reduce the expense for electrode and cell preparation. Moreover, sample and electrode preparation can be automated to a certain degree by devices that pump different solutions for cleaning, conditioning, and analysis through the cell setup. A further improvement of the instrumentation is the use of *microelectrodes* with dimensions of 1–100 μm. Because their dimensions are small in comparison with the diffusion length of the analyte, even for planar microelectrodes the diffusion is rather hemispherical than linear. Therefore, the depletion effect is less strong and the faradaic current is increased. Moreover, planar microelectrodes can be rotated (*rotating disk electrode* (RDE)) to intensify convection, and the solution can be stirred with ultrasound. Another advantage of microelectrodes is the possibility to realize several electrodes in a close neighborhood, so-called *electrode arrays*. They serve as *one* electrode if they are held at *one* potential and exhibit an improved signal-to-noise ratio due to the better diffusion conditions. In contrast, if different potentials are applied at different electrodes, the simultaneous determination of different species is possible. These techniques have just become commercially available as electrochemical detectors, for example, for high-performance liquid chromatography (HPLC). In this arrangement, the different species in the solution are separated by the HPLC and flow through the detector cell one after the other. Thus, interference between different analytes is minimized. The selectivity can often be further improved by the use of membrane-covered microelectrodes. The well-known *Clark oxygen sensor* and different biochemical sensors represent promising examples of this application in amperometry. Moreover, it opens up new possibilities for the creation of microelectrode arrays.

Due to the high analytical potential and the relatively low costs of voltammetric methods in comparison with spectroscopic techniques, all aspects of voltammetry are still subject of intense research. Current efforts concern the *miniaturization* of the whole cell, including microchannels, microvalves, micropumps, and microelectrodes by means of precision mechanics and *micromachining techniques* (Mastrangelo and Tang 1994). They employ fabrication methods of silicon planar technology and Lithographie, Galvanoformung, Abformung (LIGA) technique. Thin-film techniques, like physical and chemical vapor deposition (PVD, CVD), allow the fabrication of electrodes with a thickness in the submicrometer range and with lateral dimensions from the micrometer to the nanometer range. One goal is the realization of a *microsystem* with the sensitive components (i.e., the electrodes) and microelectronics integrated on a single chip. Currently, there are several commercially available systems. Two companies dominate the market of microelectrode arrays: Multichannel Systems (Reutlingen, Germany) and Panasonic (Tokyo, Japan). Modern microelectrode systems comprise the microelectrode arrays, electronic circuitry, and computer softwares for signal amplification and processing, respectively (Ryynänen et al. 2011).

55.3 Potentiometry

Potentiometry implies the measurement of an electrode potential in a system in which the electrode and the solution are in electrochemical equilibrium. Thus, the potential becomes the dependent variable, for example, as a function of time. In potentiometry, the current is attempted to be kept as small as possible; ideally, it should be zero. Potentiometry implies known fluxes (i.e., concentration gradients at the electrode surface) and thus information on the composition of the sample. In this section, potentiometry is

related to the measurement of potentials, where the voltage source is a form of a galvanic cell, consisting of a measuring electrode and a reference electrode (in general, electrodes of the second kind). The principles of *direct potentiometric measurements* as well as *potentiometric titrations* will be described.

55.3.1 Ion-Selective Electrodes

The equipment required for potentiometric analysis includes a measuring electrode, also called an ISE or *indicator electrode*, and a reference electrode. In addition to the sensitivity, the most important characteristic of the ISE is given by its *selectivity*. Depending on the type of membrane, ISEs can be classified into four different groups: *glass electrodes, solid-state electrodes, liquid-membrane electrodes*, and miscellaneous *combined electrodes* (Pungor 1998; Koryta and Stulik 2009). For all ISEs, the validity of the Nernst equation could be proved.

55.3.1.1 Glass Electrodes

The most common *glass electrode* is the *pH electrode*, widely used for hydrogen ion determination. The pH-glass electrode consists of a thin, pH-sensitive *glass membrane* sealed to the bottom of an ordinary glass tube. The tube is filled with a solution of hydrochloric acid (e.g., 0.1 M HCl) that is saturated with silver chloride. A silver wire, connected to an external potential-measuring device, is immersed in this solution. Note that the internal HCl concentration is constant and, thus, the internal potential (inner surface of glass membrane) of the pH electrode is fixed. Only the potential that occurs between the outer surface of the glass bulb and the test solution responds to pH changes. To measure the hydrogen ion concentration of the test solution, the glass electrode (indicator electrode) must be combined with an external reference electrode, which is required for all kinds of ISE determination. Often, pH-glass electrodes are available as a combination of the indicator electrode and an internal reference electrode (e.g., Ag/AgCl in saturated KCl solution) as schematically shown in Figure 55.17.

The composition of the glass membrane clearly influences the sensitivity of the pH electrode. Usually, three-component systems of, for example, $SiO_2/Na_2O/CaO$, are employed (Covington 1979). The pH

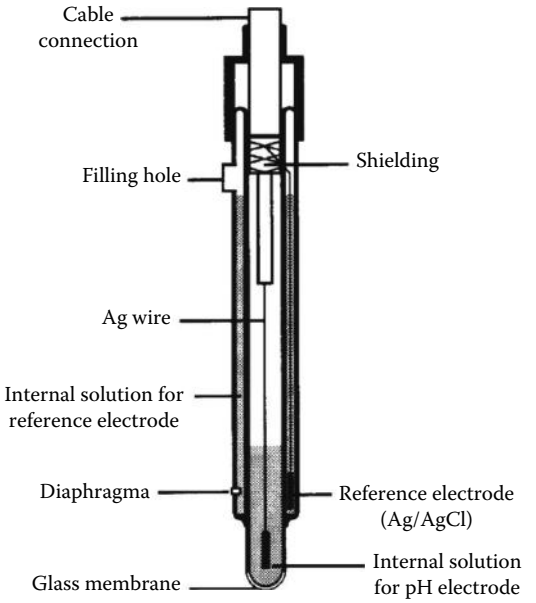

FIGURE 55.17 Combination of pH-glass electrode with an integrated Ag/AgCl reference electrode.

dependence can be expressed by the Nernst equation (Equation 55.11). At room temperature ($T = 25$ °C), Equation 55.11 can be simplified by

$$E = E^0 + 59.1 \text{ mV pH} \tag{55.44}$$

where E^0 is the standard Galvani potential with respect to the SHE. Thus, the measured potential is a linear function of pH within an extremely wide range (10–14 decades). The selective pH response of the pH ISE is due to the ion exchange process, in particular, due to the replacement of sodium ions in the glass membrane (m) by protons in the solution (s), and vice versa:

$$H^+_{(s)} + Na^+_{(m)} + \Leftrightarrow H^+_{(m)} + Na^+_{(s)} \tag{55.45}$$

The sodium ion exchange is also responsible for the *alkaline error* of pH electrodes in solution with pH greater than 10. In spite of the high resistance of the glass membrane against chemical attack, one has to deal with deviations (alkaline error) from the linear pH dependence. This error (i.e., the sensitivity toward alkali-metal ions) can be greatly reduced if Na_2O is replaced by LiO_2. Because pH-glass electrodes can be used in the presence of substances that interfere with other electrodes (e.g., proteins, oxidants, reductants, and viscous media), they have a wide range of applications. Typical fields are the clinical and food analysis, environmental monitoring (e.g., industrial waste, acidity of rain), and process control (e.g., fermentation, boiler water, galvanization, and precipitation).

The employment of glass membranes prepared with different glass compositions allows an electrode response sensitive to cations. For example, sodium-, potassium-, and ammonium-selective glasses consist of a mixture of Na_2O, Al_2O_3, and SiO_2 in various proportions (aluminosilicate glasses). Using specific compositions and mixtures of chalcogenides, ion-selective *chalcogenide glass electrodes* with sensitivities toward monovalent ions (e.g., Ag^+, Tl^+, F^-, Cl^-, Br^-, I^-) and double-charged species (e.g., Cu^{2+}, Pb^{2+}, Cd^{2+}, Hg^{2+}, S^{2-}) can be prepared (Vlasov et al. 1994). However, in all cases, some sensitivity to charged species (e.g., H^+ ions) remains. The electrode potential under these conditions is described by the *Nikolsky–Eisenman* equation:

$$E = E^0 \pm \frac{RT}{zF} \ln(a_i + K_{ij} a_j^{z_i/z_j}) \tag{55.46}$$

where

z_i, z_j and a_i, a_j are the ionic charge and activity of the primary or determined (i) and the interfering (j) ion

K_{ij} is the *selectivity coefficient*

It is a measure of the ISE ability to discriminate against the interfering ion. A small value of K_{ij} indicates an ISE with a poor selectivity.

55.3.1.2 Solid-State Electrodes

The glass membrane of an ISE can be replaced by a single or a mixed crystal or a polycrystalline (pressed) pellet (Figure 55.18a). With respect to their membrane composition, *solid-state electrodes* are divided into *homogeneous* and *heterogeneous membrane electrodes*.

A typical single-crystal electrode (homogeneous membrane electrode) is the fluoride-sensitive ISE, which contains a LaF_3 crystal doped with Eu^{2+}. The crystal with a thickness of about 2 mm is sealed into the bottom of a plastic tube. The internal solution (0.1 M of NaF and NaCl) controls the potential at the crystal inner side by means of an Ag/AgCl wire as reference electrode. In contact with the test solution at the crystal outer side, an electrochemical equilibrium is established, proportional to the fluoride ion activity. This is due to an ion exchange process at the phase boundary membrane/electrolyte. In particular, fluoride ions from the membrane are replaced by fluoride ions from the solution and vice versa, where the fluoride ions can migrate from one lattice defect to another inside the crystalline membrane.

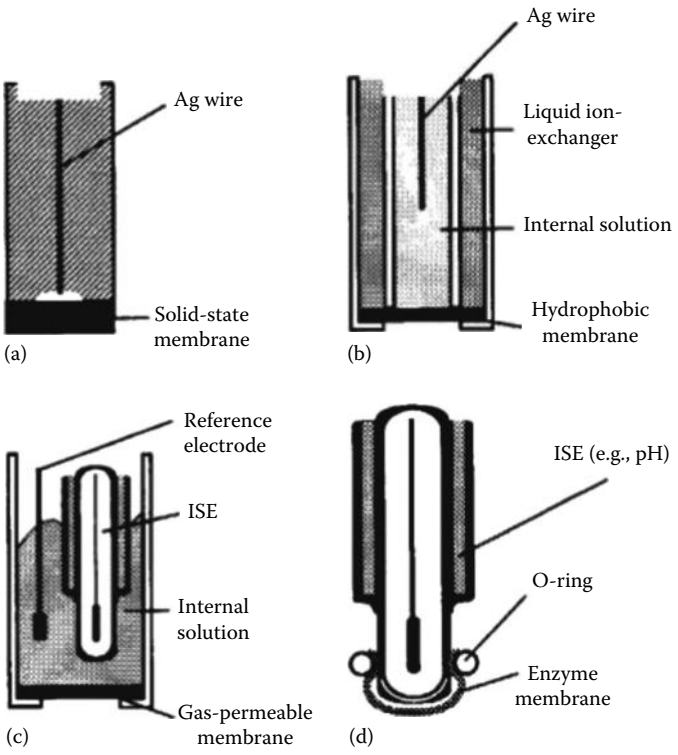

FIGURE 55.18 Typical membrane electrode types: solid-state electrode (a), liquid-membrane electrode (b), gas-sensing electrode (c), and enzyme-based electrode (d).

Further homogeneous membrane electrodes are silver halide electrodes, where the respective silver halide (AgCl, AgI, AgBr, Ag_2S) is pressed into a pellet, placed in a tube, and contacted via a silver wire. In these substances, silver ions are accordingly able to migrate. Such electrodes have been successfully used for the selective determination of chloride, bromide, iodide, silver, and sulfide ions. Likewise, if the pellets contain Ag_2S together with the silver halides or mixtures of PbS, CdS, and CuS, solid-state electrodes sensitive toward Pb^{2+}, Cd^{2+}, Cu^{2+}, and SCN^- can be realized. Moreover, the general problem of light sensitivity and high membrane resistance can be reduced by the additional use of Ag_2S.

Instead of the pressed pellets, the ion-selective material can be incorporated into an organic polymer matrix, like silicon rubber, carbon paste, or paraffin. In heterogeneous membrane electrode preparation, a mixture of the precipitate (e.g., AgI/Ag_2S) and polysiloxane is homogenized, and the polymerization is carried out. The resulting disks are fixed on the end of a tube and the internal solution (e.g., 0.1 M Kl) is contacted via a Ag/AgCl wire. *Coated-wire electrodes* represent another possibility. They can be manufactured by coating an appropriate polymeric membrane onto a conducting wire. Often, the conductor (Pt, Ag, Cu, or graphite) is dipped in a solution of polymer (e.g., polyvinylbenzylchloride (PVC) or polyacrylic acid) and the active substance. These electrodes allow the determination of K^+, Na^+, amino acids, and some drugs (e.g., cocaine). In addition to their simple miniaturization, the preparation is easy and inexpensive. However, further work is necessary to improve their analytical performance with regard to reproducibility and long-term stability.

55.3.1.3 Liquid-Membrane Electrodes

Liquid-membrane electrodes are based on two different membrane-active components: *solid ion-exchanger* and *complex-forming neutral-charged carriers*. They permit the determination of several polyvalent cations as well as certain anions. The sensor membrane (10–100 μm thickness) is usually prepared

of a plasticized PVC containing the organic sensor-active component that is insoluble in water; a Ag/AgCl wire is immersed into the internal reference solution. The liquid-membrane electrode differs from the glass electrode only in that the test solution is separated from the solution with the known target ion activity by a hydrophobic membrane, instead of the glass layer (Figure 55.18b). As membrane materials besides PVC, Teflon, sintered glass, filtering textile, or disks can be employed to hold the organic layer.

Liquid-membrane electrodes with ion exchangers have been realized for the determination of, for example, Ca^{2+}, K^+, BF_4^-, ClO_4^-, IO_4^-, SCN^-, I^-, Br^-, Cl^-, HCO_3^-, $H_2PO_4^-$, and NO_3^-. On the other hand, the synthesis of compounds containing individual cavities of molecule-sized dimensions results in complex-forming neutral-charged carriers. These *ionophores* (e.g., crown ethers like cyclic polyether, depsipeptides like valinomycin, and macrotetrolides like nonactin and monactin) are capable of enveloping various target ions reversibly in their pockets. For example, valinomycin membranes show a high K^+ selectivity. Many cyclic and monocyclic carriers with remarkable ion selectivities have been successfully developed for the determination of Li^+, Cs^{2+}, Ca^{2+}, Na^+, NH_3^+, Mg^{2+}, Ag^+, Hg^{2+}, SCN^-, and $H_2PO_4^-$. For all kind of membranes, a high molecular weight (i.e., a slight overpressure) prevents the quick intrusion of the test solution inside. Hence, the electrode's lifetime is limited as a consequence of diffusion of the sensor-active component into the analyte (*leaching out*).

55.3.1.4 Combined Electrodes

Two different types of *combined electrodes* will be presented here: *gas-sensing electrodes* and *enzyme-based electrodes*. Gas-sensing electrodes can be used to determine solutions of gases. They consist of an inner sensing element, normally a suitable ISE with an electrolyte solution (0.1 M), surrounded by a gas-permeable membrane (Figure 55.18c). On immersion of this ISE, the gas-permeable membrane contacts the liquid of the gas that diffuses through it, and the resultant internal solution will be examined with the ISE. The partial pressure of the gas attains equilibrium between the test solution/membrane and the membrane/ISE phase boundary. For example, the determination of carbon dioxide, which diffuses through the semipermeable membrane, lowers the pH values of the inner solution:

$$CO_2 + H_2O \Leftrightarrow HCO_3^- + H^+ \tag{55.47}$$

Such pH changes are detected by the ISE, in this case by a pH-sensitive glass electrode. Semipermeable membrane materials are polytetrafluoroethylene, polypropylene, or silicone rubber. The internal solution contains sodium chloride and an electrolyte with the corresponding ion that is determined. Gas-sensing electrodes have been realized for gases dissolved in solution, such as NH_3, NH_4Cl, CO_2, H_2CO_3, $NaHCO_3$, NO_2, $NaNO_2$, SO_2, H_2SO_3, $K_2S_2O_5$, CN, SCN, Cl_2, Br_2, I_2, and H_2S.

Enzyme electrodes are based on the coupling of an enzymatic membrane with any type of appropriate ISE. The enzyme converts (*catalyzes*) the analyte (*substrate*) to be determined extremely selective into an ionic product. The latter can be detected by the known ISE (Figure 55.18d). The coupling of the enzyme can be carried out by several *immobilization procedures*, such as entrapping in a gauze or gel, adsorptive or covalent binding, and cross-linking. A typical example for the operation of an enzyme electrode is given by the urea electrode. The enzyme urease hydrolyzes urea in order to liberate ammonium ions:

$$CO(NH_2)_2 + H_2O + 2H^+ \xrightarrow{\text{urease}} 2NH_4^+ + CO_2 \tag{55.48}$$

Either the alteration of the pH by a pH ISE or the variation of the NH_4^+ concentration by an ammonium-sensitive gas electrode can be detected. Likewise, penicillin, glucose, lactate, phenol, creatinine, cholesterol, salicylate, or ethanol will be catalyzed by means of the respective enzyme. Using different biological components (enzymes, cells, tissues, antibodies, receptors, or nucleic acids), a wide variety of analytically important substances for clinical, environmental, and food analysis can be determined. However, disadvantages of this type of electrode are its slow response time (several minutes) and the insufficient stability in the long term.

55.3.2 Instrumentation and Measurement

For potentiometric measurements, one uses an indicator electrode (ISE) versus a reference electrode and a *potentiometer*, also called *pH meter* or *ion meter*. Owing to the high resistance of the ISE membranes (e.g., 5–500 MΩ for the glass membrane), a potentiometer with a high input resistance is required. Modern potentiometers consist of an electronic digital voltmeter with a suitable operational amplifier, scaled directly to pH units or mV, with a resolution of better than ±0.002 pH and ±0.1 mV. They may range from simple handheld instruments for field applications to more convenient laboratory models. Frequently, potentiometers include a bias control that can be adjusted to correspond to the temperature of the test solution (*automatic temperature compensation*).

Direct Potentiometry: Direct potentiometric measurements can be performed for the determination of ionic species for which an appropriate ISE is available. A schematic measuring setup for direct potentiometry is shown in Figure 55.3. The measuring technique is quite simple: comparing the potential of the ISE in the test solution with its potential in a known *standard solution*. That means, before the determination, the ISE must be calibrated in solutions of known concentration of the chosen ionic species. Thus, for the ion determination to be made, at least two to three reference solutions are necessary that differ by two to five concentration decades. Typical resulting *calibration curves* for anions and cations are plotted in Figure 55.19. The curves can be separated into three distinct regions: (1) the straight part corresponding to the Nernstian slope (i.e., the sensitivity of the ISE), (2) the curve portion, and (3) the horizontal part below the LDL, where almost no sensitivity exists. The LDL of the ISE is defined as the concentration at which the extrapolated horizontal portion of the graph intersects the extrapolated Nernstian portion of the graph.

For practical applications, there are two aspects to be dealt with: often a *total ionic strength adjuster buffer* (TISAB) is added to both the standard solutions and the test solution (same temperature) to achieve comparable ionic strengths. Then, the potential difference can be assigned to the equivalent concentration of the calibration curve. Various methods for calibration calculations are described by, for example, Gran's plot or the standard addition method (Mendham et al. 2000). Because all measurements take place in dilute solutions (≤0.1 M), ion concentrations can be used in the Nernst equation instead of ion activities.

Potentiometric Titration: Potentiometric titration can be applied in the fields of *acid–base, precipitation, complex formation*, and *redox reactions*. Therefore, the ISE is used in combination with a reference electrode in order to establish the *EP* in a titration curve. A typical S-shaped potentiometric titration curve,

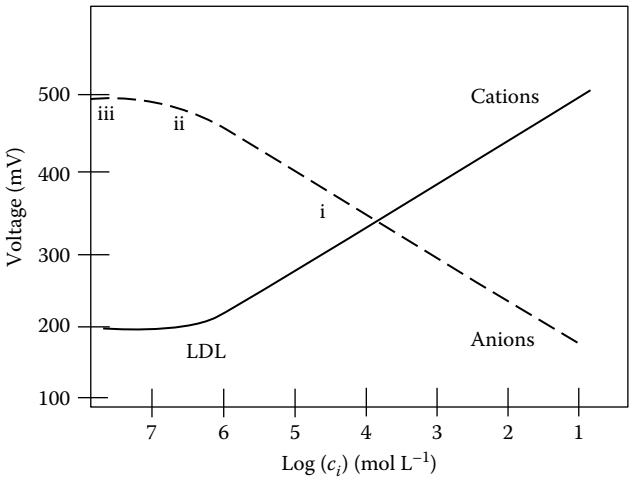

FIGURE 55.19 Schematic calibration curves for anions and cations (LDL).

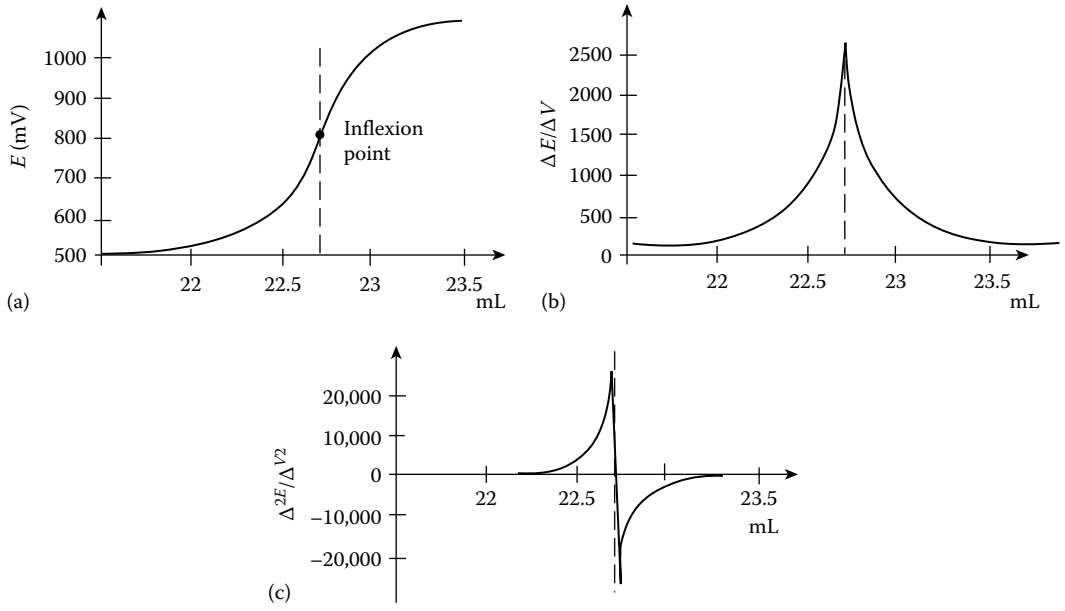

FIGURE 55.20 Characteristic potentiometric titration curve (a), first-derivative curve (b), and second-derivative curve (c).

where the electrode potential is plotted versus the reagent volume (*titrant*), is given in Figure 55.20a. The titrant is added to the initial solution that is stirred, and the ISE records the potential value at equilibrium. The EP (*endpoint*) of the reaction is reached when a sudden change in the potential of the ISE occurs. The midpoint in the curve (i.e., the steeply rising portion) is termed *endpoint* or *inflection point*. It can be evaluated by analytical methods, namely, the first- and second-derivative curves (Figure 55.20b and c). The first-derivative curve gives the potential change per unit change in volume of reagent and depicts the endpoint at the maximum of the inflection point. The second-derivative curve is zero where $\Delta E/\Delta V$ reaches its maximum. The greater the slope at the endpoint, the smaller should be the volume increment in order to reduce titration errors.

For practical applications, modern microprocessor-controlled titrators are commercially available (*auto-titrator*), coupled to a chart recorder to produce the titration curve directly. Such instruments also allow to evaluate the first- and second-derivative curves and provide Gran's plot. Acid–base (neutralization) titrations are performed with a glass/calomel electrode system and can be used to titrate a mixture of acids that differ greatly in their strengths (e.g., acetic (ethanoic) and hydrochloric acids). For precipitation titrations, the ISE consists of an electrode (e.g., silver or a platinum wire) that quickly reaches equilibrium with the ions to be precipitated. A typical precipitate reagent represents silver nitrate for the determination of halogens, halogenides, mercaptans, sulfides, arsenates, phosphates, and oxalates. For complex-formation titrations, membrane electrodes can be used that involve the formation of soluble complexes, like ethylenediaminetetraacetic acid (EDTA) or silver cyanide ($Ag(CN_2)^-$). Oxidation–reduction titrations are performed by a platinum indicator electrode to any redox couples where the potential depends on the concentration ratio of the reactants. Some experimental details for potentiometric titration are described in Mendham et al. (2000).

As an alternative principle, *chronopotentiometry* is based on the observation of the change in potential of a working electrode as a function of time during electrolysis. Usually, this electrolysis is performed with a constant current, whereas the time is measured that is necessary for the potential to go from one level to another. Since chronopotentiometry is disappointing at concentrations below 10^{-4} mol L^{-1}, it is only a powerful tool for studying electrode processes at higher concentrations. Consequently, this method is not very important for practical applications.

55.4 Semiconductor Field-Effect Chemical and Biological Sensors

The integration of thin ion-selective membranes with solid-state devices leads to miniaturized *chemically sensitive solid-state devices*. Among the variety of concepts and transducers principles proposed for solid-state chemical and biological sensors, the integration of chemically or biologically sensitive materials (recognition elements) with semiconductor *field-effect* devices based on the *electrolyte–insulator–semiconductor* (*EIS*) system is one of the most attractive approaches (Bergveld and Sibbald 1988; Madou and Morrison 1989; Grattarola and Massobrio 1998; Bergveld 2003). Representative examples are *chemically sensitive field-effect transistors* (*ChemFETs*), *chemically sensitive capacitive* EIS sensors, and *light-addressable potentiometric sensors* (*LAPS*), which are currently being one of the basic structural elements of various chemical and biological microsensors (Poghossian and Schöning 2006, 2007). Although these three kinds of (bio-)chemical sensors have different device configurations and measurement setups, the transducer principle of using an electric field to create excess charge regions in a semiconductor substrate is common to all of them. These field-effect devices are based on the technology used for manufacturing microelectronic chips and thus offer the possibility of mass production. (Bio-)chemical sensors based on other types of field-effect devices, like *silicon-nanowire transistors* (Timko et al. 2010), *silicon thin-film resistors* (Neff et al. 2006), or *carbon-nanotube transistors* (Lee et al. 2009a), are still in the initial state of research and development.

55.4.1 Chemically Sensitive Field-Effect Transistors

The ChemFETs can react sensitive to some ions (*ion-sensitive FET [ISFET]*), biomolecules (*biologically sensitive FET [BioFET]*), or gases (*gas-sensitive FET [GasFET]*) in aqueous media, or they can be insensitive (*reference FET [ReFET]*). They incorporate the sensitive membrane directly on the gate area of a field-effect transistor (FET). A schematic of an *n*-channel ISFET, mounted in a measuring cell and contacted via a reference electrode (e.g., Ag/AgCl electrode), is given in Figure 55.21a.

It consists of a *p*-type silicon substrate with two *n*-doped regions, source (*S*) and drain (*D*), separated by a short channel that is covered by the gate insulator (typically, a thin SiO_2 layer) and the ion-sensitive membrane. For operating an ISFET, the gate voltage, V_G, is applied by a reference electrode. When the sensor membrane is placed into contact with the test solution containing the ions or analytes to be detected, an additional potential (ΔV) is generated at the membrane–electrolyte interface. If a sufficiently positive bias potential is applied to the gate (with respect to the bulk silicon substrate), an n-type *inversion layer* (usually less than 10 nm) is formed in the channel and the current, I_D, starts to flow between source and drain.

The *drain current* and *threshold voltage* V_T (the gate voltage at which a conductive channel is formed between source and drain) of the ISFET can be deduced from that of its electronic analogue *metal–oxide–semiconductor FET* (*MOSFET*) by simply adding the potential drops at the additional interfaces (Bergveld and Sibbald 1988; Poghossian and Schöning 2006):

$$I_d = \frac{C_i \mu b}{L}\left[(V_G - V_T)V_D - \frac{V_D^2}{2}\right] \tag{55.49}$$

for the *nonsaturated region* ($V_D < V_G - V_T$), and

$$I_d = \frac{C_i \mu b}{2L}(V_G - V_T)^2 \tag{55.50}$$

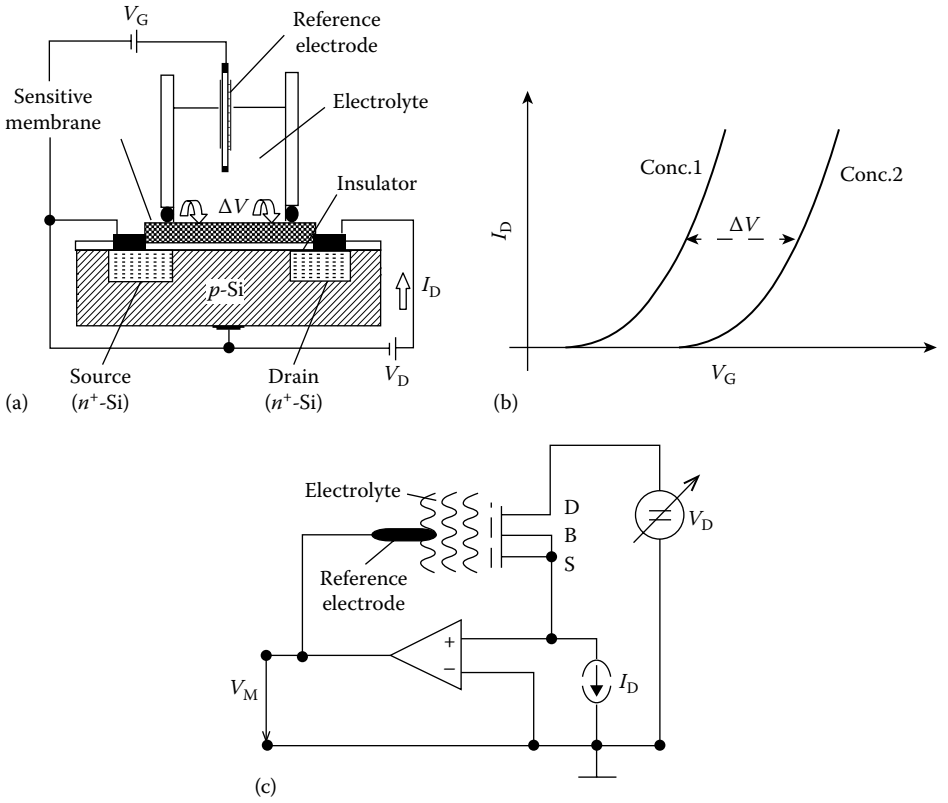

FIGURE 55.21 ISFET configuration (a), transfer characteristic (b), and schematic circuit of CCM (c). The metallic gate from a MOSFET is replaced by the arrangement sensitive membrane/test solution/reference electrode (V_G, gate-source voltage; V_D, drain-source voltage).

for the *saturated region* ($V_D > V_G - V_T$), with

$$V_T = E_{ref} - \Delta V + \chi - \frac{W_S}{q} - \frac{Q_i + Q_{ss}}{C_i} - \frac{Q_{sc}}{C_i} + 2\phi_B \tag{55.51}$$

where,

μ is the mobility of the electrons in the channel between source and drain
b is the width
L is the length of the channel
C_i represents the capacitance of the gate insulator per unit area
E_{ref} is the potential of the reference electrode
χ is the surface-dipole potential of the solution
W_S is the silicon electron work functions
q is the elementary charge (1.6×10^{-19} C)
Q_{sc}, Q_i, and Q_{ss} are the charges per unit area in the space-charge region as well as located in the oxide and the surface/interface states, respectively
ϕ_B is the potential difference between the Fermi level in the bulk semiconductor and the intrinsic Fermi level

If the applied gate (V_G) and source-drain (V_D) voltages are fixed, the only variable term is the analyte concentration-dependent interfacial potential ΔV. Changes in the chemical composition will

induce changes in the potential drop at the electrolyte–membrane interface that consequently will modulate the drain current of the ISFET. After calibration of the ISFET with standard solutions of known ion activity, the variation of I_D can be used to determine the ion concentration in the test solution (Figure 55.21b). Often, the ISFET is operated in a feedback loop (e.g., the *constant charge mode*, Figure 55.21c), and the voltage V_M needed to maintain I_D at a fixed value represents the sensor response. The sensor response can be described by the same Nernst and Nikolsky equations that characterize conventional IESs.

Like with the ISEs, the most attention is gained to pH-sensitive ISFETs, built up of SiO_2 and an additional thin film (about 30–100 nm) of other oxides and nitrides. The additional layer is necessary because the pH response of SiO_2, initially used as pH-sensitive dielectric, is poor (20–40 mV/pH) and the material was indeed found to be unstable and to suffer from considerable drift of the sensor signal. Therefore, different materials, like Si_3N_4, Al_2O_3, Ta_2O_5, IrO_x, ZrO_2, TiO_2, SnO_2, WO_3, HfO_2, AlN, TiN, $PbTiO_3$, barium strontium titanate, diamond-like carbon, and nanocrystalline diamond, have been investigated with respect to their pH sensitivity and stability (see, e.g., Poghossian and Schöning 2006). For example, Si_3N_4 shows a sensitivity of about 45–55 mV/pH. The sensitivity can be improved by using Al_2O_3 or Ta_2O_5 with 53–57 and 55–59 mV/pH, respectively. Also, the reported drift values are less than 1 mV h^{-1}. The pH sensitivity of these gate-insulating materials can be explained by the site-binding theory, which is exemplary discussed for SiO_2 in Madou and Morrison (1989). Other more exotic materials such as AlN, HfO_2, PbTiO3, and WO_3 sometimes show nearly Nernstian sensitivity, but have only rarely been studied. Methods that have been used to deposit pH-sensitive materials include electron-beam evaporation, thermal evaporation, CVD, sputtering, thermal oxidation, pulsed laser deposition (PLD), and solgel technique.

Being in its basic structure a pH-sensitive device, the selectivity of an ISFET toward other ions can be achieved by means of a modification of the gate surface or a deposition of subsequent organic or inorganic ion-sensitive membranes on top of the gate insulator. For instance, by implantation of high doses of B, Al, Ga, In, Ti, Li, or Na, potassium- and sodium-sensitive ISFETs were achieved. Also, the deposition of thin layers of modified chalcogenide glasses offers the determination of heavy-metal ions for biological investigations and industrial applications (Vlasov 1994; Schöning and Kloock 2007). By means of vacuum evaporation, ion-sensitive films of LaF_3, Ag_2S, or AgX (X = Cl, Br, I) for the determination of F^-, Cl^-, Br^-, I^-, Ag^+, and S^{2-} can be prepared. A chemical surface modification of the original gate insulator (e.g., the covalent linking of hydrophilic layers that contain the sensing molecule) leads to organic gate materials for the determination of different ions such as Ca^{2+}, NH_4^+, K^+, Cl^-, NO_3^-, Na^+, and Ag^+ (Rheinhoudt 1992). Similar results were obtained for homogeneous polymeric membranes, containing solid ion-exchanger or neutral-charged carriers (see section on ISE). In order to achieve well-defined and highly ordered sensor membranes, the gate can be coated with ultrathin Langmuir–Blodgett films (Schöning et al. 1995).

BioFETs are constructed from an ISFET by modifying the gate or coupling it with *biological recognition elements*. The biomolecules of various complexity (e.g., enzyme, antibody, protein, deoxyribonucleic acid [DNA]) or even living biological systems (e.g., cell, tissue slice, or whole organism) can be used as recognition element. Based on the hierarchy of biological complexity, the BioFETs can be subdivided as follows: *enzyme-modified FET* (*EnFET*), *DNA-modified FET* (*DNA-FET*), *cell-based FET*, and *beetle/chip FET*. A review of basic concepts of different kinds of BioFETs is given in Schöning and Poghossian and Schoning (2006), Lee et al. (2009b), and Poghossian et al. (2009).

EnFETs are usually constructed by immobilizing an enzyme or multienzyme system onto the gate insulator of an ISFET using different immobilization techniques (e.g., physical adsorption, enzyme entrapment within polymeric matrices, covalent binding, cross-linking). The EnFET directly corresponds to the enzyme ISE and detects the potentiometric response to either the concentration change in one of the products or reactants catalyzed by the enzyme. A multitude of EnFETs have been reported for the detection of numerous analytes such as glucose, penicillin, urea, lactose, sucrose, lactate, organophosphorus pesticides, creatinine, and glycoalkaloids (see, e.g., Poghossian and Schöning 2006 and

references there). Frequently, EnFETs are built up of pH ISFETs, in which hydrogen ions are produced or consumed by the enzymatic reactions. For an exact measurement, an on-chip integrated pH-ISFET/EnFET differential arrangement is often employed, where the pH ISFET contains a blank enzyme-free membrane and serves as a reference device. The demand of compatibility with integrated circuit technology provides enzymatic membranes that can be photolithographically patterned (e.g., photo-crosslinkable materials). Intensive researches during the last years were focused on the improvement of EnFET characteristics and to circumvent problems, which actually prevent the successful commercialization of EnFETs (e.g., dependence of the sensor response on buffer capacity, ionic strength, and pH of the test sample; restricted dynamic range and nonlinearity; relatively slow response and recovery times; operating and storage stability; reproducibility; dependence on enzyme immobilization method; the incompatibility of most used enzyme-containing layer deposition and patterning methods with silicon technology).

DNA-FETs: Generally, field-effect devices are surface-charge-measuring devices, and therefore, they are principally able to detect charged biomolecules (including DNA molecules) by their intrinsic molecular charge. Due to their small size and compatibility with advanced micro- and nano-fabrication technologies, these devices could offer a next generation of DNA chips with direct electronic readout for a label-free, fast, simple, and real-time analysis of nucleic acid samples. The core principle behind DNA chips is the hybridization event between two single-stranded DNA (ssDNA), where an unknown target ssDNA is identified by its complementary ssDNA molecule. As a result, a double-stranded DNA (dsDNA) helix structure with the two complementary strands is formed. Since DNA molecules are polyanions with negative charges at their phosphate backbone, the charge associated with the target molecule can effectively alter the charge applied to the gate, resulting in a modulation of the threshold voltage and the drain current of the DNA-FET. A critical review of different types of DNA-FETs is given in Poghossian et al. (2007) and Schöning and Poghossian (2008). The major disadvantage of electrostatic DNA detection by its intrinsic charge is the screening of the DNA charge by mobile ions in the surrounding solution. This could significantly reduce the expected sensor signal, especially in high-ionic-strength solutions, where the screening length (Debye length) is very short (~1 nm for a 0.1 M solution of monovalent 1:1 salt). To enhance the sensor signal, the DNA-FET must be operated in a very low-ionic-strength solution (<1 mM) and/or with a tightly packed probe ssDNA ($>10^{13}$ ssDNA cm^{-2}). To overcome the described problems, an alternative approach based on the detection of the DNA hybridization-induced redistribution of the ion concentration within the intermolecular spaces and/or the alteration of the ion sensitivity of the field-effect device has been proposed in (Poghossian and Schöning 2006).

Cell-based FETs or cell/transistor hybrids are obtained by direct coupling of single living cells (the smallest self-sustaining biological entity) or cell systems to the gate insulator of FETs (Wang 2005; Poghossian et al. 2009). Cell-based FETs can be used for both the monitoring of cellular metabolism (the extracellular acidification rate, concentration of ions, oxygen consumption, CO_2 production, and other metabolic products caused by different external stimuli) and the measurement of action potentials of electrogenic cells such as neuronal and muscle cells. For example, with the commercially available Bionas® 2500, analyzing system metabolically relevant data, including oxygen consumption, acidification rate, and adhesion (cell impedance) of cells, can be noninvasively measured in parallel and over a long period of time (Thedinga et al. 2007). Moreover, a cell-monitoring system, which includes both FETs for detecting the action potential and ISFETs coupled with different ion-sensitive membranes for the measurement of concentration of extracellular ions, like Na^+, K^+, and Ca^{2+}, has been realized (Wang et al. 2005). Those devices are of great interest for a large variety of applications including the detection of pharmaceutical agents, toxic substances, or pollutants and the monitoring of electrical communication within neuronal networks or transmission paths of ionic channels. Moreover, direct electrical interfacing of semiconductor and nerve cells is the physical basis for the development of hybrid neuroelectronic devices.

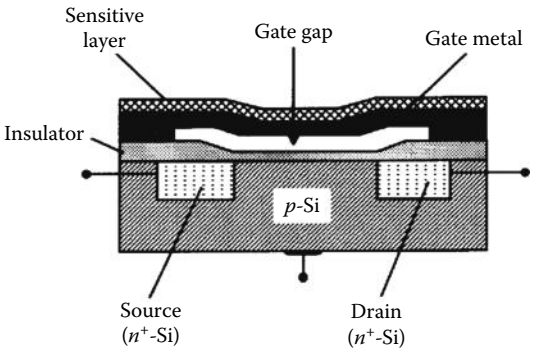

FIGURE 55.22 Schematic of an SGFET.

ReFETs consist of a sensor surface that is as insensitive as possible to all kinds of substances in the test solution. Thus, a differential pair of an ISFET and a ReFET eliminates disturbances, like influence of temperature or light. Appropriate materials to cover the ISFET surface with an insensitive layer are blocking materials, such as Teflon or different polymers (e.g., parylene, polyacrylate, PVC). However, not well-defined potential processes as well as some ion exchange will result in nonideal behavior. Alternative concepts use nonblocking polymer membranes with a fixed membrane potential or quasi-ReFETs with a delayed pH response. The most promising approaches are the application of an inert metallic layer or wire in a differential ISFET setup as a *quasi-reference electrode* and the miniaturization of conventional reference electrodes. For example, by means of PVD methods, Ag/AgCl electrodes were miniaturized on silicon chips inside anisotropically etched cavities (Madou and Morrison 1989).

The basic mechanism of *GasFETs* is due to the chemical modification of the *electron work function* of a metal–insulator–semiconductor (MIS) field-effect structure, for example, of a *suspended gate FET* (*SGFET*) as schematically shown in Figure 55.22.

The SGFET contains an additional insulator, the "*gap*" within the gate structure, which consists of a vacuum, a gas, or a nonconducting liquid. As gate metal, usually a platinum layer or mesh is used. The chemically sensitive layer on top of this structure, for example, palladium, exhibits sensitivity toward hydrogen. The hydrogen molecules adsorb and dissociate atoms (H_a) on the metal surface (Pd), depending on their partial pressure, as well as desorb from the metal surface by recombination into H_2 and reacting with oxygen to form water:

$$H_2 \Leftrightarrow 2H_a \quad \text{and} \quad 4\,H_a + O_2 \Leftrightarrow 2H_2O \tag{55.52}$$

The adsorbed atoms diffuse rapidly to the inner surface gap/insulator where they become polarized and form an interface dipole layer, resulting in a potential drop. For example, SGFETs with Pd, operated at 100 °C–140 °C, are sensitive to H_2, CO, and H_2S in the ppm range, whereas an increased operating temperature up to 240 °C allows the detection of alcohols (methanol, ethanol, propanol, butanol). To achieve selectivity, the surface of the suspended gate can be modified by inorganic or organic layers. Ammonia sensitivity can be achieved by catalytic metals such as Pt, Ir, Ru, or Rh. By the deposition of organic layers, like polypyrrole, sensitivities to alcohols and aromatic hydrocarbons are achieved. Several related devices based on SGFETs are explained in Josowicz and Janata (1988).

55.4.2 (Bio)Chemically Sensitive Capacitors

Sensors on the basis of capacitive field-effect EIS structures are much simpler to fabricate than ISFETs, and consequently they are favorable for laboratory use. Such *structures* correspond to MIS *capacitors*

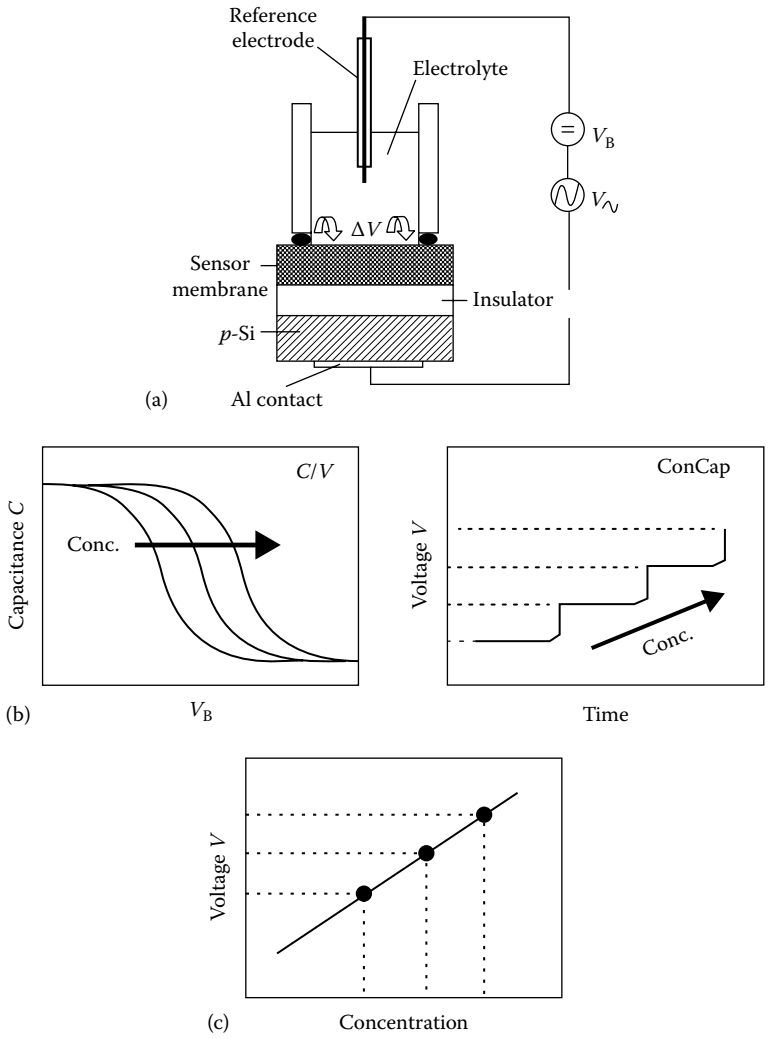

FIGURE 55.23 Schematic of an EIS structure (a), measurement of the EIS sensor in the *C*/*V* (capacitance/voltage) and the ConCap mode (b), and resulting calibration curve (c).

and their operation principle can be derived from the fundamental MIS devices (Sze and Ng 2007). A schematic buildup of an EIS structure and the measuring principle is given in Figure 55.23a.

The sensor consists of a *p*- or *n*-type semiconductor (silicon) covered by a thermally grown SiO_2 insulating layer (<100 nm) and the sensor membrane that is directly exposed to the test solution. For operation, a dc polarization voltage V_B is applied via the reference electrode to set the working point, and a small superimposed ac voltage (10–50 mV) is applied to the system in order to measure the capacitance of the sensor.

The functioning principle and physical properties of a capacitive EIS sensor can be explained by the charge carrier distribution at the insulator/semiconductor interface, which is controlled by both an external dc voltage (V_B) and an electrochemical interaction between the test solution and the sensor membrane (ΔV) (Poghossian and Schöning 2006). For a *p*-Si substrate, a negative potential ($V_B < 0$) on the reference electrode accumulates positively charged mobile carriers (i.e., holes) at the Si/SiO_2 interface (*accumulation regime*). When V_B becomes positive ($V_B > 0$), the holes are displaced from the interface, resulting in a space-charge region depleted of mobile carriers (*depletion regime*). If the potential

gets more positive ($V_B >> 0$), an inversion layer of *n*-type Si is created although the substrate is *p*-type (*inversion regime*). The electric behavior is given by the small-signal capacitance of the EIS structure. The whole capacitance (C) can be described as a series connection of the membrane capacitance (C_M), insulator capacitance (C_i), and space-charge capacitance (C_{SC}) of the semiconductor:

$$\frac{1}{C} = \frac{1}{C_M} + \frac{1}{C_i} + \frac{1}{C_{SC}} \tag{55.53}$$

with

$$\frac{1}{C_i} = \frac{\varepsilon_i}{d} A \tag{55.54}$$

where

A is the contact area of the gate with an electrolyte solution
d is the thickness
ε_i is the permittivity of the gate insulator

C_{SC} is, among others, a function of the gate voltage applied to the EIS structure and interfacial potential at the membrane–electrolyte interface. Typical C/V (*capacitance/voltage*) curves of a *p*-type EIS sensor are exemplary given in Figure 55.23b (left) for different ion concentrations. Due to the electrochemical interaction (ΔV), a horizontal shift of the C/V curve is provided, depending on the change of the ion concentration in the test solution. As resulting measuring signal (calibration curve), the potential shift can be evaluated at a fixed capacitance value within the linear region of the C/V curves (e.g., 60% of the maximum capacitance, Figure 55.23c). Using a feedback circuit, the measured capacitance can be adjusted at a fixed value in the *constant capacitance* (*ConCap*) mode (Figure 55.23b, right). Thus, potential shifts can be recorded directly.

Chemical and biological sensing EIS structures with different organic and inorganic sensor membranes have been developed within the last years (see, e.g., Poghossian and Schöning 2006 and references there). They consist of nearly identical sensor membrane materials and compositions as ISFETs, ranging from inorganic pH-sensitive layers (e.g., Si_3N_4, Al_2O_3, Ta_2O_5) or crystalline films (e.g., LaF_3, silver halides) over organic Langmuir–Blodgett films to enzymatic layers (e.g., urease, penicillinase). Much effort has been done in order to improve the limiting long-term stability that is often disclosed by FET devices in permanent contact with the analyte. Novel approaches pursue a further optimization with regard to the preparation (e.g., due to specific immobilization procedures) or the deposition of the sensor membrane in order to raise the sensor performance. For example, an extremely long-term stable pH sensor was developed by the suggestion of the PLD process as the thin-film preparation method. The EIS structure consists of a layer sequence of Al/p-Si/SiO_2/Al_2O_3, where no degradation of the pH sensitivity during a measurement period of 2 years was found (Schöning et al. 1996). In addition, a highly sensitive and corrosion-resistant non-glass unbreakable pH sensor has been developed using a Ta_2O_5 layer as pH-sensitive material (Schöning et al. 2005). The capacitive EIS sensors have been integrated into a flow-through microfluidic channel (fabricated by combining Si and SU-8 technologies) for pH and penicillin measurements (Poghossian and Schöning 2007). Moreover, EIS sensors have been applied for the detection of charged macromolecules (e.g., polyelectrolytes, DNA, dendrimers) and nano-objects (e.g., gold nanoparticles, carbon nanotubes) (Siqueira et al. 2009; Abouzar et al. 2011; Gun et al. 2011) Recently, a highly sensitive DNA hybridization/denaturation sensor has been realized using an array of individually addressable field-effect nanoplate *silicon-on-insulator* (*SOI*) capacitors modified with gold nanoparticles (5–8 nm) (Abouzar et al. 2012). Finally, the feasibility of EIS sensors for the creation of *molecular "**AND**" and "**OR**" logic gates* has been demonstrated in Poghossian et al. (2011).

Like GasFETs, MIS capacitors and *MIS Schottky diodes* are also available as gas-sensitive devices. For the MIS capacitor, a concentration-dependent dipole layer is detected as a shift of the C/V curve.

To reduce the drift of these devices, additional insulating layers, such as Al_2O_3, Si_3N_4, or Ta_2O_5, can be deposited between the metal layer and the SiO_2 insulator. Experimental results of $Pd/Al_2O_3/SiO_2/Si$ structures show sensitivities of 25 mV ppm^{-1} around 1 ppm (Armgarth and Nylander 1991). Schottky barrier diodes consist of a thin insulating layer (e.g., 2 nm SiO_2) between the metallic gate (e.g., Pd) and the semiconductor, in order to allow the current to pass through it. By variation of the metallic gate films, different sensitivities can be achieved, comparable to those of the SGFETs.

55.4.3 Light-Addressable Potentiometric Sensors

A schematic structure (a), a simplified equivalent circuit (b), and typical *photocurrent* response (c) of the LAPS are presented in Figure 55.24. The LAPS structure is similar to that of an EIS structure. Therefore, in the absence of illumination, the LAPS behaves like an EIS capacitor. As in the case of the capacitive EIS sensor, a dc bias voltage (V_{Bias}) is applied between the reference electrode and the semiconductor substrate in order to induce a space-charge region at the gate insulator–semiconductor interface. However, to detect the variation of the capacitance, the LAPS is, in contrast to EIS-based measurements, illuminated with a intensity-modulated light, which induces an ac photocurrent to be measured as the sensor signal (Wagner and Schöning 2007; Poghossian et al. 2009; Yu et al. 2010). The excitation light can be directed to the semiconductor either from front- or backside of the LAPS structure by placing

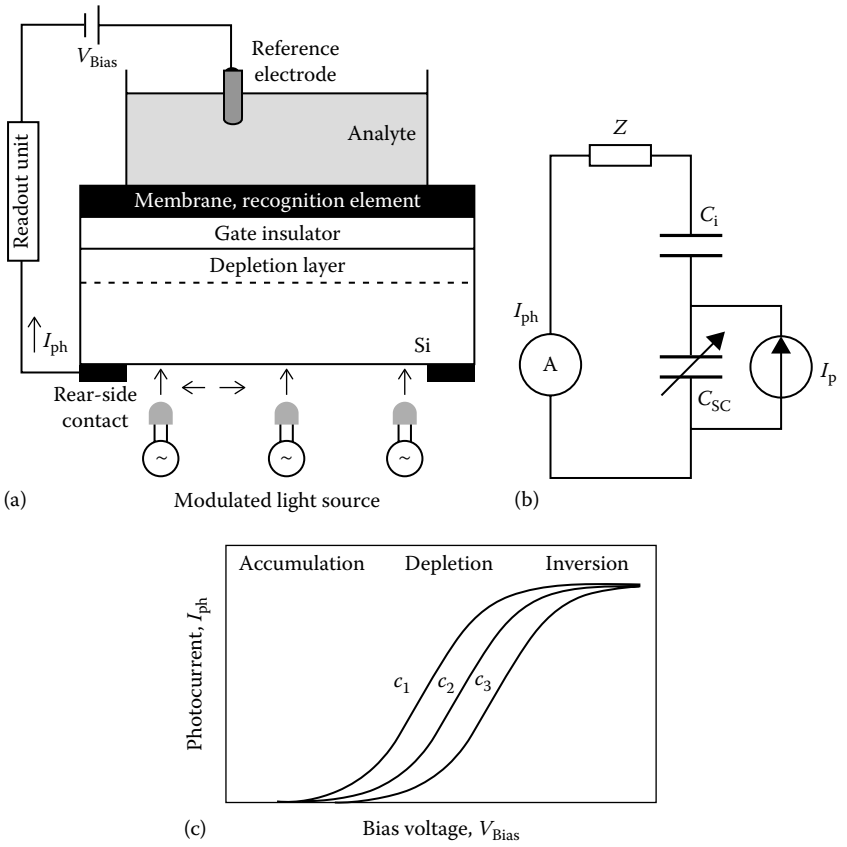

FIGURE 55.24 Schematic structure (a), simplified equivalent circuit (b), and typical photocurrent response by different analyte concentrations (c) of the LAPS. I_{ph}, measured photocurrent; I_p, generated photocurrent; Z, impedance of a reference electrode and a solution; C_i, gate capacitance; C_{SC}, space-charge capacitance; c_1, c_2, and c_3, analyte concentrations.

one or multiple light pointers (light-emitting diode [LED] or laser beam) just below the semiconductor, as shown in Figure 55.24a. When silicon is illuminated with infrared light, there is a generation of electron–hole pairs in the semiconductor. The electron–hole pairs that have diffused from the bulk semiconductor into the depletion region or that are photogenerated within this region are separated in the electric field. Modulating the intensity of an excitation light will modulate the depletion capacitance in the illuminated region of the semiconductor, thus, generating a photocurrent (I_{ph}) in the external circuit. Under the condition of strong depletion, the photocurrent I_{ph} of the LAPS can be described by the following simplified equation (Grattarola and Massobrio 1998):

$$I_{ph} = I_p \frac{C_i}{C_i + C_{SC}} \tag{55.55}$$

where I_p is the alternating component of the photogeneration of electron–hole pairs. Because the capacitance of the space-charge region, C_{SC}, depends on the applied dc voltage, the measured photocurrent is a function of the bias voltage applied to the LAPS structure.

Figure 55.24c depicts typical photocurrent–voltage characteristics of a *p*-type LAPS. By sweeping the applied voltage, the semiconductor surface potential can be driven from accumulation to inversion condition. The amplitude of photocurrent saturates as the bias voltage is increased toward inversion, and the photocurrent disappears when the device is biased into accumulation, where the depletion region and therefore the electric field no longer exist. The LAPS uses this dependence of the photocurrent on bias voltage to sense the interfacial potential changes at the gate/solution interface. For different ion or analyte concentrations, the photocurrent–voltage curve shifts along the voltage axis (Figure 55.24c). By measuring this shift, the analyte concentration can be quantitatively determined. The photocurrent is most sensitive to changes in the chemical composition of the solution in the depletion range (a sharp transition region between a maximum [in inversion mode] and a virtually zero value [in accumulation mode]). Therefore, the shift of the photocurrent–voltage curve is often quantified by tracking the potential of the inflection point of the curve. For chemical imaging applications (a typical chemical image consists of an enormous number of measured spots or pixels), however, the measurement of the complete current–voltage curve is too time-consuming, and a faster measuring method is required. One possible measuring mode is the constant-voltage mode, which is often used for the LAPS-based chemical imaging sensor (Wagner and Schöning 2007). In this mode, the applied bias voltage is simply fixed at a constant value (usually near the inflection point of the current–voltage curve, where the linearity of the curve is high), and the analyte concentration-dependent variation of the photocurrent is recorded. Another mode of operation is the constant-photocurrent mode, in which a feedback system controls the applied bias voltage so that the photocurrent is maintained at a constant value. This mode is most suitable for applications, where measurement of dynamic changes of the sensor signal is necessary.

Thus, not only the sensor structure but also the measurement principle of the LAPS is very similar to that of the EIS capacitance sensor, in which the current signal is induced by the application of an ac voltage. However, in contrast to the capacitive EIS sensor, where the measured value of the ion or analyte concentration is an average over the whole sensing surface in contact with the analyte, the LAPS measurement is spatially resolved. An attractive feature of the LAPS, compared to the EIS sensor and ISFET, is its light addressability. The measurement spot on the sensing surface is defined by the illumination area, where the ac photocurrent to be measured is generated. The main disadvantages of the LAPS are the light sensitivity and the dependence of the photocurrent on the electrolyte conductivity.

Due to the structural similarity between LAPS, capacitive EIS sensor, and ISFET, many of the sensitive materials, deposition or immobilization techniques, and surface modification strategies, which have already been developed for ISFETs and EIS sensors, are also applicable to LAPS devices. Traditionally, the LAPS is mostly employed for pH recording (see, e.g., Poghossian and Schöning 2006, Wagner and Schöning 2007, and references there). Si_3N_4 is the most frequently used pH-sensitive material in LAPS

devices, although several alternative materials such as Ta_2O_5 and Al_2O_3 have also been proven as alternative pH-sensitive materials. The first and successfully commercialized system using the pH-sensitive LAPS for the determination of extracellular acidification of living cells is the cytometer microphysiometer system, realized in 1990s by the company Molecular Devices Corporation (United States) (Hafner 2000). More recently, various portable miniaturized LAPS devices (e.g., LAPS-card sensor or a pen-shaped LAPS) with integrated signal processing unit have been realized (Wagner and Schöning 2007).

In contrast to ISFETs or capacitive EIS sensors, ion-sensitive and enzyme-modified LAPS are studied in less detail. For example, the application of LAPS as an ion sensor for the detection of different cations (Li^+, K^+, Cs^+, Ca^{2+}, and Mg^{2+}) and anions (NO_3^- and SO_4^-) has been demonstrated. A LAPS for heavy-metal detection using a chalcogenide glass membrane was developed. An enzyme-modified LAPS has been realized for the detection of penicillin, urea, glucose, and butyrylcholine. LAPS devices became popular in many chemical and biological applications such as the detection of bacterial growth, the measurement of cell metabolism, and the study of mechanisms of drug action on cell physiology. For example, with the aim to study the influence of drugs on the metabolism of cells, a microphysiometer, based on the multi-light LAPS concept, has been developed for the simultaneous measurement of several extracellular ion concentrations (H^+, Na^+, K^+, and Ca^{2+}) (Yicong et al. 2001). More details about different types of LAPS can be found in Poghossian and Schöning (2007) and Wagner and Schöning (2007).

In order to measure a pH- or ion-concentration distribution along the LAPS sensor surface with a spatial resolution, either the light pointer (e.g., focused laser beam) can be scanned along the surface or multiple light pointers can be used. In this way, a map of a 2D distribution of the pH value or the ion concentration can be visualized (chemical imaging). The detection of the metabolic activity of bacteria immobilized on a LAPS surface and the potentiometric imaging of a solution inside the fluidic microchannel are two examples of a possible application of LAPS as chemical imaging sensor. The spatial resolution of the LAPS is the most important parameter for both the multi-sensor application and the chemical imaging application. It limits both the smallest size of structures that can be visualized by the chemical imaging sensor and the density of measuring points on the sensor surface. Because of lateral diffusion of photogenerated carriers, the spatial resolution is limited by the diffusion length of the minority carriers or the thickness of the Si substrate. The best values of lateral resolution reported for bulk silicon have been about 20 μm. The high spatial resolution down to several micrometers or less can be achieved using SOI substrates with ultrathin Si (<0.5 μm) or poly-Si films as well as a LAPS based on amorphous silicon films.

For a detailed understanding of physicochemical phenomena at semiconductor device/cell interfaces, electrically excitable cells have to be connected individually, that is, each cell has to be interfaced with a separate potential-sensitive device (e.g., with a FET). However, because of the restriction of microelectronic fabrication, the number of FETs and therefore the number of active measuring sites are limited. Instead of placing single cells on the separate gates of the FET arrays, cells grown on a LAPS surface can be individually addressed by scanning the light pointer and illuminating the LAPS surface below the single cell of interest. In this way, it should in principle be possible to record the metabolic or electrical activity of a single cell, although there are many cells cultured on the chip surface. Therefore, several attempts have been made to record action potentials of single cells by means of a LAPS; however, the measured signals were small (about 10 μV). In addition, a hybrid device, a so-called scanning probe potentiometer based on cantilever-type micro-LAPS, capable for the measurement of the pH distribution in microvolume solution with the spatial resolution of 10 μm has been developed (Manalis et al. 2000). It is expected that such a scanning probe potentiometer could be used to image pH gradients produced by individual cells. The main technical problem preventing measurements of extracellular acidification rate of single cells with LAPS devices is the problem of confining the produced protons in a very small and defined volume.

55.4.4 Practical Applications and Limitations

Possible practical applications of field-effect chemical and biological sensors reach from medicine, biotechnology, and environmental monitoring over food and drug industries up to defense

and security purposes (see, e.g., Bergveld and Sibbald 1988, Wang et al. 2005, Poghossian and Schöning 2006, Lee et al. 2009a, and Jimenez-Jorquera et al. 2010). For example, ISFETs have been utilized for pH- and ion-concentration measurements in whole blood, plasma, and urine; in vivo pH monitoring in the stomach; acid-rain monitoring; marine monitoring; soil analysis; monitoring of nutrient solutions in greenhouses; online detection of microorganisms in water; determination of pH in meat and Ca^{2+} in milk; and online process control of pH, K^{+}, Ca^{2+} in wine industry. Moreover, EnFETs were applied for the determination of glucose in blood serum and urine, urea in blood serum and in hemodialysis fluids, and creatinine in hemodialysis solutions and in serum of renal failure patients as well as for transcutaneous blood glucose monitoring of diabetic patients. However, despite the intensive research and practical realization of different field-effect (bio-) chemical devices, generally, it could be concluded that their transfer from scientific laboratories to real life remains rather slow. Only very few of field-effect (bio-)chemical sensors, namely, pH-ISFET electrodes and cell-monitoring systems based on ISFET (Bionas 2500 analyzing system) and LAPS (cytometer microphysiometer, Molecular Devices Corporation), have successfully been commercialized so far. Commercially available pH ISFETs are exceptionally stable, fully temperature-compensated, rugged, reliable devices and exhibit performances that are comparable to those of pH-glass electrodes. Resistance to breakage is the most obvious feature of the pH ISFETs compared to the pH-glass electrode. Therefore, nowadays in many in-line process-monitoring systems in biotechnology, food, and drug industries, the breakable pH-glass electrode is gradually replaced by non-glass, unbreakable pH sensors based on ISFETs.

The study of the current state of BioFETs reveals that some BioFETs, like EnFETs or cell-based FETs, are at a well-developed stage, whereas other BioFETs (e.g., DNA-FETs) are still in the experimental stage or starting phase. Although, many improvements have been made in the last few years, there are, however, still a number of fundamental and technological problems that must be overcome before the first reliable BioFET-based bioanalytical microsystem will appear on to the market. The same can be stated for biologically sensitive capacitive EIS sensors and LAPS.

In general, ChemFETs possess significant advantages over classical ISEs, such as high input impedance, a fast response time, and a small weight. The small sensor area includes the possibility of multiple sensor applications (*sensor arrays*) on a single chip. Moreover, temperature compensation is possible. However, most of these sensors are exposed to a chemically very reactive environment, and therefore, a highly long-term stable protection (encapsulation) of the electronics from the analyte is required. The instability of the materials used induces a sensor drift. In some cases, attachment and fixation of the sensor membranes must be improved. To take the advantage of miniaturized FET devices, there is also the necessity of a small reference electrode. For ChemFETs, there exist two approaches for successful commercialization: dealing with small sample volumes for biomedical use and the high-volume fabrication for a low-price market (e.g., environmental and process monitoring, agriculture and food analysis, leak detectors). The employment of capacitive EIS and MIS sensors offers besides the easier manufacturing technique distinct advantages concerning the improved mechanical and electrochemical stability and sensor lifetime.

55.5 Conductometry

In addition to potentiometry, *conductometric analysis* represents the most important nonfaradaic method. *Conductometry* is based on the measurement of the electrical conductance of an electrolyte solution, which directly depends on the number of positively and negatively charged species in the solution. This analysis method is limited due to its nonselective nature, because all ions in the solution will contribute to the total conductance. Nevertheless, *direct conductance measurements* play an important role in the analysis of binary water/electrolyte mixtures, for example, in chemical water monitoring. The technique can also be applied to ascertain the endpoint detection in *conductometric titrations* for the determination of numerous substances.

55.5.1 Measurement of Conductance and Instrumentation

The *conductance G* of a solution is the reciprocal of the electrical resistance *R* and has the units of siemens (S) that correspond to ohm^{-1} (Ω^{-1}). The conductance of a uniform sample with the length *l* and cross-sectional area *A* is given by

$$G = \kappa \frac{A}{l} \tag{55.56}$$

where the proportionality constant $\kappa = 1/\rho$ (ρ: resistivity) describes the *conductivity* (*specific conductance*) of the solution, expressed in units of S cm^{-1}. The *equivalent conductivity* Λ (*molar conductivity*) of a solution is defined as the conductivity due to one mole, measured between two electrodes that are spaced 1 cm apart and is

$$\Lambda = \frac{1000\ \kappa}{c} \tag{55.57}$$

where *c* corresponds to the concentration of the solution in mol L^{-1}. The units of Λ are S cm^{-1} mol^{-1}. Equation 55.56 permits the calculation of the molar conductivity for a solution of known concentration by considering the experimental values of κ. The molar conductivity Λ, that is, the mobility of ions in solution, is mainly influenced by interionic effects for strong electrolytes and the degree of dissociation for weak solutions. For strong electrolytes, the molar conductivity increases as the dilution is increased. By linear graphical extrapolation for diluted solutions of strong electrolytes, a limiting value is defined as *molar conductivity at infinite dilution* Λ_0. At infinite dilution, the interionic attraction is nil, the ions are independent of each other, and the total conductivity is

$$\Lambda_0 = \lambda_+^0 + \lambda_-^0 \tag{55.58}$$

where λ_+^0 and λ_-^0 are the ionic molar conductivities of the cations and anions, respectively, at infinite dilution. For weak electrolytes, due to the nonlinear relationship between Λ and *c*, a graphical extrapolation cannot be made. Typical values for the limiting molar conductivities for various species in water are listed in Table 55.2.

TABLE 55.2 Molar Conductivity at Infinite Dilution Λ_0 (Ω^{-1} cm^2 mol^{-1})

Cations λ_+^0		Anions λ_-^0	
H^+	349.8	OH^-	198.3
Na^+	50.1	F^-	55.4
K^+	73.5	Cl^-	76.3
Li^+	38.7	Br^-	78.1
NH_4^+	73.4	I^-	76.8
Ag^+	61.9	NO_3^-	71.5
$N(CH_3)_4^+$	44.9	ClO_4^-	67.3
Ca^{2+}	119.0	$C_2H_3O_2^-$	40.9
Mg^{2+}	106.2	HCO_3^-	44.5
Cu^{2+}	107.2	AcO^-	40.9
Zn^{2+}	105.6	SO_4^{2-}	160.0
Ba^{2+}	127.7	CO_3^{2-}	138.6
Pb^{2+}	139.0	$C_2O_4^{2-}$	148.4
Fe^{3+}	204.0	PO_4^{3-}	240.0
La^{3+}	208.8	$Fe(CN)_6^{4-}$	442.0

The equipment needed for measuring the conductivity includes an electric power source, a cell containing the solution, and a suitable measuring bridge. The electric power source consists of an alternating current source that produces signals of about 1 kHz in order to eliminate effects of faradaic current. The measurement is performed by a Wheatstone bridge arrangement. Modern *conductivity meters* supply the alternating current and allow the measurement in a wide range of conductivities (0.001 μS cm^{-1} to 1300 mS cm^{-1}). Additional electronics eliminate disturbing capacitance effects and offer automatic range switching. An integrated temperature sensor corrects automatically conductivities to their value at 25°C. The conductivity cell consists of a pair of electrodes placed in a defined geometry to each other. Usually, the electrodes are platinized to increase their effective surface (high capacitance). Thus, disturbing faradaic currents are minimized. For accurate conductivity determination, the precise area of the electrodes A and their distance apart d, the *cell constant* K, must known exactly. Therefore, the cell constant ($K = A/d$) must be evaluated by calibration with a solution of accurately known conductivity (e.g., a standard KCl solution). Details of calibration standards and concepts of conductivity cells are given in Oehme (1991).

55.5.2 Applications of Conductometry

55.5.2.1 Direct Conductometric Measurement

In spite of the insufficient selectivity of *direct conductometric measurements*, the high sensitivity of this procedure makes it an important analytical tool for certain applications. The specific conductivity of pure water (distilled or deionized) is about 5×10^{-8} S cm^{-1}, and the smallest trace of ionic impurity leads to a large increase in conductivity by an order of magnitude and more. Therefore, conductometric monitoring is employed where a high purity of water is required (e.g., laboratories, semiconductor processing, steam-generating power plants, ion exchanger). Conductometric measurements are widely used to control pollution of rivers and lakes and in oceanography to control the salinity of seawater.

55.5.2.2 Conductometric Titration

In *conductometric titration*, the reaction is followed by means of conductometry and is used for locating endpoints (i.e., the EP in acid–base titrations [neutralization titration]). To define the titration curve, at least three or four measurements before and after the EP are required. The obtained data of the conductivity are plotted as a function of the titrant volume, and the EP is given as the intersection of the two linear extrapolated fractions. A characteristic titration curve of a strong acid (hydrochloric acid) with a strong base (sodium hydroxide) is depicted in Figure 55.25. The solid line represents the resulting

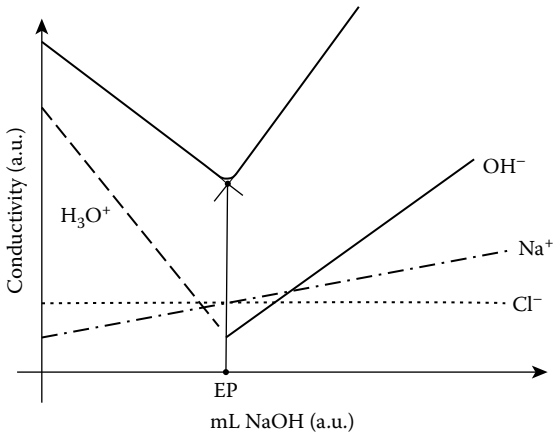

FIGURE 55.25 Conductometric titration of a strong acid (HCl) with a strong base (NaOH). The EP is represented by EP.

titration curve, whereas the broken lines indicate the contribution of the individual species. By adding NaOH to the solution, the hydrogen ions are replaced by the equivalent number of less mobile sodium ions (and $H^+ + OH^- \rightarrow H_2O$). As a result, the conductivity decreases to lower values. The solution exhibits its lowest conductivity at the EP, where the concentrations of hydrogen and hydroxide ions are at the minimum. Further addition of NaOH reverses the slope of the titration curve, since both the sodium ion concentration and hydroxide ion concentration increase.

Due to the high linearity between the conductance and the volume of the added species, this method possesses a high accuracy and can be employed in dilute as well as in more concentrated solutions. In contrast to potentiometric titration methods, the immediate EP region has no strong significance. Thus, very weak acids, such as basic acid and phenol, can be titrated. Moreover, mixtures of hydrochloric acid or another strong acid and acetic (ethanoic) acid or any other weak acid can be titrated with a weak base (e.g., aqueous ammonia, acetate) or with a strong base (e.g., sodium hydroxide). Moreover, precipitation and complex-formation titrations of, for example, sodium chloride with silver nitrate are possible. For practical applications, the volume of the solution should not change appreciably during the titration. Therefore, the titrating reagent may be 20–100 times more concentrated than the solution being titrated, whereas the latter should be as diluted as practicable. For additional examples of analytical procedures and results of conductometric titrations, see Skoog et al. (2007).

55.5.2.3 Oscillometry

In order to investigate electrolyte solutions with high resistivities and dielectric constants, *high-frequency titration* (*oscillometry*) can be performed at 10^5–10^7 Hz. For that, a specific measuring cell is required, where the metal electrodes encircle the outside of a glass container. In this arrangement, the electrodes are not in contact with the test solution, which is advantageous for dealing with corrosive materials. Oscillometric measurements can be employed for the determination of binary mixtures of nonionic species, where the dielectric behavior predominates (e.g., ethanol/nitrobenzene, benzene/chlorobenzene, and alcohol/water). Further practical examples are EDTA titrations and the determination of thorium Th^{4+}) with sodium carbonate, beryllium (Be^{2+}) with sodium hydroxide, and hydrocarbons (e.g., benzene). However, the instrumentation and the interrelations are more complicated than for the classical conductivity method. Thus, oscillometry gets only significance for specific applications, where the presence of the electrodes interferes.

55.5.2.4 Conductometric Sensors

Depending on the demanded size and geometry, miniaturized cells with two or more electrodes (e.g., a four-electrode conductivity meter) as well as contactless cells are commercially available as *conductometric sensors*. The contactless methods use *capacitive* and *inductive conductivity cells*, which are advantageous to circumvent electrochemically caused electrode reactions. Conductivity cells can be coupled as detectors to ion chromatographic systems for measuring ionic concentration in the eluate. For this, special *micro-conductivity cells* with a volume of about 1.5 µL have been developed.

Within the last 10 years, two aspects of conductometric applications became important: *conductometric gas sensors* and the use of *conductometric chemiresistors* as sensors. In the former, a phase change that transfers the gaseous component into a solution is necessary (e.g., by a bubbler nebulizer). All methods deal with acidic gases such as HCl or SO_2 or with alkaline gases, like NH_3. Also, organic halogens can be detected after their conversion into HCl or HF. By means of integrated circuit technology, thin metal films can be photolithographically patterned as interdigital electrodes onto semiconductor substrates with insulating dielectric layers of SiO_2 or Si_3N_4. Both the thin metal films and additionally deposited organic layers on top of the metallic films can lead to a change of the total resistance by variation of the ionic composition of the reacting solution. For chemiresistors, the organic layer usually consists of an ion-selective polymer layer or a Langmuir–Blodgett membrane; for biosensors enzymatic layers are used (see the ISE section). Such sensors allow the determination of different gaseous components, such as CO, NO_2, H_2S, SO_2, or NH_3, as well as the detection of

biologically relevant species like urea, glucose, penicillin, and choline chlorides. Although several companies offer such gas analyzer systems, conductometric sensors and chemiresistors are still in the state of research and development.

55.6 Coulometry

Coulometry represents an electroanalytical method, where the analyte is specifically and completely converted due to direct or indirect electrolysis. The quantity of electricity (in coulombs) consumed by this reaction, the charge, is measured. A fundamental requirement of coulometry is that the species in the solution interact with 100% current efficiency; that is, the reaction corresponds to the Faraday law. According to this condition, there exist two alternatives: the analyte participates in the electrode reaction (*primary* or *direct coulometric analysis*) and the analyte reacts with a reagent, generated by an electrode reaction (*secondary* or *indirect coulometric analysis*). Two general techniques—*controlled-potential coulometry* and *coulometric titration* (*controlled-current coulometry*)—are used for coulometric analysis.

55.6.1 Controlled-Potential Coulometry

In this method, the potential of the working electrode is held at a constant value compared to a reference electrode. The resulting current is adjusted continuously to maintain the desired potential. The substance being determined reacts without involvement of other components in the sample. The reaction is completed when the current has practically decreased to zero. To measure the charge, a potentiostat, an instrument for measuring the time-dependent current, and a current–time integrating device are used. Modern potentiostats have a built-in electronic coulometer and allow extremely accurate determinations. Otherwise, one can use free-standing coulometers.

Controlled-potential coulometry has been widely employed for the determination of various metal ions, such as Cu, Bi, Cd, Zn, Ni, Co, Pu, and U. To apply this method, current–voltage diagrams must be available for the oxidation–reduction system to be measured as well as for any reaction system at the working electrode. Current–voltage diagrams can be obtained by plotting the measured current versus the cathode-reference electrode potential. To fulfill the requirement of the 100% current efficiency in generation, it is necessary to control the potential of the working electrode. With regard to their determination, the metals are deposited at controlled potentials with a mercury cathode as working electrode and a silver wire or a platinum cylinder as anode. Typical applications are the electrolytic determination and synthesis of organic compounds like acetic acid and picric acid. Further, controlled-potential coulometry is frequently used for monitoring the concentration of constituents in gas or liquid streams, typically small oxygen contents. Here, the reduction of oxygen takes place within the pores of a porous silver cathode:

$$O_2(g) + 2H_2O + 4e^- \Leftrightarrow 4OH^- \tag{55.59}$$

Using a cadmium sheet (m) as anode, the electrode reaction in solution (s) is

$$Cd(m) + 2OH^- \Leftrightarrow Cd(OH)_2(s) + 2e^- \tag{55.60}$$

The quantity of the electricity (current) is passed through a standard resistor and converted to a voltage signal. Hence, the oxygen concentration is proportional to the recorded potential drop. Controlled-potential coulometry needs relatively long electrolysis times, although it proceeds virtually unattended with automatic coulometers. With a multimeter, changes in the range from 1 ppm to 1% can be dissoluted. Thus, controlled-potential coulometry permits analysis with an accuracy of a few tenths of a percent.

55.6.2 Coulometric Titration (Controlled-Current Coulometry)

Controlled-current coulometry maintains a constant current throughout the reaction period. Here, an excess of a redox buffer substance must be added in such a way that the potential does not cause any undesirable reaction. That means the product of the electrolysis of the redox buffer must react quantitatively with the unknown substance to be determined. *Coulometric titrations* need an electrolytically generated titrant that reacts stoichiometrically with the analyte to be determined. As in controlled-potential coulometry, 100% current efficiency is required. The current is accurately fixed at a constant value and the quantity of electricity can be calculated by the product of the current (in A) and the time (in s) using endpoint detection. In principle, any endpoint detection system that fits chemically can be used, for example, chemical indicators (color change) and potentiometric, amperometric, or conductometric procedures. For coulometric titrations the instrumentation consists of a titrator (constant-current source, integrator) and a cell. As the constant-current source, an electronically controlled amperostat is preferably used. The integrator measures the product of current and time (i.e., the number of coulombs). The electrolysis cell, filled with the solution from which the titrant will be generated electrolytically and the solution to be titrated, is schematically shown in Figure 55.26. The generator electrode, at which the reagent is formed, possesses a large surface area (e.g., a rectangular strip of platinum). The auxiliary electrode (e.g., a platinum wire) is in contact with an appropriate electrolyte of higher concentration than the solution to be titrated. It is isolated from the analyte by a sintered disk or some other porous media. This is required to avoid the interference of additional products generated at the second electrode. To circumvent these limitations of internal generation, an external generator cell is often used.

Typical applications of coulometric titrations are neutralization titrations, precipitation and complex-formation titrations, and oxidation–reduction titrations. Neutralization titrations can be employed for both weak and strong acids and bases. The former can be performed with hydroxide ions generated at a platinum anode by the following reaction:

$$2H_2O + 2e^- \Leftrightarrow 2OH^- + H_2(g) \tag{55.61}$$

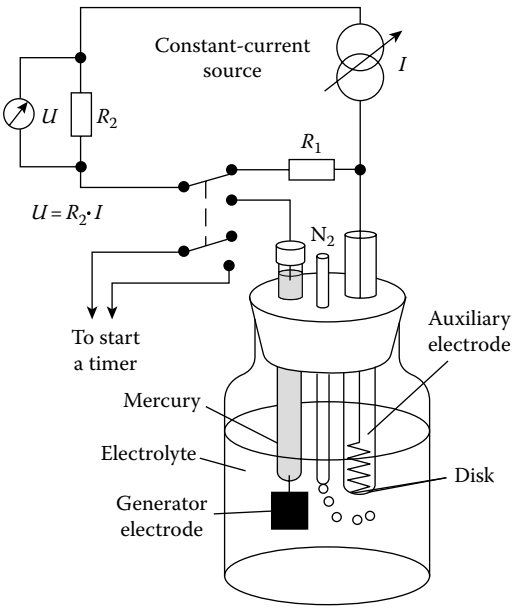

FIGURE 55.26 Coulometric titration cell with working electrode and auxiliary electrode and equivalent circuit diagram (schematically).

the latter one with hydrogen ions by the following reaction:

$$H_2O \Leftrightarrow \tfrac{1}{2}O_2(g) + 2H^+ + 2e^- \tag{55.62}$$

A working (*generator*) electrode of silver as anode offers the determination of Cl^-, Br^-, I^-, and mercaptans in solution(s). For bromide, the reaction becomes

$$Ag + Br^-(s) \Leftrightarrow AgBr(s) + e^- \tag{55.63}$$

Similar precipitation and complex-formation titrations as well as oxidation–reduction titrations are described in Skoog et al. (2007).

Coulometric titrations possess some practical advantages: no standard solutions are required and unstable reagents can be generated or consumed immediately, small amounts of titrants can be electrically quantified with high accuracy, pretitration is possible, and the method can be readily adapted to automatic remote control. Thus, with respect to controlled-potential coulometry, a wider field of practical applications exists. Often, automatic titrators for multipurpose and single analysis employ potentiometric endpoint detection. Examples are sulfur dioxide monitors and water titrators (*Karl Fischer*). For more detailed information concerning applications of coulometry, see Dahmen (1986).

56.1 Introduction

Thermal analysis is the measurement of a physical parameter as a function of temperature. The area comprises several techniques where thermogravimetry (TG), thermometric titrimetry, thermomechanical analysis (TMA), differential thermal analysis, differential scanning calorimetry, and some specialized techniques are among those described in this section. Applications are found in the characterization of organic materials, both solids and liquids. Materials of interest can be polymers, mineral and synthetic oils, lubricants, greases, paper (cellulose), and pharmaceuticals. Material to be analyzed (typically 10 mg) must be isolated and subjected to thermal treatment; hence, the technique is destructive. The obvious advantage is that the thermal profile or structure of a large specimen can be investigated. The disadvantage is that the small sample size can give rise to excessive statistical errors. However, recent advances in microcalorimetry techniques to look at slow degradation of pharmaceuticals allow thermal analysis to be performed at room temperature on samples up to a few grams without destruction of the sample. A general schematic of thermal analysis apparatus is shown in Figure 56.1.

The history of the development of thermal analysis methods from the sixteenth century is the subject of a number of excellent papers by Mackenzie [1–3], Wendlandt [4], and Keattch [5]. Lavoisier and Laplace [6] were pioneers in the development of thermal analysis by their practical approach.

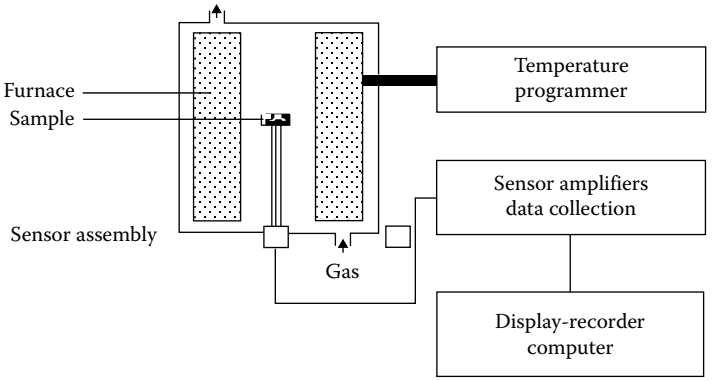

FIGURE 56.1 Schematic thermal analysis apparatus. The figure shows the essential components of a generalized thermal analysis apparatus.

TABLE 56.1 Factors Affecting Thermal Analysis

Factor	Details
Sample	History of sample and preparative technique used can affect the curve, and the presence of trace impurities (in some cases) may catalyze decompositions. Particle size can alter shape of curve (e.g., by surface reaction).
Crucible	The crucible (or sample holder) material should be such that it does not react with the sample or catalyze a reaction. The geometry of the sample holder may affect the results [12].
Rate of heating	Thermal lag: rate of heat transfer between furnace and all parts of the sample is not instantaneous. Therefore, care should be taken when working at different heating. Corrections can be applied [12].
Atmosphere	Various effects [12], including dissociation of sample.
Mass of sample	Size and packing density.

Note: Details the five main areas that would affect analysis of a sample via thermal experiments. The effects can be marked and would certainly affect repeatability also.

The International Confederation for Thermal Analysis and Calorimetry (ICTAC) has produced definitive guidelines regarding nomenclature and calibration [7–10].

56.1.1 Factors Affecting Results

The five factors affecting thermal analysis can be remembered by the acronym SCRAM [11]. This refers to the Sample, Crucible, Rate of heating, Atmosphere, and Mass. See Table 56.1.

56.2 Thermogravimetry

TG or thermogravimetric analysis (TGA) [8] is a technique in which the mass of the sample is monitored against time or temperature while the temperature of the sample, in a specified atmosphere, is programmed.

Derivative thermogravimetry (DTG) shows the change in mass per unit time as a function of temperature.

56.2.1 Apparatus

The apparatus is referred to as a thermobalance or thermogravimetric analyzer. There are a number of configurations: horizontal, simultaneous (TGA–differential thermal analysis [DTA]), and vertical. The vertical design provides better sensitivity and weight capacity. The thermobalance consists of five essential components: furnace, temperature regulator, weighing mechanism, atmosphere controller, and recording system.

56.2.2 Calibration

Small furnaces can be calibrated by a method [8] using Curie points of a range of metals and alloys. The Curie point is the temperature at which a ferromagnetic material loses its ferromagnetism. At the Curie point, the magnetic force is reduced to zero and an apparent mass change is observed.

The study of the reactions can be divided into the following stages: (1) intermediates and (2) products of reaction, (3) energetics of reaction, and (4) the reaction kinetics. Stages (1) and (2) can be readily studied by TG and differential scanning calorimetry (DSC).

For example, the decomposition of calcium oxalate monohydrate shows three distinct steps. The first around 200°C with a loss of 12.4% corresponds to dehydration, while those at 500°C and 800°C match with a loss of CO and CO_2. These are confirmed by analysis of residues.

56.2.2.1 Kinetics of Reaction Including Measurement of α and dα/dt

The use of TG as a means for the elucidation of the reaction kinetics is attractive. The nature of solid–solid interactions is quite complex [13] and will not be discussed in this section.
Consider an endothermic solid-state reaction:

$$\text{A(solid)} \rightarrow \text{B(solid)} + \text{C(gas)} \tag{56.1}$$

During the course of the reaction, there is a mass loss, combined with the loss of gas. Heat absorption also occurs. This process can be modeled. However, it should be noted that the equation (although generally applicable) is not valid for all cases. Methods and mathematical treatment of results are given in the papers by Šatava, Šesták, and Škvára [14–17].

Static (isothermal) and dynamic methods can be used in a kinetic study of the weight change. The former is based on the determination of the degree of transformation at constant temperature as a function of time. The latter is the determination of the degree of transformation as a function of time during a linear increase of temperature. The static method is probably better suited for obtaining information about the slowest process, the reaction order, and reaction mechanism. The dynamic method is better if data on the kinetics of the reaction from a single curve for the whole temperature range are required. Comparisons between both methods have shown comparable results with respect to precision [18].

The extent of a reaction ξ may be defined [19] by Equation 56.2:

$$n_B = n_{B,0} + \nu_B \xi \tag{56.2}$$

where

n_B is the amount of substance B
$n_{B,0}$ is the amount of substance B at $t = 0$
ν_B is the stoichiometric number of B (positive number if B is a product and negative if B is a reactant)

For solid-state reactions, the changes in the portion reacted α are followed with respect to time. Therefore, the rate of reaction can be defined by Equation 56.3:

$$\text{Rate} = \frac{d\alpha}{dt} \tag{56.3}$$

For solution reactions (referring to Equation 56.1), the change in concentration C_B of B is followed.

Since the rate of reaction varies with time (even at constant temperature), at a value of α, Equation 56.2 is derived:

$$\text{Rate} = \frac{d\alpha}{dt} = k_T, f(\alpha) \tag{56.4}$$

where

k_T is the rate constant at temperature T

$f(\alpha)$ is a mathematical expression in α

It should be noted that the form of $f(\alpha)$ sometimes alters partway through a reaction.

If hyphenated group-specific techniques are employed to study a reaction simultaneously (e.g., as is the case in TGA and FTIR), the IR-active species may not contribute the greatest mass loss, and therefore, the values of α will not be the same.

There are many equations relating the rate of solid-state reactions to α and they have been summarized by Sestak and Berggren [20].

A general *integrated* kinetic equation is given in Equation 56.5:

$$g(\alpha) = k_T t \tag{56.5}$$

where

$$g(\alpha) = \int \frac{d\alpha}{f(\alpha)}$$

The rate constant k_T can be calculated from the Arrhenius equation given in Equation 56.6:

$$k_T = A \exp\left(-\frac{E_A}{RT}\right) \tag{56.6}$$

where

E_A is the activation energy (J mol^{-1})

A is the preexponential factor

R is the molar gas constant, 8.314 J (K mol)$^{-1}$

56.2.3 Measurement of α and dα/dt

Consider a thermogravimetric curve consisting of one step. α at a particular time can be found using

$$\alpha = \left(\frac{m_i}{m_i - m_f}\right) - \left(\frac{m_t}{m_i - m_f}\right) \tag{56.7}$$

The differential is hence,

$$\frac{d\alpha}{dt} = -\left[\frac{dm_t/dt}{(m_i - m_f)}\right] \tag{56.8}$$

This states that the rate of reaction can be measured from the slope of the mass–time curve. Since dm_t/dt is already measured by the DTG curve, $d\alpha/dt$ can be found directly from the curve.

Combination of a number of the equations discussed [21] gives

$$\ln \frac{d\alpha}{dt} - \ln(f(\alpha)) = \ln\left(\frac{A}{\beta}\right) - \frac{E_A}{RT} \tag{56.9}$$

where $\beta = dT/dt$.

56.3 Thermometric Titrimetry

Thermometric titration is the measurement of the temperature change in a system as a function of time or volume of titrant. The technique consists of the measurement of the change in temperature as the titrant is added to it, under near-adiabatic or more commonly referred to as isoperibol conditions. The experiments are typically carried out in a small dewar flask submerged in a well-controlled constant-temperature bath. The method can be used to study oxidation–reduction, complexation, precipitation, and neutralization reactions in aqueous solvents. Publications by Zenchelsky [22] and Jordan [23] review the technique in detail.

The basic principle is that a free energy change occurs in the system [24] and is based on the measurement of the free energy-dependent term

$$\Delta G^{\Theta} = -RT \ln K \tag{56.10}$$

where

ΔG^{Θ} is the change in free energy under standard conditions
R is the molar gas constant
T is the temperature in kelvin
K is the equilibrium constant for the system at the temperature T

A calorimetric method (entropy titration) for the determination of ΔG, ΔH, and ΔS from one thermometric titration has been described by Christensen et al. [24].

56.4 Thermomechanical Analysis

TMA relates to techniques where deformation is measured as a change in either volume or length. The deformation is plotted against temperature when a sample is heated under a controlled temperature program. Thermodilatometry measures the dimensional changes as a function of time under negligible loads. TMA is similar to thermodilatometry but also provides information regarding penetration, extension, and flexure using various types of loads on the test specimen. In dynamic mechanical analysis (DMA), the test specimen is subjected to a sinusoidally modulated stress under specified temperature. The viscoelastic response of a material is then monitored under tensile, compressive, shear, or torsional load [25].

56.4.1 Apparatus

A typical instrument for thermal mechanical analysis is called a dilatometer and is equipped with a linear variable differential transformer (LVDT). The displacement of the sample is transferred to the LVDT via a rod (probe) that is unaffected by heat and dimensional changes. A zero weight is accomplished for thermodilatometry by a float system so that a minimum of a load is subjected to the sample. The sample is placed on a sample holder in an oven. A force is applied through the probe in TMA and DMA. The sample cylinder and the probe are independently connected to the measuring device. The top of the probe is also connected to a balance arm. Probe movement and sample length changes are detected. The recorded signals are time, temperature, dimensional changes, and load. Various probes are available, depending on the analysis needs. Expansion, compression, and penetration probes are standard. Tension, three-point bending, and cubical expansion probes are available. Measuring temperature from –150 °C to 600 °C or even up to 1500 °C is possible, depending on the instrument.

56.4.2 Calibration of Probe

The temperature is usually the measured quantity in TMA. Therefore, calibrating the temperature axis is important. Thermomechanical analyzers can be temperature calibrated according to ASTM standard test method E 1363 [26]. An equation is developed for a linear correlation of the experimentally obtained

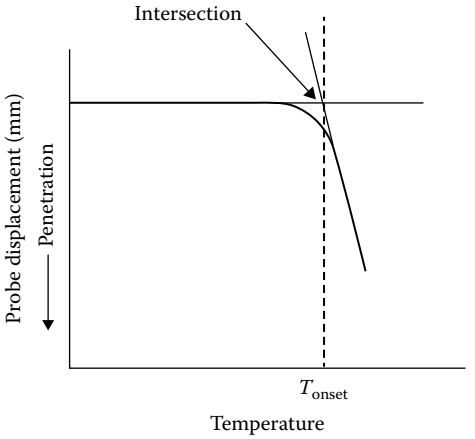

FIGURE 56.2 The calibration of a TMA instrument is a two-point method. There is an assumption that there is a relationship $T_t = (T_o \times S) + I$ between the actual specimen temperature and the onset temperature (Equation 56.11).

program temperature and the actual melting temperature for known melting standards (i.e., mercury, water, tin, benzoic acid). A penetration probe is used to obtain the onset temperatures for two melting standards. The two-point calibration assumes the relationship Equation 56.11 between the actual specimen temperature (T_t) and the observed extrapolated onset temperature (T_0). S and I are the slopes and intercept, respectively, in the TMA thermal curve (Figure 56.2):

$$T_t = (T_0 \times S) + I \tag{56.11}$$

Thermomechanical methods are generally applied on solid-shaped samples like polymeric products. Special clamps are used for testing of soft samples made of rubbers, adhesives, fats, etc. Films and fibers can be tested using clamps. Liquid polymers are tested on support. DMA is used for detecting α, β, and γ transitions in cured epoxy systems [25]. TMA is used for measuring the volume change of bitumen. Scratching and crack propagation at low temperatures is simulated. This is useful when investigating asphalt paving materials [27]. The thermal expansion coefficient of linear expansion is calculated from the slope of the expansion–temperature curve. This is obtained under zero load in thermodilatometry mode. Thermodilatometry can also provide information on phase changes, sintering, and chemical reactions. Softening temperatures are measured using small-diameter tips on the probe under a load (TMA). This sensitive technique is also used for the measurement of heat distortion temperatures and glass transition temperatures of polymers [28].

56.5 Differential Thermal Analysis and Differential Scanning Calorimetry

DTA is the detection of the temperature difference between the sample holder and the reference holder using the electromotive force of the thermocouples, which are attached to the holders. The sample and reference are subjected to a controlled temperature program. The differential is output as the DTA signal. DSC is similar to a DTA in construction, but the DSC measures the difference in heat flow rate to the sample and the reference. Consequently, more information is received on the thermodynamic behavior of the material using DSC. Quantitative DTA is also addressed as a DSC. This definition results in that the major part of all differential thermal analyses performed today uses DSC. An application is found for combined TGA/DTA analysis for kinetic evaluation of petroleum products [29].

56.5.1 Apparatus

The DTA apparatus has a sample and a reference cell subjected to the same temperature program. The measuring device consisting of a thermocouple or any temperature measurement device placed in each cell, measuring the difference in temperature. Operating temperature range is ambient to 1000°C or higher depending on the construction of the instrument and sample pan material. Differential scanning calorimetry is originally defined as individually heated cells. Equal temperature is maintained in the cells, giving an electrical signal proportional to the power needed. The DSC curves represent the rate of energy absorption. Today, most DTA units that can be calibrated to give calorimetric response are called DSC [25]. For qualitative applications, both classical DTA and DSC are equally good. In quantitative work, the DSC is claimed to be better at low heating rates [30].

56.5.2 Calibration and Reference Materials

The dynamic nature of thermal analysis requires a calibration and standard compound to be able to relate results obtained by different instruments. Temperature calibrations can be done using a range of selected materials. Different materials are chosen depending on the temperature range. Common standards are 1,2-dichloroethane, indium, silver sulfate, and quartz. Other organic compounds, metals, inorganic nitrates, sulfates, or chromates are also used [25].

56.5.3 Theory of DTA and DSC

The measured quantity is ΔT, the difference between the temperature of the sample and the reference material. In Equation 56.12, T_S is the temperature of the sample and T_R is the temperature of the reference material:

$$T_S - T_R = \Delta T \tag{56.12}$$

The result is presented as a plot of ΔT against T under a stated temperature program, the differential thermal curve. An endothermic process is then shown as a negative signal. A quantity of material decomposition or the enthalpy of the process is obtained from the area of the peak. It is then, in fact, a calorimetric analysis and the technique is referred to as differential scanning calorimetry.

In DTA, heat transfer to a sample and reference causes a difference in temperature ΔT, which can be related to the energy of any transition of the sample:

$$\Delta H = K \text{ (peak area)} \tag{56.13}$$

For heat flux DSC, a similar process occurs, whereas in power-compensated DSC, electric heating is supplied to the sample and reference to keep their temperatures as close as possible. For best calorimetric accuracy, the constant K should vary little with T.

56.6 Specialized Techniques

56.6.1 Thermoelectrometry

Electrical properties such as resistance/conductance and capacitance can be measured as a function of temperature. A variation that can measure the generated EMF is called thermovoltaic detection [8].

56.6.2 Modulated DSC

In Modulated DSC (MDSC), the heating rate is modulated. This is performed using a small alternating power supply in combination with the standard programmed heating. The heating program is given by the equation

$$T = T_0 + \beta t + B\sin(\omega t) \tag{56.14}$$

and the heat flow is given by

$$\frac{dq}{dt} = C_p[\beta\omega\cos(\omega t) + f(t,T) + C\sin(\omega t)] \tag{56.15}$$

where

T_0 is the initiation temperature
B is the amplitude of temperature modulation
ω (angular frequency) = $(2\pi f)$
C_p is the heat capacity
$f(t,T)$ is the kinetic response (average)
C is the amplitude of response to sine-wave modulation

56.6.3 Simultaneous Techniques

Each of the techniques discussed earlier provides information about the sample. However, a synergistic effect exists, in that the total amount of information obtained (by using techniques simultaneously) regarding the sample is greater than the sum of the information from the individual techniques.

56.6.3.1 Evolved Gas Analysis

This allows the identification of gases evolved during thermal analysis and is performed by replacing the detector with a mass spectrometer or FTIR. An alternative technique is to precede the detector by passing gases evolved during the thermal analysis through a gas chromatograph.

56.6.3.2 Thermomicroscopy

This can be incorporated under thermoptometry (a family of techniques that measure changes of an optical property with temperature change). Thermomicroscopy uses observations under a microscope.

56.7 Applications (Including the Analysis of Electrical Insulating Materials)

56.7.1 Oxidative Stability of Oils and Greases and Polymers

Oxidative degradation of oils upon heating can be monitored using a DSC apparatus. The detected onset *time* or *temperature* of the exotherm can be taken as a measure of the thermal/oxidative stability of the oil. The detected onsets are a strong function of the sample size, instrument sensitivity, kinetics, and scan rate. This enables DSC to be used in an oxidation test. Isothermal high-pressure DSC (PDSC) has been used to characterize the oxidative stability and the oxidation mechanisms of lubricants [34,35]. A PDSC works at pressures up to 3.5 MPa of a selected gas, using a wide temperature range. The technique is useful in the development of new lubricants with improved thermal and oxidative properties. The influence of metal catalysis on oil oxidation can be determined using PDSC. The volatile degradation products have been determined using combined PDSC–gas chromatography–mass spectrometry (GC/MS) [36]. PDSC gives information about relative oxidation stability used for comparing the lifetime of oils [37,38]. It has been a good technique for evaluating the thermal and oxidative stability of lubricating oils [34,39]. PDSC has also been used for evaluating deposit-forming tendencies of liquid lubricants [39].

Volatilization occurs when low-boiling oil is heated, especially at high temperatures. This leads to uncontrolled changes in composition. It also affects the size and shape of the DSC exotherm, causing imprecise determination of the oxidation onset [34]. Use of high pressure in the DSC cell reduces

volatility and evaporation interference with it. Added to this, the onset value is shifted to lower temperatures [34]. The onset becomes better defined and the peak size increases [40].

DSC is a fast technique for oxidation stability testing. This is a great advantage in the quality control of electrical insulating oils. Experimental evaluations of transformer insulating oils have shown ranking to be possible. The remaining lifetime of inhibited oils may correlate to the oxidation induction time [41]. Important parameters in PDSC are sample weight, pressure, and temperature program and have to be carefully considered before applying the technique. The sample pans must not be overlooked. Results are significantly influenced by variations in metallurgy, due to the catalytic and inhibiting effects of various metals. Oxidation induction time of lubricating greases can be determined by ASTM method D5483-93.

56.7.1.1 Predicting the Lifetime of a Product

Estimating the lifetime of a product typically uses some form of accelerated testing. TGA decomposition kinetics can be used to arrive at aging stability information and lifetime predictions in relatively short timescales (hours compared months in conventional oven aging). The sample (e.g., insulating paper) can be heated through its decomposition at several heating rates and the weight loss as a function of temperature recorded. The activation energy is calculated from a plot of log heating rate versus the reciprocal of the temperature for a constant decomposition level. The activation energy is subsequently used to calculate kinetic parameters such as specific rate constant (k) or half-life times, as well as to estimate the lifetime of the material at a given temperature. DTA and DSC have been employed in the electric industry to study polymeric insulation and for the determination of dielectric stability and lifetime prediction.

56.7.1.2 Thermal Analysis and Stability of Materials

TGA is widely employed in the determination of thermal stability of materials and analysis of their composition. The thermal history of electric cable insulation has been determined using DSC [42]. Thermal analysis techniques have greatly improved the quality control and inspection of electric cables. Hyphenated techniques have been employed in the analysis of trace components in electrical insulation [42–44]. ASTM method D3386-84 standardizes measurement of coefficient of linear thermal expansion of electrical insulating materials, while D3850-84 refers to the rapid determination of thermal degradation of solid electrical insulating materials by thermogravimetric methods.

56.7.1.3 Mechanical Stress Determinations

Longitudinal mechanical stresses, frozen into electric cable insulation during the fabrication process, can produce "shrink back." This causes the insulation to shrink away from freshly cut cable ends to varying degrees. TMA can be used to determine these stresses and has been found more versatile than the traditional BS6469 shrinkage measurement [45,46].

56.7.1.4 Evolved Gas Detection and Evolved Gas Analysis

The main use of EGD is to distinguish between phase transitions and endothermic decompositions (e.g., coordination chemistry). It has been used for the analysis of effluents [47]. TGA coupled with FTIR has been used to establish the failure mechanisms of electrical insulating materials [48]. EGA is also used for assessing the thermal endurance of polymeric materials and is of particular value in thermosetting polymers used in the electric industry [49].

56.7.1.5 Investigation of Polymeric Systems

TG can be applied to the study of polymer processes (pyrolysis, oxidative degradation, volatilization, absorption, adsorption, and polymerization) in which a change in weight occurs. The degree of crystallinity provides information regarding the thermal history of a polymer and can be measured by DSC. Physical and mechanical properties of polymers are related to the degree of crystallinity [50]. Thermophysical

property measurements and analysis of additives in polymers can also be performed using thermal analysis techniques [51]. ASTM method D4000-89 can be used for the identification of plastic materials.

56.7.1.6 Pharmaceutical Applications

Calorimetric purity determinations are used in the pharmaceutical industry. The concentration of the impurity is regarded as inversely proportional to its melting point. Therefore, an increase in the sample's impurity content decreases the melting point and broadens the melting range. DTA can also be used but DSC is preferred since it also gives the ΔH_f (heat of fusion) of the melt [52]. The DSC method is based on the van't Hoff equation. A compound may exist in various crystal forms; DSC and TG are used to characterize polymorphs and assess the stability of the compounds. DSC has been used for investigating the effect of inhibitors with model membranes [53]. Drug incompatibility is defined as "an interaction between two or more components to produce changes in the chemical, physical, microbiological, or therapeutic properties of the preparation" [54]. DTA and DSC are used to record reactions as a function of temperature and investigate drug compatibility [55]. Recent advances in microcalorimetry have allowed nondestructive analysis at room temperature [56,57]. The technique is gaining popularity in the pharmaceutical industry and also in the study of ballistics.

56.7.1.7 Characterization of Greases and Lubricants

Greases and lubricants are, in application, exposed to high temperatures in both inert and in oxidizing atmosphere. Material losses due to evaporation and loss or alteration due to thermal cracking or oxidation of the molecular structure are possible. The various aging reactions are usually inhibited by additives. TG, DTA, and DSC are used as test instruments, but the overall difficulty is to find methods that correlate with real thermal aging of the greases and lubricants.

The peak onset and peak maximum temperatures from DTG, DTA, and DSC curves are used or the peak onset from TGA curve. The evaporation behavior of greases is the most used parameter, but wax content, glass temperature, and cloud point are other characteristics of greases that are studied using thermoanalytical techniques [27].

In the Noack test of evaporative loss (DIN 51 581), the sample is held at 250°C for 60 min in an airflow. The sample is weighed before and after treatment. The cause of the weight loss is not clear, whether it is evaporation of parts of the original sample or evaporation of oxidative degradation products. The question has arisen whether isothermal TG could replace the Noack test. This would provide continuous loss information during the thermal exposure. It has been shown that there is a higher weight loss in the thermobalance than in the Noack test at equal test conditions. The deviation is caused by the difference in surface: volume ratio between the two methods [27].

Oxidation studies of low-boiling lubricant or lubricating oils do not give representative results. This is due to the evaporation of oil and existence of low-boiling oxidative degradation products. A TGA curve of a lubricant produced in an air atmosphere does not always represent the oxidation reaction. The use of an elevated oxygen or air pressure in DSC has been shown to reduce sample evaporation due to increased evaporation temperature and increase the rate of the oxidation. Several papers deal with this technique, which has found application in the characterization of lubricants [27,34–41,58].

56.7.1.8 Insulation Paper/Cellulose

The rate of weight loss on pyrolysis of cellulosic materials has applications to engineering problems in many industries. On heating, cellulose undergoes a number of linked physical and chemical changes [59]. Properties such as weight, strength, crystallinity, and enthalpy are affected.

TGA can be used to perform a collective measurement of the weight loss due to the production of H_2O, CO, and CO_2 during degradation. Of course, the measurement will include evaporation of other pyrolysis products. The enthalpy changes can also be measured by DSC. These methods are very useful in determining the temperature range at which physical and chemical processes occur. The rate of these processes can be determined by using DTG.

Defining Terms

Derivative: Techniques where a measurement or calculation of the first derivative is performed.

Differential: Techniques where a difference in a property is measured.

Thermal analysis: A group of techniques in which a property of the sample is monitored against time or programmed temperature (in a specified atmosphere).

Kinetic Composition Measurement

General Electric Company Schenectady

57.1 Introduction

Kinetic methods involve the measurement of chemical reactions or processes in a time-dependent manner. Rates of dynamic processes are measured rather than the properties of a system at equilibrium. Of course, this approach is a central one for the study of chemical reactions and reaction mechanisms; however, it has much value in analytic chemistry; that is, in the determination of the composition of materials. This fact has been recognized for some time, but in recent years, there has been resurgence in interest in the use of kinetic methods in analytic chemistry. There have been several world congresses on this subject and numerous monographs [1,2], and the number of papers on kinetic methods has dramatically increased in the last decade [3].

Why is there such an interest? After all, there are many analytic procedures that are quite general and sensitive. As a specific example, consider the analysis for various metals in environmental samples. Metal ions can be detected by numerous means such as by ion-selective electrodes, atomic flame spectroscopy, or ion-coupled plasma spectroscopy, yet there is abundant literature on metal detection by catalyzed reactions in a kinetic manner [1–3]. In this case, the method of choice is dictated by cost of analysis, speed, sensitivity, and convenience. Furthermore, certain molecular species may be difficult to discriminate from others in conventional analysis. In this case, with a proper reaction, the kinetic approach is a powerful tool in detecting such constituents. Finally, the kinetic approach is the only method capable of elucidating the nature of binding sites in molecular binding because the determination of an equilibrium association constant alone is insufficient to elucidate mixed binding sites [4]. It is also the principal means of identifying short-lived intermediate species in a reaction [5].

Thus, kinetic methods comprise an important group of methods available for the analysis of substances. In some cases, kinetic methods offer unique advantages as in the study of mixed binding sites,

TABLE 57.1 Classification of Kinetic Methods Based on System and Catalyst

System	Catalyst	Reaction Examples
Homogeneous	Enzymatic	Hydrolysis electron transfer
	Nonenzymatic	Redox
		Complexation
		Chemiluminescence
	No catalyst	Redox
		Chemiluminescence
Heterogeneous	Enzymatic	Immunoenzymatic
		Electrode reactions
		Electrocatalysis
		Fluorescence
	Nonenzymatic	Electrode reactions
		Electrocatalysis
		Fluorescence
	No catalyst	Fluorescence
		Radioimmunoassay

in the delineation of competing species and in the determination of short-lived intermediates. In other cases, kinetic methods offer speed and convenience, and low cost, as, for example, in such applications as clinical analysis and environmental field analysis.

In a broader sense, time-dependent changes in chemical, physical, and biological processes are universal. Because equilibrium may not be achieved in certain processes, time-dependent effects must be considered and accounted for in a satisfactory manner for analytic determinations to be accurate and reproducible. In some instances, for reasons of speed of analysis, kinetic rates are measured rather than equilibrium values. The range of time dependencies can range from picoseconds, studied with mode-locked lasers, to seconds or minutes, studied with batch mixing procedures. Kinetic methods encompass a broad range of processes and time domains. The methods of simple chemical reactions can often be applied to complicated biological processes. This is possible because often one reaction in a group of coupled reactions controls the overall rate of the process.

Kinetic methods have been classified according to different criteria. The most common classification is based on whether the method involves a catalyst. This is so because reactions are frequently quite slow. In such cases, a catalyst must be added to speed up the reactions and make rate determinations practical. In other instances, the catalyst is the analyte itself. There are two major groups of catalysts: enzymatic and nonenzymatic. Another common classification of kinetic methods is based on whether the reaction proceeds in a homogeneous or heterogeneous system. Most of the discussion will be focused on homogeneous liquid and heterogeneous liquid–solid systems because these comprise the majority of kinetic analytical methods that have been developed. Presented in Table 57.1 are classifications based on the aforementioned criteria along with example reactions.

57.2 Theoretical Aspects

A reaction involving species A and B proceeds to a product with a rate constant, k', such that the rate of change of species A is given by

$$-\frac{\mathrm{d[A]}}{\mathrm{d}t} = k'[\mathrm{A}][\mathrm{B}] \tag{57.1}$$

where the brackets denote concentration. If the species A is of interest, then the reactant B can be in excess, in which case changes in [B] can be ignored. A pseudo-first-order reaction can be written as

$$-\frac{\mathrm{d}[\mathrm{A}]}{\mathrm{d}t} = k[\mathrm{A}] \tag{57.2}$$

where $k = k'$ [B] and the time evolution of [A] is just

$$[\mathrm{A}] = [\mathrm{A}]_0 e^{-kt} \tag{57.3}$$

The product, P, which is the species that is usually detected, evolves as

$$[\mathrm{P}] = [\mathrm{A}]_0 (1 - e^{-kt}) \tag{57.4}$$

The species A can be expressed in terms of product by

$$[\mathrm{A}] = [\mathrm{P}]_\infty - [\mathrm{P}] \tag{57.5}$$

where $[\mathrm{P}]_\infty = [\mathrm{A}]_0$. By measuring [P] as a function of time, the initial concentration of A can be deduced from a plot of

$$\ln\,[\mathrm{A}] = \ln\,[\mathrm{A}]_0 - kt \tag{57.6}$$

In this way, a calibration curve can be generated against which an unknown sample can be measured for the content of species A.

In case the reaction is of a different order, the time-dependent plots for determining $[\mathrm{A}]_0$ take on a different form. For example, in a second-order reaction, the rate of change of [A] is given by

$$-\frac{\mathrm{d}[\mathrm{A}]}{\mathrm{d}t} = k[\mathrm{A}]\,[\mathrm{A}] \tag{57.7}$$

where, as before, the reactant [B] is considered in excess and its time dependence can be assumed to be negligible. The calibration curve is now

$$\frac{1}{[\mathrm{A}]} = \frac{1}{[\mathrm{A}]_0} + kt \tag{57.8}$$

Clearly, the order of the reaction under study must be known for a correct analysis. There are straightforward ways to determine the order by varying the initial concentration of [A] and noting the initial velocity of the reaction. A plot of the initial velocities versus initial [A] will reveal the order of the reaction [1].

One of the strong points of kinetic methods is that closely related species that may be difficult to resolve by other means can be resolved by kinetic measurements. This is particularly true when enzyme reactions are employed. Enzymatic reactions are extremely sensitive to molecular structure and closely related structural analogs may have significantly different kinetics. For example, consider species A and B going through a reaction to a product but each having a different rate constant, k_a and k_b. The detected product is given as a sum of the two components by

$$[\mathrm{P}]_\infty - [\mathrm{P}] = [\mathrm{A}]_0 \exp(-k_\mathrm{a} t) + [\mathrm{B}]_0 \exp(-k_\mathrm{b} t) \tag{57.9}$$

Then, by computer fitting or graphical analysis of a semilog plot of

$$\ln \{[P]_\infty - [P]\} = \ln [A]_0 - k_a t + \ln [B]_0 - k_b t \tag{57.10}$$

one can extrapolate to $t = 0$ and determine $[A]_0$ and $[B]_0$.

The important case of catalyzed reactions must be considered separately as there are important differences from the case of uncatalyzed reactions considered earlier. The catalyst is usually the species to be determined as it often is a metal ion or nonorganic ion of interest. Usually, the catalyst combines with the reactant species [B] in a very fast reaction with a given equilibrium constant to give

$$[C] + [B] \leftrightarrows [CB] + [Y] \tag{57.11}$$

Here, CB, the reactant B bound to C, reacts with A with a much faster rate than if B is unbound. This develops because of the reduction of the activation energy provided by the catalyst C in combination with B as discussed later. Thus,

$$[CB] + [A] \leftrightarrows [P] + [Y] \tag{57.12}$$

This more complex kinetics simplifies to pseudo-first-order if one considers only the initial rates of the reaction. The initial velocity of the indicator product, P, takes the simple form

$$V_0 = \frac{d[P]}{dt} = K'[C]_0 + K'' \tag{57.13}$$

where K' are K'' constants. A calibration curve for C can thereby be generated through initial velocity measurements.

57.2.1 Enzyme Reactions

Enzymes are a class of proteins that catalyze reactions with exquisite specificity. The activity of certain enzymes is in itself of great importance in clinical diagnosis, but enzymes can be useful in determining substrate concentration—also very important for clinical applications and for environmental analysis. The rates of enzyme reactions are directly proportional to enzyme concentration; however, there is a saturation of reaction rates with increasing substrate concentration. This saturation effect must be considered when analyzing such reactions. The essential feature of enzyme reactions involves the enzyme, the substrate, the enzyme–substrate complex, and the product. It is the formation of the enzyme–substrate complex that leads to the saturation kinetics [5]. The reaction can be represented as follows:

$$[E] + [S] \overset{k_2}{\underset{k_1}{\rightleftarrows}} [ES] \overset{}{\underset{k_3}{\rightarrow}} [P] + [E] \tag{57.14}$$

where the reaction to form the enzyme–substrate complex is reversible as indicated by the arrows and k_1 is the forward rate and k_2 is the backward dissociation rate, and there is no reversion of product to substrate in the initial stages of reaction.

With the condition that initially $P \sim 0$, and setting $d[ES]/dt = 0$, it is easy to show that

$$\frac{[ES]}{[E][S]} = \frac{1}{K_M} \tag{57.15}$$

where K_M is the Michaelis–Menten constant. Now, since the velocity of the reaction (and here, one considers the initial velocity only) is given by

$$V_i = k_3[ES] \tag{57.16}$$

and one can define a maximum velocity such that

$$V_{imax} = k_3[E]_{tot} \tag{57.17}$$

The velocity is maximum when all of the enzyme binding sites are filled with substrate. Solving for [ES] and using $[E] = [E]_{tot} - [ES]$, one obtains

$$V_i = \frac{k_3[E]_0[S]}{(K_M + [S])} \tag{57.18}$$

This is the functional form that expresses saturation kinetics with respect to substrate concentration. Generally, for determination of activities, enzyme reactions are performed in a fully saturated regime (i.e., $[S] \gg K_M$); otherwise, the kinetic rates need corrections and the Michaelis–Menten constant must be known or needs to be determined. For determination of substrate concentration, the analysis must account for the nonlinearity of V_i with respect to [S].

Enzyme activity is defined in terms of units, rate of formation of product under given conditions, since the protein content in the enzyme preparation can be misleading—not all of the enzymes in a preparation need be active. Because enzymes are proteins, and in some cases rather delicate ones, great care must be exercised in handling and storing. The activities of enzymes are very sensitive to pH, salinity, and temperature. All of these factors must be precisely controlled for reliable kinetic determinations.

57.2.2 Temperature Dependence

Rate constants obey the Arrhenius relation

$$k = A \exp\left\{\frac{-E_a}{RT}\right\} \tag{57.19}$$

where

E_a is the activation energy
R is the gas constant
T is the absolute temperature
A is a prefactor term

Knowledge of the activation energy allows for the extrapolation of a kinetic rate to any temperature. It is the lowering of this activation energy that is at the heart of catalysis and enzymatic reactions. Because of the exponential dependence, a reduction of the activation energy can lead to a rate constant increase of many orders of magnitude.

The prefactor A is determined by some collision frequency. However, in general, reactions proceed slower than the collision theory would predict. This is because, in addition to collisional frequency, there are also configurational and entropic terms that play a role in determining A. Nevertheless, it is useful to consider the concept of diffusion-controlled reactions. Here, it is the collisional frequency that

dominates the reaction. In that situation, it is possible to utilize the diffusion theory of random motion in a medium to derive A such that

$$A_{\text{diff}} = \frac{4\pi(r_{ij})(D_i + D_j)N_0}{1000} \tag{57.20}$$

where

N_0 is Avogadro's number
D_i and D_j are the diffusion constants for species i and species j
r_{ij} is the encounter distance

For D of the order of 1.5×10^{-5} cm^2 s^{-1}, which is a value appropriate for small molecules, A_{diff} is 10^{10} M^{-1} s^{-1}. Reactions involving protonation or the OH^- ion proceed at this rate, but only a few enzyme–substrate complex-formation reactions approach the diffusion limited rate [6].

57.3 Experimental

The kinetic methods can be further classified according to experimental approaches as presented in Table 57.2.

The principal instrumental elements of a kinetic apparatus are the mixing chamber, timing device and control of data acquisition, and detector. Automation and computer controls have allowed kinetic measurements to be done routinely and with great accuracy for even very fast reactions. We consider those aspects of instrumentation unique to the problem of mixing and proper fast sampling—the essential issues of the experimental method. The other components of instrumentation are beyond the scope of this chapter; the readers may refer to the monographs for more details on those topics [1,2].

Although the nature of kinetic measurements does not require absolute quantitation of a product, it does require care in accurate timing and fast mixing of reactants. For slow reactions, the mixing chambers can be closed systems without any need for elaborate devices or techniques to initiate the reaction

TABLE 57.2 Classification of Kinetic Methods Based on Mixing Technique or Equilibrium Perturbation

Technique	Methods
Batch mixing (for slow reactions)	Stirring in cuvette or flask
Flow mixing (fast reactions)	Continuous flow
	Accelerated flow
	Pulsed flow
	Stopped flow
Thermodynamic jump	Temperature jump
	Pressure jump
	Electric current jump
	Concentration jump
Periodic relaxation	Cyclic voltammetry
	Dielectric relaxation
Pulse relaxation	Time-resolved fluorescence
	Time-resolved phosphorescence
	Flash photolysis
	Pulse NMR
	Pulse EPR

of interest. The so-called batch mixing can be done in ordinary optical cuvettes with a suitable magnetic stirring rod or mixing plunger. These straightforward experimental techniques are not discussed here; rather, the time domain for which kinetic methods require specialized equipment will be considered. This domain is in the region of 1 ms to 1 s, for example. Reactions with time constants in this domain are very common in current applications of kinetic methods.

57.3.1 Mixing Methods

In the so-called open systems, there are three approaches to initiating and monitoring reactions: (1) continuous flow, (2) pulse and accelerated flow, and (3) stopped flow.

In method (1), the reactants are brought together into a capillary under fast-flow conditions and the product is monitored (e.g., by a photodiode) along the length of the capillary, thus tracing out the kinetics in so far as the time dependence of the reaction is transformed into distance along the capillary by

$$t = \frac{d}{v} \tag{57.21}$$

where

v is the flow velocity

d is the distance along the capillary after the junction in which the reactants are introduced

A high flow rate ensures a high Reynolds number condition and the achievement of turbulent flow and good mixing in the capillary. This method has the disadvantage of requiring rather high molar extinction coefficient for the product to achieve sensitivity and the high consumption of sample and reactant. In addition, multiple measurements along the tube are required to trace out the kinetics.

Method (2), pulsed and accelerated flow, was devised to address these deficiencies. By accelerating the flow, it is possible to do a single-point measurement: the kinetics can be deconvoluted from the known change of flow as a function of time. In addition, integrated detection can be used in which the light path of the detector and source look down the flow tube, thus affording much greater sensitivity by virtue of a long absorption path length. Rather small quantities of analyte and reactant are consumed by this method because the flow is not continuous and a single-point measurement is sufficient for the measurement of the kinetic parameters.

Method (3), the stopped-flow method has all the advantages of method (2), is simpler analytically, and can measure even faster kinetics. In this method, reactant and analyte are combined from two syringes driven simultaneously by a push block as shown schematically in Figure 57.1. As the stop syringe plunger hits a precalibrated stop position, the flow is halted. Data are accumulated after the flow is stopped, free from effects of flow turbulence and other time-dependent interferences. Dead times (i.e., the time between inception of mixing and start of measurements) can be as short as 0.5 ms. The steps involved in the measurements can be automated for multisample, high throughput applications. A particularly simple stopped-flow system has been described by Harvey [7]. The drive syringes are standard 10 mL syringes that are manually pushed by a plunger. The mixing chamber is at the bottom of a 3 cm^2 observation cell. As the mixed solution enters the cell, it pushes up a float past the level of the light beam by which the reaction is monitored. After the measurement, the spent solution is displaced by pushing down on the float. This very simple approach is adequate for reactions slower than some 100 ms or so.

Reactions fast as 1 ms can be measured by stopped-flow techniques. Fully automated sampling and data acquisition systems have been implemented [8]. Computer-controlled, three-wave valves are used to charge up the drive syringes and to flush them clean between measurements. Very fast reactions such as those involved in the folding of proteins have been studied in this way [9].

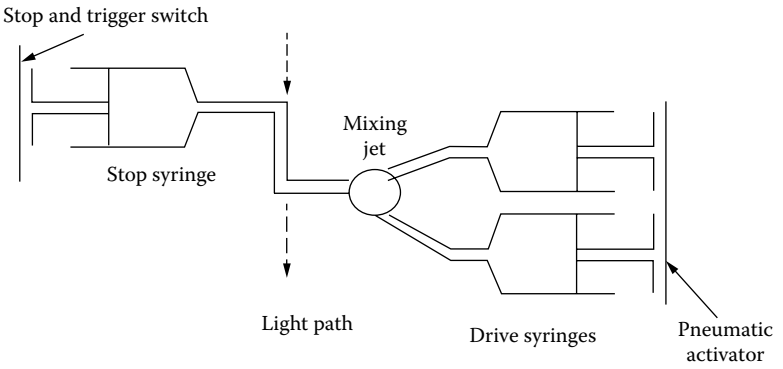

FIGURE 57.1 Schematic diagram of stopped-flow system. The reactant solutions are taken up into the two drive syringes as shown. The charging of the syringes is accomplished by valves and reservoirs not shown in the schematic for simplicity. As the activator plunger pushes the solutions through the mixing chamber, which is designed for efficient and fast mixing through tangential injection and turbulent flow (as in the Dionex Corp. system, for example), the old spent solution in the observation chamber is forced out into the stop syringe. The stop syringe plunger hits a stop, which causes immediate cessation of flow and activates the data acquisition system, which may be an oscilloscope, strip chart, or computer. The observation chamber shown here is oriented parallel to the light beam path for maximum path length and maximum sensitivity to absorption changes. The dead time of such a system can be as low as 0.5 ms and the quantity of solutions required can be as low as 100–500 μL. At the end of a measurement, the stop syringe is purged and the drive syringes are recharged for another measurement cycle.

57.3.2 Relaxation Methods

An entirely different approach to kinetics is to probe the reactions of two reacting species that are in equilibrium by perturbing the equilibrium by a sudden change of temperature or pressure. These methods, known as relaxation methods, have as their virtue the ability to resolve kinetics in the very fast time regime much shorter than 1 ms [10]. If the equilibrium is disturbed, the relaxation to the new equilibrium state will proceed with a time constant τ given by

$$\frac{1}{\tau} = k_1 + k_{-1} \tag{57.22}$$

where k_1 and k_{-1} are the forward and back reaction rate constants between the two species, respectively. The magnitude of the response depends on the enthalpy change with temperature or volume change with pressure of the particular reaction under study.

In the temperature jump method, a pulse of energy is supplied to the sample, either by a current pulse if the solution is conducting or by a light pulse if the solution is absorptive at a suitable wavelength. Light pulses can be made extremely short with a suitable laser source—nanoseconds to picoseconds—and this approach lends itself to the examination of the very fast molecular processes such as the intermediate states in photoreception [11].

These methods are well suited for the study of fast reactions but less useful for compositional analysis. However, a type of relaxation that is well known (i.e., fluorescence and phosphorescence) has become very valuable analytical tools. In such methods, a light pulse populates an excited state of molecules under study, and the rate of decay of that state provides an identifying signature of the species, even in a background of other emissions at the same wavelength. This holds as long as the signal of interest decays with a different time constant from the background signals.

The steady-state aspect of fluorescence and phosphorescence spectroscopy is a well-established "equilibrium" analytical technique that relies on the spectral differences for identification and intensity

differences for quantitation. Its application, however, becomes invalid when an analytical sample contains multiple species that have indistinguishable luminescence spectra. However, it is frequently the case that the different species have different luminescence lifetimes. Thus, time-resolved spectra may produce a resolution of the species. For example, some tetracyclines have overlapping phosphorescence spectra that prevent characterization of each individual tetracycline. By using time-resolved, room-temperature phosphorescence, simultaneous determination of these tetracyclines was achieved based on their decay times in a continuous-flow system [12]. Even if two species have similar lifetimes, one can attach luminescence groups with different lifetimes to differentiate them. For example, different antigens tagged with different dyes with different lifetimes [13] were used to allow simultaneous detection of the antigens.

There are many benchtop fluorescence instruments capable of measuring lifetimes as short as nanoseconds. However, most of them are capable of monitoring only one specific wavelength as a function of time. Recently, fast optical spectrometers have been developed that have nanosecond time resolution over the entire visible spectrum [3].

57.4 Catalytic Reactions

Catalytic methods are based on the kinetic determination of catalyzed reactions. Such reactions can be extremely sensitive when the catalyst is the analyte. For example, chemiluminescence reactions of the oxidation of luminol by hydrogen peroxide catalyzed by metal ions provide extremely low detection limits for Co(II), Cu(II), Ni(II), Cr(III), and Mn(II). It should be pointed out that the term "catalyst" is loosely defined here as a substance that modifies the rate of a reaction without altering its equilibrium. Thus, the term "catalyst" includes the notion of promotion, inhibition, and, of course, true catalysis in which the catalyst remains chemically unchanged at the end of the reaction. Catalysts are usually categorized into two groups: enzymatic and nonenzymatic. Discussed later are overviews of catalytic-based kinetic methods applied in both homogeneous and heterogeneous systems.

57.4.1 Homogeneous Systems

Most applications of homogeneous kinetic methods are based on rate determination of catalyzed indicator (or substrate) reactions. Most frequently, the catalyst is the analyte to be determined, although, occasionally, it may serve simply as a reagent. Enzymes are one special type of catalyst. They are proteins possessing a very high degree of specificity. For example, certain enzymes can only exert catalytic actions on particular chemical bonds or steric isomers. Homogeneous enzymatic methods are widely used in clinic diagnoses to determine enzyme activity as well as enzyme–substrate concentrations. The theoretical aspects of enzyme kinetics have been discussed in the previous section. Analytical applications for both enzyme activity determination and enzyme–substrate detection can be found in the literature [3,14].

Homogeneous nonenzymatic catalytic methods are mainly applied for detection of metal ions and other simple inorganic and organic species [3,15]. There are three major types of indicator reactions: redox, chemiluminescence, and complexation. One popular redox indicator reaction is the reduction of hydrogen peroxide by iodide catalyzed by metal ions (Fe, Mo, W, and Zr) that are also the analytes. The most common chemiluminescence indicator reaction is the decomposition of luminol (5-amino-2,3-dihydrophthalazine-1,4-dione) accompanied by the generation of luminescence at 425 nm. This decomposition is achieved through the oxidation of the doubly charged anion by the oxidant in this reaction (metal ions in most cases). Although the oxidant in this case is consumed during the reaction, it is often termed a "catalyst" in the literature because its consumption is negligible in the time frame of the initial rate measurement, principally because of the ultrasensitivity of the chemiluminescence measurement. For complexation reactions, there are two main groups: ligand-exchange and complex-formation reactions. They are less studied compared with the aforementioned two indicator reactions

but have promising application in the determination of nontransition metals. For example, a reaction involving ligand exchange can be used to detect 0.4 ppm Ca. The most widely used detection technique for the complexation indicator reaction is UV/VIS absorbance.

57.4.2 Heterogeneous Systems

Many kinetic methods depend on the application of different heterogeneous catalysis processes where the catalytic reaction takes place at the interface between two immiscible phases, usually between the liquid–solid phases. The discussion here focuses on two main areas of heterogeneous catalysis that are important in chemical analysis. The first encompasses immobilized enzymes in which the labeled enzymes are either physically or chemically attached onto a solid surface. The measurement of surface enzyme activity is then related to the analyte concentration. The second is the area of electrocatalysis, in which chemical reactions occur at the interface of an electrode and an electrolyte solution. The catalyst in this case is the charged electrode surface in either the intrinsic state or in a chemically modified state. The analyte concentration in the solution is determined by the electrode dynamic current.

The most widely used format for immobilized immunoenzymatic techniques is known as enzyme-linked immunosorbent assay (ELISA). This type of assay combines the great selectivity provided by specific antibody–antigen recognition, the high sensitivity provided by enzymatic amplification, and general applicability provided by the use of common detection methods. It has proven to be a very powerful technique for simple, rapid, and cost-effective trace analysis and is widely used today in clinical diagnosis [16], drug screening [17], food safety inspection [18], and environmental analysis [19,20].

ELISA can be operated in several different modes, depending on the nature of analyte, sample environment, and requirements on speed, cost, and detection limits. Different assays are usually classified according to their operating procedure (competitive or noncompetitive), to the signal detection technique used (calorimetric, luminescent, electrochemical, or radioactive), or to the physical arrangement of the antibody–antigen binding structure (single layer or sandwich layers). For a more detailed description, the reader is referred to several references [21,22].

A typical immunoassay procedure involves three steps: (1) immobilization of antibodies onto a solid surface, (2) competitive binding of analytes and enzyme-tagged conjugates to the antibody sites, and (3) rate measurement of a substrate reaction catalyzed by the enzyme. In most cases, only the latter two steps operate in a kinetic mode. Illustrated in Figure 57.2 is the chemiluminescence ELISA developed for rapid field analysis for polychlorobiphenyls (PCBs) in which the kinetic response of the enzymatic reaction enables the quantitative determination of PCB concentration [19]. First, a solid support of specified material and format is chosen based on the analysis requirement. The support surface is then treated with protein A, a procedure to allow for the immobilization of antibodies in the proper orientation as shown in Figure 57.2. The third step is to immobilize the antibodies onto the protein A–coated surface. Then an enzyme–antigen conjugate (specifically the bromobiphenyl–alkaline phosphatase) is introduced to the well so as to saturate all of the antibody binding sites. After thorough rinse with pH 7 buffer solution, these conjugate treated well plates are ready for use in analysis of samples. The analysis of PCB-containing samples proceeds simply by adding the PCB-containing solution into the well for a fixed time to allow the PCBs to displace the previously bound enzyme conjugates. The higher the PCB concentration in solution, the higher will be the displacement of the enzyme conjugates in a given amount of time. After a fixed time, the well is then thoroughly rinsed and a chemiluminescence substrate is added. Under the catalysis of alkaline phosphatase, the substrate is transformed into a luminescent species that is then detected. The initial luminescence generation rate or the total intensity within a fixed time is proportional to the surface alkaline phosphatase and thus inversely related to the PCB concentration, as shown by the results in Figure 57.3.

Electrocatalytic reactions have been widely used for measuring chemical variables for electroactive species. However, not all electroactive species can be measured by electrochemical methods because

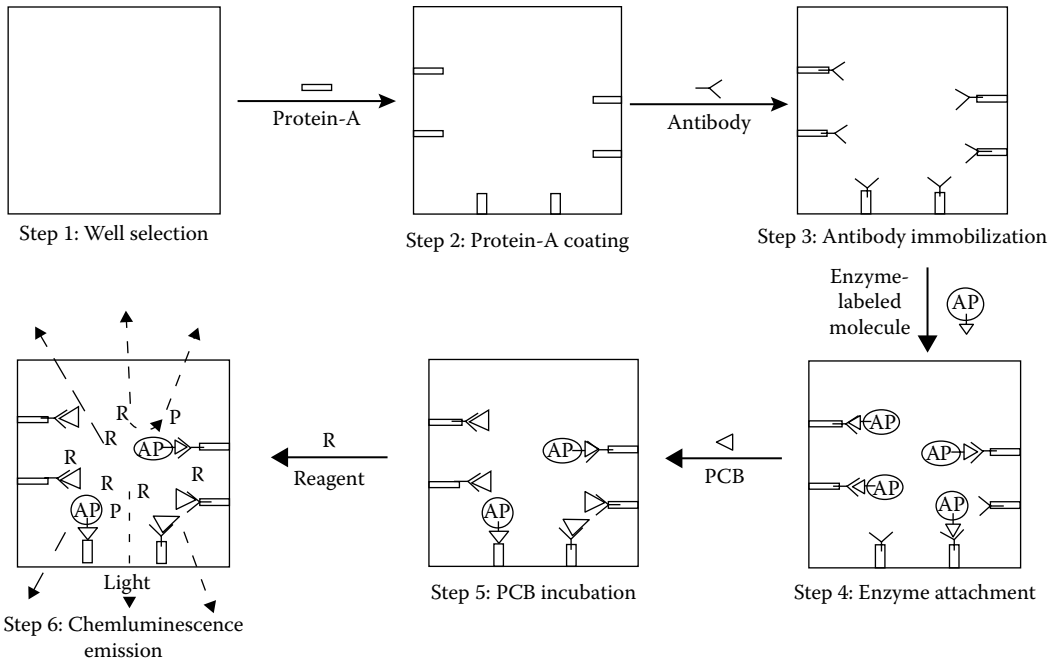

FIGURE 57.2 Pictorial presentation of chemiluminescence immunoassay.

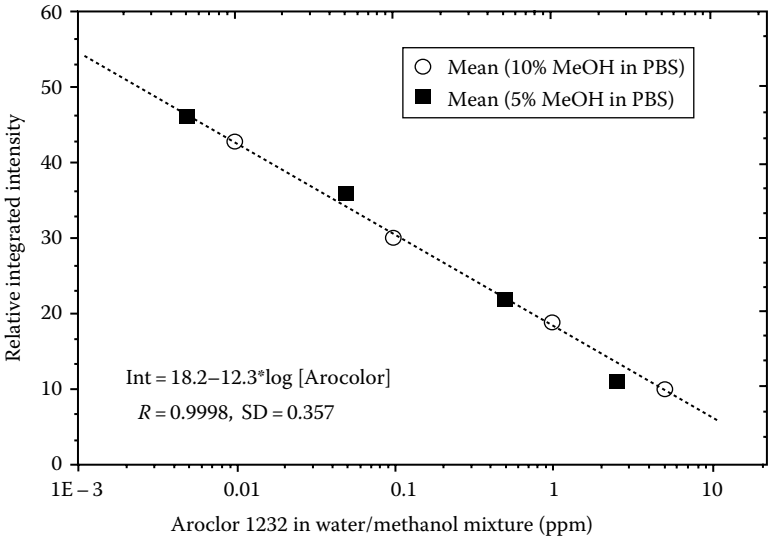

FIGURE 57.3 Dependence of chemiluminescence relative intensity on PCB Aroclor concentration. Plotted are chemiluminescence signals integrated during the first minute of enzymatic reaction (adamantyl dioxetane decomposition catalyzed by alkaline phosphatase in pH 10 buffer.) Samples contain various amount of Aroclor 1232 in pH 7 PBS buffer solution containing 5% (open circles) or 10% (solid squares) methanol.

for some species, the electrode reaction kinetics may be very slow. A simple example is the reduction of molecular oxygen (O_2) at bare Pt electrodes in an aqueous solution. Oxygen cannot be reduced at the thermodynamic potential of the electrode. In this case, one can apply a large overpotential to drive the O_2 reduction. Unfortunately, in many cases, a large overpotential cannot be used because of the limited available potential window or because of the interference from other electroactive species.

Thus, to overcome this problem, electrochemists have chemically modified electrode surfaces in order to accelerate electron transfer rates at the electrode–solution interface [23].

Chemical modification is produced by coating a monolayer of atoms, molecules, or thin layers of polymers onto the electrode surface. These surface-attached molecules may or may not be electrochemically active, but they can accelerate electrode kinetics for the target analyte. When the surface species is electrochemically active, it is termed a mediator; when inactive, it is called a promoter. For example, cytochrome c, like many other large macromolecules, has a large electron transfer rate in a homogenous solution phase, but it exhibits extremely slow electron transfer kinetics at many metal electrode surfaces. Eddowes and Hill, as well as Gui and Kuwana [24], have successfully demonstrated that by adsorbing a monolayer of heteroaromatic molecules such as 4, 4′-bipyridyl and *trans*-1,2-bis (4-pyridine) ethylene onto Au or Pt electrode surfaces, electron transfer kinetics of cytochrome c is significantly promoted. Recently, Dong, Cotton, and coworkers [25] have used a halide-modified Au electrode to study cytochrome c electrode kinetics. They adsorb different halides onto the Au electrode and find that they all can accelerate the electron transfer rate for cytochrome c and the promoting effort is of the order of $F^- < Cl^- < Br^- < I^-$. Various theories for the aforementioned phenomenon have been proposed. One possible explanation is that cytochrome c and related electron transfer molecules can adsorb onto bare electrode surfaces in undesired orientations. Besides the aforementioned atomic and molecular modified electrodes, lipid-modified electrodes [26] have also shown some promoting effect for cytochrome c electron transfer. Direct immobilization of cytochrome oxidase in a lipid bilayer at an Au electrode has resulted in electrochemical reactivity of cytochrome c in solution [27].

Electrochemical methods can also be applied to analyze electrochemically inactive species. The electrochemical immunoassay is a typical example. It combines the great selectivity provided by specific antibody–antigen recognition, the sensitivity provided by catalytic amplification, and the simplicity of electrochemical detection. It has proven to be a useful technique for measuring chemical variables for biological, clinical, and environmental samples. There are many forms of electrochemical assays: homogeneous versus heterogeneous, competitive versus noncompetitive, enzymatic versus nonenzymatic, and simple versus sandwich. Details can be found in Refs. [21,28,29].

The great advantage of the electrochemical immunoassay compared with enzyme-modified electrode methods is that it is a universal method and can be configured to analyze wide range of analytes, regardless of their electrochemical reactivity. For example, Heineman and coworkers have used this technique to detect dioxin, with a detection limit of one attomole using alkaline phosphatase as enzyme to convert 4-aminophenyl phosphate to the electroactive species 4-aminophenol [28]. They also used multiple metal labels rather than enzyme labels for simultaneous detection of multiple analytes [29].

57.5 Noncatalytic Reactions

As stated earlier, most kinetic-based analytical methods are catalytic systems. Noncatalytic systems have more limited applications because equilibrium methods are usually adequate in providing the necessary accuracy and sensitivity, and the noncatalytic kinetic methods do not provide any advantages of sensitivity. However, kinetic methods have been found to be more valuable or even the only choice in some special cases, as illustrated by the following examples:

1. When a sample contains hard-to-separate interference species that demand laborious and time-consuming separation before final measurement with a classic equilibrium method. A kinetic method may provide a simpler and faster determination by not requiring a prior separation.
2. When the equilibrium method is based on a very slow reaction or a reaction cannot proceed to completion due to side reactions. In this case, an initial rate measurement is much preferred and may be the only method of analysis.
3. When the species of interest has an extremely short lifetime, such as in the case of a reaction intermediate.

TABLE 57.3 Companies Providing Kinetic Instrumentation or Kinetic Assay Materials

Instrument	Company
ELISA apparatus	Dynatech Laboratories 14340 Sullyfield Circle Chantilly, VA 22021
Immunoenzymatic assays	Becton Dickinson Microbiology Systems P.O. Box 243 Cockeysville, MD 21030
Enzyme assay kits, ELISA kits	Pierce Chemical Co. 3747 N Meridian Rd. P.O. Box 117 Rockford, IL 61105
Electroanalytic instruments	EG&G Princeton Applied Research P.O. Box 2565 Princeton, NJ 08543
Stopped-flow apparatus	Dionex Corp. 1228 Titian Way Sunnyvale, CA 44088
Spectrometer with stopped-flow attachment	On-Line Instruments, Inc. 130 Conway Drive Bogart, GA 30622
Time-resolved spectrometers	Perkin-Elmer Corp. 761 Main Ave. Norwalk, CT 06859

Note: As examples, one company is listed for each category. For more complete listings, the reader is referred to the latest buyer's guide of *Analytic Chemistry*.

Table 57.3 lists some vendors of appropriate apparatus and assay kits for performing kinetic determinations.

Defining Terms

Antibody: One of a class of immunoglobulins produced by an animal's immune response to antigens (i.e., substances foreign to the body). Antibodies bind to molecular determinants of the antigen with great specificity.

Catalyst: A substance that accelerates a chemical reaction but is not itself consumed by the reaction.

Enzyme: A protein molecule that catalyzes reactions with great specificity.

Substrate: That which is being transformed by an enzyme-mediated reaction.

58.1 Introduction

During the early development of modern analytical chemistry, the study of natural materials was a primary concern of organic chemists and biologists. A major problem facing these scientists was the formulation of methods to separate and analyze the complex mixtures encountered in biological research.

Chromatography (literally "color writing") is a physical or physicochemical technique for separation of mixtures into their components on the basis of their molecular distribution between two immiscible phases. One phase is stationary and is in a finely divided state to provide a large surface area relative to volume. The second phase is mobile and is caused to move in a fixed direction relative to the stationary phase. The mixture is transported in the mobile phase, but interaction with the stationary phase causes the components to move at different rates.

Origination of the technique, early in the twentieth century, is generally attributed to Tswett, who separated plant chlorophylls by allowing solutions in petroleum ether to percolate through a vertical glass tube or column, packed with calcium carbonate. The separated components formed colored bands

that were later isolated. Chromatography was adapted for qualitative or quantitative analysis of mixtures by inclusion of a suitable detector at the downstream end of the column and allowing the separated components to pass completely (elute) through the column and detector.

To analyze a sample, a suitable volume is injected into the stream of mobile phase or onto the upstream end of the column and the output of the detector is continuously monitored. The composition of the stream (eluent) passing through the detector then alternates between the pure mobile phase and mixtures with each of the components of the sample. The output record of the detector (chromatogram), plotted as a graph of response versus time, shows a series of deflections or peaks, spaced in time and each related to a component of the mixture. For a given column, mobile phase, and set of operating conditions, the time for a component to pass through the column (retention time) is characteristic and can be used to identify the component. The peak area is proportional to the concentration of the component in the mobile phase.

In modern instrumental applications of chromatography, the stationary phase is either a solid or a liquid, and the mobile phase either a liquid or a gas. The various types of chromatography are classified according to the particular mobile and stationary phases employed. The solid stationary phase may be a granular solid packed in a tube (column) or coated as a thin layer on a suitable supporting plate (thin-layer chromatography, TLC). Liquid stationary phases may be coated onto granular solids or bonded as a thin film to the inner wall of a capillary tube. In gas chromatography (GC), the mobile phase is a gas (carrier gas), and the stationary phase is either a high-boiling liquid (gas–liquid chromatography, GLC) or a solid (gas–solid chromatography, GSC). In liquid chromatography (LC), the mobile phase is a liquid and the stationary phase is either a solid (liquid–solid chromatography) or a second liquid, immiscible with the mobile phase, coated on a granular solid (liquid–LC).

58.2 Principles

Chromatographic theory is given in general textbooks [1,2] and also in specialized texts on different types of chromatography [3,4]. Chromatographic separation involves continuous interchange of solute molecules between the mobile and stationary phases. Four principal processes are involved: adsorption, liquid–liquid partition, ion exchange, and size exclusion. In GC, the predominant processes are adsorption, while LC may involve all four processes. Where liquid–liquid partition is the predominant separation mechanism, the sample components are eluted in order of increasing boiling points.

Since the analyte is transported in the mobile phase, chromatography is limited to solutes that are distributed between the two phases. In practice, this means that GC is limited to substances that are thermally stable in the vapor phase and are volatile at temperatures up to the maximum operating temperature of the GC column (about 350 °C–400 °C for most columns and packings, although some metal columns can be operated at higher temperatures). LC can be used for analysis of thermally labile and high molecular weight materials such as polymeric materials and proteins, at temperatures below their boiling point and that of the eluent.

The separating power of a chromatographic column is described by analogy with distillation–separation processes. It is given as the number of theoretical separation plate (either per meter of column length or in total for the column) and depends on its length, internal diameter, and the stationary phase employed. The height equivalent to a theoretical plate (HETP) value may also be quoted. Separating power is enhanced by use of long, narrow-bore columns with packings of the finest possible mesh size to allow intimate contact between the mobile and stationary phases, but these columns require higher operating pressures to overcome the column resistance, and analysis times increase with column length.

The chromatographic separation process is highly dependent on the temperature of the column, and temperature effects can be related to the temperature dependence of the distribution or adsorption equilibria of the solute between the stationary and mobile phases. However, in practice, the choice of column operating temperature involves a compromise between resolution and speed of analysis. LC is commonly carried out with the column at ambient temperature, although applications requiring

operation at temperatures up to 100 °C are becoming more common. In GC, the column temperature has a major influence on the speed of elution and the separation of sample components. GC can be carried out at a single controlled temperature (isothermal) or the oven temperature can be increased during the analysis in one or more linear ramps (temperature programming). Temperature programming speeds the elution of later components relative to early ones and enables mixtures containing a range of components to be separated more quickly than would be possible with isothermal operation. The broadening of later peaks due to diffusion in passing through the column is also minimized by temperature programming.

58.3 Gas Chromatography

A block diagram of a gas chromatograph is shown in Figure 58.1. The essential components are the column or columns; the carrier gas supply and flow and pressure controllers to enable carrier gas to be delivered to the column at a constant, controlled, and known rate; and the detector or detectors and associated electronics and data recording and processing system. An injector or facility for introducing suitable volumes of sample must be provided at the upstream end of the column. The column must be contained in an environment whose temperature can be held at a constant known value or heated or cooled at known rates. Temperature control in the range 25 °C–400 °C (–0.1 °C) and heating and cooling rates of 0.1 °C–40 °C min^{-1} are typically required. Subambient operation at temperatures down to about –30 °C may be required for separation of some volatile materials or for certain specialized eluents such as liquid carbon dioxide. Both injectors and detectors must be temperature controlled to allow rapid volatilization of the sample in the injector and to prevent condensation in the detector.

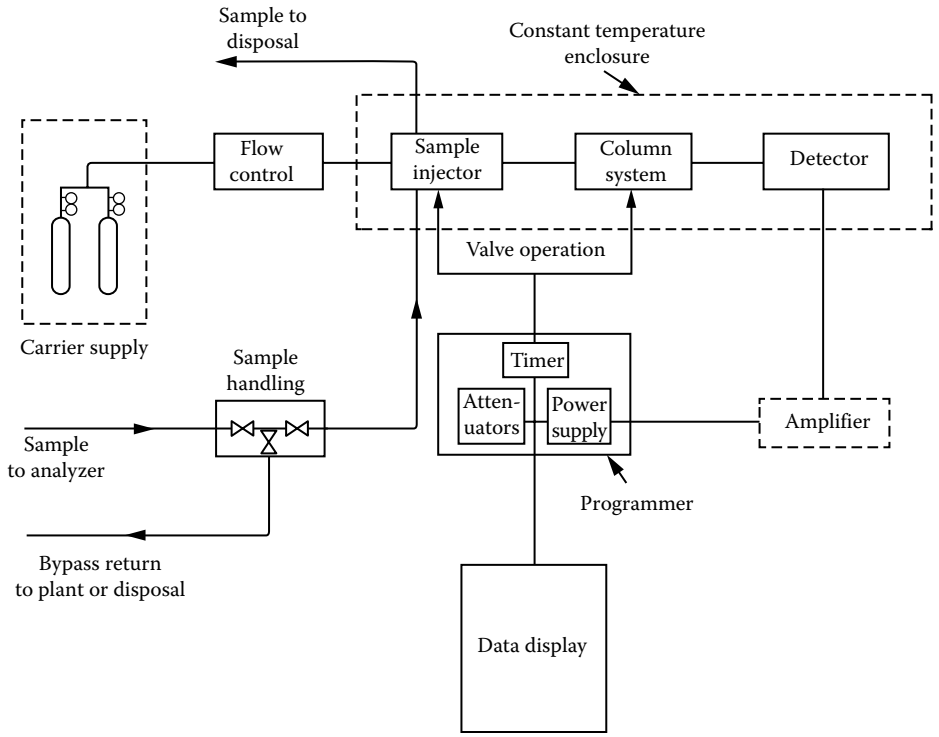

FIGURE 58.1 Functional diagram of process GC. The system consists of gas flow control, sample injection, separation of the components through the column, and a detector. Carrier gas at high pressure is used to move the sample through the column.

58.3.1 Columns

In GC, the processes involved in separation are predominantly adsorption and liquid–liquid partition when the eluent is liquid CO_2. Separation is almost entirely dependent on the nature of the stationary phase, with the gas phase acting mainly as an inert carrier. Separations of permanent gases are carried out by GSC using adsorbents such as silica gel, alumina, or synthetic zeolites (molecular sieves, particularly MS 5A and MS 13X) as the stationary phase. Proprietary porous polymers, such as Porapak (styrene–divinylbenzene copolymer), Chromosorb, and Tenax (polymer of 2,6-diphenyl-*p*-phenylene oxide), and various "carbon molecular sieves" are also used, and some of these materials are also used in separation of liquid samples.

In GLC, the stationary phase is a high-boiling liquid, coated to a few percent by weight on an inert granular support such as silica, firebrick, diatomaceous earth, or Teflon. A wide range of liquids, gums, and waxes have been employed that provide stationary phases that are usable over different temperature ranges and with different polarities. Examples include silicone oils and gums, hydrocarbons, polyphenyl ethers, and high molecular weight polymeric alcohols.

Originally, in both GLC and GSC, the stationary phase or coated support was packed into a column, typically a glass or stainless steel tube, 1–3 m long, and coiled to fit the chromatograph oven. Developments in column technology have led to the gradual, but not yet complete, replacement of the packed GC columns by capillary columns. These columns are usually formed from drawn silica tubing, typically 10–100 m long, 0.2–0.5 mm o.d., with an outer protective coating of polyimide or, for operation above about 350 °C, aluminum. The stationary phase is often silicone oil—for example, polydimethylsiloxane, which instead of being coated on a granular support, is present as a film, 0.1–5 μm thick, chemically bonded to the inner wall of the column (wall-coated, open-tubular or WCOT column). Such open-tubular columns operate at lower carrier gas pressures (typically 34–69 kPa [5–10 psig] instead of 138–340 kPa [20–50 psig] and carrier gas flow rates [1 mL min^{-1} or less instead of 20–30 mL min^{-1}]) than packed columns. Capillary GC columns can typically have 3,000 theoretical plates per meter (50,000 plates per column), compared with 1,000 plates per meter or 2,000 plates per column for a typical packed column. The capacity of the column (i.e., the size of sample that can be separated) depends on the thickness of the film of stationary phase but is of course smaller than for a packed column and is typically in the microgram to nanogram range. Columns with thicker films have higher capacity, but lower resolving power, than thin film columns. Chemical bonding reduces the loss of stationary phase (column bleed), especially during temperature programming, and bonded columns are almost essential for critical applications such as coupled gas chromatography–mass spectrometry (GC–MS). Although low-or medium-polarity general-purpose capillary columns have high performance and can be used with a variety of samples, customized columns are available with stationary phases developed and optimized for particular analyses.

As an alternative to coating the inner wall of the capillary column with liquid stationary phase, the column wall can be coated with finely divided support, which is itself coated with stationary phase (support-coated open-tubular or SCOT column). SCOT columns are one category of the more general group of porous-layer, open-tubular (PLOT) capillary columns where the inner wall of the capillary is coated or bonded with the stationary phase. PLOT columns are available with a range of solid adsorbents, including Porapak, molecular sieve, carbon molecular sieve, and alumina suitable for separation of mixtures of permanent gases and gaseous hydrocarbons, and bring the separating power of capillary columns to GSC. However, the difficulty of reproducibly injecting gas samples into these columns has meant that packed columns are often still favored for separation of gaseous samples.

58.3.2 Carrier Gas

The theory of the influence of carrier gas on the separation process was given by van Deemter, Zuidweg, and Klinkenberg [5]. The van Deemter equation combines rate theory and plate theory

and gives the relation between carrier gas velocity, u, and HETP, H, for a given carrier gas and column. The equation has the form

$$H = A + \frac{B}{u} + Cu \tag{58.1}$$

where A, B, and C are constants. A depends on the particle diameter and irregularity of column packing, B depends on the tortuosity of the channels and the first power of the diffusion coefficient of solute molecules in the gas phase, and C depends on the distribution coefficient of the solute, on the ratio of stationary-phase and gas-phase volumes, on the effective film thickness, and inversely on the diffusion coefficient of the solute in the gas phase.

Plots of H versus u show a minimum value for H corresponding to an optimum carrier gas flow rate, where

$$u_{\text{opt}} = \left(\frac{B}{C}\right)^{1/2} \tag{58.2}$$

The van Deemter equation shows that for a given column, a carrier gas of higher molecular weight can give a more efficient separation (lower value of H_{min}) than one of lower molecular weight, and H_{min} occurs at higher gas velocities for carrier gases of lower molecular weight. However, the equation refers to a single solute, and since chromatography involves separation of several solutes, the optimum carrier gas velocity is necessarily a compromise. The van Deemter equation also shows that for low molecular weight carrier gases, particularly hydrogen and helium, the minimum is less pronounced; that is, that carrier gas flow is less critical to column performance, and these two gases are the preferred choice, especially for capillary chromatography. Where hydrogen or helium is not suitable for the detector in use, a separate "makeup" gas supply is provided at the downstream end of the column; for example, nitrogen makeup is necessary for capillary operation of an electron capture detector (ECD).

The H versus u curve is not symmetrical, carrier gas flow rates being more critical at values below u_{opt} than above. Thus, analyses may be speeded by increasing carrier gas flow rates above the optimum without much deterioration in column performance, but operating at flow rates that are too low leads to a relatively rapid loss of separating power.

58.3.3 Detectors

Detectors for GC should ideally have high sensitivity, rapid and reproducible response, and a wide range of linear response to concentration. Early detectors had universal or near universal response to all solute molecules; more recently, the emphasis has been on the development of detectors with some selectivity to particular groups of compounds.

58.3.3.1 Thermal Conductivity Detector

The thermal conductivity detector (TCD) or katharometer was one of the earliest GC detectors and utilizes the change in thermal conductivity of a gas mixture with composition. The detector consists of either two or four electrically heated filaments or, for highest sensitivity especially at low temperatures, thermistors. The filaments or thermistors are connected in a Wheatstone bridge circuit, with external resistors to complete the bridge if there are only two sensing elements. The filaments or thermistors are mounted in a metal block to provide thermal stability, and provided with channels to allow the effluent from the GC column, and a separate, controlled "reference" flow of pure carrier gas to pass over the sensors or pairs of sensors. The loss of heat from the filaments depends on the filament temperature and on the conductivity of the surrounding gas. The katharometer can be operated under constant current or

constant voltage conditions, or feedback circuitry can be used to maintain the filament resistance constant, but in each case, changes in gas composition lead to an out-of-balance voltage in the Wheatstone bridge circuit.

The TCD is a universal detector; however, it is less sensitive than other detectors such as the FID and is principally used for detection and measurement of permanent gases such as oxygen, argon, nitrogen, carbon monoxide, and carbon dioxide, which either cannot be measured by the FID or require special pretreatment of the effluent gas (see succeeding text). It can be shown that the sensitivity is greatest when the filaments are operated at the maximum possible current and when the difference in conductivity between the carrier gas and sample components is greatest. Both these conditions are fulfilled by use of helium or, better, hydrogen as the carrier gas, as these two gases have higher thermal conductivities than other common gases.

58.3.3.2 Flame Ionization Detector

The flame ionization detector (FID) is one of a group of gas detectors in which changes in the ionization current inside a chamber are measured. The ionization process occurs when a particle of high energy collides with a target particle that is thus ionized. The collision produces positive ions and secondary electrons that can be moved toward electrodes by application of an electric field, giving a measurable current, known as the ionization current, in the external circuit.

The FID utilizes the fact that while a hydrogen–oxygen flame contains relatively few ions, it does contain highly energetic atoms. When trace amounts of organic components are added to the flame, the number of ions increases and a measurable ionization current is produced. The effluent from the GC column is fed into a hydrogen–air flame. The flame jet serves as one electrode, and a second collector electrode is placed above the flame. A potential is applied between the electrodes. When sample molecules enter the flame, ionization occurs—yielding a current that can be amplified and recorded.

The main reaction in the flame is

$$>\mathrm{CH} + \frac{1}{2}\mathrm{O_2} \rightarrow -\mathrm{CHO} + \mathrm{e^-} \tag{58.3}$$

However, the FID also gives a small response to substances not containing hydrogen, such as CCl_4 and CS_2. It is probable that the reaction earlier is preceded by hydrogenation to form CH_4 or CH_3 in the reducing part of the flame. In addition to the ionization reactions, recombination also occurs, and the response of the FID is determined by the net overall ionization process.

The FID is a mass-sensitive detector; that is, the response is proportional to the amount of organic material entering the detector per unit time. For many substances, the response is effectively proportional to the number of carbon atoms present in the flame, and the detector sensitivity can be expressed as the mass of carbon per second required giving a detectable signal. A typical figure is 10^{-11} g C s^{-1}.

The FID responds to practically all organic molecules. It is robust; has high sensitivity, good stability, and a wide range of linear response; and is widely used.

The FID is insensitive to inorganic molecules and water. However, it can be used for measurement of carbon oxides (CO and CO_2) by mixing the effluent from the GC column with a controlled stream of hydrogen. The mixed gas is passed over a heated catalyst to convert the CO or CO_2 to methane (methanation), followed by FID measurement of the methane generated. This allows GC determination of these gases at lower concentrations than can be detected by the TCD.

58.3.3.3 Photoionization Detector

The photoionization detector (PID) has some similarities to the FID, and like the FID, it responds to a wide range of organic and also to some inorganic molecules. An interchangeable sealed lamp produces monochromatic radiation in the ultraviolet (UV) region. Molecules having ionization potentials less

than the energy of the radiation can be ionized on passing through the beam. In practice, molecules with ionization potentials just above the photon energy may also be ionized, due to a proportion being in excited vibrational states. The ions formed are driven to a collector electrode by an electric field, and the ion current is measured by an electrometer amplifier.

The flame in the FID is a high-energy ionization source and produces highly fragmented ions from the molecules detected. The UV lamp in the PID is of lower energy, leading to the predominant formation of molecular ions. The response of the PID is therefore determined mainly by the ionization potential of the molecule, rather than the number of carbon atoms it contains. In addition, the ionization energy in the PID can be selected by choice of the wavelength of the UV source, and the detector can be made selective in its response. Commonly available UV lamps for the PID have energies of 11.7, 10.2, and 9.5 eV. The ionization potentials of N_2, He, CH_3CN, CO, and CO_2 are above the energy of all the lamps, and the PID does not respond to these gases. The 10.2 eV lamp is particularly useful as it allows ionization, and thus detection of alkynes and alkenes (except ethene), but not alkanes.

The PID is highly sensitive, typically to picogram levels or about one order of magnitude more sensitive than an FID, and has a wide linear range. Any of the commonly used carrier gases is suitable, although some gases (e.g., CO_2) absorb UV radiation and their presence may reduce the sensitivity of the detector. The main disadvantage of the detector is the fragility of the UV lamp, the need for periodic cleaning of the UV window, and the difficulty in cleaning the window if the detector becomes heavily contaminated.

58.3.3.4 Electron Capture Detector

The ECD is an ionization chamber in which molecules of electronegative species are allowed to attach to or "capture" electrons that have been slowed to thermal velocities by collision with inert gas molecules. The detector consists of a cell containing an emitting radioactive source (usually ^{63}Ni) and purged with inert gas. Electrons emitted from the source are slowed to thermal velocities (thermalized) by collision with the gas molecules and are eventually collected by a suitable electrode, giving rise to a standing current in the cell. If molecules with greater electron affinity are introduced into the cell, some of the electrons are "captured," forming negative ions that are more massive with less mobile from free electrons, and the current in the cell is reduced. This effect is the basis of the ECD.

Originally, the ECD was operated under dc conditions, potentials up to 5 V being used, but under some conditions, space charge effects produced anomalous results. Modern detectors operate under constant current conditions and use a pulsed supply, typically 25–50 V. The pulse width and/or frequency are varied by feedback circuitry to maintain the ionization current in the cell at a constant level. This extends the linear range of the detector response and ensures optimum response for a range of molecules. The ECD must be used with a suitable inert gas, usually either an argon–methane mixture or nitrogen, either as the chromatograph carrier gas or (more usually) as an auxiliary gas supply.

The ECD is extremely sensitive to electronegative species, particularly halogenated molecules. It is widely used in the analysis of pesticides and some trace atmospheric components such as halocarbons, halogenated solvents, and nitrous oxide. The selectivity and extreme sensitivity is valuable, but the use of a radioactive source is a disadvantage. In certain cases, the detector response is highly sensitive to the cell temperature. The cell may be contaminated by "dirty" samples and cleaning can be difficult or impossible.

58.3.3.5 Flame Photometric Detector

In the flame photometric detector (FPD), the column effluent is passed through a fuel-rich hydrogen–air or hydrogen–oxygen flame, where the sample molecules are broken into simple molecular species and excited to higher electronic states. Under these conditions, most organic and other volatile compounds containing sulfur or phosphorus produce chemiluminescent species. The excited species return to their ground state, emitting characteristic molecular band spectra. The emission is monitored by a photomultiplier through a suitable filter, thus making the detector selective to either sulfur or phosphorus.

The FPD is most commonly used as a detector for sulfur-containing species. In this application, the response is due to the formation of excited S_2 molecules, S_2^*, and their subsequent chemiluminescent emission. The original sulfur-containing molecules are decomposed in the hot inner zone of the flame, and sulfur atoms are formed, which combine to form S_2^*, in the cooler outer zone. As the S_2^* revert to their ground state, they emit light in a series of bands in the range 300–450 nm, with the most intense bands at 384.0 and 394.1 nm. The 394 nm band is monitored.

The FPD is highly sensitive (typically 10^{-11} g S s^{-1} or 10^{-12} g P s^{-1}), selective, and relatively simple. However, the response is nonlinear, given by

$$I_S = I_0[S]^n \tag{58.4}$$

where

I_S is the observed emission intensity (photomultiplier tube output)
$[S]$ is the mass-flow rate of sulfur atoms
n is a constant (value of 1.5–2, depending on flame conditions)

Some systems incorporate circuitry to produce a linear output over 2 or 3 orders of magnitude concentration range.

58.3.3.6 Other Detectors

A number of other GC detectors are available but are less frequently used than those listed earlier. Examples include the nitrogen phosphorus detector, which is selectively sensitive to analytes containing those elements and is used in pesticide analysis, and the helium ionization detector, in which the ionization process is due to highly energetic metastable helium atoms. The helium ionization detector is the only GC detector that permits analysis of the permanent gases at ppb levels. However, it is difficult to use, as the response is highly susceptible to the presence of trace impurities in the helium carrier gas. Additionally, gas chromatographic separation can be combined with detector systems specifically developed to measure a particular analyte. For example, trace levels of carbon monoxide in air can be measured by passing the effluent of the GC column through a heated bed of mercuric oxide. Carbon monoxide reduces the mercuric oxide, liberating mercury vapor, which is detected with high sensitivity by UV atomic absorption spectrometry.

58.3.4 Sample Injection

The purpose of the injection system introduces defined and reproducible aliquots of sample into the chromatograph column. To minimize loss of resolution by diffusion, the sample must be injected as quickly as possible and as a sharply defined slug. For analysis of liquids using packed columns, the injector is usually a zone heated to a temperature to ensure rapid volatilization of the sample, swept by carrier gas and fitted with a silicone rubber septum cap. Liquid injections are made by microsyringe through the septum cap. The syringe can be manual or controlled by an autosampler. Gas injections can also be made by syringe, but this is unsatisfactory for quantitative work as the compressive effect of the column head pressure in the injector makes syringe injections of gas unreproducible, and valve injection is preferable.

The injection valve is a six-port changeover valve that allows a fixed volume of gas, defined by a length of tubing (the sample loop), to be connected in either one of two gas streams with only momentary interruption of either stream. The valve is connected in the carrier gas stream just upstream of the column. The sample loop is filled with sample gas and the valve is operated to connect the loop into the carrier gas stream.

Injection into capillary columns is more difficult than into packed columns due to their smaller sample capacity. An internal standard (i.e., a compound similar to the analyte but separated from it by the

chromatograph) is often added to the sample to enable correction to be made for random differences in injection volume. The most widely used injection technique is the so-called split–splitless injector. In the "split" mode, an aliquot of liquid sample is injected into a heated zone at the head of the column. The injector is swept by carrier gas at constant pressure. A valve allows a variable but known proportion of the carrier gas to flow to waste. Carrier gas flow rates through the column are typically 1–2 mL min^{-1} and the "split" flow is typically 30–50 mL min^{-1}. Thus, only a few percent of the aliquot of sample injected actually passes through the column. In the "splitless" mode, the valve controlling the waste stream of carrier gas is momentarily closed for a fixed time after injection, thus increasing the amount of sample transferred to the column for increased sensitivity.

Split/splitless injectors are relatively simple and can be used with conventional syringes. However, the injector must be carefully designed to obtain reproducible results, and there may be some discrimination (particularly loss of high-boiling components) in samples containing components with a wide range of boiling points. Techniques where the sample is injected directly onto the column, without splitting, can give less discrimination and better sensitivity and reproducibility but are more difficult to use. Examples include cold on-column or programmed temperature injectors. In this technique, a length of column at the head is cooled to trap the sample. The injector is subsequently flash-heated to a high temperature to release the sample.

Alternative injection techniques include headspace analysis, where the vapor in equilibrium with a volatile liquid is sampled, and purge-and-trap techniques, where volatile components are purged from a liquid sample by a stream of inert gas. The purged components are trapped in a cooled zone at the head of the GC column and subsequently released by rapid heating for chromatographic separation and determination.

58.4 Liquid Chromatography

In early applications of LC, the adsorbent was contained in a vertical column through which the liquid phase was passed under gravity. The performance of such systems is limited by the tortuosity of the passage of the liquid phase through the column and by the efficiency and speed of solute exchange between the mobile and stationary phases. Column performance is enhanced by use of microparticulate packings, but to achieve reasonably rapid separations in such systems, the mobile phase must be pumped through the column under pressure. The technique is known as high-performance (or sometimes high-pressure) liquid chromatography (HPLC).

58.4.1 High-Performance Liquid Chromatography

Figure 58.2 provides an illustration of process HPLC.

58.4.1.1 Columns

HPLC columns are formed from precision-bore stainless steel tubing, 30–3 cm long, with 25 and 12.5 cm being the most common lengths. Standard columns have bores in the range 3.0–4.6 mm. Narrow-bore (2 mm) or microbore (1 mm) columns give increased sensitivity and higher chromatographic performance, together with reduced consumption of mobile phase, but require higher operating pressures and specially designed detector systems. The columns are packed under controlled conditions with granular packing material of controlled size range, particle shape, and porosity. The "standard" particle diameter for packing materials is 5 μm, as it allows good column performance at moderate operating pressures, but columns packed with 10 or 3–4.5 μm particles can also be used.

A wide range of general-purpose and specialist packing materials have been developed for HPLC. The most widely used base material is silica, as it has high efficiency and physical rigidity and good solvent compatibility and can be bonded with organosilanes for reversed-phase chromatography (see succeeding text). Other base materials include ceramics such as alumina, polymers, and graphitic carbon.

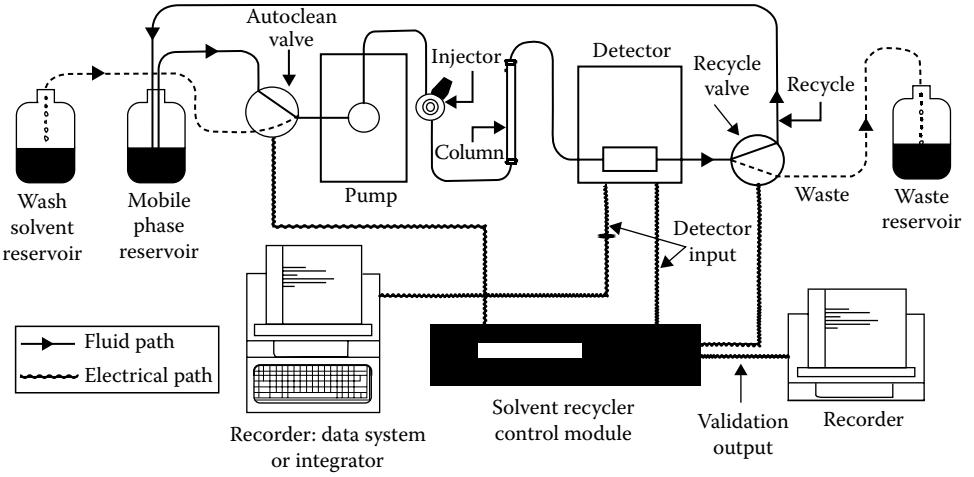

FIGURE 58.2 Functional diagram of process high-performance chromatography. The system consists of pump, sample injector, separation column, and detector. Mobile phase is liquid and wash solvent is used for cleanup. The used solvent can be recovered.

Alumina has better pH stability than silica, but cannot be bonded with organosilanes. Polymers have limited organic solvent compatibility but tolerate strong alkali; they are less robust than silica and cannot be used at high operating pressures.

In liquid–solid chromatography, the samples are retained by adsorption on the support surface. The support may be coated with a liquid phase (liquid–LC). In bonded-phase HPLC, the support (usually silica, although alumina has also been used) is derivatized with a functional group covalently attached to the surface. In both coated and bonded phases, the separation is predominantly by partition, but like their counterparts in GC, bonded phases are inherently more stable than coated phases and can be used with a range of solvent and buffer systems.

In "normal" or traditional LC, the stationary phase is polar and the mobile phase relatively nonpolar. The polar surface may be silica or may be modified by chemical bonding of a suitable functional group. In reversed-phase chromatography, the stationary phase is nonpolar and the mobile phase is relatively polar. Reversed-phase chromatography is almost always carried out on modified silica columns, with octadecylsilyl (ODS or C18) or C8 groups being most commonly used, and the development of these systems has been largely responsible for the present popularity of HPLC.

58.4.1.2 Mobile Phase

In contrast to GC, the mobile phase in HPLC plays a vital role in the separation process, with the rate and order of elution being determined by the relative polarities of the mobile and stationary phases and by the nature of the sample components. In normal-phase chromatography, the eluting power of the mobile phase increases with polarity, while in reversed-phase chromatography, the reverse situation applies, and eluting power decreases with increasing solvent polarity. Most of the common solvents can be used as mobile phase, but *n*-hexane is a common nonpolar solvent, while polar solvents in reversed-phase chromatography are often mixtures of water and methanol or acetonitrile. When a single solvent or mixture of fixed composition is used throughout a separation, the process is referred to as isocratic. In gradient elution procedures, the composition of the solvent is changed continuously during the separation process. The change in solvent composition can be either linear with time or according to a predetermined profile. Gradient elution has some similarities in its effects to temperature programming in GC.

In HPLC, the mobile phase is pumped through the column. Flow rates for mobile phase are 0.5–10 mL min^{-1} for conventional columns and 50 μL–5 mL min^{-1} for narrow-bore columns at

pressures up to 48,263 kPa (7000 psi). The flow rate must be precisely controlled and the outlet stream must be pulse-free. Metered mixing of up to four solvent streams may be required for gradient elution and column washing. HPLC pumps must be capable of delivering a pulse-free stream of mobile phase, at pressures up to 48,263 kPa (7000 psi). Variations in mobile-phase flow rate lead to irreproducibility in chromatographic retention times, and pulses in the flow give noise in the detector baseline.

To ensure optimum pump performance and to remove dissolved oxygen, the mobile phase must be degassed. Degassing can be by vacuum, but periodic purging with helium is more usual. Dissolved oxygen causes noise and drift in UV detectors, quenching in fluorescence detectors, and high background currents and noise in electrochemical detectors.

58.4.1.3 Detectors

Performance requirements for HPLC detectors are similar to those in GC, and the detector system should be sensitive, have a rapid and reproducible response, and have a wide linear range of response. The following types are most commonly used:

1. *Refractive index*: Detectors based on measurement of the refractive index of the mobile phase are applicable to a wide range of solutes. However, they are temperature sensitive, are generally less sensitive than UV or fluorescence detectors, and cannot easily be used with gradient elution systems.
2. *UV–VIS*: UV or visible detection is the most common detection technique. Photometers or spectrophotometers measure the absorption of UV or visible radiation in the range 190–700 nm by the solute molecules. Detectors can be either fixed or variable wavelength. Fixed-wavelength detection at 254 nm is suitable for many solutes. The response is linear according to the Beer–Lambert law and detection limits are subnanogram in favorable cases. "HPLC grade" solvents that have been specially purified to remove UV-absorbing impurities may be required.
3. *Diode array*: The diode array, or photodiode array (PDA), detector allows the UV or UV–VIS spectrum of the mobile phase to be repeatedly scanned during the elution. The resulting spectra are stored by the data system and are useful for checking or monitoring peak purity during elution and may provide some information on the identity of the analyte. Diode array detectors are typically two or three times less sensitive than conventional, single-wavelength UV or visible detectors.
4. *Fluorescence*: Detection of suitable molecules by fluorescence is typically one or two orders of magnitude more sensitive than UV–VIS detection, allowing detection down to low picogram levels in favorable cases. The fluorescence cell volume can be made as small as 5 μL, making fluorescence detection suitable for use with narrow-bore columns.
5. *Electrochemical*: Electroactive (oxidizable or reducible) substances can be detected by electrochemical techniques. The flow-cell volume may be as low as 1 μL, making the detectors suitable for narrow-bore columns. By choice of working conditions, the detector can be made specific to particular compounds or groups of compounds. Examples of suitable compounds for electrochemical detection include aromatic amines, phenols, and chlorinated phenols.

58.4.1.4 Injectors

The injection process is critical in obtaining good performance in HPLC. Injection may be made directly by syringe, but for optimum results, valve injection is essential and is now almost universal. The injection valve is a six-port changeover valve, which allows a defined volume of liquid sample, contained in a sample loop, to be injected into the mobile phase. The sample loop typically has a volume in the range of 10–100 μL for conventional HPLC columns and is loaded by a syringe.

58.4.2 Ion Chromatography

Ion chromatography (IC) is a variant of HPLC in which inorganic and some organic cations and anions are separated on columns packed with high-efficiency pellicular ion-exchange resins. Anion separator

columns are resin based with positively charged fixed ionic sites, usually quaternary amines. The eluent is commonly dilute aqueous sodium hydroxide or sodium carbonate/sodium bicarbonate mixture. Cation separator columns have negatively charged fixed ionic sites, usually sulfonic acid groups, with methane sulfonic acid as eluent. Although conductimetric, amperometric (polarographic), UV–VIS photometric, and fluorescence detectors can all be used in IC, conductimetric detection is the most commonly used technique. When conductimetric detection is used, the sensitivity of the measurement is increased by reduction of the conductivity of the mobile phase (suppression) before detection. The conductivity is suppressed by conversion of the eluent to the corresponding acid or base form in a suppressor column, or membrane suppressor, downstream of the separation column. Thus, for anion analysis, the suppressor is a cation exchanger that replaces sodium ions in the eluent with hydrogen ions. IC allows detection and measurement of anions and cations in solution, typically down to ppb ($\mu g\ L^{-1}$) levels. The common inorganic anions can be determined in a single sample aliquot. The technique is particularly useful for routine analysis of water and environmental samples.

58.4.3 Gel Permeation and Size-Exclusion Chromatography

Gel permeation chromatography (GPC) and size-exclusion chromatography (SEC) separate sample molecules on the basis of their effective molecular size in solution in aqueous or nonaqueous media. Column packings are porous materials with pores in controlled size ranges and can be either resin (e.g., styrene–divinylbenzene copolymers) or silica based. The solute molecules interact with the column packing. Small molecules are "trapped" in the pores and pass through the column more slowly than larger molecules that do not interact so strongly. GPC was developed for polymer chemistry and is useful for the determination of the molecular weight distribution of polymers, but the techniques are also finding other applications, for example, size separation of small organics and petrochemicals and in sequential analysis and sample cleanup of environmental samples.

58.5 Hyphenated Techniques

Chromatographic methods give powerful techniques for separation of mixtures. However, the commonly used detectors give little information about the identity of the separated components, and identification from retention times may be incomplete or ambiguous. The so-called hyphenated techniques, in which chromatographic separation is combined with another, usually spectrometric, technique, have been developed to combine chromatographic separating power with spectrometric identification.

58.5.1 Gas Chromatography–Mass Spectrometry

Developments in column, mass spectrometer, and computer technology have made GC–MS the most widely used of the hyphenated techniques. Modern systems commonly incorporate the following features:

1. Capillary column gas chromatograph, with the column effluent fed directly to the ion source of the mass spectrometer through a heated transfer line.
2. Miniaturized quadrupole or quadrupole-type mass spectrometer, optimized for use as a GC detector and limited to this application. The mass spectrometer may have a limited mass range (maximum mass 650 or 700), corresponding to the maximum molecular weight of compounds that can commonly be analyzed by GC.
3. Control of the mass spectrometer and gas chromatograph, data recording, and mass spectral library searching by dedicated computer.

Such so-called "benchtop" GC–MS systems typically have sensitivities in the nanogram to picogram range and unit mass spectral resolution. They give a valuable means of identification and quantitative

determination of a variety of analytes, particularly in complex matrices such as biological or environmental samples. However, for applications requiring the highest sensitivity or mass spectrometric resolution, gas chromatographs coupled to high-resolution magnetic sector mass spectrometers must still be used. If it is necessary to use a packed chromatograph column, the carrier gas flow rate is likely to be too high for direct coupling to the mass spectrometer, and an interface, which allows selective removal of carrier gas, will be required.

58.5.2 Gas Chromatography–Infrared Spectrometry

Coupling a gas chromatograph with an infrared (GC–IR) spectrometer is an alternative to GC–MS. The effluent from the GC column is fed to a miniaturized flow-through absorption cell (light pipe) where the IR spectra are measured. Fourier transform infrared (FTIR) spectrometry is used to achieve the combination of high spectral scan rates and resolution required to measure spectra from peaks eluting from capillary columns. Computer control and data processing are used, together with computer matching with stored libraries of IR spectra. The IR spectra are vapor phase and differ in some respects from liquid- or solid-phase spectra. GC–IR is to some extent complementary to GC–MS in that some molecular properties, particularly those relating to overall structure or shape, which may be lost in the fragmentation process in the mass spectrometer, may be identified in the IR spectra. However, the technique is some three or more orders of magnitude less sensitive than GC–MS and has received less attention. GC–IR–MS can be used for particularly complex mixtures.

58.5.3 Liquid Chromatography–Mass Spectrometry

Coupling a mass spectrometer to a liquid chromatograph, in principle, offers the advantages of GC–MS to the greater range of materials that can be analyzed by liquid, compared to gas, chromatography. However, interfacing a liquid chromatograph to a mass spectrometer is more difficult than a gas chromatograph, and while GC–MS is a well-established technique, liquid chromatography–mass spectrometry (LC–MS) is only now becoming a useful routine method.

The principal difficulty in interfacing LC and MS lies in the very different physical conditions required for operation of the two techniques. LC uses relatively large quantities of liquid mobile phase, which may include inorganic buffers, while the mass spectrometer operates under vacuum. An interface must be used to selectively remove mobile phase before sample can be introduced to the mass spectrometer. Direct liquid injection and moving belt interfaces have been used but are unreliable. Three main types of interface are currently in use:

1. *Thermospray*. The LC effluent is passed through a probe and heated to 350 °C–400 °C, in an evacuated region just outside the source of the mass spectrometer. The mobile phase, which often includes a volatile buffer such as ammonium ethanoate, is vaporized, and the sample molecules are ionized by a chemical ionization (CI) process. A series of lenses focuses a proportion of the ions into the mass spectrometer, while the solvent is pumped away. Under these conditions, the ionization is soft, that is, there is little fragmentation in the mass spectrometer and the principal peak in the mass spectra is the molecular ion, M^+, MH^+, or MNH_4^+. This can be useful for molecular weight determination, but fragmentation may be increased and, in some cases, sensitivity enhanced, by including a filament in the ion source to give electron impact (EI) mass spectra. The thermospray interface is suitable for ionic and nonvolatile compounds. However, it requires the use of volatile buffers and the spectra are dependent on the solvent matrix.
2. *Particle beam interface*. The particle beam interface utilizes the principle of momentum to separate the solvent from the heavier solute molecules. The column effluent, mixed with helium in some designs, is passed through a series of chambers under pressure, exiting through a nozzle. As the effluent emerges, the solvent is vented, while the solute molecules continue on their original

trajectory and pass into the ion source of the mass spectrometer. The interface allows the use of a standard ion source in either El or CI modes. It can therefore be used to produce standard library-searchable mass spectra and is the only commonly used interface where this facility is routinely available. The interface requires some sample volatility, and some compounds (such as complex sugars) do not give satisfactory spectra.

3. *Electrospray.* In the electrospray interface, the column effluent is mixed with a nebulizing gas and passed through a jet nebulizer into a high-voltage electric field. Drop formation and ionization, by a CI process, occur. The ions enter the mass spectrometer through a capillary tube charged to a different voltage from the remainder of the interface, while the solvent is pumped away. Electrospray interfaces have, thus far, mainly been used for very high molecular weight analytes, although systems for lower molecular weights are being developed. Atmospheric pressure chemical ionization (APCI) is somewhat similar to electrospray except that the ionization process takes place at atmospheric pressure. Both systems can be used for polar compounds, molecular weights up to 100,000 Da, and are highly sensitive. However, ionization and separation involve a complex series of mechanisms, and setup and operation of the system, and interpretation of the spectra produced, may be difficult.

58.6 Applications in the Electricity Industry

58.6.1 Dissolved Gas Analysis

GC analysis of gases dissolved in transformer oil has been used for condition monitoring since the early 1970s [6–8]. The large volumes of gas often generated during a transformer fault have been used to trip mechanical relay for some 60 years [9]. It was later realized that if gases are evolved from the oil in sufficient quantities to operate a Buchholz relay, then slowly developing faults would also produce decomposition gases that would be dissolved in the oil. They only appear in the Buchholz at the end of a complicated system of interchange between the gases contained in bubbles rising to the surface and the less soluble atmospheric gases dissolved in the oil. It should therefore be possible to detect any incipient faults that may be present in the transformer early by analysis of the gases dissolved in the oil, using a gas chromatograph. Thermal and electric faults in a transformer produce various characteristic gases that are, to some extent, soluble in the oil. Extraction and GC analysis of dissolved gases can be used for monitoring of transformer condition. Dissolved gas analysis (DGA) has been accepted as an important and vital condition monitoring technique for power transformers [10–12].

Oil samples can be collected from the equipment using syringes, bottles, or other sampling techniques, as described in IEC 567 [13]. The analysis requires extraction of the dissolved gases from the oil and then injection into a GC. The details of extraction of the gases from the oil are given in IEC 567. Generally, gases are extracted under vacuum using a mercury Toepler pump and the total volume of the extracted gas is measured by bringing to atmospheric pressure. The gases are then separated and determined by GC. An automated mercury-free instrument can also be used for extraction of dissolved gases [14] and other techniques have been used for extraction of the gases from the oil [15]. A static headspace sampling technique has been combined with capillary GC to allow dissolved gases and furan-related compounds to be determined in power transformer oils in a single GC run [16].

Regardless of the technique used for the extraction of the gases from the oil, GC is used for analysis of the gases. Alternative techniques such as MS, although very sensitive, have not been used for routine analysis. IR spectrometry has been used for the detection of gaseous hydrocarbons and carbon oxides [17]. The technique is rapid and accurate, and the detector is very stable. However, it cannot detect hydrogen and atmospheric gases. Hydrogen is a very important incipient gas for transformer condition monitoring. The ratio of oxygen to nitrogen dissolved in the oil is also used as an indication of oil or paper degradation in the transformer (the oxygen is used by reaction with the cellulose).

The gas chromatograph used for analysis of the gases is usually dual channel with FID and TCD detectors. A Porapak column is used for separation of hydrocarbons, and a methanizer is used for converting carbon oxides to methane followed by FID detector, while hydrogen, oxygen, and nitrogen are separated on a molecular sieve column and measured by TCD. Other arrangements such as column switching–backflushing should be used if a single detector is going to be used. In such cases, a TCD is usually used as a detector. IR detection of hydrocarbons followed by TCD is an alternative arrangement. A combination of Porapak and molecular sieve column is used for separation of hydrogen, oxygen, and nitrogen, followed by TCD detection. This arrangement requires a flash backflush system to prevent carbon dioxide from entering the molecular sieve column—where it would be so strongly adsorbed that it would require prolonged heating at a high temperature to remove it. The system is capable of detecting 1 ppm hydrocarbons and carbon oxides and 5 ppm hydrogen in the oil. Oxygen and nitrogen in the oil are usually present at high concentration, and therefore, their detection does not present any problem. High concentrations of acetylene gas in the oil may present some problems, such as poisoning the methanizer catalyst, and it may stay in the column for a long time. In such cases, a longer isothermal time and higher oven temperature for cleaning of the column is the recommended technique.

Water has been determined in transformer oils with accuracy better than 3%, precision better than 4% at the 10 ppm level, and detection limit of 0.3 ppm, by headspace sampling and capillary chromatography with TCD detection. The technique could be automated using the headspace GC system proposed for DGA [18].

58.6.2 Furfuraldehyde Analysis

Under normal operating conditions, the insulation system of transformers gradually deteriorates and produces various degradation by-products. Thermal degradation, or aging of the paper insulation, is one of the most important factors in limiting the lifetime of a transformer. Detection and analysis of the degradation by-products have been widely used to evaluate and monitor the degradation state of the insulation. The aging process of the paper is accompanied by the production of several by-products—mainly carbon monoxide, carbon dioxide, and furfurals. Carbon oxides can be monitored by DGA, but their production is not specific to paper degradation. The measurement of furfurals could provide an early indication of paper degradation, and their analysis by HPLC has been used as a tool for the monitoring of transformer performance [19–22]. A spectrophotometric method has also been used for analysis of furfuraldehyde [23]. The method is only capable of measuring furfuraldehyde and not other furanic compounds present in the oil.

The oil is dissolved in cyclohexane for HPLC analysis and passed through a solid-phase silica cartridge, where the furfurals, phenol, and *m*-cresol (which are products of degradation of phenol-formaldehyde resins in the transformer) are retained. The remaining oil in the cartridge is removed by washing with the solvent. The furfurals, phenol, and *m*-cresol are extracted from the cartridge with water/acetonitrile. The collected extracts are analyzed by HPLC. For separation of furfuraldehyde and other compounds, a C18 column is recommended. A UV detector at 276 nm is usually employed for detecting these compounds. The use of a UV PDA detector gives improved discrimination of products in what is often a complex chromatogram at the expense of some slight loss of sensitivity.

58.6.3 Analysis of Antioxidants in Oil

The presence of antioxidants is a key factor in controlling the oxidation of insulating oil. Their use results in substantial savings by prolonging the oil service life and slowing down the transformer aging process. A large number of antioxidant additives are used, and HPLC is a useful technique for quantitative determination of their concentrations in insulating oil [24,25]. TLC has also been used for quantitative determination of antioxidant in insulating oil [26].

HPLC is also used for evaluation of the quality of mineral insulating oil [27,28]. The presence of certain characteristic chemical compounds is of considerable importance in the electric industry. This technique is also used to identify the presence of some by-products of oil under electric stress, such as x-wax and fluorescence materials. Polar compounds, such as acids and aldehydes, are also products of oxidation of oil and they can also be determined by HPLC. Early detection of such products is important in transformer condition monitoring to provide prior warning of a developing fault and to enable appropriate corrective action to be taken.

HPLC is also used for health and safety monitoring of the polyaromatic hydrocarbon (PAH) content of transformer oils [29]. The toxic and carcinogenic nature of PAH compounds is well established.

58.6.4 Molecular Weight Distribution of Insulating Paper

GPC has been used to measure the change in molecular weight distribution of insulating paper during aging [30]. This technique has been used for measurement of the degree of polymerization of the paper but requires a sampling of the paper in the transformer, which is not generally practical. Measurement of paper degradation by analysis of products dissolved in the oil, such as furfuraldehyde analysis (FFA), although much easier, is indirect and therefore dependent on a knowledge of the history of the transformer and its components. GPC can provide direct information of the state of the paper and the average molecular weight of the cellulosic chains and currently is mostly used as a forensic analysis tool for the investigation of failures.

Two techniques are available for getting the paper into solution for analysis. Direct dissolution into dimethylacetamide/8% lithium chloride is possible for most forms of cellulose, followed by dilution to 1% lithium chloride for analysis. However, high levels of lignin (3%–4%) in the paper interfere with the dissolution process. The alternative is to derivatize the cellulose to the tricarbanilate in pyridine. The product can then be analyzed in solution in tetrahydrofuran, but there is evidence in the literature that the derivatization process itself degrades the paper.

58.6.5 Polychlorinated Biphenyls

Polychlorinated biphenyls (PCBs) are synthetic materials with dielectric and chemical properties that in the past made them attractive alternatives to petroleum-based products. However, they have since been identified as environmental pollutants and possible health hazards. PCBs are not used today, but their use in the past has led to widespread contamination of mineral oil with PCBs. Current legislation requires that oil in service shall have a PCB content of less than 50 ppm. Therefore, the PCB content of insulating oil in the transformer must be measured quantitatively and capillary GC is the technique currently used [31].

The sample is diluted in hexane and deoxygenated. A small volume of the resulting solution is injected into a narrow-bore capillary gas chromatographic column. The capillary column separates the PCBs into individual or small groups of overlapping congeners. Their presence in the effluent is measured by an ECD.

58.6.6 Feedwater and Boiler Water Analysis

IC is well suited to the analysis of highly pure water such as boiler feedwater and often gives better precision, sensitivity, and speed of analysis than established techniques. For example, IC has been used for the determination of carbonic acid in steam–condensate cycles [32].

Morpholine is added to the thermal cycle of some CANDU reactors and has been determined, together with its amine breakdown products, by reversed-phase HPLC on a C18 column with visible detection at 456 nm [33].

58.6.7 Other Applications

The size and scope of the electricity supply industry imply that it has a major effect on the environment. Chromatographic techniques are widely applied in environmental monitoring and research, and the electricity industry is both a major user of standard techniques and sponsor of research.

Defining Terms

Adsorption: The noncovalent attachment of one substance to the surface of another.

Analyte: The substance that is being analyzed.

Baseline resolution: Separation of components at the peak base (no overlap of any peak area).

Chromatography: The physicochemical technique for separation of mixtures into their components.

Column: A steel, glass, or plastic tube containing the stationary phase.

Detector: A device for monitoring the separated compounds from the chromatography by sensing chemical or physical properties of the sample.

Eluent: The moving solvent in a chromatographic column.

Elute: To travel through and emerge from the column.

Gel permeation chromatography (GPC): A mode of LC in which samples are separated according to molecular size.

HPLC: High-performance liquid chromatography.

IC: Ion chromatography.

Mobile phase: The following solvent.

Stationary phase: The material that is contained in the column and does not move during the chromatographic process.

pH Measurement

Norman F. Sheppard, Jr.
Gamera Bioscience Corporation

Anthony Guiseppi-Elie
Virginia Commonwealth University and Abtech Scientific, Inc.

The measurement of pH is arguably the most widely performed test in the chemical laboratory, reflecting the importance of water as a ubiquitous solvent and reactant. In the 90 years since the first use of an electrode to determine hydrogen ion concentration, the glass electrode and its variants have matured into routine tools of analytical and process chemists. Yet, there continue to be developments that promise to broaden the scope and reach of these measurements. Among recent developments are miniature pH-sensitive field-effect transistors (pHFETs) being incorporated into pocket-sized pH "pens," metal/metal oxide pH sensors for measurements at high temperatures and pressures, and flexible fiber-optic pH sensors for measuring pH within the body. This chapter discusses electrochemical and optical methods for pH measurement and is by necessity limited in scope; readers interested in a more comprehensive treatment may wish to refer to the recent text by Galster [1].

59.1 Definition of pH

In its most common interpretation, pH is used to specify the degree of acidity or basicity of an aqueous solution. Historically, pH was first defined as the negative logarithm of the hydrogen ion concentration (*Pondus hydrogenii*, literally hydrogen exponent), to simplify the handling of the very small concentrations (on the order of 10^{-7} mol L^{-1}) encountered most commonly in nature. This definition of pH is expressed as Equation 59.1, where $[H^+]$ is the molar concentration of solvated protons in units of moles per liter:

$$pH = -\log[H^+] \tag{59.1}$$

As a greater understanding of the behavior of ionic solutes in solution developed, chemists recognized that the measurement techniques used to determine hydrogen ion concentration were in fact

TABLE 59.1 pH of Common Substances

Substance	pH
Soft drinks	2.0–4.0
Lemon juice	2.3
Vinegar	2.4–3.4
Wine	2.8–3.8
Beer	4.0–5.0
Cow's milk	6.3–6.6
Pure water	7.0
Blood	7.3–7.5
Seawater	8.3

measuring the hydrogen ion activity, often referred to as the "effective concentration." This led to the adoption of the more rigorous definition of pH as the negative logarithm of the hydrogen ion activity in solution:

$$\mathrm{pH} = -\log a_{\mathrm{H}^+} = -\log \gamma[\mathrm{H}^+] \tag{59.2}$$

where

a_{H^+} is the hydrogen ion activity
γ is the activity coefficient

The two definitions expressed in Equations 59.1 and 59.2 are equivalent in dilute solution where concentration approximates activity, a_{H^+}. In practice, the routine measurement of pH is not accomplished by the direct determination of the hydrogen ion activity. Rather, pH is determined relative to one or more standard solutions of known pH.

The hydrogen ion activity of common substances ranges over many orders of magnitude, as evidenced from the tabulation presented in Table 59.1. Water, in the absence of other chemicals that might alter its equilibrium, contains 10^{-7} molar hydronium ions [H^+] and 10^{-7} molar hydroxonium ions [OH^-] at 25 °C. Under these idealized conditions, water has a pH of 7.0 and is said to be neutral:

$$2\mathrm{H_2O} \xleftrightarrow{K_W} \mathrm{H_3O^+} + \mathrm{OH^-} \quad K_W = [\mathrm{H_3O^+}][\mathrm{OH^-}] = 10^{-14} \tag{59.3}$$

The addition of acids or bases to pure water increases or decreases the hydrogen ion activity, respectively. The resulting pH depends on a number of factors, such as the concentration of the added acid or base and the strength as quantified by its dissociation constant [2].

59.2 Electrochemical Methods of pH Measurement

Electrochemical measurement of pH utilizes devices that transduce the chemical activity of the hydrogen ion into an electronic signal, such as an electrical potential difference or a change in electrical conductance. The following sections review electrochemical pH measurement, with emphasis on the glass membrane electrode. Also discussed is the operation of hydrogen ion-selective pHFETs, metal/metal oxide electrodes, and other approaches used in specialized applications. Table 59.2 provides a listing of sources, features, and key properties of selected, commercially available pH electrodes.

TABLE 59.2 Sources, Features, and Key Properties of Selected pH Electrodes

Manufacturer	Reference	Range	Accuracy pH Units	Cost ($US, 1997)	Key Features
Glass combination electrodes					
ABTECH Scientific, Inc.[a]	Ag/AgCl	0–14	±0.1	285	Handheld
Miniature Combination					Refillable bulb

59.2.1 Glass Membrane Indicator Electrode

The most widely used method for measuring pH is the glass membrane electrode. As illustrated schematically in Figure 59.1a, a pH meter measures the electrical potential difference (voltage) that develops between a glass membrane pH *indicator* electrode and a *reference* electrode immersed in the sample to be tested. The indicator and reference electrodes are commonly combined into a single, functionally equivalent, probe, referred to as a combination electrode. The glass membrane of the indicator electrode develops a pH-dependent potential, as a result of ion exchange between hydrogen ions in solution and univalent cations in the glass membrane. The sensitivity of the glass electrode

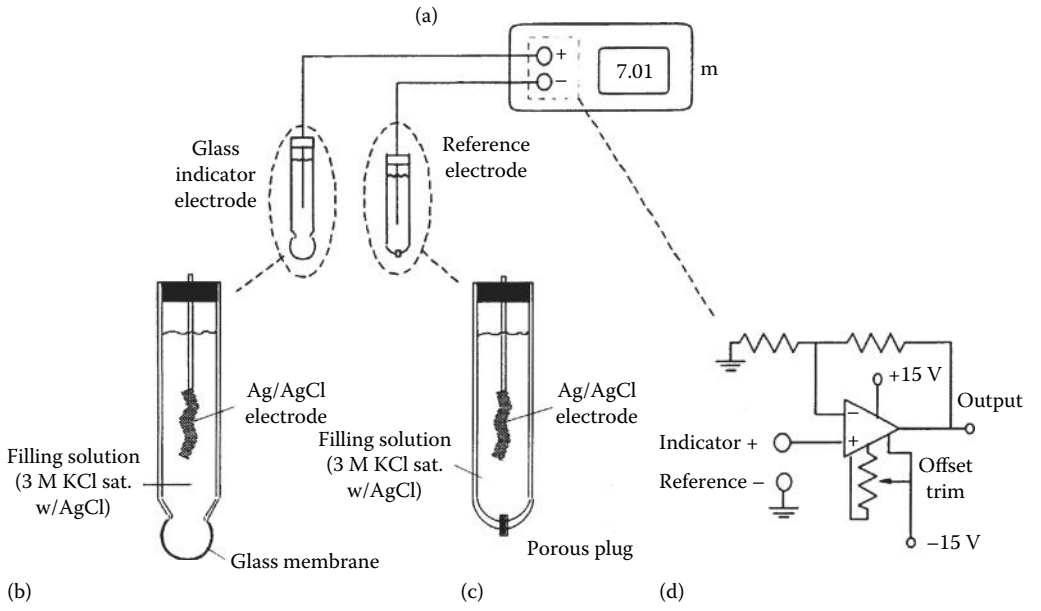

FIGURE 59.1 pH measurement using a glass membrane electrode: (a) measurement system comprising a pH meter, indicator, and reference electrodes; (b) indicator electrode construction; (c) reference electrode construction; and (d) amplifier circuit.

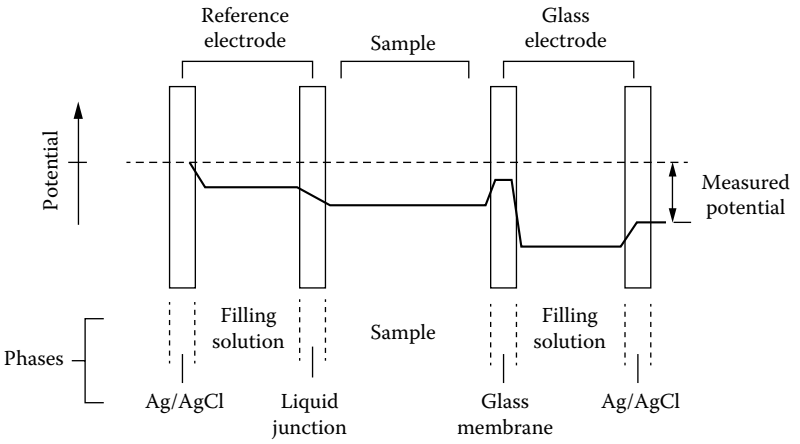

FIGURE 59.2 Schematic illustration of potential differences contributing to the measured potential between a glass membrane electrode and a reference electrode.

membrane potential to changes in pH is small, so a suitably designed reference electrode and a high input impedance meter are required in order for the potential to be precisely measured.

The construction of a typical pH indicator electrode is illustrated in Figure 59.1b. The glass membrane at the tip of the electrode, which acts as the transducer of pH, is approximately 0.1 mm thick. One side of the membrane contacts the sample, while the other contacts the electrode filling solution, an electrolyte of defined composition and pH. A reference element (e.g., a silver chloride–coated silver wire) immersed in the filling solution makes a stable electrical contact between the potential measuring circuitry of the pH meter and the electrolyte in contact with the inner side of the glass membrane.

The reference electrode illustrated in Figure 59.1c provides a means of making electrical contact between the meter and the sample that is in contact with the external side of the indicator electrode's pH-sensitive glass membrane. Like the indicator electrode, the body of the reference electrode is filled with an electrolyte into which a reference element is immersed. The electrode also has a means, such as a porous ceramic frit, by which the reference electrode filling solution can make physical and electrical contact to the sample. The importance of this "liquid junction" cannot be understated, as it is a potential source of sample contamination, measurement errors, and reliability problems.

The electrical potential difference between the pH indicator electrode and the reference electrode provides a measure of pH. Figure 59.2 provides an illustration of the potential differences, the origin of which will be discussed later, that contribute to the measured potential. The main function of the pH meter of Figure 59.1a is to measure this difference, with a precision of 0.1 mV or better. The amplifier circuit of Figure 59.1d illustrates how this may be done. Due to the high electrical resistance of the indicator electrode's glass membrane, the meter must have correspondingly high input impedance. Most pH meters currently sold contain built-in microprocessors that simplify pH measurement by performing and storing calibrations, doing diagnostics, and implementing temperature compensation.

59.2.1.1 Glass Membrane Indicator Electrode Construction

The hydrogen-ion-selective glasses used to construct pH indicator electrodes are formed by fusing silica, alkali metal oxides, and alkali earth oxides. The silica component, SiO_2, makes up approximately 70% of the glass. The alkali metal oxide contributes mobile ions such as sodium or lithium, which act as electrical charge carriers or are exchanged for protons in the hydrated glass layer. Components such as calcium oxide (CaO) are added to incorporate multivalent ions into the glass; these act to modify the network structure of the glass, imparting characteristics such as processability and chemical resistance.

59.2.1.2 Glass Membrane Indicator Electrode Response to pH

When the membrane glass is immersed in aqueous solution, a gel-like hydrated layer on the order of 100 nm thick forms at the surface of the glass. Within this hydrated layer, the exchange of sodium ions in the glass for hydrogen ions in the solution produces a potential difference between the hydrated layer and the solution that depends on the hydrogen ion activity. The net potential developed across the entire glass membrane, ϕ_{net}, is the sum of boundary potentials ϕ_b, at the inner (reference element side) and outer (sample side) extents of the membrane:

$$\phi_{net} = \phi_{b,inner} - \phi_{b,outer} \tag{59.4}$$

Under conditions where, at the outer surface, the exchange of sodium ions for hydrogen ions is complete (typically for pH less than 10), the hydrogen ion activity at the surface of the gel layer will be constant. The boundary potentials will then depend in a logarithmic manner on the hydrogen ion activity of the solution contacting the membrane, a function known as the Nernst equation:

$$\phi_b = \text{constant}' + \frac{RT}{F} \ln a_{H^+} \tag{59.5}$$

The net potential developed across the membrane is then proportional to the log of the ratio of the hydrogen ion activities of the sample and the electrode filling solution. The hydrogen ion activity of the filling solution is constant, so the membrane potential will depend linearly on pH:

$$\phi_{net} = \text{constant}'' + \frac{RT}{F} \ln \frac{a_{H^+,sample}}{a_{H^+,inner}} = \text{constant}''' - 2.3 \frac{RT}{F} \text{pH} \tag{59.6}$$

The dependence of membrane potential on pH is proportional to absolute temperature and at 25°C, the factor $2.3RT/F$ is equal to 59 mV per pH unit. Many pH meters that perform two-point calibrations calculate a slope and display it as a percentage of this theoretical value. For an electrode in good condition, this will be in the range of 90%–105%; values considerably different from this indicate a problem with the electrode.

While the membrane potential responds principally to changes in hydrogen ion activity, it also responds to sodium and other monovalent cations. These effects are most noticeable at high pH where hydrogen ion activity is small and is referred to as alkaline error. A more detailed analysis of the membrane response, which considers the effects of interfering ions, can be found in reference texts [3].

59.2.2 Reference Electrodes

A reference electrode, such as that pictured in Figure 59.1c, is used to make a stable, low-resistance electrical contact between the external measuring circuit and the sample, establishing a reference potential against which the indicator electrode can be referred. In the metallic conductors of the pH meter circuitry, current is carried by electrons, while in the sample electrolyte, current is carried by ions. The difference between reference electrodes is primarily the oxidation or reduction reactions that effect charge transfer across the reference element/electrolyte interface. The species participating in these reactions must be present in the electrolyte contained within the body of the reference electrode. As a result, the composition of the reference electrode filling solution is, in general, different from that of the sample, and the physical contact between the two dissimilar electrolytes forms what is known as a liquid junction. The two phase boundaries (reference element/filling solution and filling solution/sample) necessary to make electrical contact to the sample each introduce an additional potential, which adds to that of the indicator electrode, but proper design of the reference electrode ensures that these potentials remain constant and can be calibrated out.

59.2.2.1 Reference Elements

The most widely used reference electrode for pH measurement is the silver/silver chloride electrode. The electrode is constructed from a silver wire that has been coated with silver chloride and immersed in an electrolyte saturated with silver chloride. Current is readily passed across the electrode/electrolyte interface by the reduction of silver chloride to form silver metal and chloride ion:

$$AgCl + e^- \leftrightarrow Ag^0 + Cl^- \tag{59.7}$$

At equilibrium, the phase-boundary potential developed at the interface depends in a Nernstian manner on the chloride ion activity of the filling solution. Maintaining a constant chloride ion activity in the filling solution ensures that this potential remains constant. This type of electrode is easily and reproducibly constructed, and the phase-boundary potential has a smaller temperature coefficient than the calomel reference electrode. The main disadvantages of the Ag/AgCl electrode include the possibility that samples, biological samples in particular, may be contaminated with silver ion, and those precipitates (silver sulfide and nitrate) may form, which can clog the liquid junction.

Another commonly used reference electrode is the calomel electrode, based on the reduction of mercuric chloride to mercury:

$$HgCl_2 + 2e^- \leftrightarrow Hg^0 + 2Cl^- \tag{59.8}$$

Like the silver/silver chloride electrode, the potential of the calomel electrode depends on the chloride ion activity of the filling solution. It is more stable than the silver/silver chloride electrode, due to favorable reaction kinetics, and is therefore preferred for high-precision electrochemical determinations. However, the operating temperature of a calomel reference electrode is limited to 70 °C, compared to greater than 100 °C for the silver/silver chloride electrode.

A number of reference electrodes use a platinum reference element. Ross described a reference electrode based on the reduction of iodine to iodide [4]. The nature of the redox reaction differs from the Ag/AgCl and $Hg/HgCl_2$ electrodes, in that both the iodine and iodide are soluble in the filling solution, yielding an electrode potential that is relatively insensitive to temperature. The hydrogen reference electrode consists of a platinum electrode immersed in aqueous solution, over which hydrogen gas is bubbled. The platinum catalyzes the reduction of hydrogen ion to hydrogen gas. Historically, the standard hydrogen electrode has served as the primary reference electrode for precise electrochemical determinations. The role played by the hydrogen electrode in pH measurement, however, is primarily in its use as an indicator electrode for the determination of the hydrogen ion activity of primary pH standard solutions.

59.2.2.2 Liquid Junctions

The necessary contact between the filling electrolyte of the reference electrode and the sample forms a liquid junction and results in the development of a junction potential that depends on the compositions of the two electrolytes. The junction potential can be minimized by filling the reference electrode with an electrolyte having high concentrations of an anion and cation of comparable diffusivities. For Ag/AgCl and calomel reference electrodes, potassium chloride at concentrations ranging from 3 M to saturation is most commonly used as the filling electrolyte, as the diffusivities of the two ions are approximately equal. The stability of the liquid junction potential depends on the constancy of the interface between the filling electrolyte and the sample. A number of approaches exist to allow the filling electrolyte to controllably leak into the sample for this purpose. These include cracked bead, porous ceramic, and annular sleeve junctions. Leak rates range from less than 1 $\mu L\ h^{-1}$ (cracked bead) to greater than 100 (annular sleeve) $\mu L\ h^{-1}$.

59.2.2.3 Selection, Use, and Care of Reference Electrodes

Reference electrode selection is dictated by the sample to be studied and the measurement conditions, such as temperature. Silver/silver chloride electrodes are preferred over calomel for general-purpose use and at high temperatures (70 °C or greater). Calomel electrodes are preferred for high-precision determinations and where silver contamination of the sample presents a problem. An Ag/AgCl reference electrode incorporating a double junction is also another means of preventing silver contamination of the sample. The type of liquid junction and its flow rate is important; a high flow rate may contaminate the sample and deplete the electrode, while a low flow rate may lead to clogging. Viscous, semisolid samples or low ionic strength samples require a high flow rate junction. The reference electrolyte fill port should remain open during use of the electrode to ensure adequate flow through the junction. Leaving the fill port open at all times will prevent any contaminants from entering the body of the reference electrode and reduce the likelihood of junction clogging, at the expense of more frequent refilling. "Low maintenance" reference electrodes use a polymer gel saturated with electrolyte within the body of the electrode and will perform properly if stored in filling solution.

59.2.3 Instrumentation

The pH meter pictured in Figure 59.1a measures the potential developed between the pH indicator and reference electrodes, from which the pH of the sample is determined using a previously established calibration and possibly the sample temperature. The measurement of the potential, which may range in magnitude up to a few hundred millivolts, is complicated by the large electrical resistance presented by the glass membrane. This may range from 100 MΩ to greater than 1000 MΩ and necessitates the use of high input impedance amplifiers with FET input stages if the glass membrane potential is to be accurately measured. While the relatively low cost and high performance of commercially available meters obviates the need for amplifier construction, Figure 59.1d presents a simple amplifier suitable for use with a glass electrode. The amplifier circuitry of commercial pH meters incorporates additional functions to improve the accuracy and stability of the measurement, such as a driven shield to reduce noise pickup and chopper stabilization to reduce drift.

59.2.3.1 Calibration

The glass indicator electrode is calibrated using standard buffer solutions of known pH. A two-point calibration procedure is illustrated schematically in Figure 59.3. A pair of standards is chosen to bracket the pH range of interest. The response of the electrode is measured in each, and a calibration function is determined by linear interpolation. The slope can be compared to that expected from the Nernst equation to provide an indication of the performance of the electrode. The newest

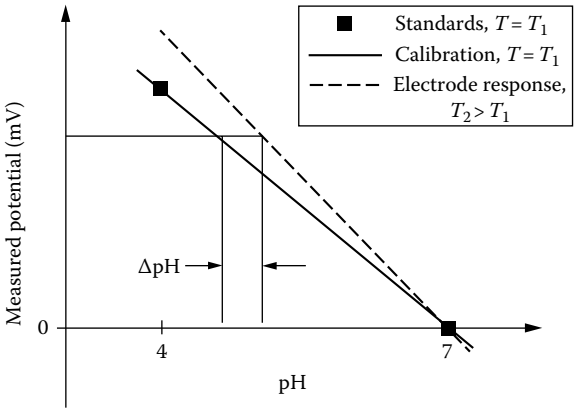

FIGURE 59.3 Calibration and temperature compensation of a glass pH electrode.

microprocessor-controlled pH meters simplify calibration by automatically recognizing the pH of standards and constructing calibration curves from as many as five buffers.

59.2.3.2 Temperature Compensation

The potential developed across the pH indicator glass electrode membrane is temperature dependent, with a temperature coefficient of approximately 0.3% per°C, as follows from Equation 59.6. The effect of temperature on the electrode calibration is illustrated in Figure 59.3. Most pH meters have provision for temperature compensation, which corrects the slope of the measured potential versus pH calibration. Manual compensation permits the user to dial in the temperature at which the measurement is going to be made. Meters equipped with automatic temperature compensation (ATC) use a platinum resistance thermometer to directly measure the temperature of the sample. The instrumentation within the meter then corrects the calibration function such that the millivolt reading is correctly interpreted as the pH of the sample at the measurement temperature.

59.2.3.3 pHFETs

A relatively recent development in pH measurement is the introduction of systems based on the use of ion-selective field-effect transistors (ISFETs) as the sensing element. ISFETs, of which the hydrogen ion-sensitive pHFET is one variant, are derived from the metal–oxide–semiconductor FET (MOSFET), the basic building block of integrated circuits. These silicon "chips" combine a pH-responsive membrane much like that of the glass electrode with the amplification of a field-effect transistor. The integral amplification and small size have led to the development of inexpensive, battery-powered, pocket-sized pH measurement systems. These devices have found unique and expanding niches, including the food industry where the measurement of pH using breakable glass electrodes presents an unacceptable safety hazard; the measurement of the pH of gels, pastes, and slurries; and for the measurement of strongly alkaline solutions where conventional glass bulbs respond to the sodium ions and give an erroneously low reading. The following sections cover the basic operation of these devices, instrumentation, and applications. Additional details can be found in reference texts [5].

59.2.3.4 Construction and Operation

A schematic cross section of a pH-sensitive ISFET is presented in Figure 59.4. The pHFET differs from a MOSFET in that the metal gate of the MOSFET is replaced by a pH-responsive membrane material

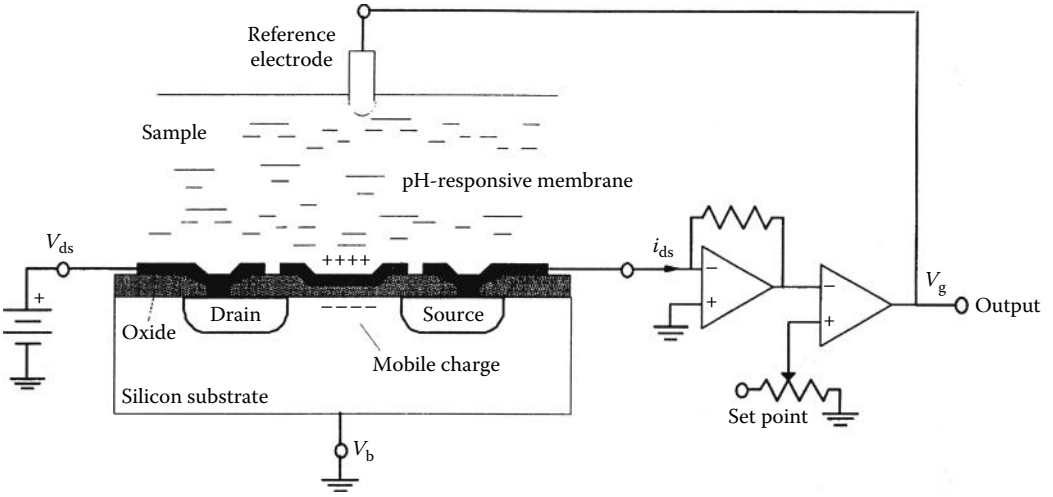

FIGURE 59.4 pH measurement using an ISFET, including an amplifier circuit for constant drain current operation.

such as silicon nitride, aluminum oxide, or tantalum oxide, which contacts the sample solution directly. As with the glass electrode, electrical contact is made to the sample through a reversible reference electrode. A suitable voltage applied to the reference electrode (relative to the silicon substrate) will charge the capacitor formed by the solution, insulating layers, and silicon substrate and create mobile charge in the channel region. A potential simultaneously applied between the drain and source electrodes will result in current flow. Using a "charge imaging" model [6], this drain current, i_{ds}, can be described by

$$i_{ds} = A\ V_{ds} Q_c = A\ V_{ds} C_2 \left(V_g - V_T - \frac{V_{ds}}{2} \right) \tag{59.9}$$

where

the constant A includes geometrical factors
V_{ds} is the voltage applied to the drain
Q_c is the mobile channel charge

The mobile charge is a function of V_g, the voltage applied to the reference electrode; V_T, the "threshold voltage" needed to produce mobile charge; and C_2, the capacitance of the gate region. The threshold voltage includes a number of terms, one of which is the phase-boundary potential at the interface between the sample and the pH-responsive insulating layer. Adsorption of protons at the surface of this layer leads to a Nernstian dependence of this potential on hydrogen ion activity with the result being that changes in pH modulate the drain current of the device:

$$i_{ds} = A V_{ds} C_2 \left(V_g - V_T + 2.3 \frac{RT}{F} \text{pH} - \frac{V_{ds}}{2} \right) \tag{59.10}$$

59.2.3.5 Instrumentation

Equation 59.10 illustrates the dependence of ISFET current on pH. The preferred method of operation of the pHFET is to operate at a constant drain current. A circuit for doing this is illustrated schematically in Figure 59.4. A transconductance amplifier converts the drain current to a voltage, which is referenced against a set point. The output of the comparator drives the reference electrode, V_g. Since the mobile channel charge Q_c is constant, as are V_{ds} and $V_{T'}$, changes in the comparator output directly reflect changes in the hydrogen ion activity. That is, a 59 mV change in output corresponds to a change in pH of one unit. Interface circuitry similar to that of Figure 59.4 allows the device to be connected directly to a glass electrode pH meter. As with the glass electrode, temperature compensation is required if the device is to be used at temperatures different from that of calibration.

59.2.4 Other Electrochemical pH Electrodes

There are a number of other approaches for electrochemical measurement of pH [1]. Two that deserve mention, as they are commercially available, either directly or incorporated within another product, are metal/metal oxide and liquid membrane electrodes.

59.2.4.1 Metal/Metal Oxide pH Sensors

A pH indicator electrode with application to measurement at high temperature and pressure can be constructed from metals coated with an oxide. These metal electrodes may take the form of a wire, polished disk, or sputtered thin film, on which an oxide has been formed through thermal oxidation, chemical vapor deposition, or electrochemical oxidation. Electrodes have been constructed from systems including W/W_2O_3, Sb/Sb_2O_3, Pt/PtO_2, Ru/RuO_2, Pb/PbO_2, and Ir/IrO_2. In aqueous solution, the metal oxide can be reduced to a lower oxidation state with the consumption of a proton in solution.

Using an iridium/iridium oxide (Ir/IrO_2) electrode as an example, this redox couple is believed to be represented by an Ir(III)/Ir(IV) half-cell reaction of the form

$$2\,IrO_2 + 2H^+ + 2e^- \leftrightarrow Ir_2O_3 + H_2O \tag{59.11}$$

The Ir/IrO_2 electrode shows a near Nernstian response of −59 mV per pH unit [7]. The chemical resistance, high-temperature and pressure performance, the nonglass construction, and the considerable potential for miniaturization suggest that these pH sensors will find application in areas not typically employed by glass membrane electrodes or pHFETs.

59.2.4.2 Liquid Membrane Electrodes

Another type of electrochemical pH electrode is based on polymeric "liquid membranes," most commonly used to construct ion-selective electrodes for ions such as potassium [8]. The membranes consist of a plasticized polymer film into which an ionophore has been incorporated. The ionophore is a molecule that selectively binds and transports a given ion across the membrane, making the membrane selectively permeable to the ion of interest. The ionophore *N*-tridodecylamine binds hydrogen ions and has been used in the construction of a pH sensor incorporated into a disposable cartridge device for measuring blood electrolytes [9].

59.3 Optical Methods of pH Measurement

For some applications, optical methods offer advantages over the use of the glass electrode or other electrochemical devices for the measurement of pH. Organic dye molecules with pH-dependent spectral properties have been routinely used for decades in acid–base titrations and in pH indicator papers. These dyes, many of natural origin, have more recently been put to use as indicators to measure localized pH within living cells and in the development of fiber-optic probes for measuring pH within the body. The following sections cover the basic principles and major applications of optical pH measurement; more detailed treatments may be found in Ref. [10].

59.3.1 Indicator Dyes

Optical measurement of pH is based on the use of organic dye molecules that are weak acids or bases. The loss or gain of a proton changes the electronic structure of the molecule, producing a measurable change in the manner in which the molecule interacts with light. This interaction can be the absorption of light at a particular wavelength or fluorescence by one form of the molecule. Equilibrium exists between the acid and base forms of the dye, whether free in solution or chemically attached to a supporting membrane, and can be described by the equilibrium

$$Dye^z + H^+ \xleftrightarrow{K_a} Hdye^{z+1} \quad K_a = \frac{a_{Dye^z} a_{H^+} a}{a_{Dye^{z+1}}} \tag{59.12}$$

where z represents the valence of the molecule. The interrogation of the solution or membrane with light will produce a response that is weighted by the relative proportions of the acid and base forms of the molecule, which in turn depends on pH. Inspection of Equation 59.12 shows that the ratio of the two forms, and hence color, varies continuously with hydrogen ion activity. The sensitivity of the measurement is greatest when the acid and base forms of the dye are present in approximately equal concentrations. This occurs when the pH of the solution is close to the pK_a ($-\log [K_a]$) of the dye. Limitations of the human eye restrict detectable changes in color to a tenfold excess of one species over the other. This corresponds to a change of ±1 pH unit. Thus, an indicator with a pK_a of 1×10^{-5} will display a color change if the solution in which it is dissolved changed from 4 to 6 pH units. The pH of interest therefore dictates selection of the particular dye.

An understanding of possible interactions between the indicator dye and the sample is important in the effective use of optical indicator dyes for pH measurement [11]. Factors such as temperature, electrolyte concentration, and the presence of organic solvents may cause a shift in p*K*, of the indicator dye; the shift could be as much as one or more pH units. As weak acids and bases, the addition of indicator dyes to a sample can change the pH, particularly in weakly buffered samples. This effect is important when using pH papers or optical sensors to measure small samples, where the potential exists for the buffering capacity of the sample to be exceeded by the amount of dye immobilized in the paper or on the sensor. As a general rule, potential errors can be minimized by calibrating in solutions similar in composition to the sample to be measured.

59.3.1.1 Absorption Indicator Dyes

The conjugate acid and base forms of absorption indicator dyes differ in the characteristic wavelengths at which they absorb light energy. A number of common absorption indicator dyes are listed in Table 59.3, and their pK_as span the range of pH from approximately 1 to 13. The absorption spectra of a solution of the dye phenol red at a number of different pHs is shown in the inset of Figure 59.5. The acid form of the dye has an absorption maxima at λ_{max} = 435 nm, while the base form absorbs maximally at λ_{max} = 565 nm. As the pH of a phenol red solution is increased from 6 toward the pK_a of 7.9, the equilibrium of Equation 59.12 shifts to the basic form of the dye. The relative absorption peaks change, reflecting that a shift in concentrations of the two is formed. For quantitative pH measurement, the absorption of light by the indicator is measured by a spectrometer or reflectometer at a specific wavelength or narrow set of wavelengths corresponding to the wavelength of maximum absorption λ_{max} for the acidic or basic form of the chromophoric dye molecule. Beer–Lambert's law describes the proportionality between absorbance, *A*, and the concentration of the indicator, c_{dye}, in moles per liter:

$$A = \log\left(\frac{I}{I_0}\right) = \varepsilon b c_{dye} \tag{59.13}$$

The quantity I/I_0 represents the ratio of the intensity of light transmitted through the sample to that incident on the sample, ε the extinction coefficient of the dye molecule, and *b* the path length. The magnitude of the absorption peak heights at 565 nm, plotted in Figure 59.5 as a function of pH, and reflects the changing concentration of the basic form of the dye as the equilibrium of Equation 59.12 shifts.

TABLE 59.3 Acid–Base Indicator Dyes

Indicator	pK_a	λ_{max}(nm) Acid Form	Base Form
Thymol blue	1.7	544	430
Methyl orange	3.4	522	464
Bromophenol blue	3.9	436	592
Bromocresol green	4.7	444	617
Methyl red	5.0	530	427
Chlorophenol red	6.0	—	573
Bromocresol purple	6.3	433	591
Bromothymol blue	7.1	433	617
Phenol red	7.9	433	558
Cresol red	8.2	434	572
Phenolphthalein	9.4	—	553
Thymolphthalein	10.0	—	598

59.3.1.2 Fluorescent Indicator Dyes

Fluorescent indicator dyes absorb light of a particular color (or wavelength) and reemit some of the absorbed energy as light of a different color. Absorption of light by the indicator promotes the molecule from the ground state energy, E_g, to a higher energy state, E_1. Subsequent processes such as molecular collisions lead to a transition to a lower energy excited state, E_2. The molecule can then emit a photon of energy E_2–E_g, resulting in the return of the molecule to the ground state from this intermediate state. The emitted light is at a longer wavelength than the exciting wavelength, and the difference is known as the Stokes shift. In principle, a fluorescence measurement is more sensitive than an absorption measurement because the only light measured by the detector originates from fluorescing molecules. Table 59.4 lists a number of common fluorescent pH indicators used for measurement of pH in the physiological range. Fluorescein is widely used because the absorption maximum at 490 nm of the fluorescent dianion is readily excited by the 488 nm emission of argon ion lasers.

59.3.1.3 Indicator Papers

Indicator papers are a simple, rapid, and inexpensive means of measuring pH when the precision of an instrumental measurement is not necessary. These are constructed from a strip of paper or plastic that has

TABLE 59.4 Fluorescent pH Indicator Dyes (for Physiological Applications)

Indicator	pK_a	Excitation Maximum (nm)	Emission Maximum (nm)
BCECF[a]	7.0	482	520
Fluorescein	6.4	490	515
HCC[b]	6.9–7.0	410	455
HPTS[c]	6.8–7.3	465	520

[a] 2′,7′-bis-(2-Carboxyethyl)-5-(and-6)-carboxyfluorescein.
[b] 7-Hydroxycoumarin-3-carboxylic acid.
[c] 8-Hydroxy-1,3,6-pyrenetrisulfonate.

been impregnated with one or more absorption indicator dyes chosen to span the pH range of interest. The dyes are generally covalently attached to the strip, to prevent contamination of the sample by leaching of the dyes. A strip for indicating pH in the range of 5.5–9.0 can be constructed using the dyes bromocresol purple, bromothymol blue, and phenol red [1]. The pH of a sample is determined to a precision of typically 0.5 units by comparing the color of the strip to a color calibration chart provided by the manufacturer.

59.3.2 Fiber-Optic pH Probes

Optical pH sensors, often referred to as optrodes, represent some of the most sophisticated pH sensors, finding use for remote sensing in the body or industrial plants due to their small size and lack of electrical connections. They are typically constructed by immobilizing an indicator dye at the tip of a light guide formed from one or more optical fibers, which are used to couple light between the indicator and the measurement instrumentation, as illustrated schematically in Figure 59.6a. The resulting probes can be made very small, and with high-quality optical fibers, pH can be measured over considerable distances in electrically noisy environments that would interfere with potentiometric-type electrodes.

59.3.2.1 Construction and Instrumentation

The pH indicator dye must be immobilized in close proximity to the fiber tip. The method of immobilization impacts the sensor's response, response time, long-term stability, and mechanical integrity. The dye can be immobilized to a solid support, such as a membrane or porous glass bead, which is then attached to the end of the fiber. Indicator dyes have been covalently linked to the tip of glass fibers or entrapped within polymer films formed at the tip using light energy from the fiber to initiate polymerization. The construction of probe tips and the instrumentation used for a fiber-optic pH probe depend on the type of indicator being used. Unlike the glass electrode, which has remained largely unchanged for more than

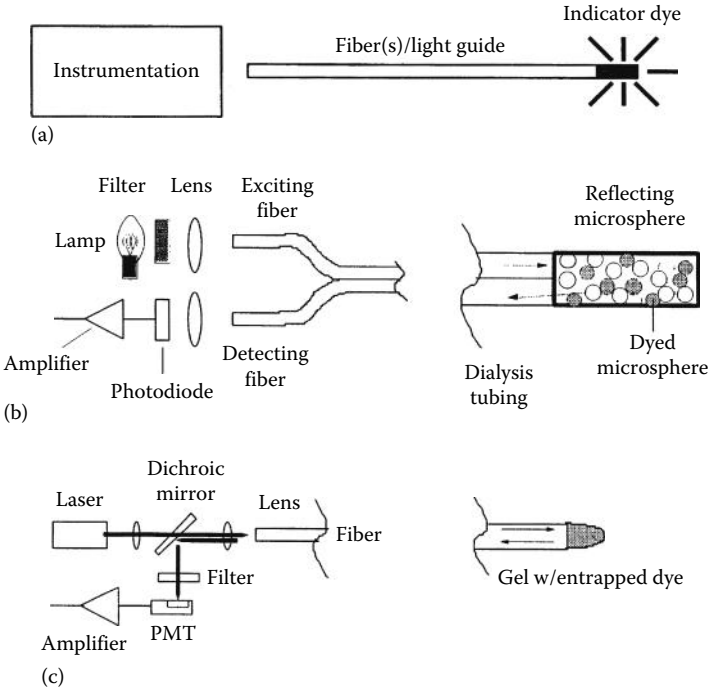

FIGURE 59.6 Optical fiber sensors: (a) Generic. (b) Based on absorption indicator dyes. (From Peterson, J.I. et al., *Anal. Chem.*, 52, 864, 1980.) (c) Based on fluorescent indicator dyes. (From Munkholm, C. et al., *Anal. Chem.*, 58, 1427, 1986.)

75 years, there is considerable variety in the design of fiber-optic pH sensors. While a complete review of the literature is beyond the scope of this work (interested readers may wish to consult Leinevand Wolfbeis [10] and a recent review of chemical sensors by Janata et al. [12]), the following examples illustrate the approaches to construct optical fiber pH sensors using absorption and fluorescent dyes.

Absorption optrodes measure the change in intensity of the light returned from the fiber tip/sensing region relative to the interrogating light of specific (or a narrow band) wavelength. These require a separate collection fiber or fibers and a means to reflect the light, such as a reflector or the use of scatterers such as polystyrene beads. In the example of Figure 59.6b [13], polyacrylamide beads containing the indicator dye phenol red were mixed with white polystyrene latex microspheres that served as scatterers. The beads were contained within dialysis tubing attached to the end of a pair of plastic optical fibers, one used for excitation, the other to collect scattered light. Light from a lamp was filtered to alternately select the λ_{max} of the base form of the dye (565 nm) and a wavelength (600 nm) where the absorbance is pH independent as a reference. (The isosbestic point at 480 nm could also have served as a reference.) The intensity of light scattered back into the second detector fiber was quantified by a photodiode. The ratio of the scattered intensities at the two wavelengths was then related to the pH of the sample.

Fluorescent indicator optrodes measure the Stokes-shifted fluorescence emission by the indicator and may use a single fiber to both interrogate and collect signal-carrying light. The amount of fluorescent pH indicator at the fiber tip must be maximized since fluorescence is emitted omnidirectionally and only a small fraction of the emitted fluorescence will be captured by the fiber. In the example of Figure 59.6c [14], the indicator dye was entrapped within a polymer gel formed at the tip of a glass fiber. The source of excitation light is typically a high-intensity lamp or a laser. If a lamp, its output is filtered to select a narrow band of wavelengths at the absorption maximum of the specific form of the indicator, which is then introduced into the fiber to excite the fluorophore at the tip. Emitted light collected by the fiber exits the fiber and is incident on a dichroic mirror, which reflects the long-wavelength light and passes shorter wavelengths. A filter then selects a narrow band of emission wavelengths, and finally, the light is detected. Due to the relatively small light intensities, the detector is typically a photomultiplier tube rather than a photodiode.

59.4 Frontiers of pH Measurements

Because of its wide-ranging importance, there is likely to be continued innovation in both approaches and opportunities for pH measurements. Some important developments, such as pHFETs and metal/metal oxide pH sensors, have already occurred and are now achieving noteworthy commercialization. Investigators continue to seek new materials for constructing transducers. Examples include electroconductive (electroactive and inherently conductive) polymers such as polyaniline [15] and polyelectrolyte hydrogels [16], which form pH-responsive membranes suitable for the construction of microsensors.

A noteworthy innovation is the application of pH measurement devices as transducers that are integrated into more complex analytical systems directed at other analytes. A pH indicator dye forms the basis of the pCO_2 measurement in an indwelling fiber-optic catheter [17]. Because protons are generated and/or consumed in many biological reactions involving enzymes, pH sensors have found use as transducers in biosensor devices.

An expanding area for pH measurement is likely to be the study of biological systems. The light-addressable potentiometric sensor is a device that measures the pH change resulting from the metabolic activity of cells, with application to examining cellular response to toxins and infectious agents [18]. The measurement of intracellular or subcellular pH using pH-sensitive fluorescent indicators [19] can provide insights into the physiology of the cell.

60.1 Introduction

Recent advances in telecommunications are changing our society. The main reasons for this evolution are the increase of connectivity and the monitoring advances, which provide mobility to humans and increase accessibility for the handicapped.

Wireless telecommunications allow transferring information between two or more devices that are not physically connected. Figure 60.1 shows wireless networks transmission technologies comparing bandwidth with power consumption. As shown in this figure, higher transmission speeds imply higher power consumption. In order to guarantee people mobility, there has to be a compromise between these two variables. It is required to use technologies that transmit with enough bandwidth but without high power consumption.

From all the standards defined for wireless communications, IEEE 802.11 and 802.15, standards have a higher impact. IEEE 802.11 describes a set of standards for implementing Wireless Local Area Networks (WLAN) and IEEE 802.15 is specialized in Wireless Personal Area Networks (WPAN).

WPAN is a network used to communicate devices in proximity to an individual's body using wireless technologies such as Bluetooth, ZigBee, and IrDA. This group of standards includes a wide range of devices.

A wireless sensor network (WSN) consists of a WPAN composed by autonomous sensors (sensing nodes) that cooperate to monitor physical or environmental conditions, such as temperature, sound, vibration, and pressure. WSN components are sensing nodes, transmission technology, and a standard to define the communication. WSN allows cooperation between systems where devices are close to the human body.

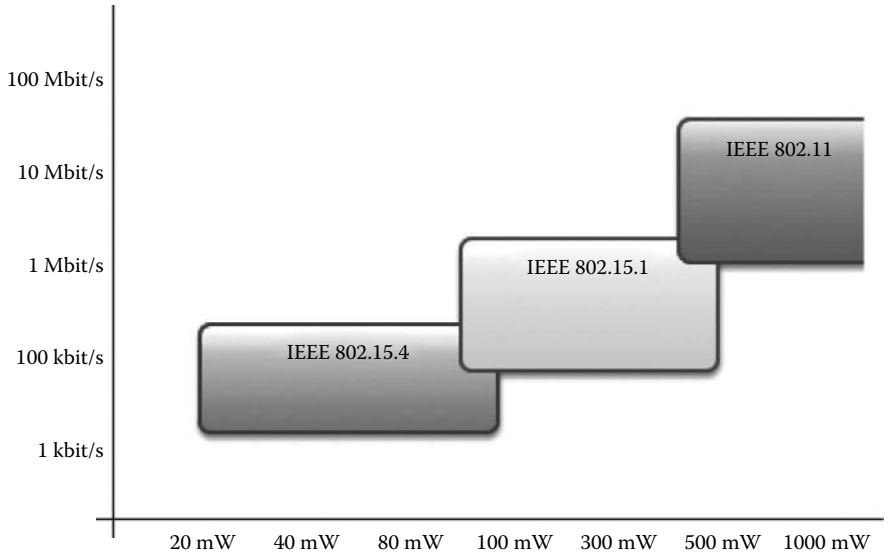

FIGURE 60.1 Body Area Network (BAN) power versus bandwidth. WLAN and IEEE 802.15 are specialized for WPANs.

60.1.1 Wireless Sensor Networks in Health

WSN are becoming increasingly important for monitoring patients both in the clinical setting and at home. Remote monitoring allows monitoring of sports activities, emergencies, catastrophe responses, etc.

Wireless communications also provide more comfort for the patients, with the absence of wires reducing costs and providing more flexibility. WSNs can integrate vital sign sensors and also environmental sensors such as air quality.

The following section describes the WSN transmission technologies including a state of the art of the publications that implement a WSN system in health. This review has been published in Ref. [45] and updated with recent progress.

60.2 Wireless Communication Standards

As previously presented, IEEE 802.11 and IEEE 802.15 family of standards are more relevant for wireless communications. But due to the high power consumption of IEEE 802.11, the IEEE 802.15 family selected for WSN. IEEE 802.15 is divided in different sections:

- IEEE 802.15.1, Bluetooth.
- IEEE 802.15.3 defines physical layer (PHY) and medium control access (MAC) layers for high-speed WPANs.
- IEEE 802.15.4 defines PHY and MAC layers. In some occasions, ZigBee is used to implement upper layers.
- IEEE 802.15.6, a task group is formed to be in charge of developing a communication standard optimized for low-power devices and operation on, in, or around the human body (but not limited to humans) to serve a variety of applications including medical, consumer electronics/personal entertainment, and others.

60.2.1 IEEE 802.15.1

Originally developed by Bluetooth SIG., the IEEE 802.15.1 standard is defined to operate with devices that provide a short range with medium transmission speed. In 1999, the committee came up the first Bluetooth specification, version 1.0. From this moment, it started spreading because of its low power consumption and low cost.

60.2.1.1 Frequency

Bluetooth operates on the 2.45 GHz frequency band (ISM band; Industrial, Scientific and Medical band). This band is shared with Wi-Fi, so to solve possible interference problems, it implements some key technologies. One of these solutions consists of using low power signals (1 mW). Even with the low power, Bluetooth devices do not need to be in the line of sight to communicate.

60.2.1.2 Range

The maximum distance that Bluetooth can reach is based on the power of the transmission. There are three classes with different ranges and signal power levels as shown in Table 60.1.

60.2.1.3 Bandwidth

Bluetooth devices can be also classified according to the bandwidth (Table 60.2).

60.2.1.4 Network Topologies

Bluetooth networks are called piconets. A piconet is composed of a master device that controls seven different devices. In this way, all the devices that belong to the same piconet share the same hop frequency and their clocks are synchronized with the master. One device can be part of different piconets at the same time irrespective of whether it is a master or a slave.

It is possible to connect different piconets in a scatternet in order to expand the physical size of the network beyond the Bluetooth's limited range. Having eight devices in less than 10 m causes interference between members. To prevent this problem, Bluetooth defines time slots to avoid two or more devices transmitting at the same time.

TABLE 60.1 RF Power Classification Levels

Class	Power (mW)	Maximum Allowed Range (m)
Class 1	100	100
Class 2	10	10
Class 3	1	1

TABLE 60.2 Bandwidth Classification

Version	Bandwidth (Mbit/s)
Version 1.2	1
Version 2.0 + EDR	3
Version 3.0 + HS	1
Version 4.0 + HS	1

However, this is not the only interference problem. The interference can also be caused by near piconet clusters in the vicinity. This problem is not resolved by time slots as this solution only works for the devices on the same piconet. This is the reason why Bluetooth implements a frequency-hopping spread spectrum (FHSS) mechanism to avoid interference between piconets. FHSS is a transmission process where the devices involved in the communication change their frequency in regularly hops according to a predetermined code.

Summarizing, time slots prevent interference between Bluetooth devices that belong to the same piconet and FHSS prevents interferences between Bluetooth devices of different piconets.

60.2.1.5 State of the Art

One of the advantages of Bluetooth is that it can be integrated in most mobile devices and laptops. It is common to use these devices as the master devices of the topology that is in control of the sensors that compose the network. Based on this topology, a laptop may be used as the master device on the piconet. Bluetooth publications are summarized in Table 60.3. Most of these reviewed publications are focused on monitoring parameters for a specific scenario. Some examples of the applications of Bluetooth in health are discussed later:

- A polysomnography sensor is used to remotely record sleep disorders [27].
- An accelerometer and optical sensor are used in sport activities [42]. An elastic belt encircles the user's chest and measures low frequency components of belt circumference change. Variations in this length are measured by an optical sensor and outputted as serial digital data. The accelerometer measures dynamic acceleration force produced by the user.
- Electrocardiogram (ECG) sensors, Electrooculography (EOG) sensors, and Electroencephalography (EEG) sensors are mounted on a helmet for general monitoring [28].

But there is also the possibility of using Bluetooth in a smartphone as the master device [26] to collect data from other sensors such as a glucose sensor to control diabetes.

Many medical systems are also using Bluetooth sensors [38]. One example uses a system with a wireless ocular telemetry sensor for glaucoma. Another example is found in [40] where the study of photoplethysmography using an accelerometer can provide valuable information about the cardiovascular system, such as heart rate, arterial blood oxygen saturation, blood pressure, cardiac output, and autonomic functions. A last example is a system for the detection of gait abnormalities or deteriorations in a patient's home environment by using accelerometers and gyroscopes [24].

Other classes of systems are focused on monitoring activities [18,43]. This kind of monitoring system is aimed for elderly people and rehabilitation therapies. Sensors used in these applications are presented in Table 60.4.

60.2.3 IEEE 802.15.3

The IEEE 802.15.3 standard is designed to provide a high data rate and low power consumption solution for WPAN. It is designed to provide sufficient quality of services for the real-time distribution of content such as video and music. The original standard uses a traditional carrier-based 2.4 GHz radio as the physical transmission layer.

IEEE 802.15.3a is a follow-on standard still in the formative stages, which will define an alternative and improved physical layer. Current proposals based on ultra wide band (UWB) will provide more than 110 Mbit/s at a distance of about 10 m and 480 Mbit/s at 2 m. This will allow the streaming of high-definition video between media servers and high-definition monitors, as well as fast transfer of files among servers and portable devices.

Reference [44] compares the 802.11e hybrid coordination function (HCF) MAC and 802.15.3 time division multiple access (TDMA) MAC mainly in terms of throughput and power management. The conclusion after the comparison is that the throughput differences between them are quite small. On the other hand, the power management of 802.15.3 is easier than that of 802.11e. But unfortunately, its power consumption is similar to that in a Wi-Fi device, around 227 mA, when transmitting and receiving [31] so it is high for the telemedicine field when using wireless sensors.

60.2.4 IEEE 802.15.4

IEEE 802.15.4 is a standard that specifies the physical layer and MAC layer for low-rate wireless personal area networks (LR-WPANs). It offers short range and low bandwidth but with the benefit of low power consumption. It is mainly used for industrial control, embedded sensors, and it is also adequate for healthcare systems. Healthcare systems can benefit from this technology as a node can go to sleep and wake up when a new task is due thus saving battery power.

60.2.4.1 Characteristics

- Frequency: Uses ISM frequency band, mainly at the 2.4 GHz band, 868 MHz (Europe) and 902–928 MHz (North America).
- Range: 10–50 m, but it depends on the environment.
- Bandwidth: Data transmission range up to 250 kbps.

60.2.4.2 IEEE 802.15.4 Devices

Two different device types can participate in an LR-WPAN network; a full function device (FFD) and a reduced function device (RFD). The FFD can operate in three modes serving as a personal area network (PAN) coordinator, a coordinator, or a device. An FFD can talk to RFDs or other FFDs, while an RFD

can talk only to an FFD. An RFD is intended for applications that are extremely simple, such as a light switch or a passive infrared sensor; they do not have the need to send large amounts of data and may only associate with a single FFD at a time. Consequently, the RFD can be implemented using minimal resources and memory capacity.

60.2.4.3 Topologies

It is important to understand that the network layer is not defined for this standard. This means there is no possibility to route the data between the different nodes that compose the network.

There are two defined topologies. Both require a PAN coordinator that works as a network coordinator. This device must be an FFD. These topologies are illustrated in Figure 60.2.

- *Star topology*: Communication is established between a central device and other IEEE 802.15.4 devices. This central device is called a PAN coordinator and it is unique in the network.
- *Point to point topology*: IEEE 802.15.4 devices can form an ad hoc network. This standard does not define how to route data between nodes hence there must be a network layer implementator who is in charge of this task. Being able to route data allows the network to cover a wider area than the network topology but the power consumption is increased.

60.2.4.4 State of the Art

Recent publications in this area are in Table 60.5 and the sensors used are in Table 60.6. Two of the three publications focus on fall detection [22,41] and the other is a monitoring system [21].

It is important to mention that it is a common mistake to consider that IEEE 802.15.4 and ZigBee are the same, that is, Ref. [22]. As it will be presented next, the ZigBee is implemented over IEEE 802.15.4 in a different manner and with different characteristics.

The monitoring system described in Ref. [21] is composed by three different sensors, accelerometer, ECG, and saturation of peripheral oxygen (SpO_2). Sensors are located into a chest band (accelerometer and ECG) and a wristband (SpO_2). Although three different measures are acquired, the system is designed for general monitoring without a specific aim. References [22,41] present two systems for falling detection using a triaxial accelerometer. In Ref. [41], the information provided by the accelerometer is complemented with passive infrared (PIR) motion detectors. All three publications implement star topologies as they connect more than a sensor with a PAN coordinator.

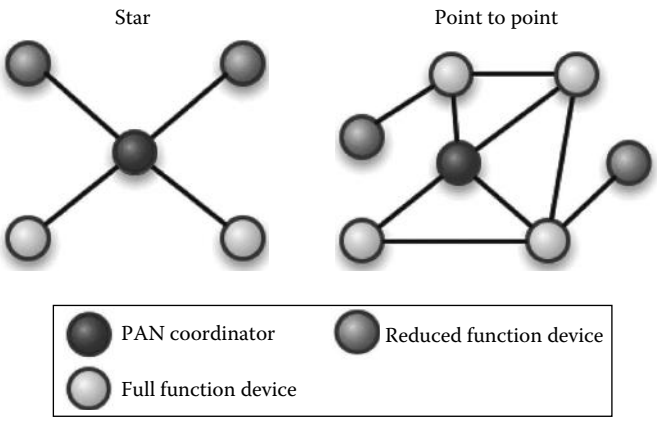

FIGURE 60.2 Topologies IEEE 802.15.4.

60.2.5 IEEE 802.15.4/ZigBee

ZigBee is a specification set built for IEEE 802.15.4 protocol. ZigBee naming is derived from the waggle dance of honeybees after their return to the beehive.

ZigBee is designed to provide connectivity between high-efficiency devices with a reduced packet load. The aim of the standard is to offer low power consumption even if the bandwidth and range have to be sacrificed. It is mainly used in industrial control systems, embedded sensors, and healthcare. These applications benefit from the low node capacity and sleep modes. At this mode, power consumption is highly reduced. ZigBee is promoted by ZigBee Alliance, an international community supported by more than one hundred companies (Motorola, Mitsubishi, Phillips, Samsung, Honeywell, Siemens, etc.).

Because ZigBee is built using IEEE 802.15.4, it shares frequency, range, and bandwidth as described in the previous section.

60.2.5.1 ZigBee Devices

There are three different types of ZigBee devices with differing roles in the network:

- *ZigBee coordinator* (*ZC*): There must be one coordinator per network. It is in charge of controlling the network.
- *ZigBee router* (*ZR*): Connects separate devices in the network topology. It also provides a user application layer.
- *ZigBee end device* (*ZED*): End devices transmit information to ZR or ZC devices; they cannot route data (IEEE 802.15.4 RFD).

60.2.5.2 Topologies

There are three topologies defined for ZigBee networks, shown in Figure 60.3:

- *Star topology*: The communication is established between a central device and the other ZigBee devices, powered by batteries. This central device is called a PAN coordinator and it is unique in the network.
- *Mesh topology*: It is similar to the star topology. The difference between them is that any device can connect with other device, not just the PAN coordinator.

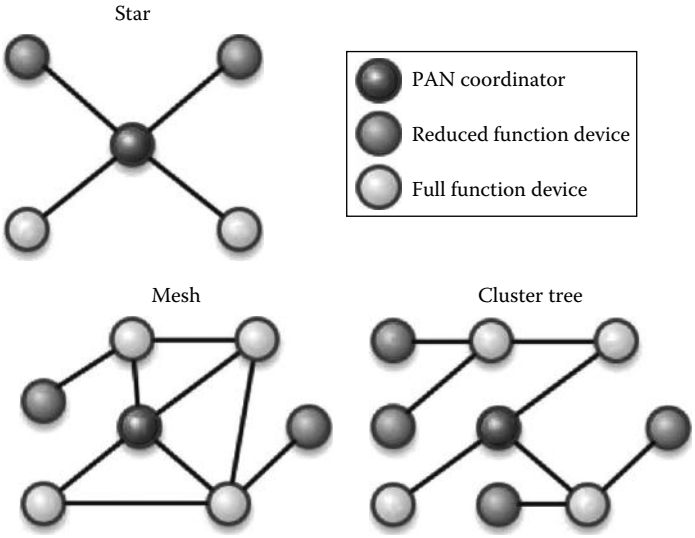

FIGURE 60.3 ZigBee topologies.

- *Cluster tree topology*: Cluster tree is a special scenario for a mesh topology where most of the devices are IEEE 802.15.4 FFD, and RFDs are connected to the network as leaves at the end of each branch. One of the IEEE 802.15.4 FFD is the PAN coordinator and the others can provide synchronization and coordination services.

60.2.5.3 State of the Art

ZigBee is one of the most popular transmission technologies in WSN in health. Its low power consumption increases the battery life of the systems. Table 60.7 summarizes the recent implementations that use this standard.

TABLE 60.7 Sensors Used with IEEE 802.15.4/ZigBee

Reference	Health Focus	Sensors	Battery Life	Device
Campo and Grangereaw [20]	Fall detection	Accelerometer Global positioning systems (GPS)	15 days	ADXL202 Analog Devices [5] SAM-LS U-BLOX

Lou et al. [36]	Scoliosis monitoring	Force transducer	130 days	Honeywell FSO 1 [3]
Morris [et al. 39]	Body fluids analysis	pH Sodium	N/A	N/A N/A

Fall detection applications [20,29,33] are similar to the ones presented in the previous section. Falls are detected using an accelerometer but there are additional sensors that provide extra information in some cases. Global positioning system (GPS) [20] for location and ECG in Ref. [33] are collected for cardiac abnormality detection.

Monitoring is another typical focus on the application of WSN in health. References [36,37] are two interesting research papers about scoliosis monitoring. The trials of 24 h of continuous monitoring for 4–6 months are challenging to battery life of the sensors. At this point is where ZigBee shows its potential. Patients have to wear the sensors for long-time monitoring. As comfort is one of the main advantages of using WSN, patients shouldn't have to recharge sensors batteries quite often. Low power consumption of ZigBee becomes an important factor at these types of applications.

Other monitoring systems measure parameters such as respiratory rate [28], ECG [32], pulse wave signals [30] and bloody fluids analysis [39]. The battery life of these systems is important. Table 60.7 shows that there are ZigBee systems that can work continuously for more than a week [20] or even months [36,37]. Sensors used in these publications are also presented at Table 60.7.

60.2.5.4 Proprietary Solutions

Even if the most popular transmission technologies presented earlier are used extensively, there are other solutions where proprietary technologies are used as listed in Table 60.8. Some publications that use proprietary solutions are discussed later.

A radiotelemetry capsule is used to monitor pH, pressure, and temperature of the intestinal track [19]. The transceiver operates at the license-free 433.92 MHz industry, ISM band. It uses a frequency with ranges between 1 MHz and 1 GHz to avoid energy attenuation in human tissues. It covers a distance of about 2 m and has a battery life over 180 h.

A low-power wireless acquisition module is used within wearable health monitoring systems and ambient assisted living (AAL) applications [23]. The measures are acquired by three different sensors, ECG, accelerometer, and thermometer, but it does not aim to provide a specific solution. It focuses on general-purpose monitoring. The communications on this module is via a Toumaz Sensium system on chip (SoC) [16]. This solution operates at 868 MHz avoiding the ISM band because it is overly crowded. The battery life is high, over 90 h.

An example of fall detection system that implements a wireless proprietary solution is in Refs. [34,35]. The sensor used in this system is the usual one for fall detection, an accelerometer. The communication protocol in the link layer uses ShockBurst [13]. ShockBurst technology permits a low-cost microcontroller with a bit rate of 1 Mbit/s.

ShockBurst technology is also used in Ref. [25], a data acquisition system for diabetic and cardiac monitoring. Sensors used in these publications are presented at Table 60.8.

60.3 Conclusion

Several challenges need to be overcome to enrich the current implementations of WSN [45] in health applications. However, as presented in this chapter there are numerous implementations of WSN for health. The main applications focus on fall detection and general monitoring systems. It has been observed that IEEE 802.15.4 provides high battery life for WSN giving longer operational times and the ZigBee power consumption is much lower than Bluetooth.

In order to compare, the power consumption for IEEE 802.15.1 has been tested on a BlueCore2 and for IEEE 802.15.4 on a CC2430. Results are presented in Table 60.9, which shows that IEEE 802.15.4 power consumption is significantly smaller than Bluetooth both for transmission and reception. It is important to point out that the end devices in IEEE 802.15.4 networks can enter sleep modes, reducing their power consumption. In order to provide network transmission capabilities, they are usually attached to motes or a custom board.

Many different kinds of sensors have been used but some of them are not medical sensors, accelerometers, gyroscopes, etc. The sensors have not a smart status, which means they are not able to connect by themselves to a WSN. In order to provide them with network transmission capabilities they are usually attached to motes or a custom board.

In this chapter, it has been shown that there are several standards available in applications. But it is important to understand that the lack of any standard for the format of the data to be transmitted turns these solutions into isolated systems. The problem is the interoperability issues that reduce opportunities for integration in different platforms. A recent standard, IEEE 1451 [17], describes a set of open, common, network-independent communication interfaces for connecting transducers; it is not restricted to a single transmission technology, being able to operate with the most popular ones (ZigBee, Bluetooth, etc.). Other proposals use the X73, ISO/IEEE11073 standard, also defined by IEEE, which was originally designed to provide connectivity between medical devices.

Sensors for Electrical Impedance Tomography

Tushar Kanti Bera
Indian Institute of Science, Bangalore

J. Nagaraju
Indian Institute of Science, Bangalore

61.1 Computed Tomography

In medical computed tomography (CT) [1] some kind of energy (such as x-rays, optical, electrical, sound, near infrared, etc.) is applied to the subject under test (SUT), and the modified or transformed form of the energy is collected or detected and compared with the incident one to reconstruct the spatial distribution of the tissue properties of the SUT called the parameters of interest (POI). The POI of the SUT gives anatomical, physiological (biophysiological or physiochemical), or pathological information. Hence, in medical tomographic imaging, the energy used to produce the image must penetrate the body tissues [2] to get information about the tissues. If the energy applied to the SUT does not experience any type of interaction (e.g., absorption, attenuation, scattering), the detected energy would not

contain any useful information about the internal anatomy of the SUT [2]. Therefore, it would not be possible to construct an image of the anatomy using that information. In the x-ray computed tomographic technique, x-rays are applied to the boundary of the object under test, and the attenuated x-rays at the boundary are collected for the different projection angles to obtain a complete scan around a 360° rotation. Thus, the x-ray CT involves gathering the output x-rays (X_{Out}) generated by applied x-ray signal (X_{In}) at the boundary from multiple directions and reconstructing the domain parameter relating the X_{Out} to X_{In} (POI) using a software called reconstruction algorithm in a personal computer (PC).

61.2 Electrical Impedance Tomography

Electrical impedance tomography (EIT) [3–7] is an image reconstruction technique in which the electrical conductivity or resistivity of a conducting domain (Ω) is reconstructed from the surface potentials developed by the current signals injected at the domain boundary ($\partial\Omega$). In EIT, the electrical signals (current or voltage) are applied to the boundary of the SUT through different pairs of the surface electrodes (yielding different current projections) attached to the SUT, and the signals generated at the boundary (voltage or current) are collected (Figure 61.1) across the pairs of electrodes for all current projections to obtain a complete scan (around the entire boundary or 360° angular orientation). Thus, the EIT involves gathering the output signal, Y (voltage [V] or current [I]), generated by applying an input signal X (current (I) or voltage (V)) at the boundary from multiple directions and reconstructing the domain parameter (POI) or the transfer function, T (impedance [Z] to admittance [Y]), using a software called reconstruction algorithm in a PC.

In EIT, if the input signal injected to the object boundary is voltage, the method is called electrical potential tomography or applied potential tomography (APT) [8]. On the other hand, if the current signal is applied to the object boundary as an input signal, the method is termed as electrical current tomography or applied current tomography (ACT). Generally, most of the literature used the abbreviation "EIT" to indicate the current tomography, although the term EIT does not indicate the type of excitation (current or voltage). Like most of the literature, in this chapter also, we will use the term EIT for indicating the electrical current tomography unless stated otherwise.

61.3 How It Works?

In EIT, a low-frequency constant sinusoidal current is injected to the domain under test (Ω) through the surface electrodes (shown in rectangles on the domain periphery in Figure 61.2) attached to the domain boundary ($\partial\Omega$), and the boundary potentials are measured on the other electrodes using a

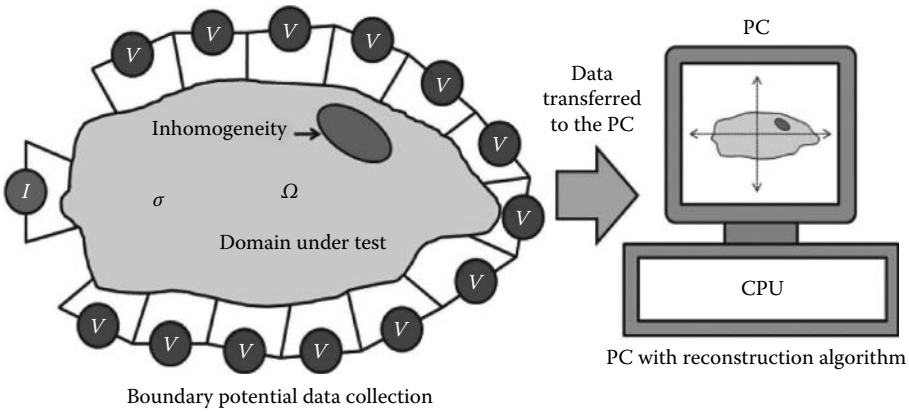

FIGURE 61.1 EIT schematic.

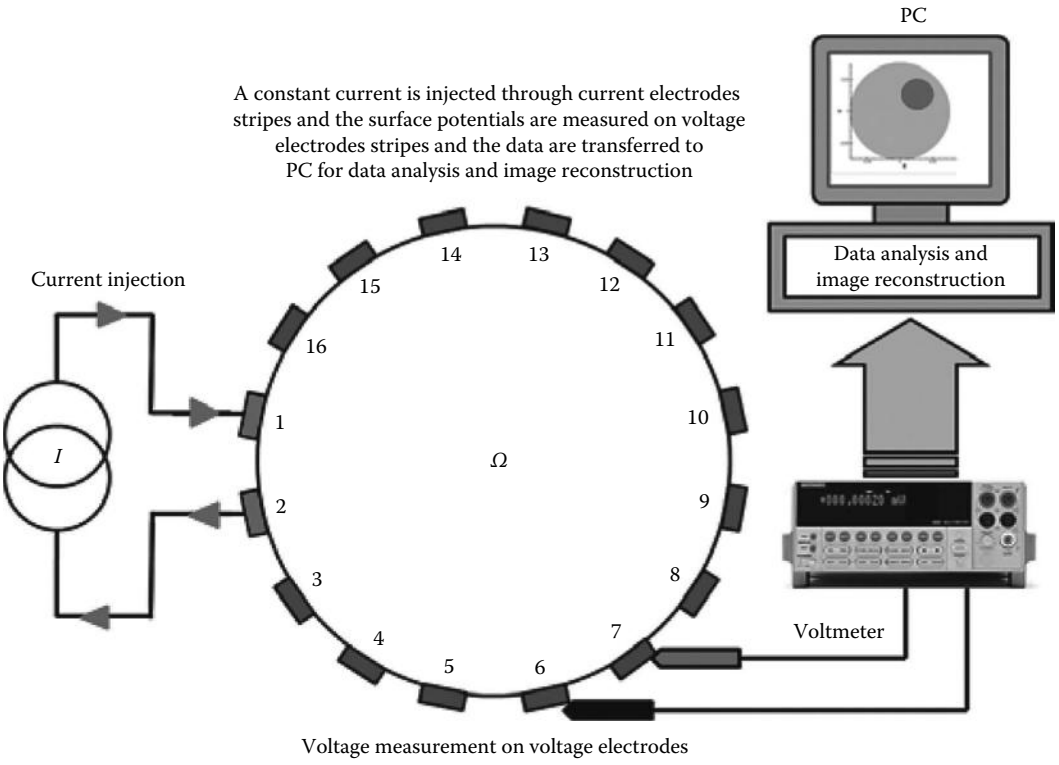

FIGURE 61.2 How EIT works.

voltmeter or any other voltage-measuring device. The electrodes, through which the current signal is injected, are called current electrodes (EC), shown as electrode 1 and 2 in Figure 61.2, and the electrodes on which the voltage data are measured are termed as voltage electrodes (EV), shown as electrode 3 through 16 in Figure 61.2. The voltage data are transferred to the PC for data analysis and image reconstruction (Figure 61.2). The spatial distribution of the electrical resistivity or the conductivity is reconstructed from the boundary data using a mathematical algorithm or computer program called the image reconstruction algorithm [1–4].

When a constant current is injected to the domain under test in EIT, the current fluxes are produced and the current signal interacts with the medium of the domain. The profile of the current fluxes produced within the domain depends on the electrical properties of the medium of the domain, that is, its impedance profile. If the medium is homogeneous (Figure 61.3a), the current flux lines will be symmetric; whereas the inhomogeneous domain (domain with inhomogeneity) will distort the current fluxes (Figure 61.3b).

As the current fluxes develop the voltages at the points interacted with the current fluxes, the potential distribution profile within the domain depends on the profile of the current flux. Similarly, the voltages developed at the domain boundary will also depend on the current flux profile. As the profile of the current flux depends on the profile of the impedance or conductivity distribution of the domain, the domain voltage profile will depend on its impedance profile. Therefore, the boundary potential profile will provide the information about the internal impedance profile of the domain under test. The boundary potential profile for a homogeneous medium will be different from a domain with inhomogeneity. If we have a boundary potential data set and an idea of the domain properties (initial guess of the impedance or the conductivity or resistivity), then we can reconstruct the impedance (or conductivity or resistivity) profile of the domain from the measured boundary data by comparing it from the calculated data.

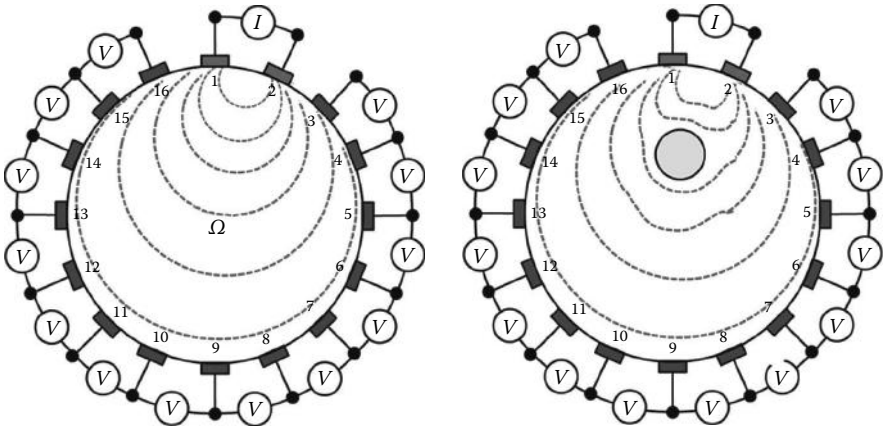

FIGURE 61.3 How EIT works: (a) current flux in homogeneous medium and (b) current flux in medium with inhomogeneity.

61.4 EIT Hardware

An EIT system is developed with mainly three parts: EIT sensors or surface electrodes [3,9], electronic instrumentation [10,11], and a PC (Figure 61.4) with reconstruction algorithm [12–16]. The object to be imaged in EIT is surrounded by the surface electrodes encircling the object boundary, and the constant current signal is injected through two particular electrodes (called current electrodes), and the surface

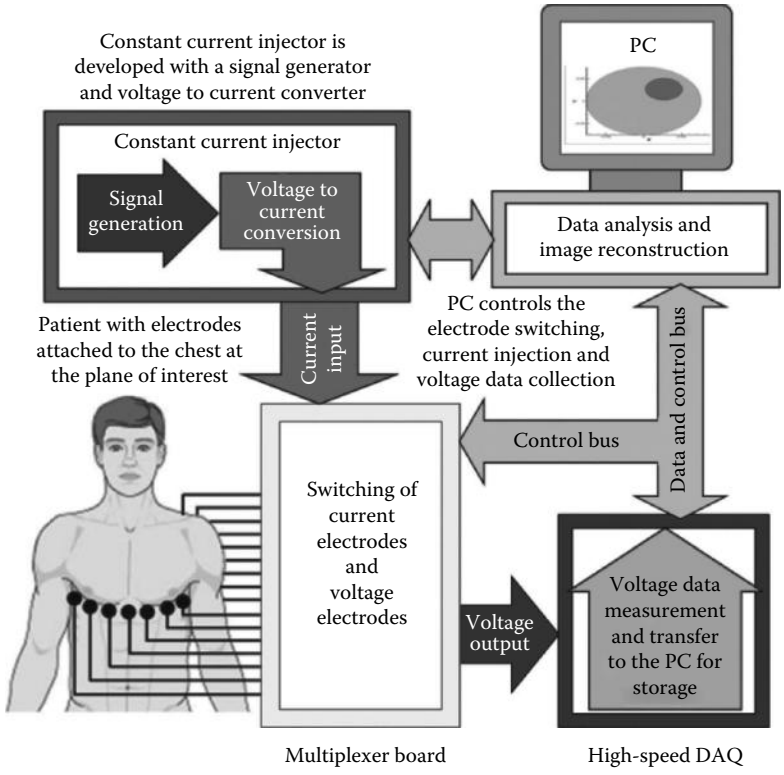

FIGURE 61.4 A medical EIT schematic.

potentials are measured on some particular electrodes (called voltage electrodes). The electrodes or sensors in EIT interface the object under test to the EIT instrumentation for current injection and voltage measurement.

61.5 Sensors and Electrodes

Sensors [17] are the signal sensing devices or signal detectors that measure a physical quantity and send by converting it (sometimes without converting although) into a readable and observable signal to an observer or analyzable and measurable signal to an instrument. For example, a medical thermometer [17] converts the temperature (input or measurand) into a volumetric change (observable output) of a mercury or other liquid, which can be observed and read on a calibrated transparent glass tube. Similarly, a thermocouple [18] converts temperature to an output voltage, which can be observed, measured, and read by an electronic or electrical voltmeter. Sensors are generally tested and calibrated against the known standards for reducing the measurement errors. Electrodes [19] are the sensors that are used to supply or sense the electrical signal (voltage or current) to or from any system. For example, the filaments of a general fluorescent lamp act as the electrodes.

A simple electrolytic cell contains two electrodes: one, called anode, supplies the electrical current (receives the electrons) and the other one, called cathode, receives the electrical current (supplies the electrons). In an x-ray tube, the heater filament and the tungsten target also work as the electrodes: filament supplies the electrons (called cathode) and tungsten target receives the electrons and generates the x-rays. The biomedical electrodes are the electrodes that are used to supply or sense the electrical signals (voltage or current) in a biomedical system. Biopotential electrodes are the transducers that are used to measure the surface potentials by converting the ionic current (caused by the movement of ions) in the body into the electronic current (caused by the movement of electrons). In some biomedical measurement or monitoring processes, current or voltage signals are injected to the body to observe, read, and measure the responses of the body tissue using biopotential or biocurrent electrodes.

61.6 Sensors and Electrodes for EIT

Surface electrodes [3,19] interfacing the EIT hardware and computer with the object under test (i.e., patient) are required to inject a constant current and measure the surface potentials. EIT electrodes generally play a very crucial role in the boundary data accuracy as a number of errors are contributed by the electrodes, electrode–patient interfaces/contacts, and electrode–wire connections. In EIT, generally, $16^{*}N$ ($N = 1, 2, 3, \ldots$) electrodes are used, and a constant current is injected to the object boundary through the different current electrode pairs (called current electrode pairs). The differential potentials are measured across the other pairs of electrodes (called voltage electrodes pairs) using the four-probe measurement technique.

61.6.1 Four-Probe Measurements in EIT

In EIT, a low-frequency constant sinusoidal current is injected to the domain under test through two particular electrodes, and the boundary potentials are measured between the other electrodes (Figure 61.5). The current is injected through different current electrode pairs, and for each current injection through the current electrode pairs, voltage data are collected from the voltage electrode pairs except the electrode pairs containing one or more current electrodes (Figure 61.6). Hence, in EIT, the current injection and voltage measurement are conducted using the repetitive four-electrode method (Figure 61.6) or tetrapolar method [8,20,21]. The four-electrode method is an impedance measurement technique in which a constant current is injected through two electrodes (outer electrodes) called current electrodes and the voltages are measured on other two electrodes (inner electrodes) named as voltage electrodes [20] as shown in Figure 61.6. On the contrary, the two-probe or two-electrode method uses only two electrodes for both

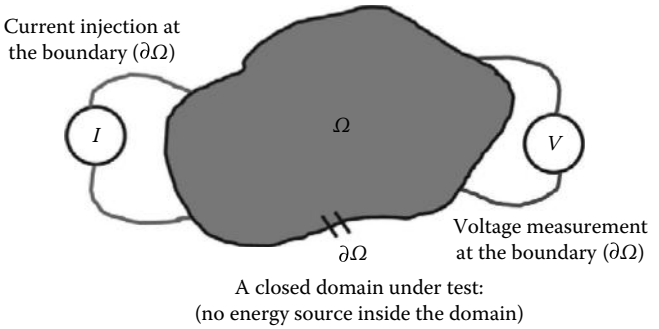

FIGURE 61.5 Four-electrode method in EIT.

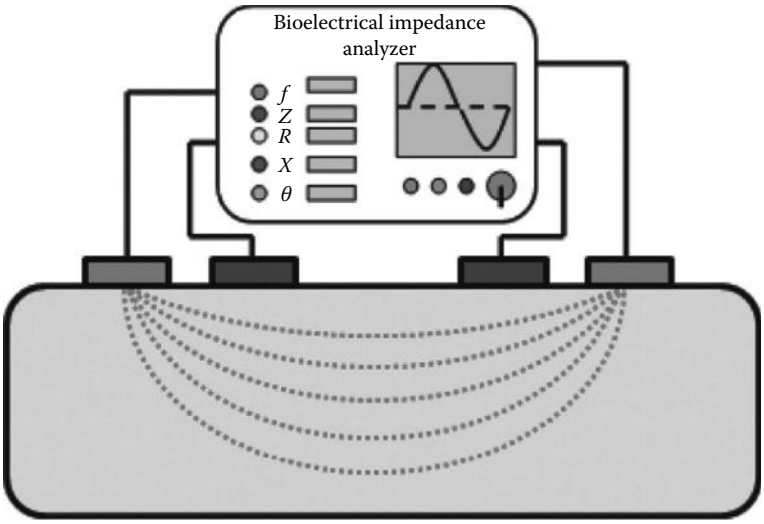

FIGURE 61.6 Four-electrode method for impedance measurement.

the current injection and the voltage measurement. As the same electrode pair is used for current injection and voltage measurement in the two electrode method, it has a contact impedance problem [8]. In two-electrode systems, as the voltages are measured on the current-carrying electrodes, the voltage drop (developed due to the high current magnitude) for the electrode contact impedance is also included with the measured data. Hence, in the two-probe method, the electrode contact impedance reduces the system accuracy. In the four-electrode method, the current injection and voltage measurement are done with two separate electrode pairs, and hence, the electrode contact impedance problem is neglected and the measurement accuracy is improved remarkably.

Boundary potentials in EIT are measured by injecting the current signal through the different current electrode pairs. The current injection through a particular current electrode pair and corresponding voltage measurement process is known as a current projection (P_n). Figure 61.7 shows the projection one (P_1). The voltage data are collected for different projections by injecting current through the different current electrode pairs to obtain a full data set from a complete scan of the object similar to the data collection process conducted at different projection angles in CT. Hence, in EIT also, the voltage data are collected for all the possible projections for obtaining the full set of boundary data.

For an EIT system with N number of electrodes, there will be N current projections (P_n: n = 1, 2, 3, …, N). Hence, a 16-electrode EIT system will yield 16 current projections. The current signal in a 16-electrode EIT system can be injected through 16 different current electrode pairs (E_1–E_2, E_2–E_3, E_3–E_4, E_4–E_5, E_5–E_6, E_6–E_7, E_7–E_8, E_8–E_9, E_9–E_{10}, E_{10}–E_{11}, E_{11}–E_{12}, E_{12}–E_{13}, E_{13}–E_{14}, E_{14}–E_{15}, E_{15}–E_{16}, and E_{16}–E_1),

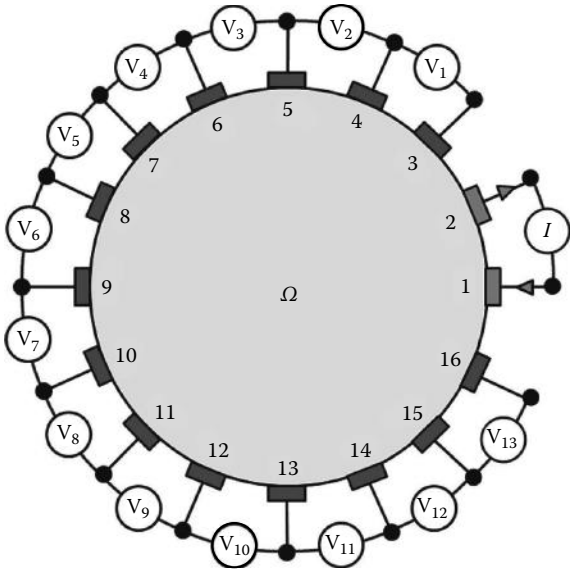

FIGURE 61.7 EIT data collection with repetitive four-electrode method.

which produce 16 current projections P_1, P_2, P_3, P_4, P_5, P_6, P_7, P_8, P_9, P_{10}, P_{11}, P_{12}, P_{13}, P_{14}, P_{15}, and P_{16}, respectively (P_1 has been shown in Figure 61.7). The voltage data are collected for all the projections (P_1 through P_{16}) for obtaining the full set of boundary data. In all the current projections, all the single voltage data measurement is conducted with a four-electrode method (Figure 61.6) as discussed earlier. For a particular current projection (say P_1: current injected through, say, E_1 and E_2), the voltage data are measured from all the possible voltage electrode pairs with four-electrode method keeping the current electrode unchanged. And after completing the P_1, current electrode pair is changed to another pair, say E_2 and E_3, to inject the current signal through them and start the data collection through the second projection P_2, and all the voltage data are collected with the four-electrode method. Hence, the EIT data collection is conducted using a repetitive four-electrode method (Figure 61.6).

61.6.2 Current Injection Methods in EIT

In EIT, a low-frequency constant sinusoidal current is injected to the domain under test through the electrodes called current electrodes. The boundary potentials are measured on the electrodes called voltage electrodes. The method or pattern in which the current is injected to the object under imaging is called the current pattern or current injection protocol [3,4,9]. The famous four different current injection protocols as reported by the researchers are summarized in the below. In general, the differential potentials are measured across the different electrode pairs containing one or both the current electrodes to avoid the contact impedance problem [3]. In some cases [9,22], however, in spite of the problem of skin impedance, to obtain the greatest sensitivity [22] to the changes in the resistivity of the body, voltages on current electrodes are also measured.

61.6.2.1 Neighboring Method

Brown and Segar [23] proposed a current injection method called the neighboring or adjacent current injection protocol (Figure 61.8). In this method the current is applied through two neighboring or adjacent electrodes, and the differential potentials are measured successively from all other adjacent electrode pairs excluding the pairs containing one or both the current electrodes. Figure 61.8 illustrates the neighboring method for a 16-electrode EIT system with a circular domain under imaging (DUI) surrounded by 16 surface electrodes denoted as electrode 1 through electrode 16 (E_1, E_2, E_3, E_4, E_5, E_6, E_7, E_8, E_9, E_{10}, E_{11}, E_{12}, E_{13}, E_{14}, E_{15}, and E_{16}). In the neighboring method, the current is injected through all the possible

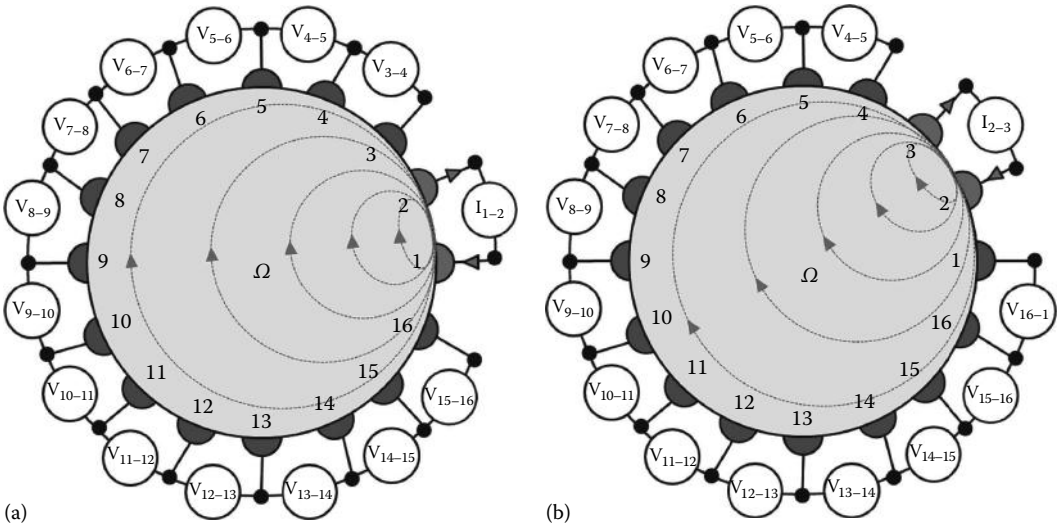

FIGURE 61.8 Neighboring or adjacent current method of boundary potential data collection illustrated for a cylindrical volume conductor and 16 equally spaced electrodes: (a) projection 1 and (b) projection 2.

adjacent electrode pairs and the differential voltage data are measured from the voltage electrode pairs. As discussed earlier, the current injection through a particular current electrode pair and corresponding voltage measurements on voltage electrode pairs is called a current projection. Hence, for a 16-electrode EIT system, there will be 16 current projections (P_1, P_2, P_3, P_4, P_5, P_6, P_7, P_8, P_9, P_{10}, P_{11}, P_{12}, P_{13}, P_{14}, P_{15}, and P_{16}) obtained by injecting the current signals through the 16 possible adjacent current electrode pairs: (E_1–E_2), (E_2–E_3), (E_3–E_4), (E_4–E_5), (E_5–E_6), (E_6–E_7), (E_7–E_8), (E_8–E_9), (E_9–E_{10}), (E_{10}–E_{11}), (E_{11}–E_{12}), (E_{12}–E_{13}), (E_{13}–E_{14}), (E_{14}–E_{15}), (E_{15}–E_{16}), and (E_{16}–E_1), respectively.

Hence, for a 16-electrode EIT system, the first current projection (P_1) of the neighboring data collection method (Figure 61.8a) injects the current signal through electrode 1 (E_1) and electrode 2 (E_2) and measures the 13 differential potentials (V_d: V_1, V_2, V_3, …, V_{13}) successively across the 13 electrode pairs E_3–E_4, E_4–E_5, …, and E_{15}–E_{16} (Figure 61.8a), respectively. Therefore, the first current projection yields 13 differential voltage data: V_1 or V_{3-4} (measured between E_3 and E_4), V_2 or V_{4-5} (measured between E_4 and E_5)…, and V_{13} or V_{15-16} (measured between E_{15} and E_{16}). The 13 differential voltage data obtained in this process are assumed to represent the impedance between the equipotential lines intersecting their corresponding measurement electrodes [3] and are all independent to each other [3]. In the neighboring method, the current density is, of course, highest between the current electrodes (E_1 and E_2 for the projection 1), decreasing rapidly as a function of distance [3]. Similarly, each of all the other current projections (P_2, P_3, …, P_{15}, and P_{16}) yields 13 voltage data and hence a 16-electrode system, and the adjacent current injection method yields $16 \times 13 = 208$ voltage measurements. Figure 61.8b shows the data collection process in P_2. But due to reciprocity [3], the measurements made on the boundary yield identical voltage data in which the current electrodes and voltage electrodes are interchanged [3]. Therefore, among the 208 differential voltage measurements, only 104 data are independent of each other. In the neighboring method, the measured voltage is at a maximum with adjacent electrode pairs, while in the opposite electrode pairs, the voltage is only about 2.5% of that [3].

61.6.2.2 Opposite Method

Hua et al. [24] proposed an alternative current injection method called the *opposite method* (Figure 61.9). In this method current is injected through the current electrodes placed diametrically opposite to each other, and hence, the method is known as the opposite method. Differential potentials are measured on the voltage electrodes with respect to the electrode (called as the voltage reference electrode) adjacent to the current-injecting electrode (Figure 61.9).

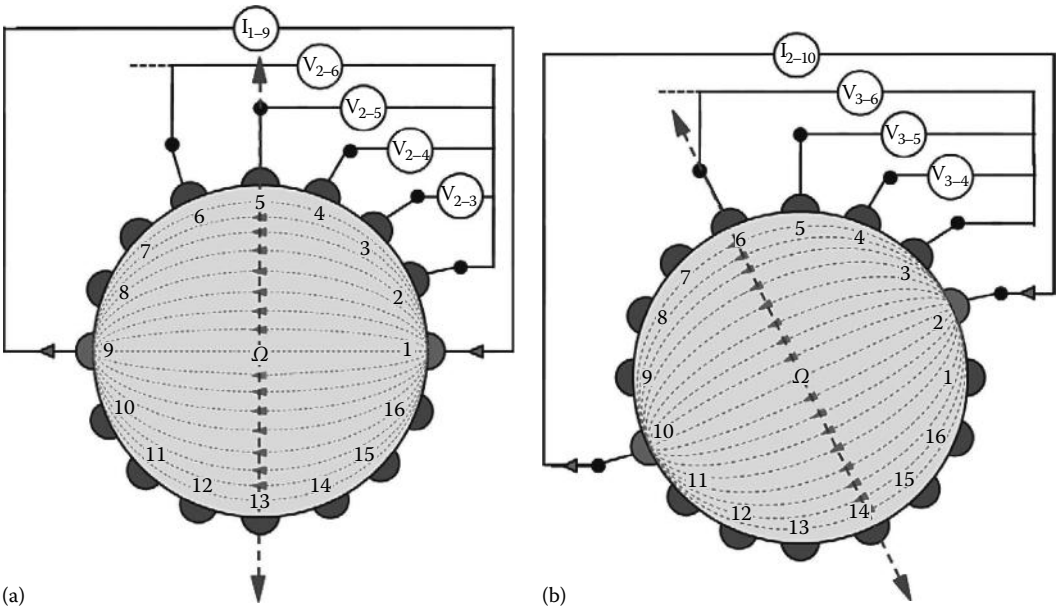

FIGURE 61.9 Opposite method of boundary potential data collection: (a) projection 1 and (b) projection 2.

Figure 61.9 illustrates the data collection strategies of opposite method for a 16-electrode EIT system with a circular DUI surrounded by 16 surface electrodes (E_1, E_2, E_3, E_4, E_5, E_6, E_7, E_8, E_9, E_{10}, E_{11}, E_{12}, E_{13}, E_{14}, E_{15}, and E_{16}). In opposite current injection method, the current is injected through all the possible opposite electrode pairs, and the differential voltage data are measured on all the voltage electrode pairs obtained with 13 voltage electrodes (E_V) and one voltage reference electrodes (E_{VR}). Hence, a 16-electrode EIT system will yield 16 current projections (P_1, P_2, P_3, P_4, P_5, P_6, P_7, P_8, P_9, P_{10}, P_{11}, P_{12}, P_{13}, P_{14}, P_{15}, and P_{16}) obtained by injecting the current signals through the 16 possible opposite current electrode pairs: (E_1–E_9), (E_2–E_{10}), (E_3–E_{10}), (E_4–E_{12}), (E_5–E_{13}), (E_6–E_{14}), (E_7–E_{15}), (E_8–E_{16}), (E_9–E_1), (E_{10}–E_2), (E_{11}–E_3), (E_{12}–E_4), (E_{13}–E_5), (E_{14}–E_6), (E_{15}–E_7), and (E_{16}–E_8), respectively.

Therefore, in the opposite current injection method for a 16-electrode EIT system, the first current projection (P_1) (Figure 61.9a) injects the current signal through electrode 1 (E_1) and electrode 9 (E_9). In P_1, the 13 differential potentials (V_d: V_1, V_2, V_3, V_4, V_5, V_6, V_7, V_8, V_9, V_{10}, V_{11}, V_{12}, and V_{13},) are successively measured across the 13 voltage electrode pairs obtained by combining the 13 voltage electrodes (E_V: E_3, E_4, E_5, E_6, E_7, E_8, E_{10}, E_{11}, E_{12}, E_{13}, E_{14}, E_{15}, and E_{16}) with the voltage reference electrodes ($E_{VR} = E_2$). Therefore, the P_1 yields 13 differential voltage data $V_1 = V_{2-3}$, $V_2 = V_{2-4}$, $V_3 = V_{2-5}$, $V_4 = V_{2-6}$, $V_5 = V_{2-7}$, $V_6 = V_{2-8}$, $V_7 = V_{2-10}$, $V_8 = V_{2-11}$, $V_9 = V_{2-12}$, $V_{10} = V_{2-13}$, $V_{11} = V_{2-14}$, $V_{12} = V_{2-15}$, and $V_{13} = V_{2-16}$ across the electrode pairs E_2–E_3, E_2–E_4, E_2–E_5, E_2–E_6, E_2–E_7, E_2–E_8, E_2–E_{10}, E_2–E_{11}, E_2–E_{12}, E_2–E_{13}, E_2–E_{14}, E_2–E_{15}, and E_2–E_{16} (Figure 16.9a), respectively.

Similarly, in the opposite method, each of all the other current projections (P_2, P_3, …, P_{15}, and P_{16}) yields 13 voltage data and hence, for a 16-electrode system, a complete scan with opposite current injection method yields $16 \times 13 = 208$ voltage measurements. Figure 61.9b shows the data collection process in P_2. But, in the opposite method also, due to the reciprocity [3], the measurements made on the boundary yield identical voltage data in which the E_C and E_V are interchanged [3]. Therefore, among the 208 differential voltage measurements made in the opposite method, only 104 data are independent from each other [3]. In the opposite method, the current distribution is more uniform [3] and, therefore, has a good sensitivity [3].

61.6.2.3 Cross Method

Hua et al. [24] proposed a current injection method called the *cross method* (Figure 61.10) in which a more uniform current distribution is obtained when the current signal is injected between a pair of more distant electrodes [24]. As shown in Figure 61.10a, in the cross method, adjacent electrodes E_{16} and

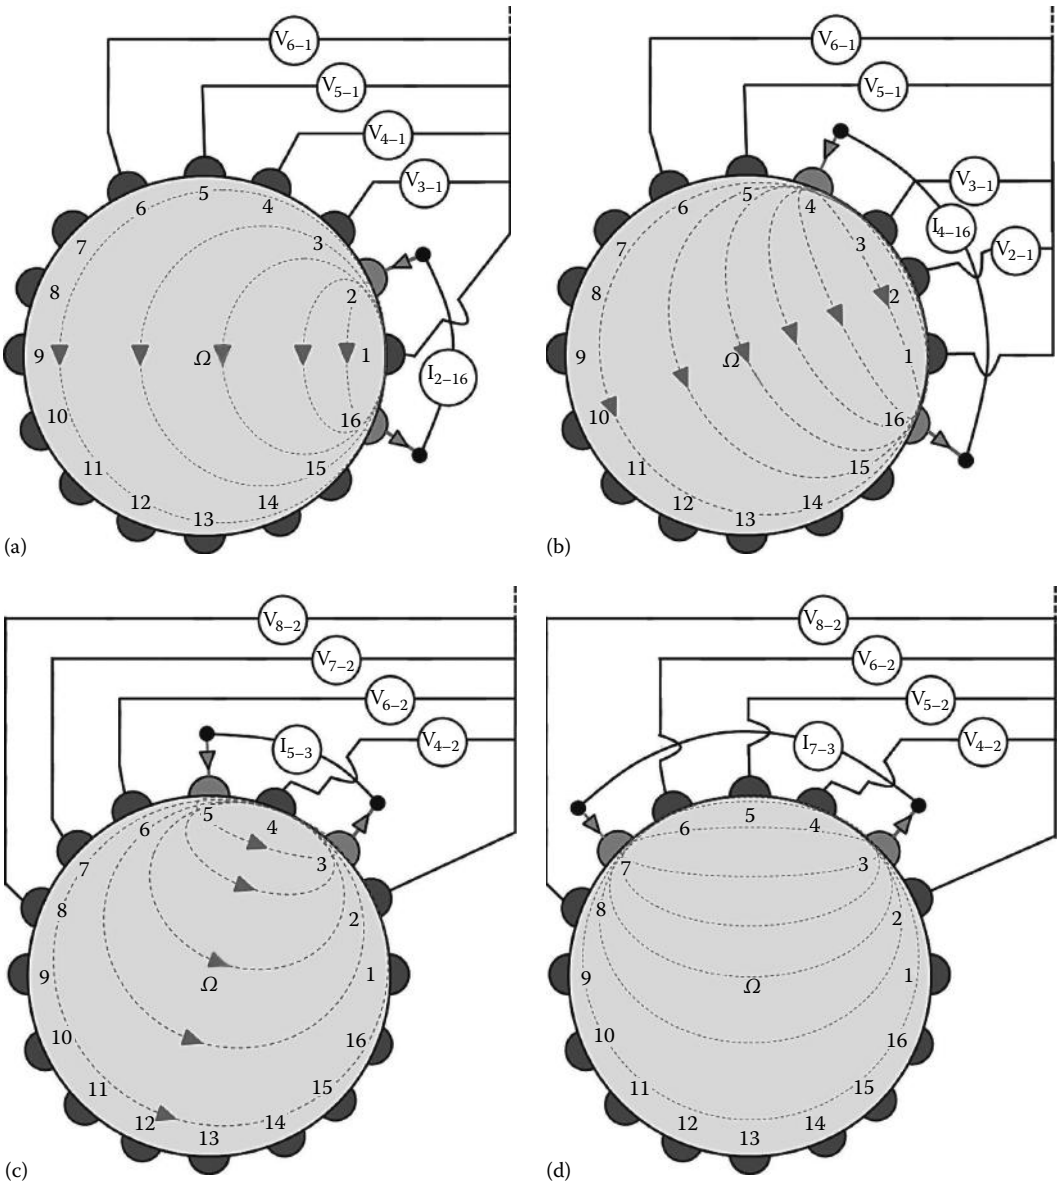

FIGURE 61.10 Cross method of boundary data collection: four different steps of this procedure are illustrated in (a) through (d).

E_1 are first selected as the current reference electrode (E_{CR}) and voltage reference electrode (E_{VR}), respectively. The positive terminal of the current source is connected to the electrode E_2, which acts as the positive current-injecting electrode. The 13 differential voltage data (V_d: V_1, V_2, V_3, … V_{13}) are measured successively across the 13 voltage electrode pairs obtained by combining 13 voltage electrodes (E_V: E_3, E_4, E_5, E_6, E_7, E_8, E_9, E_{10}, E_{11}, E_{12}, E_{13}, E_{14}, and E_{15}) with the voltage reference electrodes ($E_{VR} = E_1$) as shown in Figure 61.10a. Therefore, in the cross method, the P_1 yields 13 differential voltage data $V_1 = V_{1-3}$, $V_2 = V_{1-4}$, $V_3 = V_{1-5}$, $V_4 = V_{1-6}$, $V_5 = V_{1-7}$, $V_6 = V_{1-8}$, $V_7 = V_{1-9}$, $V_8 = V_{1-10}$, $V_9 = V_{1-11}$, $V_{10} = V_{1-12}$, $V_{11} = V_{1-13}$, $V_{12} = V_{1-14}$, and $V_{13} = V_{1-15}$ measured across the electrode pairs E_1–E_3, E_1–E_4, E_1–E_5, E_1–E_6, E_1–E_7, E_1–E_8, E_1–E_9, E_1–E_{10}, E_1–E_{11}, E_1–E_{12}, E_1–E_{13}, E_1–E_{14}, and E_1–E_{15} (Figure 61.10a), respectively.

In projection two (Figure 61.10b) another set of 13 differential voltage data are collected across the 13 voltage electrode pairs obtained by combining the 13 voltage electrodes (E_V: E_3, E_4, E_5, E_6, E_7, E_8, E_9, E_{10}, E_{11}, E_{12}, E_{13}, E_{14}, and E_{15}) with the voltage reference electrodes ($E_{VR} = E_1$). In this projection, the current injection is made by configuring the electrode 4 (E_4) as the positive current electrode and electrodes 16 (E_{16}) as the current reference (Figure 61.10b). With this current injection, the 13 differential potentials (V_d: V_1, V_2, V_3, … V_{13}) are measured successively across the 13 voltage electrode pairs obtained by combining the 13 voltage electrodes (E_V: E_2, E_3, E_5, E_6, E_7, E_8, E_9, E_{10}, E_{11}, E_{12}, E_{13}, E_{14} and E_{15}) with the voltage reference electrodes ($E_{VR} = E_1$) as shown in Figure 61.10b. Hence, in the cross method, the P_2 yields 13 differential voltage data $V_1 = V_{1-2}$, $V_2 = V_{1-3}$, $V_3 = V_{1-5}$, $V_4 = V_{1-6}$, $V_5 = V_{1-7}$, $V_6 = V_{1-8}$, $V_7 = V_{1-9}$, $V_8 = V_{1-10}$, $V_9 = V_{1-11}$, $V_{10} = V_{1-12}$, $V_{11} = V_{1-13}$, $V_{12} = V_{1-14}$, and $V_{13} = V_{1-15}$ measured across the electrode pairs E_1–E_2, E_1–E_3, E_1–E_5, E_1–E_6, E_1–E_7, E_1–E_8, E_1–E_9, E_1–E_{10}, E_1–E_{11}, E_1–E_{12}, E_1–E_{13}, E_1–E_{14}, and E_1–E_{15} (Figure 61.10b), respectively. Repeating this same procedure with a current injection by connecting the positive terminal of the current source to the electrodes E_6, E_8, …, E_{14}, other five projections (P_3, P_4, P_5, P_6, and P_7) are obtained. Hence, the cross method yields first seven projections (P_1 P_2 P_3 … P_6, and P_7) with the electrodes E_{16} and E_1 as current reference electrodes and voltage reference electrodes, respectively. Therefore, in this way the first seven current projections (P_1, P_2, P_3, …, P_6, and P_7) in cross method yield $7 \times 13 = 91$ measurements.

After collecting the 91 data from the projection P_1 through P_7, a similar measurement sequence is then repeated configuring electrodes E_3 and E_2 as current reference electrodes and voltage reference electrodes, respectively (Figure 61.10c). With positive terminal of the current source connected to the E_5, 13 voltage data (V_d: V_1, V_2, V_3, …, V_{13}) are measured successively across all the 13 voltage electrode pairs obtained by combining 13 voltage electrodes (E_V: E_4, E_6, E_7, E_8, E_9, E_{10}, E_{11}, E_{12}, E_{13}, E_{14}, E_{15}, E_{16}, and E_1) and the voltage reference electrodes ($E_{VR} = E_2$) as shown in Figure 61.10c. Therefore, in the cross method, this current projection (P_8) yields 13 differential voltage data $V_1 = V_{2-4}$, $V_2 = V_{2-6}$, $V_3 = V_{2-7}$, $V_4 = V_{2-8}$, $V_5 = V_{2-9}$, $V_6 = V_{2-10}$, $V_7 = V_{2-11}$, $V_8 = V_{2-12}$, $V_9 = V_{2-13}$, $V_{10} = V_{2-14}$, $V_{11} = V_{2-15}$, $V_{12} = V_{2-16}$, and $V_{13} = V_{2-1}$ measured across the electrode pairs E_2–E_4, E_2–E_6, E_2–E_7, E_2–E_8, E_2–E_9, E_2–E_{10}, E_2–E_{11}, E_2–E_{12}, E_2–E_{13}, E_2–E_{14}, E_2–E_{15} E_2–E_{16}, and E_2–E_1 (Figure 61.10b), respectively.

After collecting the set of 13 data from P_8, the procedure is just repeated by connecting the positive terminal of the current source to the electrodes E_7 (Figure 61.10d), and another set of 13 differential voltage data is collected (with the same current and voltage reference electrodes). Therefore, in P_9, the cross method yields 13 differential voltage data $V_1 = V_{2-4}$, $V_2 = V_{2-5}$, $V_3 = V_{2-6}$, $V_4 = V_{2-8}$, $V_5 = V_{2-9}$, $V_6 = V_{2-10}$, $V_7 = V_{2-11}$, $V_8 = V_{2-12}$, $V_9 = V_{2-13}$, $V_{10} = V_{2-14}$, $V_{11} = V_{2-15}$, $V_{12} = V_{2-16}$, and $V_{13} = V_{2-1}$ measured across the electrode pairs E_2–E_4, E_2–E_5, E_2–E_6, E_2–E_8, E_2–E_9, E_2–E_{10}, E_2–E_{11}, E_2–E_{12}, E_2–E_{13}, E_2–E_{14}, E_2–E_{15}, E_2–E_{16}, and E_2–E_1 (Figure 61.10d), respectively.

In the similar way, by connecting the positive terminal of the current source successively to the electrodes E_9, E_{11}, …, E_1, the cross method yields other five projections (P_{10}, P_{11}, P_{12}, P_{13}, and P_{14}), and similar sets of 13 voltage data are obtained with the aforementioned current and voltage reference electrodes. Hence, the cross method yields the other seven projections (P_8, P_9, P_{10}, …, P_{13}, and P_{14}) with the electrodes E_3 and E_2 as current reference electrodes and voltage reference electrodes, respectively. These seven projections give another set of $7 \times 13 = 91$ differential voltage measurements. Hence, the cross method has 14 projections yielding $91 + 91 = 182$ data. Among these 208 measurements, only 104 data are independent. Note that the cross method does not have as good a sensitivity in the periphery as does the neighboring method but has better sensitivity over the entire domain under test [3].

61.6.2.4 Adaptive or Trigonometric Method

In the aforementioned methods, current has been injected with a pair of current electrodes, and the differential voltage data have been measured between different pairs of voltage electrodes excluding the current electrodes. Gisser et al. [25] proposed a current injection method called the *adaptive method or trigonometric method* (Figure 61.11), in which the current is injected through all electrodes. Because current flows through all electrodes simultaneously, in the trigonometric method, as many independent

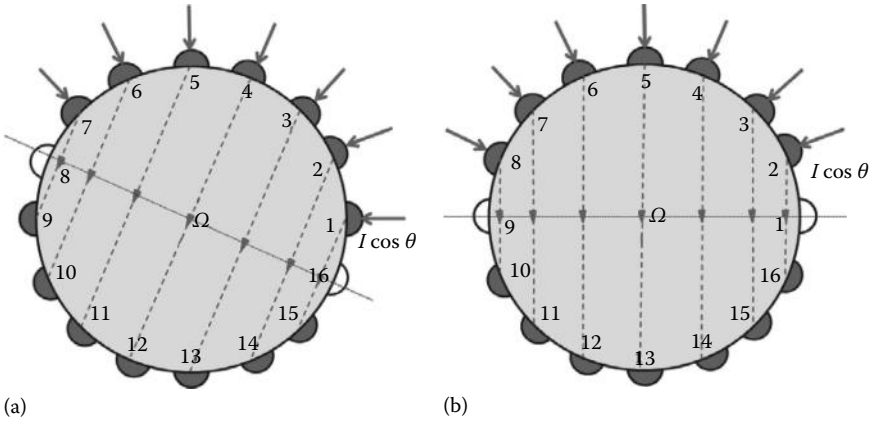

FIGURE 61.11 Adaptive or the trigonometric current injection method of voltage data collection: (a) projection 1 and (b) projection 16.

current injectors are needed as are the electrodes used in the system, and hence, a 16-electrode EIT system needs 16 current injectors. A current from $-I$ to $+I$ (I is any suitable RMS (root means square) amplitude of the current) can be fed to the electrodes, allowing different current distributions. Homogeneous current distribution may be obtained only in a homogeneous volume conductor. Hence, if the volume conductor is cylindrical with circular cross section, the injected current must be proportional to $\cos\theta$ to obtain a homogeneous current distribution (Figure 61.11). In the trigonometric method, the boundary potentials are measured with respect to a single grounded electrode and, hence, a 16-electrode EIT system, the trigonometric current injection method yields 15 voltage measurements in each current projections from projection 1 (Figure 61.11a) through projection 16 (Figure 61.11b). After collecting data from a particular projection (say P_1), the next projection (P_2) is obtained by rotating one electrode increment (22.5° for a 16-electrode system). Thus, for a 16-electrode EIT system, the trigonometric current injection method produces eight different current distributions yielding $8 \times 15 = 120$ independent voltage data.

Though the voltage measurements on current electrodes, sometimes, are avoided for contact impedance problem [26], in some present studies [9,22], measurements on current electrodes are also made to obtain the greatest sensitivity [22] to the resistivity changes in the domain under test. Hence, in this chapter EIT data collection strategies with the measurements on current electrodes in opposite and neighboring current injection are also discussed. Figure 61.12 presents the data collection procedures for both the current injection methods in which the boundary potentials are measured on all the electrodes including the current electrodes to obtain the greatest sensitivity to the resistivity changes in the domain.

Bera and Nagaraju [9] collected voltage data on all the surface electrodes for their practical phantom studies. In their data collection scheme with opposite pattern, current is injected through two diametrically opposed electrodes, and the potentials are measured on all the electrodes with respect to the ground point of the analog electronics (Figure 61.12a). Similarly, in the neighboring method, current is applied through two neighboring electrodes (Figure 61.12b) the potentials are measured on all the electrodes with respect to the ground point of the analog electronics (Figure 61.12b). Hence, for the 16-electrode system reported by Bera and Nagaraju, there will be 16 current projections (P_1, P_2, P_3, P_4, P_5, P_6, P_7, P_8, P_9 P_{10}, P_{11}, P_{12}, P_{13}, P_{14}, P_{15}, and P_{16}), each of which yields 16 voltage measurements (V_1, V_2, V_3, …, V_{16}) made on all the 16 electrodes (E_1, E_2, E_3, …, E_{16}) respectively. In opposite current method, RMS potentials on all the electrodes (including current electrodes) were measured for 16 current projections (Figure 61.12a), and the complete voltage data sets (containing 256 voltage data) were saved as a *.txt* file in a PC for computation. Bera and Nagaraju reported that the first 128 data collected from the first eight current projections (P_1 to P_8) were found independent from each other. Therefore, the boundary potentials were collected only for the first eight current projections (P_1 to P_8),

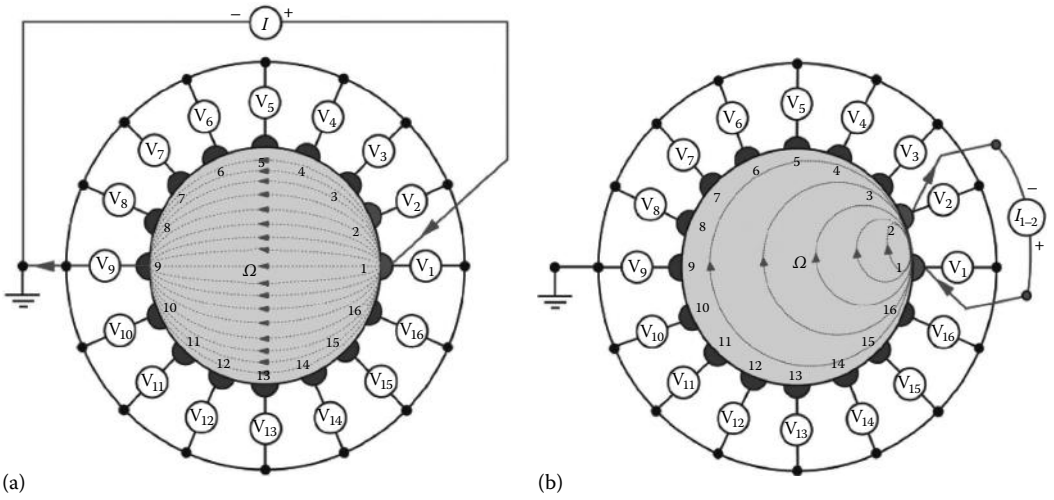

FIGURE 61.12 Current injection and voltage measurement at the phantom boundary: (a) opposite method and (b) neighboring method.

which yield $16 \times 8 = 128$ data. It was observed that the first 128 data collected in P_1 through P_8 are sufficient to reconstruct the resistivity images of the phantom domain [9]. Hence, in the opposite current injection method, instead of 256 voltage data, only 128 data (obtained from first current projections P_1, P_2, P_3, P_4, P_5, P_6, P_7, and P_8) are collected, and hence, the boundary data were not collected for the next eight current projections (P_9–P_{16}). Thus, the data collection time was reduced to 50% of the time required for a complete scan [9].

In the neighboring method with all electrode measurement, as reported by Bera and Nagaraju, the potentials were also measured on all the electrodes (Figure 61.12b) including the current electrodes to obtain the greatest sensitivity to the resistivity changes in the domain. Therefore, a 16-electrode system as reported by Bera and Nagaraju yields 16 current projections (P_1, P_2, P_3, P_4, P_5, P_6, P_7, P_8, P_9 P_{10}, P_{11}, P_{12}, P_{13}, P_{14}, P_{15}, and P_{16}), each of which gives 16 voltage measurements (V_1, V_2, V_3, …, V_{16}) made on all the 16 electrodes (E_1, E_2, E_3, …, E_{16}), respectively, as shown in (Figure 61.12b). Hence, in the neighboring current method, 16 current projections yield 256 voltage data that are used to reconstruct the resistivity images.

61.6.3 Electrode Materials

Electrodes in EIT are essentially required for injecting current and measuring potentials. Though different materials have been used for EIT electrodes, the stainless steel (SS) electrodes are found more common in phantoms and Ag/AgCl electrodes are found very popular for human body imaging in EIT. The sections that follow present a brief review of the electrode materials used for EIT sensors.

61.6.3.1 Stainless Steel Electrodes

Griffiths and Zhang [27] used SS electrodes in their phantom developed for a dual-frequency EIT system. Goble [28] used an SS electrode array for his 3D phantom developed for studying the 3D electrical impedance imaging. Boone and Holder [29] reported a saline-filled tank (88 mm diameter; 30 mm depth of 0.09% saline; SS electrodes of 8 mm diameter) developed for assessing their EIT system for imaging the neuronal depolarization in the brain using "direct current" electrical resistance tomography. Holder et al. [30] developed a number of practical biological phantoms with SS electrodes for calibrating multifrequency EIT. Goharian et al. [31] reported a phantom developed with a cylindrical phantom tank (made of acrylic plastic, 10 cm tall with a radius of 5 cm) housed with 48 circular SS electrodes (radius of each electrode was 0.3 cm) in three rings (each ring consisting of 16 electrodes with

interelectrode gap was 1.35 cm and located radially around the cylinder). The inhomogeneities were a metal rod and a plastic rod. Romsauerova et al. [32] developed a saline phantom with SS electrodes for studying the initial findings in brain tumors, arteriovenous malformations, and chronic stroke. Boyle et al. [33] developed a deformable phantom constructed with a sponge rubber plumbing gasket placed in a shallow pan and 16 SS wire electrodes. The gasket formed a thick rubber ring that was easily compressed when required, and it was rigid enough to return to its original shape easily.

61.6.3.2 Ag/AgCl Electrodes

Jossinet and Trillaud [34] investigated an EIT system using Ag/AgCl ECG electrodes. The boundary data measurements were obtained in vitro in a cylindrical tank filled with saline and in vivo using standard ECG electrodes. Holder et al. [35] reported a study on the superior surface of the cerebral cortex of paralyzed and artificially ventilated animals. The cerebral cortex was exposed by making a circular craniotomy, 20 mm in diameter; the dura mater was cut away to reveal the pia mater. A circular array of 16 Ag/AgCl spring-mounted ball electrodes, each about 1 mm in diameter, was placed on the surgically exposed dorsal surface of the cortex. Yerworth et al. [36] developed a spherical tank phantom (diameter 20 cm) filled with 0.2% saline and imaged a cylinder of banana. The phantom was built with 31 Ag/AgCl disk electrodes and imaged with the new UCLH Mk2 system. Tidswell et al. [37] tested the performance of the three types of commercially available headnet electrode arrays, designed for use in EEG, and conventional EEG Ag/AgCl cup electrodes on human subjects and a saline-filled head-shaped tank. The phantom tank was prepared with vegetable skin to simulate human skin in order to determine the optimum electrode system for EIT of the human head. Gilad et al. [38] reported the studies on the standard Ag/AgCl EEG cup electrodes (11 mm diameter) applied to abraded skin under the electrodes area using Ten20 conductive EEG paste (D.O. Weaver and Co., Aurora, CO). Author employed a conical recessed electrode design, which was made from polyoxymethylene (POM), filled with Ten20 conductive EEG paste, and had an Ag/AgCl disk, 14 mm diameter, at the vertex and circular opening to abraded skin of diameter 21 mm. Rahal et al. [39] investigated the impedance of various clinical electrodes as a function of frequency to identify the optimum electrode type. They studied six different types of self-adhesive electrodes commonly used in general and neonatal cardiology. Robitaille et al. [40] developed a practical phantom with Ag/AgCl electrodes for studying their EIT system developed for human brain function imaging. They constructed a realistically head-shaped tank using a silicone rubber cast of a head-shaped model made from a human skull covered with clay. Thirty-one Ag/AgCl electrodes (1 cm diameter each) were embedded into the inner walls of the tank filled with 0.2% saline to represent the brain. Xu et al. [41] studied the performance of the five common types of Ag/AgCl bioelectrodes by measuring the forearm and the brain of 10 healthy adult volunteers and evaluating those data in frequency or time domain in terms of contact impedance, uniformity, signal-to-noise ratio (SNR), and stability. They reported that the Ag/AgCl powder electrode has an overall best performance with as low contact impedance as commercial ECG electrodes ($p > 0.05$), high SNR (60.3 ± 4.5 dB), better uniformity (coefficient of correlation 0.95 ± 0.03), and greater stability (slope 0.68 ± 0.03).

61.6.3.3 Carbon Electrodes

Huang et al. [42] developed a rotating electrode phantom for EIT using carbon electrodes to increase the number of independent measurements. The rotating carbon electrode system increased the number of independent measurements, which enhanced the resolution of the impedance image and improves the quality arising from the ill-posed condition.

61.6.3.4 Brass Electrodes

Thomas et al. [43] reported a phantom with brass electrodes to study the correction of the nonuniform spatial sensitivity of EIT images. In their studies they developed a cylindrical Perspex tank (40 cm high with an inside diameter of 17 cm). The tank was drilled to accept 16 equi-spaced brass electrodes around the circumference of the tank, 15 cm from its threaded end.

61.6.3.5 Platinum–Iridium Electrodes

Gissert et al. [44] designed and developed a platinum–iridium electrode array for EIT for application to biological systems like the thorax. They developed the system containing 32 electrodes fashioned from a titanium plate having a platinum–iridium surface. The electrodes were attached to the interior surface of a circular plastic container 30 cm in diameter, 6.5 cm deep. The electrodes were 28.4 mm wide (with a 1 mm interelectrode gap) and extend throughout the depth of the container.

61.6.3.6 Textile Electrodes

Rahal et al. [39] investigated impedance imaging with textile electrodes and other types of Ag/AgCl electrodes for identifying the optimum electrode type in EIT.

61.6.4 Thin-Film-Based Flexible Electrodes

EIT electrodes are commonly made up of metals or metal composites. But as we have seen in the previous sections, SS electrodes and Ag/AgCl electrodes are most commonly used as surface electrodes in practical EIT systems. SS electrodes have been frequently used in practical phantoms due to their easy availability, profound rigidity, chemical and electrochemical stability, noncorrosiveness, and biocompatibility. Ag/AgCl electrodes are found very popular in medical EIT systems for their improved electrical performance characteristics and low half-cell potentials. But a special electrochemical process is to be carried out to coat the silver electrodes by AgCl layers for making an Ag/AgCl electrode. Moreover, AgCl is relatively a poor conductor [45]. Hence, increasing its layer thickness causes an increase in contact impedance, which adversely affects the boundary data accuracy in high-frequency EIT [45]. Bera and Nagaraju [46,47] proposed a flexible thin-film gold electrode array for impedance imaging in biomedical EIT for improved impedance imaging. They reported their research work on gold electrode phantoms and compared the gold electrode array performance with an identical SS electrode array.

61.6.4.1 Thin-Film-Based EIT Sensor Development

Bera and Nagaraju developed a flexible gold electrode array by depositing a gold thin film on a flexible FR4 sheet with a critical bending angle (θ_c) of 45° using an electrodeposition process. The copper patterns (Figure 61.13) of 16 identical electrodes (equally spaced with an interelectrode gap of 6.75 mm)

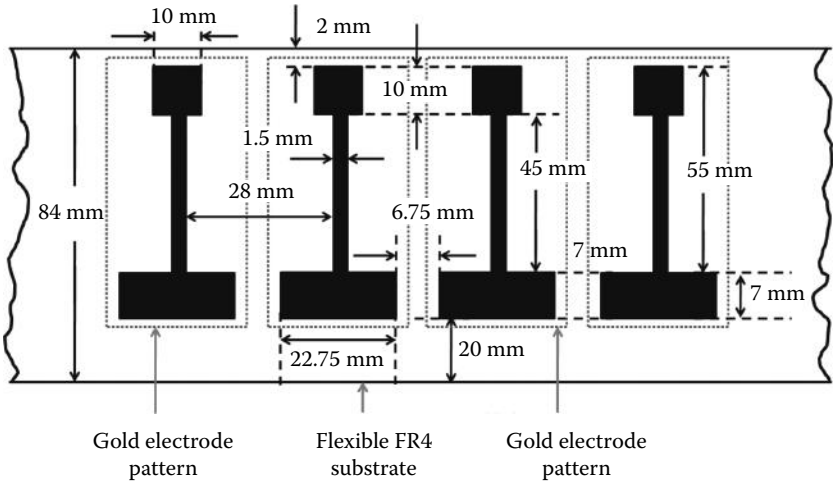

FIGURE 61.13 Electrode layout design: gold layer patterns.

with rectangular active electrode area (width 22.75 mm, height 7 mm) are made on a copper-cladded (copper layer thickness 35 μm) flexible FR4 sheet (200 μm thickness) using UV light lithography process with a proper electrode mask (Figure 61.14). Copper patterns made on the FR4 sheet are electroplated by a Ni layer of 2 μm thickness (Figure 61.15). Finally, the patterns are electroplated with a 2 μm thick gold layer and the gold electrode array is obtained (Figure 61.16a).

Thus, the electrode patterns in the gold electrode array (Figure 61.16a) are composed of a 2 μm thick gold layer, 2 μm thick Ni layer, and 35 μm thick copper layer (Figure 61.15). For comparison studies an SS electrode array (Figure 61.16b) was also developed with 16 rectangular electrodes identical to the electrodes in the gold array. Sixteen rectangular strips (width = 22.75 and height = 95 mm) were cut from an SS sheet (type-304, thickness = 50 μm). The SS strips are sandwiched between two flexible plastic sheets keeping the electrode areas (width = 22.75 mm, height = 7 mm) and the connecting pad open (Figure 61.16b).

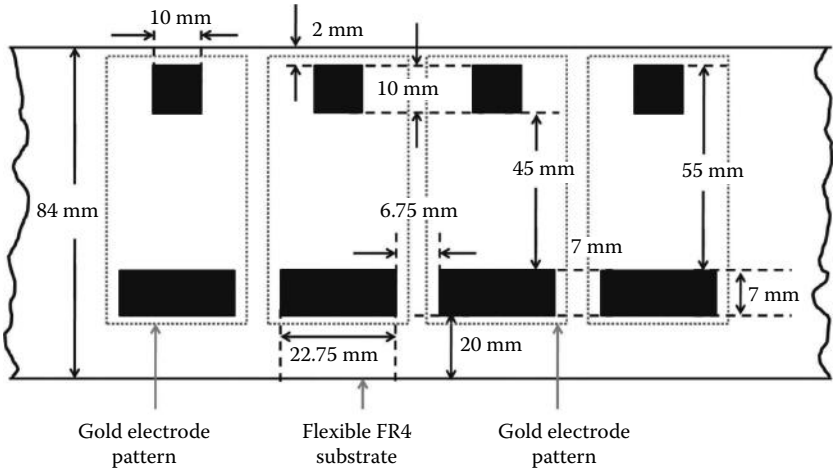

FIGURE 61.14 Schematic of the electrode patterns: mask design for lithography.

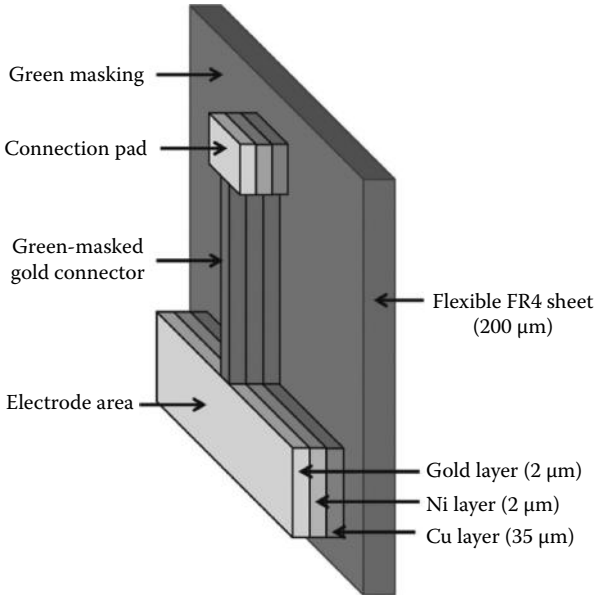

FIGURE 61.15 Schematic of the electrode patterns.

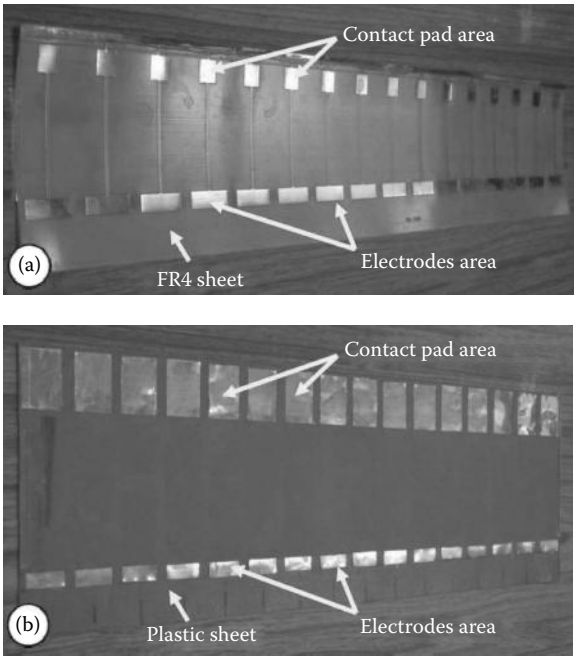

FIGURE 61.16 Developed flexible electrode arrays: (a) electroplated gold electrode array and (b) SS electrode array.

61.6.4.2 Gold Electrode Phantoms

Bera and Nagaraju reported the resistivity imaging studies with a gold electrode phantom (Figure 61.17a), and they compared the results with identical SS electrode phantom (Figure 61.17b). They reported that the gold electrodes were found suitable to connect directly to the copper wire by soldering, and hence, the contact impedance problem was reduced. The gold electrode array was put inside nylon tanks (diameter = 150 mm), and a thin layer of silicone glue was applied at the junction of the electrode array. The tank was filled by 0.9% (w/v) NaCl solution as the bathing solution of the EIT phantom. A common-mode electrode (CME) [46,47] was placed at the phantom center (Figures 61.17a and b) and connected to the ground point of the EIT hardwires to reduce the common-mode error [48] of the electronic circuits.

Nylon cylinders (diameter = 35 mm) were placed inside the phantom, and the boundary potentials were measured by injecting 1 mA, 50 kHz sinusoidal current signal using the opposite current injection protocol. Boundary potential data and electrode contact impedance parameters were analyzed [46,47].

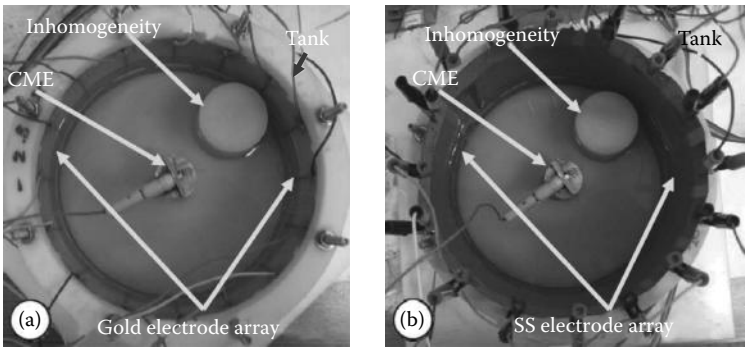

FIGURE 61.17 Phantoms with flexible electrodes: (a) SS electrode array inside the tank and connected with steel alligator clips and (b) gold electrode array inside the tank and soldered with the connecting wires.

Resistivity images were reconstructed using the Electrical Impedance and Diffuse Optical Reconstruction Software (EIDORS) [49] with a FEM (finite element method) mesh [50] containing 1968 elements and 1049 nodes. Boundary potential profiles and the resistivity images obtained with gold electrode array were compared with the SS electrode phantom with identical configurations.

Results reported by Bera and Nagaraju [46,47] demonstrated that the gold electrode array was found highly conductive, flexible, chemically stable, biocompatible, and noncorrosive in all natural circumstances compared to SS electrodes. Geometrically, gold electrode array was found more accurate to the required design exhibiting uniform and low contact impedances compared to the SS one. Electrodes in the SS electrode array were connected to the wires with steel clips as the soldering was found difficult for SS connecting pads. Hence, the electrode–wire contact impedances were found large and dissimilar for the individual electrodes in the SS electrode array. Electrode-to-electrode impedance ($Z_{\text{E-E}}$) [46] and electrode-to-CME impedance ($Z_{\text{E-CME}}$) [46] are measured, and it is observed that both the impedances are more uniform and small for gold electrode array [46] compared to the SS electrodes.

Result reported by Bera and Nagaraju [46] also showed that the standard deviation (STDV) in the $Z_{\text{E-CME}}$ [46] and $Z_{\text{E-E}}$ [46] was less for gold electrode array. Phase angles of $Z_{\text{E-CME}}$ ($\theta_{\text{E-CME}}$) and $Z_{\text{E-E}}$ ($\theta_{\text{E-E}}$) and their electrode-to-electrode variations were found also less for gold electrode array compared to the SS array [46]. They reported that the gold electrode pairs offered more uniform and low impedance path compared to that of the SS array [46] by assuming the NaCl solution has uniform resistivity throughout the whole medium.

Boundary data were collected with homogeneous medium for both the SS electrode array and the gold electrode array. It was observed that the boundary data collected from the SS electrode array were noisier than that of the gold electrode array [46]. Results showed that the boundary potential data as well as the mean boundary potential data obtained with gold electrode array were more symmetric [46] for all the 16 current projections than the data obtained from the SS electrode system. It was also noticed that the SNR of the gold electrode system was greater than that of the SS electrode system [46]. The resistivity images with gold electrode array were found with better image contrast and better spatial resolution [46]. The background noise in the reconstructed images was also found less for the gold electrode array [46]. The diametric resistivity plots (DRP) [46] of the resistivity images obtained with gold electrode system showed that the reconstructed resistivity profiles were found better and closer to the original domain resistivity profiles [46] compared to the SS electrode array.

Bera and Nagaraju also studied the gold electrode array performance for real tissue imaging and compared the results with an identical real tissue phantom with SS electrodes [47]. Bera and Nagaraju calculated the image parameters from the elemental resistivity profiles and assessed the resistivity images. IR_{Mean} [9,51,52], BR_{Mean} [9,52], CNR [9,52,53], PCR [9,52,53], COC [9,52,53], and DRP [46,52] were studied, and the reconstructed images were evaluated for both the phantoms. The reported results demonstrated that the resistivity images with gold electrode array were found with better image contrast and better spatial resolution with low background noise [47]. The DRP of the resistivity images obtained with gold electrode real tissue phantom showed that the reconstructed resistivity profiles were found closer to the original DRPs [47].

61.7 Electrode Size

Reconstructed image quality depends on the surface electrode performance and the electrode performance is dependent on electrode material as we discussed in the earlier section. One more factor that affects the electrode performance is electrode geometry, that is, electrode shape, electrode size or electrode area, and electrode position in the phantom or object boundary. Hence, the boundary potential profile is found dependent on the electrode size in EIT studies. A number of researchers have tried to find the optimum electrode size for better performance. The following section will present a literature survey conducted on the research work carried out on the electrode size and other electrode geometric parameters.

Luo et al. [54] investigated the best type, size, and location of electrodes for EIT for ventilation measurements. They compared the electrode performance and reported that adhesive-gel electrodes are easy to apply, make good body contact, and do not slip during the experimentation. They also reported that higher SNRs were obtained when electrode area was increased by connecting several small electrodes together rather than by using a single electrode with a larger area [54]. Yan and Hong [55] presented a method for EIT electrode structure and parameter optimizing design. They took an example for a compound electrode that was based on the coercive equipotential node model of line electrode. They also developed a simulation research software platform for electrode structure and parameter optimizing design. They anticipated that by the method proposed, the different influences of electrode structure and parameters on the reconstructed image can be obtained along with an estimation of the system sensitivity. They also expected that their method would provide the theory basis for the optimum design of the surface electrode structure in real EIT systems. Yan et al. [56] presented a method to optimize the EIT electrode structure and parameters based on coercive equipotential node models. The coercive equipotential node model of the compound electrode was established based on that of the line electrode. Using a simulation software platform, the line electrode and the compound electrode of EIT were studied. The authors also studied the influences of different electrode structures and parameters on measurement sensitivity and the image reconstruction quality. From simulation studies they reported that a narrower electrode was found helpful in improving the imaging quality and using too wide an electrode causes the measurement sensitivity to decrease, although it is known that a wider electrode is beneficial in decreasing the contact impedance. They also reported that the electrode width leading to the best measurement sensitivity is different for different measurement depths. The author expressed the design aspects of the compound electrodes with four parameters, which have mutual restrictions and complex influences on each other. The four parameters mentioned in their report were the excitation electrode width, the measurement electrode width, the space between the excitation electrode and the measurement electrode, and the distance between two adjacent compound electrodes. Authors concluded that it is not advised to optimize the design of a compound electrode by only using the overlay rate of electrodes.

61.8 Compound Electrode

Hua et al. [57] described the use of compound electrodes to improve the conditioning and sensitivity of our EIT imaging system. They discussed effects of electrode–skin contact impedance by showing the reconstructed results of data from phantom measurements. Hua et al. [58] developed a compound electrode composed of two electrodes: a large outer electrode to inject current and a small inner electrode to sense voltage. They measured the surface potentials from a physical phantom using these compound electrodes and showed that the measured voltages from the compound electrodes were smaller in amplitude than those from conventional electrodes, which demonstrated that the compound electrode can minimize contact impedance voltage drop from the measured data.

61.9 Active Electrode

Rigaud et al. [59] proposed active current electrodes for in vivo EIT. To increase the measurement accuracy, the authors studied the active approach for limiting the buffer input stray capacitance by positive feedback. Limitations of this technique were also discussed. Jossinet et al. [60] developed active current electrodes for in vivo EIT by designing and fabricating accurate and reproducible current generators for high-frequency EIT. The authors reported that the frequency range used was limited to 2048 kHz. They reported that sorting the components resulted in low, reproducible output conductances (0.85 μS), which reduced the influence of electrode mismatch. They also reported that the low variability (±2%) of the output admittance provided a facility of accurate current injection and reduced the common-mode signal applied to the differential amplifiers. Lead capacitance problems were removed due to the encapsulation of

the current source within the electrode shell, and therefore, it enabled the use of a high-frequency signal up to 2048 kHz. Li et al. [61] developed a wide-band high-speed EIT data acquisition system with active electrodes and its application was studied in cardiac imaging. They developed fast data acquisition with 32 active electrodes, half of them as receive electrodes and the other half as drive electrodes. The active electrode system was developed by providing a buffer mounted on the back of each receive electrode and a current source on each drive electrode. Gaggero et al. [62] presented the design and initial tests of an active electrode-based system to address the difficulties associated with the electrode contact impedance problem and the electrode placements on human subject. They developed an active electrode belt for EIT, which was designed and developed with 32 active electrodes containing the electronic amplifiers, switches, and associated logic. Experimental results showed stable device performance with a convenient ease of use and good imaging ability in volunteer tests. Gaggero et al. [63] developed and presented an active electrode-based EIT electrode belt system. The active electrode EIT system incorporated an active electrode belt, a central voltage-driven current source, central analog-to-digital converters and digital-to-analog converters, and a central FPGA-based demodulator and controller. The electrode belt was designed with 32 active electrodes containing the electronic amplifiers, switches, and associated logic. A stable device performance with a convenient ease of use and good imaging ability was observed in practical experimentation.

61.10 Electrode Number

An EIT system collects voltage data developed for a constant current injection through a set of electrodes or EIT sensors attached to the domain under test. Spatial resolution depends on the number of electrodes, but the optimum number of electrodes is decided by the computation facilities available and the computation time permissible. The electrode number is also restricted by the circumferential area of the domain to be imaged. The minimum number of electrodes used for the EIT as reported by the researchers is eight [64]. The 16-electrode EIT system is very popular in EIT imaging. Though most of the other EIT systems have an electrode number that is $2^{(3+N)}$ ($N = 0, 1, 2, 3...$), other EIT systems are also reported with electrodes other than $16*N$. The following section will present a brief literature survey conducted on the EIT system with different electrode numbers proposed by the different research groups. Though the survey shows that the electrode array of a practical EIT system generally contains $2^{(3+N)}$ where N is an positive integer ($N = 1, 2, 3, \ldots$), a few systems have electrodes other than this number series.

61.10.1 8-Electrode System

Yu et al. [64] proposed an 8-electrode rotative EIT system with eight carbon rods working as the electrodes dipped inside the saline phantom. Huang [65] developed an 8-electrode EIT system with eight carbon rods working as the electrodes dipped inside the phantom filled with saline. The electrode system was attached to a rotating system developed with an electrical motor, and the boundary data measurements were conducted each after rotation of the electrode system.

61.10.2 12-Electrode System

Ito et al. [66] proposed a 12-electrode EIT system for measuring of body fat distribution by using EIT. Alme et al. [67] developed and studied a 12-electrode EIT system for analyzing 3D and conductivity effects in electrical tomography systems using COMSOL multiphysics EM module.

61.10.3 13-Electrode System

Linderholm et al. [68] proposed a 13-electrode EIT system for probing of multilayered tissue phantoms. They developed the electrode array system of the proposed EIT system using microelectrodes.

61.10.4 14-Electrode System

Kimoto and Shida [69] developed and studied a 14-electrode EIT system for imaging of temperature-change distribution in the brain phantom by means of capacitance measurement.

61.10.5 16-Electrode System

The 16-electrode EIT system has been developed and studied by several groups such as Huang et al. [42], Shuai et al. [70], Hartinger et al. [71,77], Robitaille et al. [40], Griffithst et al. [22,72], Boyle et al. [33], Hahn et al. [29,73,78], Holder et al. [30], Thomas et al. [43], Yu et al. [64], Alme et al. [67], McArdlet et al. [74], Sadleiry and Foxz [75], Bera and Nagaraju [7,9,11,46–47,50–53], and Vauhkonen et al. [76].

61.10.6 31-Electrode System

Bagshaw et al. [79] developed and studied a 31-electrode EIT system for the imaging of human brain function. Yerworth et al. [36] developed a spherical tank phantom (diameter 20 cm) filled with 0.2% saline and imaged a cylinder of banana. The phantom system was developed with 31 Ag/AgCl disk electrodes and imaged with the new UCLH Mk2 system.

61.10.7 32-Electrode System

Gissert et al. [44] developed the system containing 32 electrodes fashioned from a titanium plate having a platinum–iridium surface, and the electrodes were attached to the interior surface of a circular plastic container 30.0 cm in diameter, 6.5 cm deep. The electrodes were 28.4 mm wide (with a 1.0 mm interelectrode gap) and extended throughout the depth of the container. Cook et al. [80] developed a 32-electrode EIT system, ACT3, for high-speed, high-precision EIT.

61.10.8 60-Electrode System

Boverman et al. [81] developed a 60-electrode test phantom for 3D mammography geometry and studied EIT imaging and formulated, implemented, and experimentally demonstrated a procedure using the complete electrode model (CEM) to compensate for poor electrode contact.

61.10.9 64-Electrode System

Yerworth et al. [82] reported a 64-electrode 3D EIT system called the UCLH Mark 1b. UCLH Mark 1b is a portable EIT system that can address up to 64 electrodes, which has been designed for imaging brain function with scalp electrodes.

61.10.10 128-Electrode System

Xu et al. [83] developed a 128-electrode 3D EIT system for impedance change detection and 3D imaging of the human thorax. The proposed system was made up of several modules, including multifrequency current source, driving, measuring, data acquisition, and controlling and signal processing modules. A high-speed digital signal processor (DSP) was used as the controller. The 128-electrode system was developed with 64 driving electrodes and 64 measuring electrodes, and all the electrodes were positioned uniformly in four planes around the surface of a cylindrical phantom filled with a saline solution and objects of varying conductivities.

61.11 Rotating Electrodes in EIT

Huang et al. [84] developed a high-performance rotational EIT (REIT) system capable of producing better-quality EIT images by increasing the number of independent measurements. The REIT system was constructed with the electrodes attached to a rotational phantom tank driven by a stepper motor. The REIT phantom was developed with a plastic tank (110 mm in height and 180 mm in diameter) and 16 compound electrode lines placed on the inner surface of the tank. The compound electrode contained a voltage electrode and a current electrode. Since the accuracy of measurements depends on the electrode geometry, in EIT it is essential to optimize the design parameters, especially their size and shape. The current electrodes were designed with a large surface area required in obtaining the uniform current density, and the voltage electrodes were designed with a small surface area that is optimal so as to avoid the influence from other equipotentials. Huang et al. constructed their current electrode from a rectangular copper slice (20 mm in width, 90 mm in height, and 0.5 mm in thickness) and voltage electrode from a copper bar (3 mm in width, 50 mm in height, and 0.5 mm in thickness) isolated by insulating tape. Using the stepper motor, the system was capable of obtaining a precise measurement, and the number of independent measurements was increased for enhancing the resolution of the impedance image. The experimental results demonstrated that the quality of the REIT images was improved by expanding the independent measurements.

61.12 Pseudo Electrodes in EIT

The quality of impedance image in EIT is limited by the number of electrodes attached to the object boundary. Yu et al. [85] proposed pseudo electrodes for EIT for enhancing the image quality. They obtained the expanded pseudo electrodes by changing the measuring sites of the physical electrodes. The number of independent measurement was increased. The result demonstrated that the pseudo electrode system improves the image quality in EIT. However, the authors reported that the large number of measurement data obtained from pseudo electrode driven pattern would cause serious problem in image reconstruction [85].

61.13 Other EIT Electrodes

61.13.1 Esophageal Electrode

Tehrani et al. [86] developed esophageal electrodes to investigate the improvements of the measurement on EIT and initial conductivity estimation of the internal electrode by modeling an internal electrode inside the esophagus.

61.13.2 Monopolar Needle Electrodes

Martinsen et al. [87] presented a study on invasive EIT for blood vessel detection using monopolar needle electrodes. They presented a novel method for localization of large blood vessels using a bioimpedance-based needle positioning system on an array of ten monopolar needle electrodes.

61.13.3 Silver Ink Electrodes

McAdams et al. [45] reported a study on the optimal electrolytic chloriding of silver ink electrodes for use in EIT. They reported that there is an optimal AgCl layer thickness which minimizes the interelectrode impedance at a given frequency. Authors reported that as this thickness is less for high frequencies, the EIT electrode systems require only relatively thin layers of AgCl.

61.13.4 Nonstationary Electrodes

Murphy et al. [88] developed an EIT system with nonstationary electrodes to improve the levels of recoverable image content by attaching electrodes to a rotating central impeller. They incorporated the rotational motion of the electrode array into an optimized measurement strategy, which provided more independent measurements without compromising the stability of a consistently regularized inverse solution.

61.14 Electrode Models

Different electrode models have been presented by researchers to explore the optimum electrode model providing better performance. They are continuum model [89], gap model [89], shunt model [89], and complete electrode model [89].

61.15 Electrodes of 3D EIT

In 2D electrical impedance tomography (2D EIT), the resistivity distribution is reconstructed by assuming that the electrical current is confined within a 2D electrode plane (plane of interest). But in the real case the electrical current is conducted in a 3D space within the volume conductor. Hence, the boundary data measured for 2D EIT are extensively influenced by the 3D conduction of electrical current. As a result 2D EIT imposes one more assumption, which reduces the accuracy of the resistivity assessment by solving the inverse ill-posed problem of EIT. Therefore, 3D EIT (Figure 61.18) was introduced for better assessment of the resistivity distribution. Moreover, a 3D EIT [90] provides 3D impedance distributions with a 3D visualization of the object interiors, which helps the doctors to get a more clear and more accurate insight of the body of the patient during diagnosis and treatment.

In 3D EIT (Figure 61.18) the boundary data from the 3D SUT using multiple electrode arrays placed at the different planes of interest within the SUT. Generally, three separate planes are chosen for data collection in 3D EIT though more planes give more boundary data, which facilitate the inverse solution with more computation time and extra cost. The data collection procedure from the surface electrodes in 3D EIT is similar to the 2D EIT only, and the number of arrays is more in 3D EIT. In the medical imaging procedure, the surface electrodes are stacked on the patient body in three different planes within the volume of interest [90]. Similarly in 3D EIT applied in multiphase flow imaging in process tomography, the fluid pipe is provided with three or more different electrode arrays placed at three or more different planes.

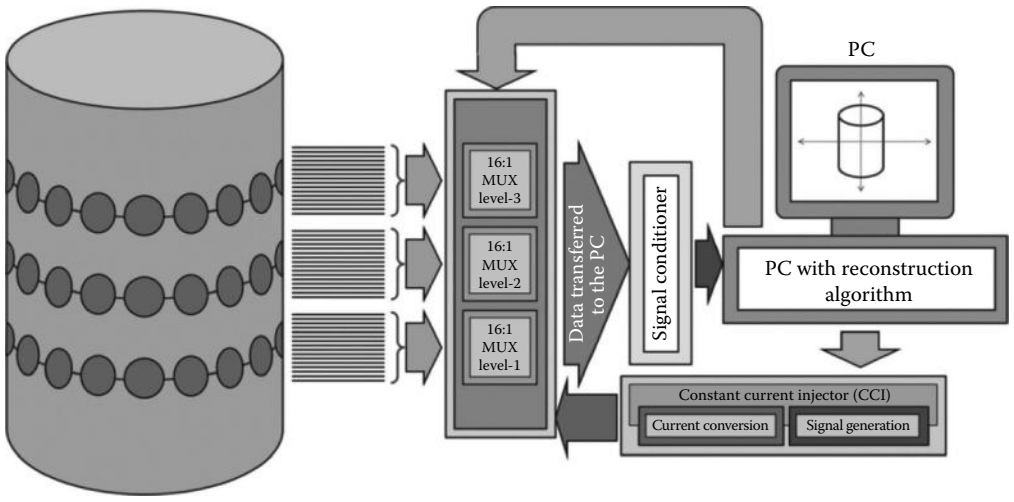

FIGURE 61.18 3D EIT schematic: phantom with multiple layers of electrodes and the data acquisition system.

TABLE 61.1 Various Errors Produced by the Electrodes and EIT Hardware

Authors	Most Significant Error Factor
Brown and Seagar [91]	Input stray capacitance
Sakamoto et al. [92]	Amplifier noise
Jossinet and Trillaud [93], Trillaud and Jossinet [94]	Mismatches between amplifiers, inadequate CMMR
Record et al. [95]	Multiplexers capacitance
Rigaud et al. [96]	Common-mode current injection
McLeod et al. [97]	Multiplexer capacitance
Riu et al. [98]	Common-mode current injection
Sansen et al. [99]	Interchannel stray capacitance
Record and Hargreaves [100]	Unequal electrode impedance

61.16 Errors of EIT Electrodes and Hardware

The EIT systems always suffer from several errors associated to the electrodes, phantoms and the electronic hardware. Boone and Holder [10] presented a summary of research work reporting on the various errors produced by the different parts of the EIT hardware.

The most significant source of errors produced by the electrodes and the associated EIT hardware as suggested by researchers are given in Table 61.1 [10].

61.17 Conclusions

EIT electrodes or EIT sensors are required to interface the EIT hardware with the object under test (i.e., patient) for current injection and boundary data collection. Therefore, in EIT, the surface electrodes play a very crucial role in the boundary data accuracy as they contribute a number of errors produced by electrode geometry, electrode number, electrode materials, improper electrode modeling, electrode–patient interfaces/contact impedance, and electrode–wire connections. The electrode size and electrode number are considered as the major influencing factors for the image quality and image resolution, respectively. It is reported that the electrodes with large contact area are preferred for current injection to minimize contact impedance, and the voltage-measuring electrodes are preferred with small contact area to obtain the maximum SNR. The wider electrodes can decrease the contact impedance between the electrode and skin, but the maximum possible number of electrodes for a particular domain will be reduced by increasing the electrode width. Hence, the wider electrode geometry will decrease the number of electrodes and the number of independent boundary data, which in turn reduces the image resolution. On the other hand, though a large number of electrodes provide more independent boundary data and better image resolution, the system cost and computation time and cost increase. Moreover, the wider electrodes reduce the interelectrode distance, and hence, an electrode array with too small interelectrode gap will reduce the measurement sensitivity, especially at the central area of the domain. It is reported that the influence of contact impedance between electrode and skin is reduced maximally when the total width of electrode array is about 80%–90% of the imaged area's perimeter. It is also reported that the optimum area underneath the electrodes as a percentage of the overall boundary area depends on the current pattern used (80% for the adjacent patterns and 60% for the opposite ones). Though varieties of electrode materials have been used in different EIT systems with their own advantages, the Ag/AgCl electrodes are found more popular in human body imaging, and the SS electrodes are widely preferred in saline phantoms for their easy availability, profound stability, chemical inertness, and low cost. Recently, thin-film-based gold electrode arrays have been found suitable for both saline phantoms and real tissue phantom imaging. The materials of EIT electrode can be

varied from application to application and with the atmosphere surrounding the system. A few studies on EIT electrode arrays have been reported, but a lot of experimental studies are still required to be conducted to obtain a proper design of electrode geometry with suitable materials.

University of Kitakyushu

62.1 Introduction

Wireless sensors that have more advantages relative to wired sensors are playing an important role in improving the quality of life in daily indoor space. The applications include home security systems to improve the safety of our home and vital signs monitoring systems to improve our health. The sensor systems can remotely detect the echo reflected from a person and then estimate the state and/or vital signs such as respiration rate and heart rate, for example. Several types of wireless sensor device have thus far been developed such as video camera, passive infrared (IR), and microwave. The video camera is unacceptable for some applications from a privacy protection point of view, although it can monitor a wide area of the indoor space. Passive IR sensors are generally developed to be dedicated to a relatively small area such as the home entrance and toilet area. Microwave sensors such as Doppler and frequency modulation continuous wave (FM-CW), which are capable of penetrating a variety of nonmetallic materials such as inner walls, provide a wider coverage area when compared with video cameras and IR, but it is susceptible to interference from other wireless radio systems, thereby causing false alarms or false detection. Ultrawideband impulse-radio (UWB-IR) has lately attracted considerable attention in short-range remote sensor applications since it offers high-ranging accuracy, multipath reduction, and environmental friendliness due to the very low energy emission [1–4]. However, it requires very-high-speed analog-to-digital converter (ADC) and high-level processors in order to synchronize and detect the received nanosecond pulse. It may also cause interference to existing or future wireless systems using the same or nearby bands because it occupies a bandwidth wider than 500 MHz. Therefore, the UWB device operated in the lower band of 3.4–4.8 GHz is required to implement the detect-and-avoid (DAA) technique in many countries such as Europe, Korea, and Japan [5].

To solve these problems, the use of the stepped-FM scheme has been suggested for the UWB sensor. The scheme has the following main advantages relative to UWB-IR [6–10]:

- *Lower-speed ADC and lower-level processor*: It transmits a series of bursts of narrowband pulses where each burst is a sequence consisting of many pulses shifted in frequency from pulse to pulse with a fixed frequency step. Each received narrowband pulse is phase-detected and then combined into the large effective bandwidth (sequentially over many pulses). Therefore, the hardware requirement is less stringent relative to UWB-IR. The detector bandwidth is smaller, resulting in lower noise bandwidth and higher SN ratio when compared with UWB-IR.
- *Inherent DAA function*: It is capable of coexisting with other narrowband wireless systems operating in the same frequency range. It detects interference radio potential by searching and is then designed to have some spectrum hole (nonactivated within a portion of the wide radio spectrum) to prevent any conflict and to coexist with the other narrowband wireless systems [11]. For example, the frequency band of interference can be detected by the phase detector, while the spectrum hole is adaptively assigned according to the interference band.

We have fabricated the sensor setup where the algorithm detecting and avoiding the interference previously mentioned has also been developed. Note that the ADC speed is 10 ks/s for the 2 GHz bandwidth. Measurements were conducted for some scenarios and the results are presented. From the results, the scheme is shown to be useful as a wireless sensor and can also coexist with other wireless systems operating in an overlaid frequency band.

62.2 Stepped-FM UWB Sensor

62.2.1 UWB-IR Sensor

UWB-IR uses nanosecond pulses spreading out all over a continuous wide bandwidth as shown in Figure 62.1a. It offers many advantages such as low-cost implementation, low transmission power, ranging, multipath immunity, and low interference. Due to the ultrashort-duration pulses, subcentimeter ranging is possible, thereby resulting in the correct identification of the complex-shaped target. It does not require up and down conversion; thus, it may reduce the implementation cost and low power consumption. In spite of the advantages, however, there are several engineering issues that need to be considered. Due to the very short pulses, accurate synchronization and detection may be difficult. Interference to existing or future radio systems using the same band is one of the difficult issues to be solved. Designing wideband RF components is also a big challenge, which includes high-speed ADCs.

Now, the received 1D signal, which is referred to as range profile, is generally presented by multiple impulses with gains $\{\beta_k\}$ and propagation delays $\{\tau_k\}$, where k is the impulse index. Suppose for a nanosecond pulse of $s(t)$, the range profile, $y(\tau,t)$, is the time convolution of $s(t)$ and the impulse echo response $\sum \beta_k \delta(t-\tau_k)$ is as follows:

$$y(\tau,t) = \sum_k \beta_k s(t-\tau_k) \tag{62.1}$$

Figure 62.1b shows an example of received power range profile for a bandwidth of 1 GHz in a room (corresponding to 1 ns pulse).

62.2.2 Stepped-FM UWB Sensor

A different approach of UWB, which solves the previous problems, is the use of stepped-FM pulse sequences instead of transmitting a nanosecond short pulse. We have fabricated an experimental setup of a stepped-FM UWB sensor. The block diagram is illustrated in Figure 62.2a. Waveforms at each stage and the external photo are given in Figure 62.2b and c, respectively. The sensor transmits a series of bursts of narrowband pulses, where each burst is a sequence consisting of N narrowband pulses shifted

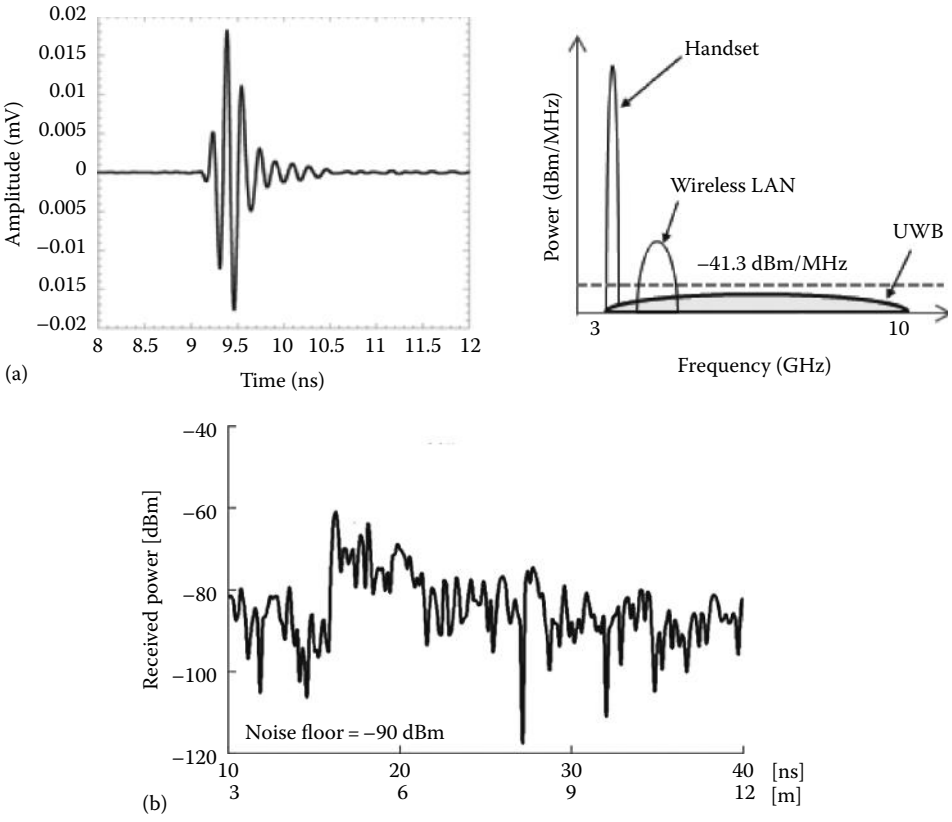

FIGURE 62.1 UWB-IR: (a) Waveform and the spectrum and (b) example of power range profile (1 GHz bandwidth).

in frequency from pulse to pulse with a fixed frequency step Δf [4]. As shown in Figure 62.2a through c, the received echo from an object is phase-detected with the transmitted stepped signal (homodyne detection) and is then In-phase and quadrature-phase (I-Q) sampled by a relaxed speed of ADC.

Then, the nth complex sample R_n is given by

$$R_n = A_n \exp(-j\theta_n) \tag{62.2}$$

$$\theta_n = 2\pi(f_c + (n-1)\Delta f) \cdot \frac{2d}{c} \tag{62.3}$$

where

A_n is the amplitude of nth pulse (A_n can be approximated by A for a stationary object)
f_c is the fundamental frequency
c is the velocity of light

Next, each complex sample is applied to the inverse discrete Fourier transformation (IDFT) device in order to obtain an N-element synthetic range profile, which is called range spectrum. The N-element range spectrum is given by

$$R(\phi) = \left| \sum_{n=1}^{N} R_n \cdot \exp\left(j\frac{2\pi}{N}(n-1)\cdot\phi \right) \right|$$

$$= N \cdot A \cdot \left| \frac{\sin c[\pi(\phi - N\Delta f(2d/c))]}{\sin c[(\pi/N)(\phi - N\Delta f(2d/c))]} \right| \tag{62.4}$$

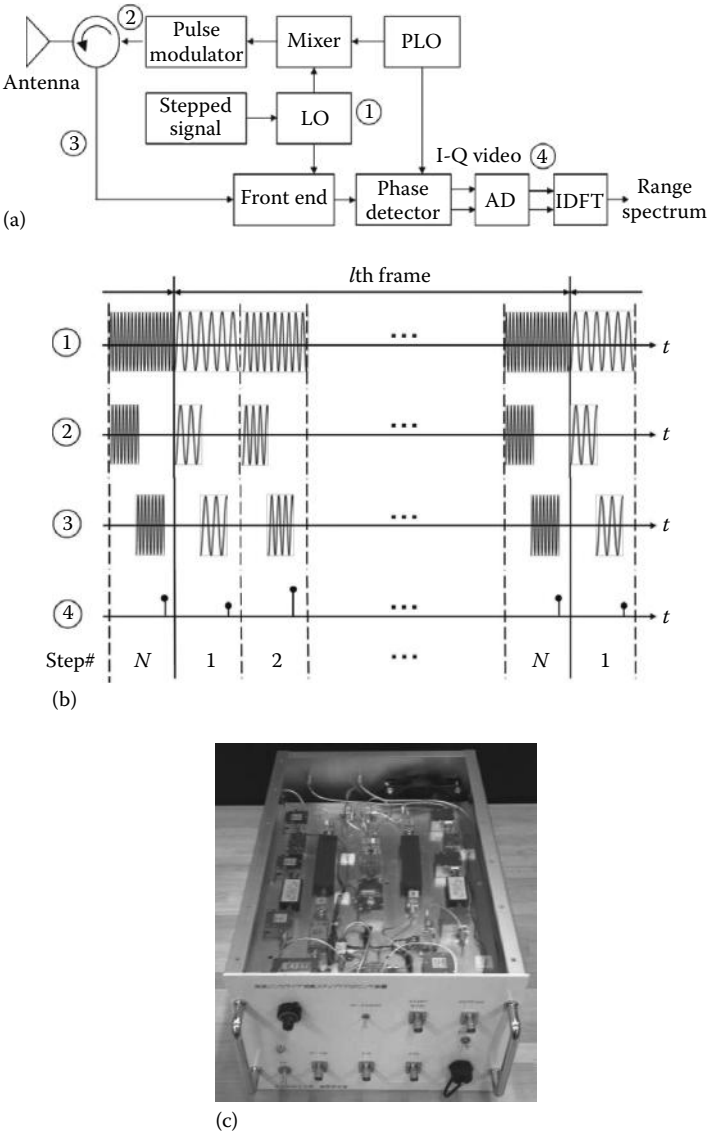

FIGURE 62.2 Stepped-FM UWB sensors: (a) Block diagram, (b) signal waveforms, and (c) external photo of setup.

$$\phi = \frac{2dN\Delta f}{c} \tag{62.5}$$

It is clear that the range resolution ΔR is approximately $1/N\Delta f$. For example, suppose $\Delta f = 34.5$ MHz and $N = 30$, the resolution is approximately 30 cm, which is equivalent to a UWB-IR with 1 GHz. Hence, it does not require high-speed ADC devices and a high-level processor at the receiver. Note that the unambiguous range (maximum detectable range) $R_{\max}$ is given by $c/2\Delta f$.

An example of the range spectrum is shown in Figure 62.3 where $\Delta f = 34.5$ MHz and $N = 30$ and zero-padding was also used for the IDFT operation. The phase detector should be generally AD sampled by 10 times of stepped pulse repetition rate or more. For example, when the pulse repletion rate of the setup is 1 kHz, the used ADC is 10 kS/s. Therefore, the hardware requirements become less stringent when compared with UWB-IR.

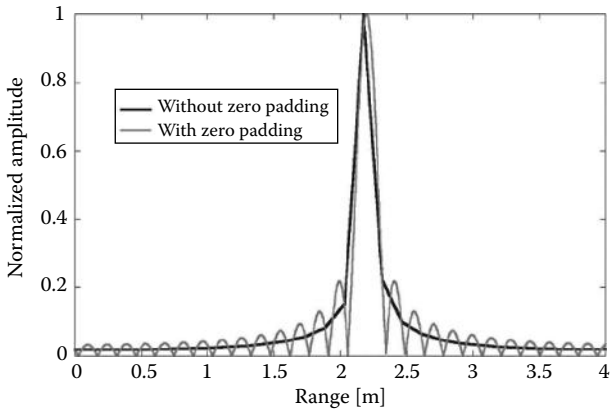

FIGURE 62.3 Example of range spectrum with zero padding ($\Delta f = 34.5$ MHz and $N = 30$).

62.2.3 DAA and Spectrum Hole

The stepped-FM UWB sensor can detect radio interference by monitoring the phase detector output in passive mode (transmitter power off/receiver on) and is then designed to have some spectrum hole (nonactivated within a portion of the wide radio spectrum) at the transmitter in order to prevent any conflict and to coexist with the other narrowband wireless systems. Note that the transmit radio consists of independent narrowband pulses with a different frequency. As such, it provides the flexibility to support regulatory measures in different areas of the world and ease concerns about interference. This section describes an interference avoidance technology called spectrum hole.

Figure 62.4a shows the power spectrum for $\Delta f = 34.5$ MHz and $N = 30$ where some stepped pulses from 3.655 to 3.724 GHz are not transmitted corresponding to the spectrum hole of 6.6% (simulation result). The band is seen to be suppressed less than –13 dB. Consider the federal communications commission (FCC)

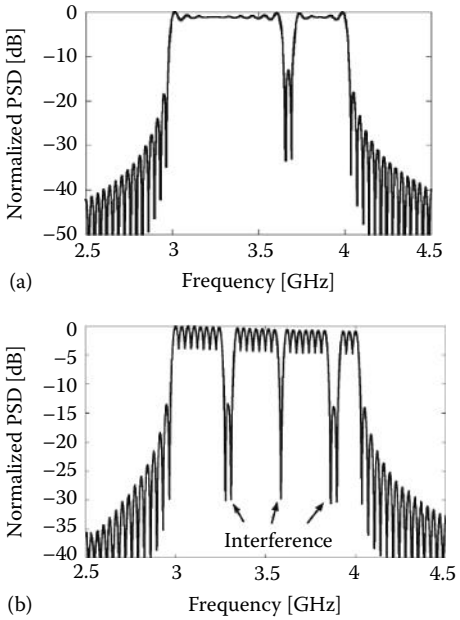

FIGURE 62.4 Power spectrums of transmit signal with spectrum hole: (a) Spectrum hole of 6.6% (b) spectrum hole of 16.6%.

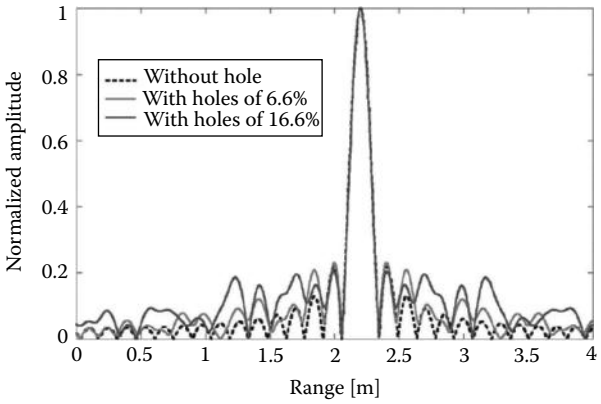

FIGURE 62.5 Range spectrums with and without spectrum hole.

regulation of −41.3 dBm/MHz, the band is suppressed to less than −55 dBm. Therefore, it does not interfere with existing radios. Figure 62.4b also shows the power spectrum against three narrowband interferences where we assumed three spectrum holes of 3.310–3.379 GHz, 3.621–3.655 GHz, and 3.897–3.966 GHz (corresponding to 16.6%) as shown in Figure 62.4b. Figure 62.5 shows the range spectrums for 6.6% and 16.6% where a zero-padding was used for the IDFT processing (1024 points).

62.3 Detection and Avoid Technology

The UWB device operating in the 3.1–4.2 GHz band is required to implement a DAA technology (narrowband signal detection and avoidance function) that allows it to detect an active wireless system operating in the same frequency range. The stepped-FM UWB sensor has inherently a DAA function unlike UWB-IR.

The flow chart of the suggested DAA algorithm is shown in Figure 62.6. Prior to transmitting the UWB radio, the receiver is activated (passive mode) and detects some narrowband radios such as

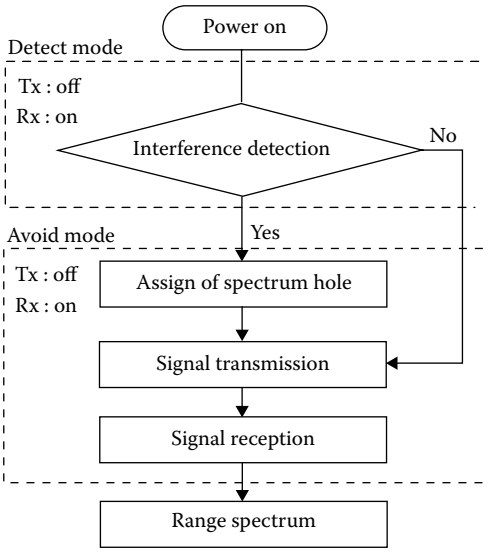

FIGURE 62.6 Flow chart of DAA algorithm.

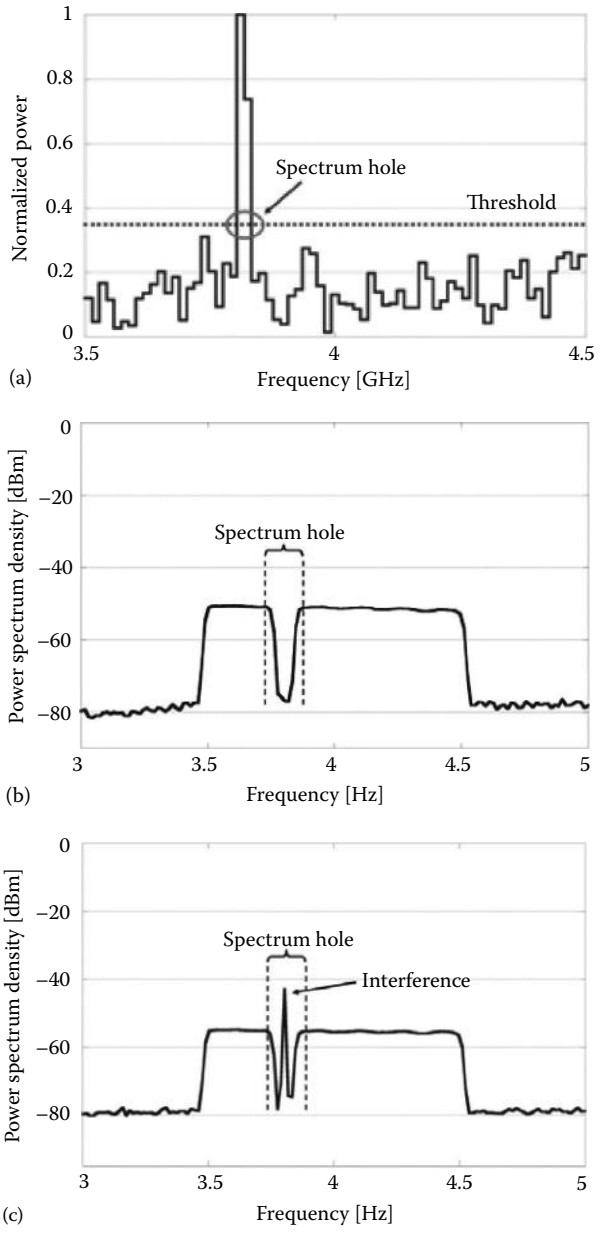

FIGURE 62.7 DAA technology: (a) Phase detector output, (b) power spectrum of transmit signal, and (c) power spectrum of received signal.

communications and broadcast signals. Figure 62.7a shows the output of the phase detector where a narrowband radio of 3.84–3.85 GHz is assumed. In the measurement, the radio was generated by an Agilent E8254A signal generator. It is seen that the radio is detected corresponding to the step number of 23 and 24 where $\Delta f = 14.5$ MHz and $N = 70$. Based on the result, the transmitter is then activated. Figure 62.7b shows the power spectrum where 7 stepped pulses from 3.76 to 3.85 GHz are not transmitted. Figure 62.7c shows the transmit signal together with the interference in frequency domain. It is seen that the UWB radio can coexist with the radio.

62.4 Patient-Care Sensing and Monitoring System

A patient-care sensing and monitoring system has been developed using the stepped-FM UWB sensor. The measurements were conducted and the results are presented.

62.4.1 Sensing and Monitoring Algorithm

The requirement for monitoring the state of the elderly person in care facilities and hospitals is increasing year by year since the increase in accidents involving the elderly persons is of great concern. When the elderly attempt to leave the bed alone, for example, it has been reported that the fall accident occurs frequently. Thereby, it is important to monitor the state of the person. The flow chart is shown in Figure 62.8 where the sensor detects various states or state in a room. The received range spectrum consists of echoes from various obstructions such as the bed, person, and walls where the state should be estimated by employing a "ranging filter" and a "motion filter."

The ranging filter $\Delta R_{pl}(\phi)$ is to detect the range from the sensor to a person, which is given by

$$\Delta R_{pl}(\phi) = \left| R_l(\phi) - R_0(\phi) \right| \tag{62.6}$$

where

$R_0(\phi)$ is a reference range spectrum that represents the range spectrum in a static room without a person
$R_l(\phi)$ is the range spectrum of lth frame

For example, when a person moves, the range spectrum would also fluctuate. Also, some motion in a room is expected to be detected by the motion filter $\Delta R_{vl}(\phi)$, which is given by

$$\Delta R_{vl}(\phi) = \left| R_l(\phi) - R_{l-1}(\phi) \right| \tag{62.7}$$

Note that $R_l(\phi)$ and $R_{l-1}(\phi)$ represent the range spectrum of lth and $(l-1)$th frame, respectively.

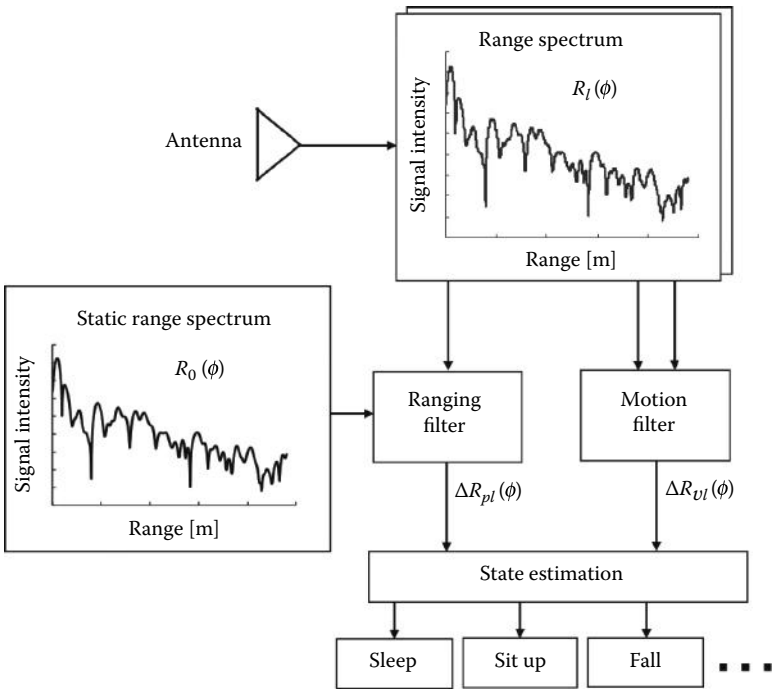

FIGURE 62.8 Flow chart of monitoring algorithm.

The motion filter is to detect some motion in a room, while the ranging filter is to estimate the range of a person. The trajectory of a moving person can also be estimated; thereby the state should be estimated such as "walk in room" and "fall." It is also possible to observe his state in bed such as "tossing about in bed" and "sitting up in bed" using the motion filter without invasion of privacy. Therefore, the state of a person can be detected that includes "out of room," "static," "walk in room," "sleep in bed," "tossing about in bed," "sitting up in bed," and "fall" in this algorithm.

62.4.2 Measurement Results

The measurements were conducted in a care room shown in Figure 62.9 and the results are presented. The specification is shown in Table 62.1. The algorithm has been developed for six states of "out of room ('out' for short)," "walk in room (walk)," "sleep in bed (sleep)," "tossing about in bed (toss about)," "sitting up in bed (sit up)," and "fall." Figure 62.10 represents an example of the measured results where the solid line is the sensor's estimated state, while the dashed line is the actual state identified by a video camera as shown in Figure 62.9. The measurements were conducted for different subjects and the detection rate was investigated. Next, it is important to investigate the detection performance for spectrum hole. The result of "fall," "sit up," "sleep," and "out" is shown in Figure 62.11. Table 62.2 summarizes the results. A detection rate of more than 88% is seen to be attained for a spectrum hole of 10%. Note that the rate is approximately 100% without a spectrum hole.

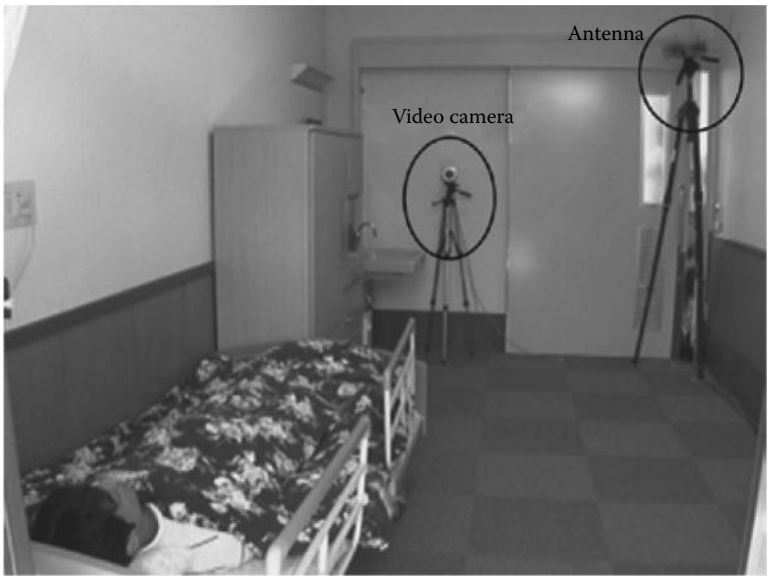

FIGURE 62.9 Scene for measurement environment.

TABLE 62.1 Measurement Specification

Transmit power	−12 dBm
Frequency	3.5–4.5 GHz
Stepped bandwidth Δf	14.5 MHz
Number of steps N	70
Frame period	0.1 s
ADC device	70 kS/s
Antenna	Horn (9.88 dBi)

State	Detection Rate (%)
Fall	100
Sit up	100
Sleep	100
Out	100
Toss about	98.80
Walk	100

62.5 Conclusions

The increase in accidents involving the elderly patient becomes a great concern, and the requirement for monitoring their activity and state is especially increasing in care facilities. This chapter presents a bed state monitoring sensor of the elderly patient using a stepped-FM UWB scheme, and the performance has been investigated for each spectrum by measurements in care facilities. The sensor provides the following advantages:

- *Lower-speed ADC and lower-level processor*: It transmits a series of bursts of narrowband pulses where each burst is a sequence consisting of many pulses shifted in frequency from pulse to pulse with a fixed frequency step. Each received narrowband pulse is phase-detected and then combined with the large effective bandwidth (sequentially over many pulses). Therefore, the hardware requirement is less stringent relative to UWB-IR.

- *Inherent DAA function*: It is capable of coexisting with other narrowband wireless systems operating in an overlaid frequency band. It can be designed to have any spectrum hole that does not cause interference with other wireless systems and medical equipment. For example, the location of the spectrum hole can be adaptively assigned according to the interference band detected by the DAA.

From the results, the scheme has been found to be useful and can also coexist with other wireless systems operating in the overlaid frequency band. Also, it has been shown that various states of the patient can be detected including "sleeping in bed," "sitting up in bed," "fall," "walk in room," "static," and "going out and in at the door."

63.1 Introduction

Understanding human activities and behavior has long been a research goal. In terms of daily lives, awareness of human activities can support many diverse applications. For example, in a home environment, users can be reminded to perform activities (e.g., taking medicine). In a hospital environment, a patient can be reminded to complete an exercise rehabilitation program. Employing a person to monitor other persons' activity 24 h a day is unrealistic; therefore, the automated, automatic recognition of human activities is important and necessary.

Although it is natural for humans to recognize their activities, it is not an easy task for a computer. Computers need to analyze the information gathered from sensors and infer the ongoing activity. Sensors' noises and variances make activity recognition (AR) even more complex for computers. For the recognition of a cooking activity, people might utilize various cues, such as recognizing a meal time, smelling the food being cooked, or seeing that the stove is on. Humans easily use evidence and their past experiences to infer activities. However, all the functions involved in sensing the environment, learning from past experience, and applying knowledge for inference are still a challenge for computers. The goal of AR research is to enable computers to have capabilities comparable to people for recognizing human activity. Only if computers can reliably recognize people's various activities can intelligent systems (such as healthcare and security systems) actually work. Moreover, research on AR has a huge impact on behavioral, social, and cognitive sciences.

To build an automatic AR system, the first thing to consider is the system's sensing ability, how the system recognizes the state of the physical world. Sensing ability comes from low-level sensors (Figure 63.1).

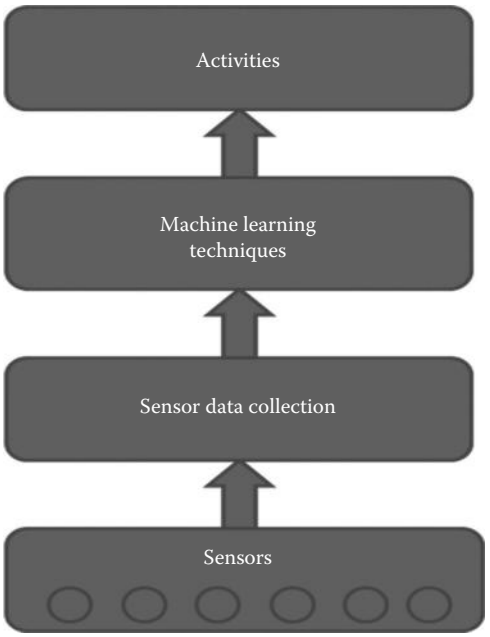

FIGURE 63.1 Workflow of AR system.

Sensed information is processed by machine learning techniques (e.g., noise filtering, feature extraction, and classification techniques) to infer the human activity (e.g., sitting, raising hand, or raising foot). Due to the variations in sensing techniques, a considerable number of AR systems have been developed.

According to the sensing techniques, the existing AR can be roughly divided into three categories:

1. *Video sensor–based activity recognition* (*VSAR*). This is the classical AR approach, which attempts to capture a human's activity information using appropriately placed cameras. Video analysis is the most important and challenging aspect of VSAR.
2. *Wearable sensor–based activity recognition* (*WSAR*). In this AR, physical sensors are attached to the body. This is a relatively new approach, which emerged with the development of wearable computing. Motion sensors (accelerometers and gyroscopes) are the most common wearable sensors. They are attached to relevant parts of the body, in particular hands and arms, to provide information about the limbs' motions. Other sensors, which are usually used as complements to the motion sensors, include microphones, Global Positioning System (GPS) devices, and light sensors. They provide additional information about the user's environment to help improve the accuracy of AR.
3. *Object usage–based activity recognition* (*OUAR*). In this AR, sensors are attached to objects. With this design, a system can recognize the objects accessed by the users and what the users do with them. Although OUAR does not explicitly monitor human activity, it is applicable, because many activities can be implicitly inferred by knowing the objects utilized. For example, if we know that the stove is on, we might infer that someone is cooking. Binary sensors and radio frequency identification (RFID)-based sensors are commonly used sensors in OUAR. They are cheap and can be ubiquitously deployed.

Of the different types of sensor-based AR systems, no one is the best. Each of them has its own characteristics and suitable applications. In this chapter, we outline the strong/weak points, main techniques, and suitable applications of each type of system, ultimately comparing them.

63.2 Video Sensor–Based Activity Recognition

VSAR is the classical AR method and is based on computer vision techniques (Figure 63.2). It is most common among the three AR approaches. Currently, it is widely used in various domains including industry, academia, security, and consumer agencies.

63.2.1 Applications

In this section, we present some typical applications of VSAR systems:

1. *Surveillance systems*. Surveillance systems can support many applications, such as healthcare and unusual event alarms. Traditional surveillance systems require a human operator to constantly monitor the scene, which is tedious and inefficient. Video-based activity recognition systems can replace or help human operators monitor anomalies and interesting activity.
2. *Human–machine interaction*. Human–machine interaction needs to understand a human's interactions. People's activity information is particularly important in understanding intentions and purposes. For example, researchers have proposed vision-based activity recognition to develop alternatives to the traditional mouse- and keyboard-controlled Graphic User Interface (GUI).
3. *Sports analysis*. In many kinds of sports (e.g., basketball, soccer), during a match or training, a player's performance and behavior is recorded. This has many potential usages. For example, the coach might adjust a soccer player's shooting action after analyzing the videos. Or during the match, if a penalty dispute happens, a referee can analyze the video. Due to the explosive increase of video use, it has been necessary to develop efficient indexing schemes, and sports players' activity information is one of the most popular schemes for video indexing.

63.2.2 Feature Extraction in VSAR

The major steps involved in VSAR include (1) video (or image) gathering, (2) feature extraction from images, and (3) AR based on the extracted features.

Among these three steps, feature extraction is important and challenging. Extracting good features is the mark of good recognition performance. The good features should generalize small variations in the images, such as personal appearance, background, and viewpoint and action execution, while being sufficient enough to support a robust recognition of activities.

The features in VSAR can be divided into two categories: global features and local features. Global features need the procedure of localizing a person and encoding a region of interest (ROI) and have powerful expressing abilities when rich information is encoded. However, they need accurate localization,

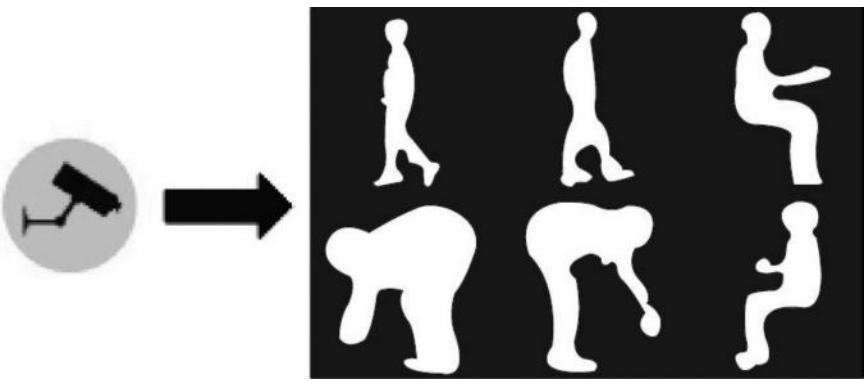

FIGURE 63.2 Video sensor–based activity recognition.

background subtraction, and tracking. Conversely, local features describe observations as a collection of independent patches, detecting patio-temporal interest points, and calculating the local patches around these points. Finally, the patches are integrated into a final representation. Compared with global features, local features are less sensitive to noises and do not require high-quality background subtraction or tracking; however, they require more preprocessing efforts to extract a sufficient amount of relevant interest points.

63.2.2.1 Global Features of VSAR

Global features represent the ROI of a person as a whole. The ROI is usually defined using background subtraction or tracking. Common global features are derived from silhouettes, edges, optical flow, or trajectories.

Background subtraction segments a scene into a background and a foreground to isolate the moving parts. The segmentation evaluates the difference in pixel features for the current scene versus the reference background image. Background subtraction is sensitive to environmental changes, like illumination variations.

In general, human silhouette information is commonly employed to represent human activities [1]. In fact, human activities can be considered as temporal variations of human silhouettes. In addition to silhouette shape, motion information is also used. Optical flow is defined as the apparent motion of individual pixels on the image plane. It often serves as a good approximation of true physical motion projected onto an image plane.

Trajectories of moving objects have also been used as features to infer the activities of objects [2]. The image-plane trajectory itself is not very useful, as it is sensitive to translations, rotations, and scale changes. Alternative representations such as trajectory velocities, trajectory speeds, and relative motion have been proposed.

Although the features extracted using previous methods are informative, they are sensitive to noise, partial occlusions, and variations in viewpoint. To overcome these limitations, grid-based features and space–time volumes have been proposed. Global grid-based features divide the ROI into a fixed spatial or temporal grid. Each cell in the grid describes the image observation locally, thus partial occlusions and changes in viewpoints can be partially solved [3]. Multiple images over time can be stacked to form a 3D space–time volume. A space–time volume was originally proposed in [4] and has since been used by other research.

63.2.2.2 Local Features of VSAR

Local features describe the observations as a collection of local patches, which can be samples, either densely spaced or at space–time interest points. Superior to global features, local features do not require accurate localization and background subtraction. The first type of local features is space–time interest point detectors, which are the locations in space and time where sudden changes of movement occur in the video. The locations are viewed as the most informative source for human AR. The research that uses space–time interest points includes [5,6]. The main limitation with using these features is that the number of stable interest points is normally small. Fortunately, this limitation has been partially addressed in [7,8].

Local descriptors are the second type of local features. They summarize an image or video patch in a representation that is ideally invariant to background clutter, appearance and occlusions, and possibly to rotation and scale. The research that has used this type of features includes [9,10]. Comparing sets of local descriptors is not straightforward due to the possibly of different numbers and the high dimensionality of the descriptors. Therefore, a codebook is usually generated by clustering patches and selecting the cluster centers of the closest patches as codewords.

Similar to the global grid-based features, local grid-based features also exist. These features are the third type of local features and have theoretical similarities to global grid-based features. Related works include [11,12]. The last type of local features is a correlation between local descriptors. Grid-based

representations model spatial and temporal relationships between local descriptors to some extent, but they are often redundant and contain unimportant or uninformative features. Therefore, some researchers exploit correlations between local descriptors as features.

63.2.3 Recognition Techniques in VSAR

Recognition techniques are used to infer activity information based on the aforementioned extracted features. An activity label can be predicted for each frame or sequence of frames. Four types of recognition techniques have been widely used in VSAR: nonparametric, volumetric, temporal-independent, and temporal-based techniques.

63.2.3.1 Nonparametric Techniques

Nonparametric approaches typically extract a set of features from each video frame. The features are then matched to a stored template. The template can be either 2D or 3D. When using nonparametric techniques, the typical procedures consist of motion detection and human tracking in the scene, which enables the construction of a sequence. Then, a periodicity index is computed and the periodicity sequence is segmented into individual cycles for recognition.

63.2.3.2 Volumetric Techniques

Volumetric techniques do not extract features on a frame-by-frame basis. Instead, they use a video as a 3D volume of pixel intensities and extend standard image features to a 3D case. Volumetric techniques mainly include four types of methods: spatiotemporal filtering, which filters video volume using a large filter bank; part-based approach, which considers video volume as a collection of local parts; subvolume matching, which matches videos by matching subvolumes between videos and templates; and a tensor-based approach, which is a generalized collection of matrices for multiple dimensions.

63.2.3.3 Temporal-Independent Techniques

Temporal-independent techniques neglect the information in the temporal domain. They summarize all of the frames for an observed sequence into a single representation, subsequently performing AR for each frame. The main techniques in this category include *k*-nearest neighbors (*k*-NN) and support vector machines (SVMs).

When using *k*-NN, the distance measurement can affect recognition performance. Euclidean distance with global features and histograms of codewords has been used [13]. Other measures, like Mahalanobis distance, have also been utilized.

Another popular temporal-independent recognition method in VSAR is SVM. It determines a hyperplane in feature space, described by a weighted combination of support vectors. SVM has been used jointly with local features of fixed lengths, such as histograms of codewords, for activity learning [14].

63.2.3.4 Temporal-Based Techniques

Temporal-based techniques fully utilize the temporal relationships of activities. They can be either generative or discriminative. Dynamic time warping (DTW) is a generative learning method. It models highly nonlinear warping functions based on the distance measure between two sequences. Hidden Markov models (HMMs) are the other common generative learning method in VSAR. They use hidden states that correspond to different phases in the performance of an action. They model state transition probabilities and observation probabilities. Although HMM is widely used, it is limited to observations that are time independent. Discriminative models overcome this issue by modeling the conditional distribution of activity labels given the observations. Conditional random fields (CRFs) are the most common used discriminative models in VSAR. They use multiple overlapping features. A detailed comparison between CRF and HMM is given in [15].

63.3 Wearable Sensor–Based Activity Recognition

WSAR occurred with the development of wearable computing. The goal is to create personal applications that can adapt and react to the user's current context. The scope of context is diverse and, in WSAR, refers to the current activity information.

Unlike VSAR, WSAR requires more from the sensors; therefore, it is a newer technology, only dating back to the 1990s, when hardware (including sensing, display, and computing equipment) became lightweight enough that an integrated mobile system could be "worn" by a single person for an extended period of time. With the development of hardware techniques, there now exist a large number of WSAR systems that use various sensors, and recognition techniques, and are used for diverse applications.

63.3.1 Applications of WSAR

An important application of WSAR is in healthcare and assisted living. There also exist a number of other applications, such as industrial applications and applications for entertainment and gaming:

1. *Healthcare and assisted living*: WSAR can help elderly people live more independent lives and thus reduces the burden of caregivers (Figure 63.3). By detecting the activities of elderly people, we can implicitly detect potentially dangerous situations in daily life. The typical functions of these systems are to detect when the people fall and to monitor vital signs.
2. *Prevention of diseases*: Some diseases can be detected from activity information prior to being diagnosed (Figure 63.4). For example, Alzheimer's can be detected through early symptoms related to human activity. These applications accumulate and summarize statistics about daily activities and continuous recordings of physiological parameters. These applications can help physicians and caregivers estimate the physical well-being of a person.
3. *Promoting exercise*: This type of system aims to aid elderly or disabled people performing everyday activities and thus generate a healthier lifestyle (Figure 63.5). With the increasing intelligence and processing power of mobile phones, many such applications use mobile phones to remind people to perform certain activities.

63.3.2 Sensors in WSAR

VSAR uses only video sensors; however, WSAR involves many different kinds of sensors. Each type of sensor has its own strengths and suitable applications.

FIGURE 63.3 WSAR for healthcare.

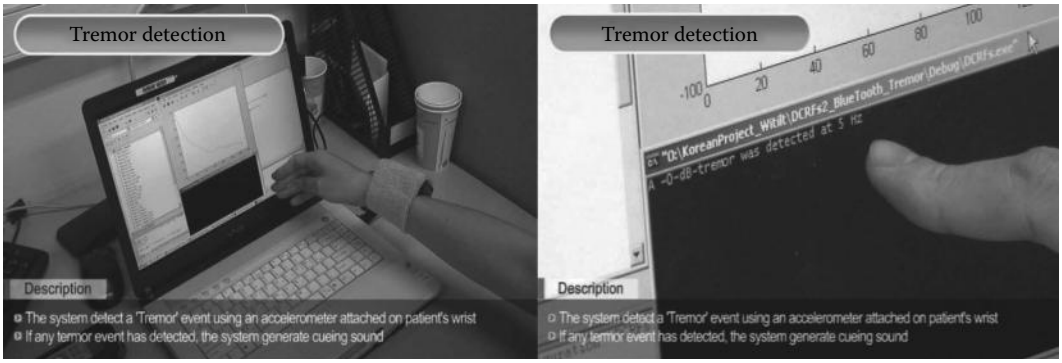

FIGURE 63.4 Tremor detection based on WSAR.

FIGURE 63.5 Gait detection based on WSAR.

The types of sensors used in WSAR range from relatively simple sensors with discrete output, such as ball switches, to sensors with continuous output such as accelerometers, to more complex sensing methods such as audio processing. Video sensors are wearable, with accelerometers being the most commonly used type of sensor, as they usually give good results in terms of physical AR. The most commonly used accelerometers and their vendor information are summarized in Table 63.1.

In addition to the aforementioned sensors, there are some sensors that are less commonly used. Fiber-optical sensors are used to measure posture. Foam pressure sensors are used to measure respiration rates. Force-sensitive resistors are used to measure muscle contractions. Moreover, various kinds of physiological sensors, such as oximetry sensors, skin conductivity sensors, electrocardiographs, and body temperature sensors, have also been used for various applications. As different types of sensors can provide complementary information, using many various sensors simultaneously usually gives more accurate results. For example, the Ubiquitous Computing Lab of Kyung Hee University has developed the Mobile Activity Sensor Logger (MASoL). MASoL consists of

TABLE 63.1 Accelerometers Used in WSAR

Sensor	Vendor

ADXL210E [17]	Analog devices
LIS302DL [18]	ST Microelectronics
MMA7260Q [19]	Freescale semiconductor
ADXL330 [20]	Analog devices

FIGURE 63.6 Mobile Activity Sensor Logger.

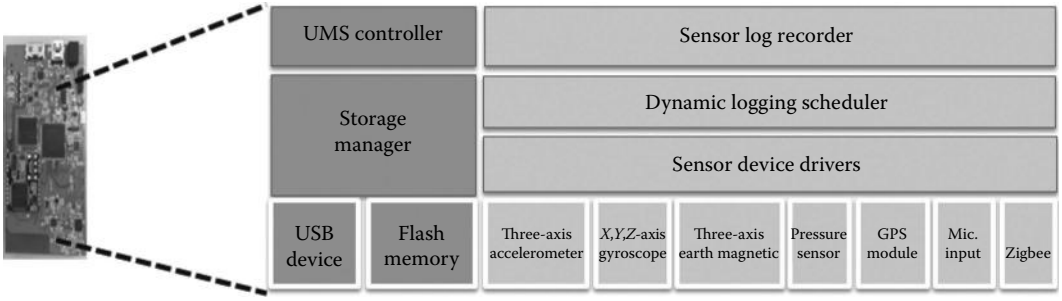

FIGURE 63.7 Key components in MASoL.

various sensors that record a personal activity log. All of the sensors in the MASoL platform are embedded in one chip, so as to decrease user discomfort (Figures 63.6 and 63.7).

Depending on the type of activity, recognition performance can be improved by using the same type of sensor at multiple body locations, employing networks of heterogeneous sensors, or integrating a variety of sensors on a single device. Combining two or more complementary types of sensor data can also help in recognizing activities, by combining motion and audio data, motion and proximity data, or motion and location data.

63.3.3 Recognition Techniques for WSAR

Quite a range of different recognition techniques have been used for WSAR. There is no one best recognition technique for WSAR, as considerations include the kind of data to be processed and the types of activities to be recognized. The recognition techniques for WSAR can be classified into two types: supervised and unsupervised. Supervised learning requires labeled data. Conversely, unsupervised learning tries to directly construct models from unlabeled data, either by estimating the properties of its underlying probability density or by discovering groups of similar examples. When using labeled data, supervised learning usually outperforms unsupervised learning; therefore, supervised learning is the predominant approach for WSAR.

63.3.3.1 Supervised Recognition Techniques

There exists a wide range of algorithms and models for supervised learning. Commonly used methods in the WSAR include Naive Bayes (NB), C4.5 decision trees, and nearest neighbors. HMMs are well-suited for capturing temporal patterns in the data but can be difficult to train due to an abundance of parameters [21,22]. Other methods that have been applied include SVMs [23,24] and more recently string-matching methods. Boosting uses multiple classifiers to boost the classification performance and has also been used in WSARs.

63.3.3.2 Unsupervised Recognition Techniques

In Ref. [25], hierarchies of HMM are used to learn the locations and scenes, such as walking through a supermarket, from audio and video data in an unsupervised fashion. Graphical model–based

unsupervised learning schemes were used in [38,39], wherein the focus was on inferring the transportation modes (such as bus, car, walking) and destinations of the users. One work [26] combines discrete string-matching techniques with continuous HMM classifiers to discover short recurring motifs in acceleration data. They aimed to discover and model short-term motion primitives, such as those occurring during physical exercise. Other research [27] used the concept of multiple eigenspaces for the unsupervised learning of activities such as walking or juggling.

63.4 Object Usage–Based Activity Recognition

In daily life, people usually perform an activity by interacting with a series of objects. For example, when bathing people may interact with a door, light, exhaust fan, shower faucet, etc. The strategy of OUAR is to attach sensors to these objects so that it is possible to determine the state of that object when a person interacts with it.

OUAR [28–30] can be particularly useful in domains such as cooking, which involves a relatively small number of repeated actions (chopping, pouring, spreading, etc). Object use information can help discriminate between activities, such as making toast and making a sandwich, which may be similar from the standpoint of the activity alone. Such distinctions can be important for application domains, such as health monitoring or memory aids.

63.4.1 Sensors in OUAR

There are two main types of sensors used in OUAR systems: RFID-based sensors and simple binary sensors.

63.4.1.1 RFID-Based Sensors

To use an RFID-based sensor, one needs RFID tags and an RFID reader. RFID tags are small and are attached to objects. Subjects need to wear the short-range RFID reader (or equipment with the RFID reader integrated). An RFID-based sensor will generate object use events when a tagged object is manipulated during an activity. Whenever the user's hand is in close proximity to a tagged object, the reader indicates this. The tags are inexpensive and maintenance free given that they do not contain batteries. For example, using an RFID-based sensor, we can detect that a user is reading (Figure 63.8).

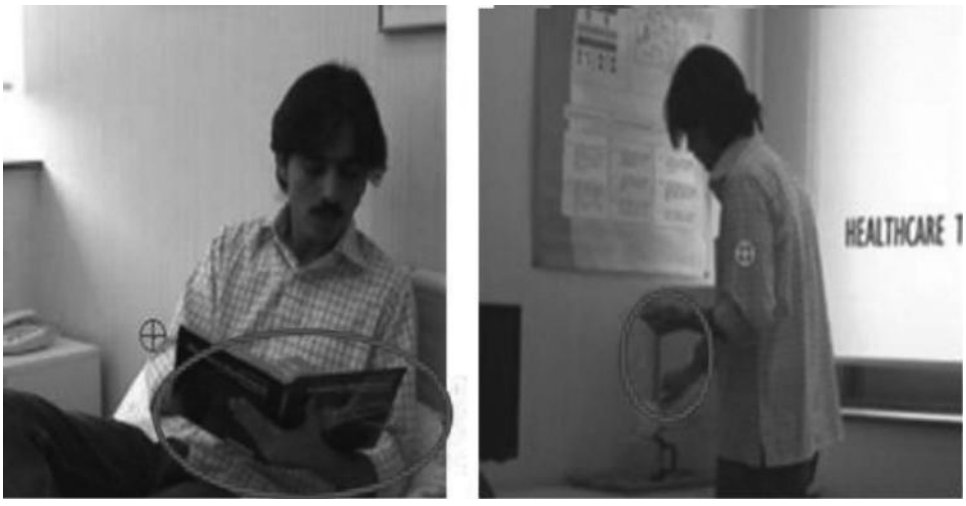

FIGURE 63.8 Using RFID for AR.

63.4.1.2 Binary Sensors

The other type of sensor that has received widespread acceptance in OUAR is the binary sensor. Binary sensors are usually simple and anonymous. They are unable to directly identify occupants; however, at any given time, a binary value may be obtained from them. Whenever the state of a certain context (object, movement) associated with a binary sensor changes, the value of the sensor changes to "1" from "0" (indicating its static state). There are many, diverse types of binary sensors, including movement detectors, contact switches, and pressure mats. They are applicable to different scenarios. For example, contact switches may be installed on the doors of cupboards, the fridge, the microwave, etc. Pressure mats may be discreetly installed in objects such as chairs, sofas, and beds and, in some instances, may be used to locate specific movements within rooms. They have the advantage that they do not require the person being monitored to wear or carry any new technology.

63.4.2 Recognition Algorithms

Temporal probabilistic models are most common in OUAR. Sets of probabilistic models have been proposed in OUAR: the NB in [31], the HMMs in [32], and the CRF in [33]. HMMs are generative probabilistic models consisting of a hidden variable and an observable variable at each time step. For OUAR, the hidden variable is the activity performed and the observable variable is the vector of the sensor readings.

A CRF is a discriminative probabilistic model. Kasteran et al. [32] compared CRF with HMMs; findings found that CRF outperformed HMMs in all cases with respect to time slice accuracy, but that HMMs achieved the overall highest accuracy. This is due to the way both models maximize their parameters. HMMs make use of a Bayesian framework in which a separate model is learned for each class. A CRF uses a single model for all classes. A comparison of HMMs and CRF was also discussed in [34], where the authors found that CRF was able to easily incorporate a wide variety of computed features, which allowed domain knowledge to be added to the models. They also showed that due to the independence assumptions inherent in HMMs, such computed features are not nearly as effective in improving classification accuracy. Thus, CRF's classification accuracy has shown to be consistently higher than HMMs.

63.5 Comparisons of VSAR, WSAR, and OUAR

In this section, we discuss the strengths and limitations of VSAR, WSAR, and OUAR. Based on our comparisons, fusing these three approaches seems to be the most promising solution for complex AR applications.

63.5.1 VSAR

VSAR is the traditional AR method. Among these three approaches, a video system with appropriately placed cameras provides the richest information and in principle could facilitate the most detailed analysis. However, the signal processing involved in extracting this information can be computationally intensive and, in general cases, remains an open problem. In general, VSAR often works well in a laboratory or well-controlled environment. However, it fails to achieve the same level of accuracy for real home settings due to the clutter, variable lighting, and highly varied activities that take place in natural environments. Video sensor–based activity recognition is complex to implement because it requires processing highly multidimensional data. Additionally, video information may violate the user's privacy.

63.5.2 WSAR

The WSAR approach tries to recognize a user's activities by employing sensors such as body-worn accelerometers and microphones to capture characteristic repetitive motions, postures, and sounds of the activities. Using these types of wearable sensors, sensing studies have successfully recognized such

activities as walking, bicycling, brushing teeth, speaking and laughing, and workshop activities such as sawing and drilling that have characteristic motions and/or sounds. An advantage of this approach is that it does not require environment-embedded sensors. That is, this approach incurs no cost in terms of money or time for embedding sensors in indoor objects and furniture. Also, users can easily turn off their wearable devices when they want to preserve their privacy. Wearable sensors are capable of measuring mobility directly. They are well suited to collecting data on daily activity patterns over an extended period of time, as they can be integrated into clothing or worn as wearable devices. Since they are attached to the subjects they are monitoring, wearable sensors can therefore measure physiological parameters, which may not be measureable using ambient sensors.

Although body-attached sensors are promising in identifying primitive sequences of movements, such as walking and running, it is difficult to identify goal-oriented activities (e.g., making tea and taking medicine). In addition, designing of wearable systems is complicated by size, weight, and power consumption requirements.

63.5.3 OUAR

OUAR is the third type of AR approach. It infers a person's activity by analyzing the person's interactions with various objects. This approach is newer than VSAR and WSAR and was proposed to overcome the limitations of VSAR and WSAR. Many people are uncomfortable living with cameras. Moreover, people are often unwilling or forget to wear sensors. However, OUAR does have some drawbacks. For extensive and detailed recognition, OUAR requires a large number of objects to be attached to sensors. This is often either infeasible or too expensive. The cost of the sensors and sensor acceptance are pivotal issues, especially in homes.

Each of the three types of AR approaches has its own advantages and disadvantages; however, given the specific application and associated requirements of this study, there is a most suitable approach (Table 63.2).

As shown in Table 63.2, the three types of AR are complementary. For example, VSAR violates user privacy; however WSAR and OUAR do not violate privacy. OUAR is usually limited to the home environment, whereas WSAR and VSAR can work outside home. In our u-healthcare project, we tried to combine these three approaches for our u-healthcare applications [35].

Our system needs to constantly monitor human activity information to improve health conditions and determine potential health problems as early as possible; therefore, all three types of AR approaches were used together (Figure 63.9).

TABLE 63.2 Analysis of VSAR, WSAR, and OUAR

Categories	Strengths	Limitations	Applications
VSAR	1. Video includes richest information; therefore, its applied range is widest 2. Setting up the environmental is easy	1. Violates privacy 2. Sensitive to environment (e.g., light condition and viewpoint variation)	1. Healthcare 2. Security 3. Interactive applications 4. Content-based video analysis
PSAR			
WSAR	1. Setting up the environmental is not required 2. Good for applications that require explicit motion analysis	1. Wearing sensors is a burden. 2. Unable to separate similar actions (e.g., making tea and coffee)	1. Healthcare 2. Interactive applications
OUAR	1. Does not violate privacy 2. Good at recognizing goal-oriented activities	1. Recognizable activities need to be related to objects 2. Setting up the environmental takes more effort than for VSAR and WSAR	1. Healthcare 2. Security

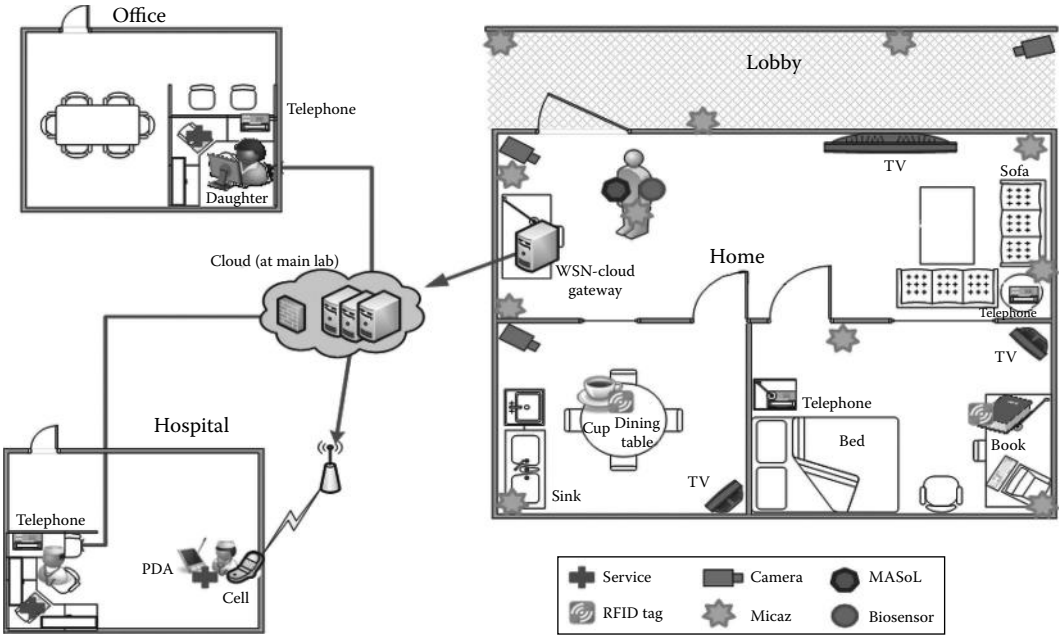

FIGURE 63.9 AR for u-healthcare application. (From http://www.tr.ietejournals.org/article.asp?issn=02564602;year=2011;volume=28;issue=5;spage=418;epage=433;aulast=Guan)

The cameras used for VSAR were in the lobby, living room, and kitchen. Due to privacy issues, they were not used in the bedroom. For WSAR, we developed the MASoL, which is a low-cost, low energy consumption sensor device. MASoL contains 13 axis sensors, gathering many kinds of behaviors and storing them. In addition, we also used the OUAR approach with an RFID-based sensor, with RFID tags attached to the book and cup.

Combining the three AR approaches enabled our system to accurately recognize many kinds of activities. Although it is logical that the combination of three AR approaches would outperform an individual AR approach, their fusion is not trivial, as we developed a sophisticated probabilistic fusion model for this task.

The experience of building our system suggests that each AR approach has some limitations and that combining them results in a promising approach for complex recognition.

63.6 Challenges in Sensor-Based Activity Recognition

The significant potential of AR systems has been recognized by many researchers who have attempted different approaches, including video sensor–based, wearable sensor–based, and object usage–based approaches. In the last twenty years, many AR systems have been developed; however, AR systems still have limited functions. The main challenges include

1. *Real-world conditions*: Most existing systems are designed and tested in constrained conditions. Many factors in the real world can severely limit the applicability of a system. For example, in VSAR, these factors can include noise, occlusions, and shadows. Another challenge is the robustness of system. In real-world conditions, there might be a wide variability within the same activity class. Therefore, we need to find methods that can explain and withstand the wide variability of features that are observed within the same activity class. Overall, more research needs to be done to address these practical issues in real-world conditions.

2. *Evaluation of systems*: A common problem in the AR community is the lack of annotated reference data and standardized test-beds that could help researchers compare the performance of their approaches. Although there exist several benchmark datasets, most of these datasets consist of simple activities, such as walking, running, sitting, and sleeping. Very few common datasets exist for evaluating higher-level complex activities and reasoning algorithms. A lack of evaluation standards is a challenge, which makes it difficult to compare the performances of different systems.
3. *Hardware challenge*: With the development of the sensor industry, sensors have gotten stronger processing power and smaller sizes. However, the energy supply is still a problem, particularly in long-term AR. Moreover, making sensors easier to use and less obtrusive also needs to be addressed.
4. *Privacy and security:* In order for AR to become widely used, the users' privacy must be considered. Therefore, comprehensive privacy and security mechanisms must be developed for activity recognition systems.

Acknowledgments

This research was supported by the National Natural Science Foundation of China (Grant No. 61100007, 61100081). It was also supported by the collaborative research project under the NSFC-NRF cooperative program (Grant No. 613111015).

Biopotentials and Electrophysiology Measurement

Nitish V. Thakor
Johns Hopkins University

64.1 Introduction

This chapter reviews the origins, principles, and designs of instrumentation used in biopotential measurements, in particular for the electrocardiogram (ECG), the electroencephalogram (EEG), the electromyogram (EMG), and the electrooculogram (EOG). These biopotentials represent the activity of the respective organs: the heart, brain, muscle, and eyes. The biopotentials are acquired with the help of specialized electrodes that interface to the organ or the body and transduce low-noise, artifact-free signals. The basic design of a biopotential amplifier consists of an instrumentation amplifier. The amplifier should possess several characteristics, including high amplification, input impedance, and the ability to reject electrical interference, all of which are needed for the measurement of these biopotentials. Ancillary useful circuits are filters for attenuating electric interference, electrical isolation, and defibrillation shock protection. Practical considerations in biopotential measurement involve electrode placement and skin preparation, shielding from interference, and other good measurement practices.

64.2 Origins of Biopotentials

Many organs in the human body, such as the heart, brain, muscles, and eyes, manifest their function through electric activity [1]. The heart, for example, produces a signal called the ECG (Figure 64.1a). The brain produces a signal called an EEG (Figure 64.1b). The activity of muscles, such as contraction and relaxation, produces an EMG (Figure 64.1c). Eye movement results in a signal called an EOG (Figure 64.1d), and the retina within the eyes produces the electroretinogram (ERG). Measurements of these and other electric signals from the body can provide vital clues as to normal or pathological functions of the organs. For example, abnormal heart beats or arrhythmias can be readily diagnosed from an ECG. Neurologists interpret EEG signals to identify epileptic seizure events. EMG signals can be helpful in assessing muscle function as well as neuromuscular disorders. EOG signals are used in the diagnosis of disorders of eye movement and balance disorders.

The origins of these biopotentials can be traced to the electric activity at the cellular level [2]. The electric potential across a cell membrane is the result of different ionic concentrations that exist inside and outside the cell. The electrochemical concentration gradient across a semipermeable membrane results in the Nernst potential. The cell membrane separates high concentrations of potassium ion and low concentrations of sodium ions (along with other ions such as calcium in less significant proportions) inside a cell and just the opposite outside a cell. This difference in ionic concentration across the cell membrane produces the resting potential [3]. Some of the cells in the body are excitable and produce what is called an action potential, which results from a rapid flux of ions across the cell membrane in response to an electric stimulation or transient change in the electric gradient of the cell [4]. The electric excitation of cells generates currents in the surrounding volume conductor manifesting itself as potentials on the body.

Figure 64.2 illustrates the continuum of electrophysiological signals from the (a) heart cells, (b) myocardium (the heart muscle), and (c) the body surface. Each cell in the heart produces a characteristic action

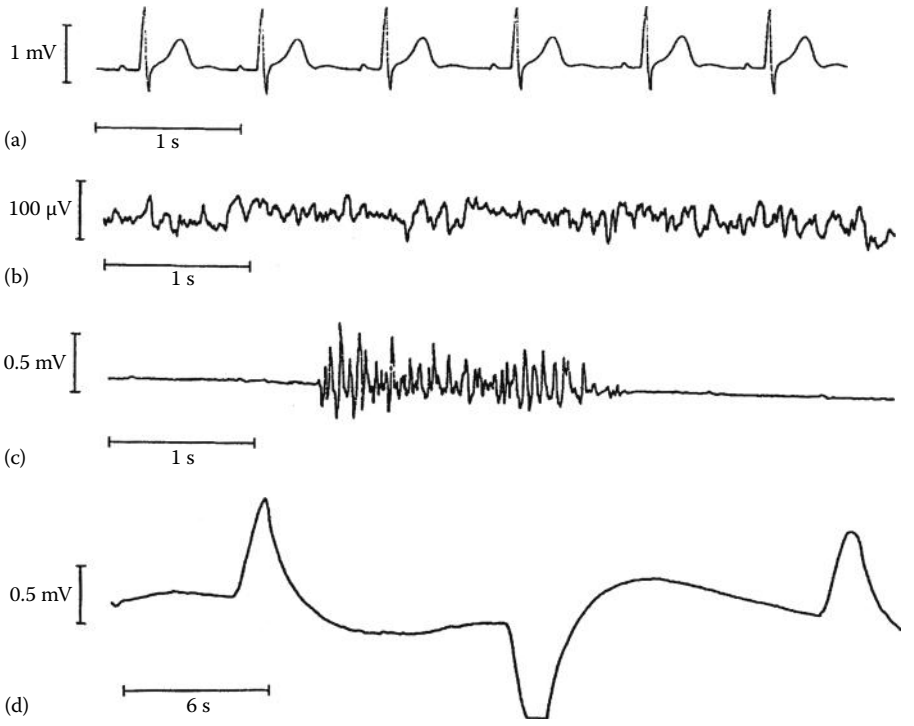

FIGURE 64.1 Sample waveforms: (a) ECG, normal sinus rhythm; (b) EEG, normal patient with open eyes; (c) EMG, flexion of biceps muscles; (d) EOG, movement of eyes from left to right.

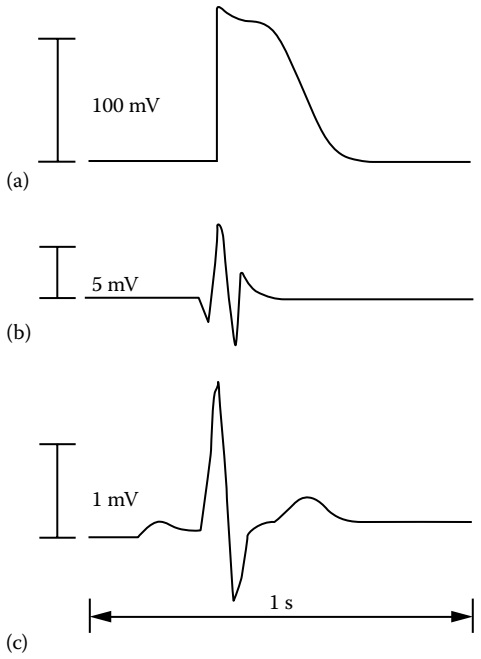

FIGURE 64.2 Schematic showing origins of biopotentials: (a) An action potential from a heart cell (recorded using a microelectrode) and (b) the electrogram from the heart surface (recorded using an endocardial catheter), and (c) the ECG signal at the chest (recorded using surface electrodes).

potential [4]. The activity of cells in the sinoatrial node of the heart produces an excitation that propagates from the atria to the ventricles through well-defined pathways and eventually throughout the heart; this electric excitation produces a synchronous contraction of the heart muscle [5]. The associated biopotential is the ECG. Electric excitation of a neuron produces an action potential that travels down its dendrites and axon [4]; activity of a massive number of neurons and their interactions within the cortical mantle results in the EEG signal [6]. Excitation of neurons transmitted via a nerve to a neuromuscular junction produces stimulation of muscle fibers. Constitutive elements of muscle fibers are the single motor units, and their electric activity is called a single motor unit potential [7]. The electric activity of large numbers of single motor unit potentials from groups of muscle fibers manifests on the body surface as the EMG. Contraction and relaxation of muscles is accompanied by proportionate EMG signals. The retina of the eye is a multilayered and rather regularly structured organ containing cells called rods and cones, cells that sense light and color. Motion of the eyeballs inside the conductive contents of the skull alters the electric potentials. Placing the electrode in the vicinity of the eyes (on either side of the eyes on the temples or above and below the eyes) picks up the potentials associated with eye movements called EOGs. Thus, it is clear that biopotentials at the cellular level play an integral role in the function of various vital organs.

64.3 Biopotentials

Biopotentials from organs are diverse. Table 64.1 lists some of these biopotentials, their representative clinical applications, and their key measurement indices and associated sensors. Note that all acquisitions are made with the aid of specialized electrodes in which actual design may be customized for specific needs. The most noteworthy features of biopotentials are [1,8]

- Small amplitudes (10 μV–10 mV)
- Low-frequency range of signals (dc to several hundred hertz)

TABLE 64.1 Biopotentials, Specifications, and Applications

Source	Amplitude (mV)	Bandwidth (Hz)	Sensor (Electrodes)	Measurement Error Source	Selected Applications
ECG	1–5	0.05–100	Ag–AgCl disposable	Motion artifact, 50/60 Hz power line interference	Diagnosis of ischemia, arrhythmia, conduction defects
EEG	0.001–0.001	0.5–40	Gold-plated or Ag–AgCl reusable	Thermal (Johnson) RF noise, 50/60 Hz	Sleep studies, seizure detection, cortical mapping
EMG	1–10	20–2000	Ag or carbon, stainless steel, needle	50/60 Hz, RF	Muscle function, neuromuscular disease, prosthesis
EOG	0.01–0.1	dc–10	Ag–AgCl	Skin potential motion	Eye position, sleep state, vestibuloocular reflex

The most noteworthy problems of such acquisitions are

- Presence of biological interference (from skin, electrodes, motion, etc.)
- Noise from environmental sources (power line, radio frequency [RF], electromagnetic, etc.)

These signal acquisition challenges and problems for each of the biopotentials are considered in greater detail in the following texts.

64.3.1 ECG

ECG signals are acquired by placing electrodes directly on the torso, arms, and legs (Figure 64.3a). The activity on the body surface is known to reflect the activity of the heart muscle underneath and in its proximity. A clinically accepted lead system has been devised and is called the 12-lead system [9,10]. It comprises a combination of electrodes taking measurements from different regions designated limb leads, the precordial leads, and the chest leads. Limb leads derive signals from electrodes on the limbs and are designated as leads I, II, and III. Precordial leads are designated aVR, aVL, and aVF and are derived by combining signals from the limb leads. The remaining six leads, V1, V2, …, V6, are chest leads. Together, ECGs from these various leads help define the nature of the activity on a specific part of the heart muscle: for example, ischemia (impaired oxygen supply to the muscle) or infarction (damage to the muscle) on the left side of the chest may be noticeable in lead III.

The ECG signals at the surface of the body are small in amplitude, which make the measurements susceptible to artifacts [11], generated by the relative motion of the electrode and the skin as well as by the activity of the nearby muscles. An important consideration in good ECG signal acquisition is the use of high-quality electrodes [12]. Electrodes made out of silver coated with silver chloride or of sintered Ag–AgCl material are recommended. An electrolytic gel is used to enhance conduction between the skin and the electrode metal. Artifacts at the electrode–skin contact as well as electromagnetic interference from all sources must be minimized [13]. Since ECG instruments are often used in critical-care environments, they must be electrically isolated for safety [14] and protected from the high voltages generated by defibrillators [15].

ECG biopotential amplifiers find use in many monitoring instruments, pacemakers, and defibrillators [16]. ECG signal acquisition is also useful in many clinical applications including diagnosis of arrhythmias, ischemia, or heart failure.

64.3.2 EEG

EEG signals are characterized by their extremely small amplitudes (in the microvolt range). Gold-plated electrodes are placed very securely on the scalp to make a very low-resistance contact. A clinically

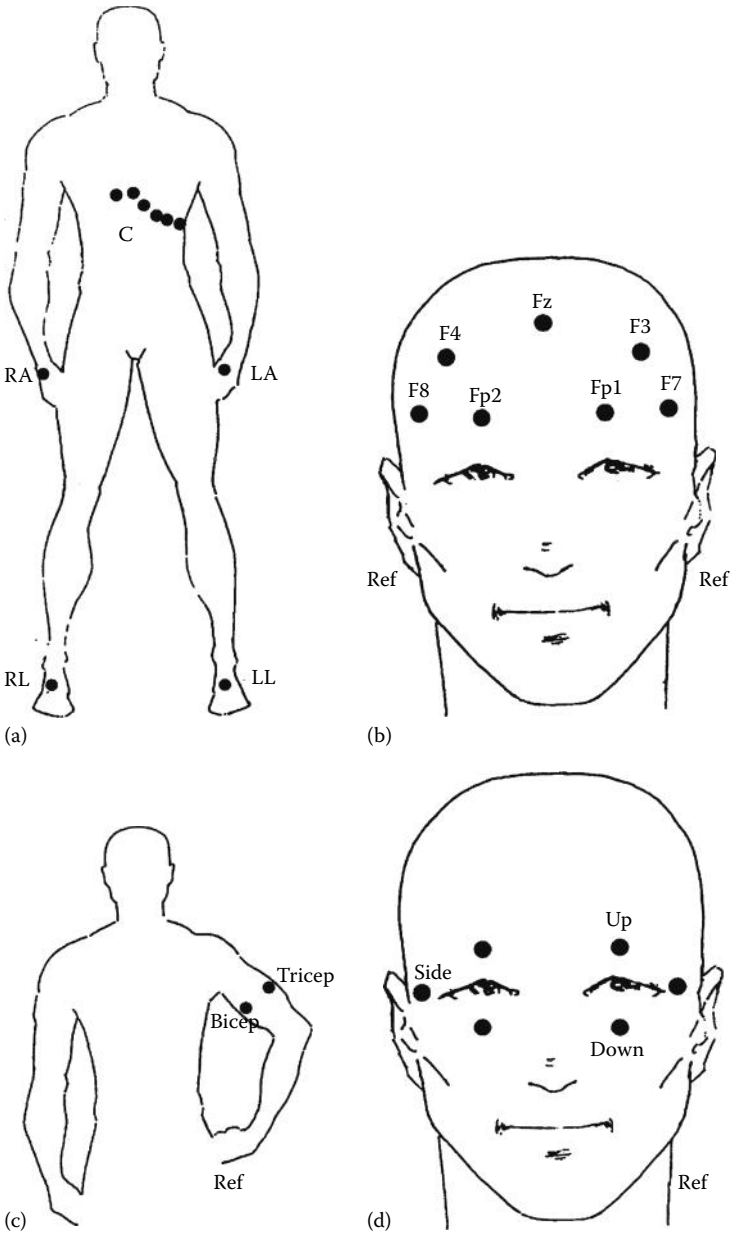

FIGURE 64.3 Schematics showing how biopotential signals are recorded from the human body: (a) ECG: 12-lead ECG is recorded using right arm (RA), left arm (LA), left leg (LL), right leg reference (RL), and six chest (C) electrodes, (b) EEG: selected electrode locations from the standard 10–20 EEG lead system with ears used as reference, (c) EMG: recording electrodes on the biceps and triceps with an independent reference, and (d) EOG: electrodes above or below (up–down) and the sides of the eyes along with an independent reference.

accepted lead system [17], which includes several electrodes placed uniformly around the head, is called the 10- to 20-lead system (Figure 64.3b). This comprehensive lead system allows localization of diagnostic features, such as seizure spikes, in the vicinity of the electrode [18].

EEG signals are difficult to interpret since they represent the comprehensive activity of billions of neurons transmitted via the brain tissues, fluids, and scalp [18]. Nevertheless, certain features can be interpreted.

In the waveform itself, it is possible to see interictal seizure spikes or a full seizure (such as petit mal and grand mal epilepsy) [18]. Analysis of the frequency spectrum of the EEG can reveal changes in the signal power at different frequencies being produced during various stages of sleep, as a result of anesthetic effects and sometimes as a result of brain injury [17].

Practical problems and challenges associated with EEG signal recordings arise from physiological, environmental, and electronic noise sources. Physiological sources of interference are motion artifact, muscle noise, eye motion or blink artifact, and sometimes even heartbeat signals. Electrical interference arises from the usual sources: 60 Hz power lines, RFs, and electrically or magnetically induced interference. Moreover, the electronic components in the amplifier also contribute noise. Good design and measuring techniques can mitigate the effects of such noise and interference.

64.3.3 EMG

Muscle fibers generate electric activity whenever muscles are active [19]. EMG signals are recorded by placing electrodes close to the muscle group (Figure 64.3c). For example, a pair of electrodes placed on the biceps and another pair placed on the triceps can capture the EMG signals generated when these muscles contract. EMG signals recorded in this manner have been shown to give a rough indication of the force generated by the muscle group [8]. Electrodes used for such applications should be small, securely attached, and should provide recordings free of artifacts. Either silver–silver chloride or gold-plated electrodes perform quite well, although inexpensive stainless steel electrodes may also suffice.

Since the frequency range of EMG signals is higher than that of ECG and EEG signals, and since the signals are of comparable or larger amplitudes, the problem of motion artifact and other interference is relatively less severe. Filtering can reduce the artifact and interference: for example, setting the bandwidth to above 20 Hz can greatly reduce the skin potentials and motion artifacts.

Recording activity directly from the muscle fibers themselves can be clinically valuable in identifying neuromuscular disorders [19]. Therefore, invasive electrodes are needed to access the muscle fibers or the neuromuscular junction. Fine-needle electrodes or thin stainless steel wires are inserted or implanted to obtain local recording from the fibers or neuromuscular junctions [7].

64.3.4 EOG

Electric potentials are generated as a result of movement of the eyeballs within the conductive environment of the skull. The generation of EOG signals can be understood by envisaging dipoles (indicating separated positive and negative potential sources) located in the eyeballs. Electrodes placed on either side of the eyes or above and below them pick up the potentials generated by the motion of the eyeball (Figure 64.3d). This potential varies approximately in proportion to the movement of the eyeballs, and hence EOG is sometimes used to study eye positions or disorders of eye movement and balance (a reflex called vestibuloocular reflex affects the nystagmus of the eye). Similarly, saccades inherent in eye motion as well as blinking of the eyelids can produce changes in the EOG signal.

This signal is small (10–100 μV) and has low frequencies (dc to 10 Hz) [8]. Hence, an amplifier with a high gain and good low-frequency response and dc stability is desirable. Additionally, the electrode–gel combination should be such that it produces low levels of junction potential, motion artifacts, and drift in the dc signal [20]. Practical problems associated with dc drift, motion artifacts, and securing electrodes in the vicinity of the eyes make their long-term use problematic. Nevertheless, EOG signals can be useful clinically in acute studies of human disorders and therefore careful acquisition of the signal followed by appropriate analysis is used to interpret the EOG potentials.

Other biopotential recording techniques follow similar principles of measurements. The electrode design should be specifically adapted to the source of the signal. A thorough effort is required to minimize the noise and interference by improving electrode design and placement and optimizing

the amplifier circuit. Good electrode attachment along with selective filtering at the amplifier can help obtain relatively noise-free recording. The design principles and practical considerations are described later.

64.4 Principles of Biopotential Measurements

The unifying principles of biopotential recordings involve

- Electrode design and its attachment suited to the application
- Amplifier circuit design for suitable amplification of the signal and rejection of noise and interference
- Good measurement practices to mitigate artifacts, noise, and interference

64.5 Electrodes for Biopotential Recordings

Electrodes for biopotential recordings are designed to obtain the signal of interest selectively while reducing the potential to pick up artifact. The design should be pragmatic to reduce cost and allow for good manufacturing and reliable long-term use. These practical considerations determine whether high-quality but reusable electrodes made of silver or gold or cheaper disposable electrodes are used [20].

64.5.1 Silver–Silver Chloride Electrodes

The classic, high-quality electrode design consists of highly conductive metal, silver, interfaced to its salt, silver chloride, and connected via an electrolytic gel to the human body [21]. Silver–silver chloride-based electrode design is known to produce the lowest and most stable junction potentials [1,20]. Junction potentials are the result of the dissimilar electrolytic interfaces and are a serious source of electrode-based motion artifacts. Therefore, additionally, an electrolytic gel typically based on sodium or potassium chloride is applied to the electrode. A gel concentration in the order of 0.1 M (molar concentration) results in a good conductivity and low junction potential without causing skin irritation.

Reusable silver–silver chloride electrodes (Figure 64.4a) are made of silver disks coated electrolytically by silver chloride [1], or, alternatively, particles of silver and silver chloride are sintered together

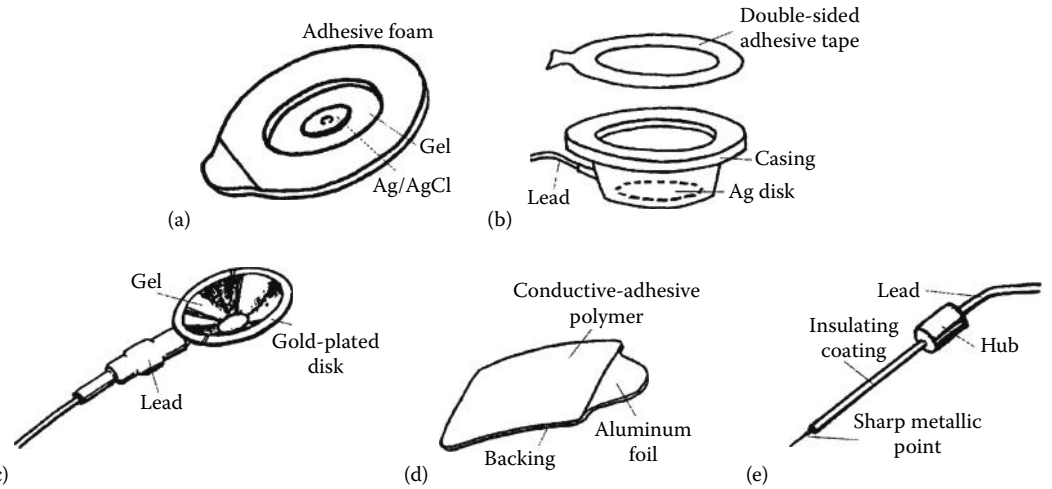

FIGURE 64.4 Examples of electrodes used in biopotential recordings: (a) Disposable Ag–AgCl electrode, (b) reusable Ag–AgCl disk electrode, (c) gold disk electrode, (d) disposable conductive polymer electrode, and (e) needle electrode.

to form the metallic structure of the electrode. The gel is typically soaked into a foam pad or is applied directly in a pocket produced by the electrode housing. The electrode is secured to the skin by means of nonallergenic adhesive tape. The electrode is connected to the external instrumentation typically via a snap-on connector. Such electrodes are well suited for acute studies or basic research investigations.

Disposable electrodes are made similarly, although the use of silver may be minimized (e.g., the snap-on button itself may be silver coated and chlorided). To allow for a secure attachment, a large foam pad attaches the electrode body with adhesive coating on one side (Figure 64.4b). Such electrodes are particularly suited for ambulatory or long-term use.

64.5.2 Gold Electrodes

Gold-plated electrodes (Figure 64.4c), which have the advantages of high conductivity and inertness desirable in reusable electrodes, are commonly used in EEG recordings [1]. Small reusable electrodes are designed so that they can be securely attached to the scalp. The electrode body is also shaped to make a recessed space for electrolytic gel, which can be applied through a hole in the electrode body [18]. The electrodes are attached in hair-free areas by use of a strong adhesive such as collodion or securely attached with elastic bandages or wire mesh. Similar electrodes may also be used for recording EMG, especially when a great deal of motion is expected. Disadvantages of using gold electrodes over silver–silver chloride electrodes include greater expense, higher junction potentials, and greater susceptibility to motion artifacts [20]. On the other hand, gold electrodes maintain low impedance, are inert and reusable, and are good for short-term recordings as long as a highly conductive gel is applied and they are attached securely.

64.5.3 Conductive Polymer Electrodes

It is often convenient to construct an electrode out of a material that is simultaneously conductive and adhesive [20]. Certain polymeric materials have adhesive properties and by attaching monovalent metal ions can be made conductive. The polymer is attached to a metallic backing made of silver or aluminum foil, which allows electric contact to external instrumentation (Figure 64.4d). This electrode does not need additional adhesive or electrolytic gel and hence can be immediately and conveniently used. The conductive polymeric electrode performs adequately as long as its relatively higher resistivity (over metallic electrodes) and greater likelihood of generating artifacts are acceptable. The higher resistivity of the polymer makes these electrodes unsuitable for low-noise measurement. The polymer does not attach as effectively to the skin as does the conventional adhesive on disposable ECG electrodes built with a foam base, and furthermore, the potentials generated at the electrode–skin interface are more readily disturbed by motion. Nevertheless, when the signal level is high and when restricting the subject movement minimizes artifact, the polymeric electrode offers a relatively inexpensive solution to biopotential recording.

64.5.4 Metal or Carbon Electrodes

Although other metals such as stainless steel or brass electrodes [21] are used rather infrequently now because high-quality noble metal electrodes or low-cost carbon or polymeric electrodes are so readily available, historically these metallic electrodes were used in laboratory or clinical settings because of their sturdy construction and reusability. Electrode gel is applied to the metal electrode that is fastened to the body by means of a rubber band. These electrodes have the potential for producing very high levels of artifact and are bulky and awkward to use but do offer the advantage of being reusable and tend to be inexpensive. Carbon or carbon-impregnated polymer electrodes are also used occasionally (although they are mainly used as electrical stimulation electrodes) [20]. These electrodes have a much higher resistivity and are noisier and more susceptible to artifacts, but they are inexpensive,

flexible, and reusable and are thus chosen for applications such as electric stimulation or impedance plethysmography. For these applications, gel is usually not applied and the electrodes are used in "dry" form for easy attachment and removal.

64.5.5 Needle Electrodes

Needle electrodes (Figure 64.4e) comprise a small class of invasive electrodes, used when it is absolutely essential to record from the organ itself. The most common application is in recording from muscles or muscle fibers [8]. A metallic, typically steel, wire is delivered via a needle inserted at the site of the muscle fiber. The wire is hooked and hence fastens to the muscle fiber, even as the needle is removed. Small signals such as motor unit potentials can be recorded in this manner [7]. For research applications, similar needle or wire electrodes are sometimes connected directly to the heart muscle. Since such electrodes are invasive, their use is limited to only highly specialized and supervised clinical or research applications.

64.6 Biopotential Amplifier

Biopotentials exhibit small amplitudes and low frequencies [22]. Moreover, biopotential measurements are corrupted by environmental and biological sources of interference. Therefore, the essential, although not exhaustive, design considerations include proper amplification and bandwidth, high input impedance, low noise, and stability against temperature and voltage fluctuations. The key design component of all biopotential amplifiers is the instrumentation amplifier [21]. However, each biopotential acquisition instrument has a somewhat differing set of characteristics, necessitating some specialization in the design of the instrumentation amplifier. Table 64.2 summarizes the circuit specialization needed in various biopotential amplifiers, with the ECG amplifier used as the basic design.

64.6.1 Instrumentation Amplifier

The instrumentation amplifier is a circuit configuration that potentially combines the best features desirable for biopotential measurements [8], namely, high differential gain, low common-mode gain, high common-mode rejection ratio (CMRR), and high input resistance [23]. Figure 64.5 shows the design of the basic instrumentation amplifier. The basic circuit design principles have been described elsewhere [23,24]. The instrumentation amplifier is constructed from operational amplifiers, or op amps, which have many of the desirable features listed earlier [25]. The front end of the amplifier has two op amps, which consists of two noninverting amplifiers that have been coupled together by a common resistor R_1. The gain of the first stage is $(1 + 2R_2/R_1)$. The second stage is a conventional differential amplifier with gain of $-(R_4/R_3)$. This design results in the desired differential gain distributed over two stages of the amplifier.

TABLE 64.2 Distinguishing Features and Design Consideration for Biopotentials

Biopotential	Distinguishing Feature	Exclusive Amplifier Design Consideration	Additional Features Desired
ECG[a]	1 mV signal, 0.05–100 Hz BW[b]	Moderate gain, BW, noise, CMRR, input *R*	Electrical safety, isolation, defibrillation protection
EEG	Very small signal (microvolts)	High gain, very low noise, filtering	Safety, isolation, low electrode–skin resistance
EMG	Higher BW	Gain and BW of op amps	Post-acquisition data processing
EOG	Lower frequencies, small signal	dc and low drift	Electrode–skin junction potential, artifact reduction

[a] The ECG signal acquisition is considered as the standard against which the other acquisitions are compared.
[b] BW, bandwidth.

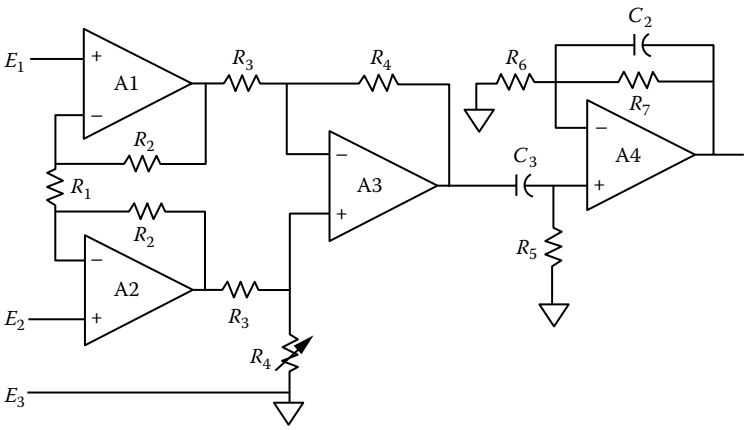

FIGURE 64.5 The instrumentation amplifier. This amplifier has a very high input impedance, high CMRR, and a differential gain set by the resistors in the two amplifier stages. The gain of the first stage (amplifiers Al and A2) is $1 + 2R_2/R_1$, the second stage (amplifier A3) is R_4/R_3, and the third stage (amplifier A4) is $1 + R_7/R_6$. The lower corner frequency is $1/(2\pi R_5 C_1)$ and the upper corner frequency is $1/(2\pi R_7 C_2)$. The variable resistor R is adjusted to maximize the CMRR. Electrodes E_1 and E_2 are the recording electrodes, while E_3 is the reference or the ground electrode.

It also achieves a very high input resistance as a result of the noninverting amplifier front end. It exhibits a very high CMRR as a result of the differential first stage followed by a second-stage differential amplifier. The CMRR is enhanced by adjusting one of the matching resistors and by selecting high CMRR op amps. This instrumentation amplifier is a key design component universal to many biosensor interfaces and almost all biopotential instruments [22]. The LT1167 can replace the front end, while the AD8232 provides a complete ECG amplifier.

64.6.2 ECG Amplifier

The ECG amplifier can readily be designed using the instrumentation amplifier as the principal building block. Active filters with a lower corner frequency of 0.05 Hz and an upper corner frequency of 100 Hz are also typically added [8].

ECG amplifiers are needed in many applications, such as monitoring in cardiac intensive-care units, where safety and protection are of paramount importance. Because the possibility of a direct or low-resistance access to the heart via catheters or intravenous lines exists in such settings, very small electric leakage currents can be fatal. Consequently, leakage from the amplifier is required to be below the safety standard limit of 10 μA [14]. Additionally, safety of the patient is achieved by providing electrical isolation from the power line and the earth ground, which prevents passage of leakage current from the instrument to the patient under normal conditions or under reasonable failure conditions. Electrical isolation is achieved by using transformer or optical coupling components [9], although it is important to remember that any such design should preserve the bandwidth and linearity of the amplifier. ECG amplifiers are also likely to be operated in circumstances where defibrillators might be used; thus, the amplifier circuit must be protected against the high defibrillation voltages and must be augmented by circuit components such as current-limiting resistors, voltage-limiting diodes, and spark gaps [15].

64.6.3 EEG Amplifiers

The distinguishing feature of an EEG amplifier is that it must amplify very small signals [8]. The amplifier gain must be suitably enhanced to deal with microvolt or lower levels of signals. Furthermore, all

components of the amplifier must have a very low thermal noise and in particular low electronic (voltage and current) noise at the front end of the amplifier. EEG amplifiers used in clinical applications again must be electrically isolated and protected against high defibrillation voltages, similar to the ECG amplifier.

64.6.4 EMG Amplifiers

EMG amplifiers are often used in the investigation of muscle performance, neuromuscular diseases, and in building certain powered or smart prostheses. In such applications, slightly enhanced amplifier bandwidth suffices. In addition, postprocessing circuits are almost always needed. For example, a rectified and integrated EMG signal has been shown to give a rough indication of the muscle activity, approximately related to the force being generated at the location of the EMG electrode [8].

64.6.5 EOG Amplifiers

The EOG signal is small in amplitude and consists of very low frequencies. Therefore, an EOG amplifier must not only have a high gain but also a very good low frequency, or even dc, response. This frequency response also makes the amplifier potentially susceptible to shifts in the junction potential at the skin–electrode interface and to drift in the electronic circuit characteristics. In addition to using good electrodes (Ag–AgCl) and gel (high conductivity), some type of active dc or drift cancellation or correction circuit design may be necessary.

64.7 Circuit Enhancements

The basic biopotential amplifier described earlier, along with the specific design considerations for each biopotential, can yield a signal acquisition of acceptable quality in most laboratory settings. In practice, however, further enhancements are always necessary to achieve acceptable clinical performance in novel applications. These enhancements include circuits for reducing electric interference, filtering noise, reduction of artifacts, electrical isolation of the amplifier, and electrical protection of the circuit against defibrillation shocks [9].

64.7.1 Electrical Interference Reduction

Environmental electric interference is always present, especially in urban hospital environments. It is desirable to eliminate interference before it enters the amplifier, for example, by proper shielding of the subject, leads, and the instrument and by grounding the subject and the instrument. Sources of interference include induced signals from power lines and electric wiring; RF from transmitters, electric motors, and other appliances; and magnetically induced currents in lead wires [13]. Interference induced on the body common to the biopotential sensing electrodes is called the common-mode interference (as distinguished from the biopotential that is differential to the sensing electrodes). If the induced current is i_d and the resistance to ground is R_0, then the common-mode interference potential is $V_c = i_d R_0$. The common-mode interference is principally rejected by a differential or instrumentation amplifier with a high CMRR. Further improvement is possible by use of the "driven right leg circuit." The right leg lead, by standard convention, is used as the ground or the circuit reference. The driven right leg circuit employs the clever idea of negative feedback of the common-mode signal into this lead. The common-mode signal is sensed from the first stage of the instrumentation amplifier, amplified and inverted, and fed back into the right leg lead (Figure 64.6a). At this stage the common-mode signal is reduced to $(i_d R_0)/(1 + 2R_2/R_1)$. Thus, the common-mode interference is greatly reduced at its source. The driven right leg circuit along with a high CMRR of the amplifier and filtering permit very high-quality biopotential measurements.

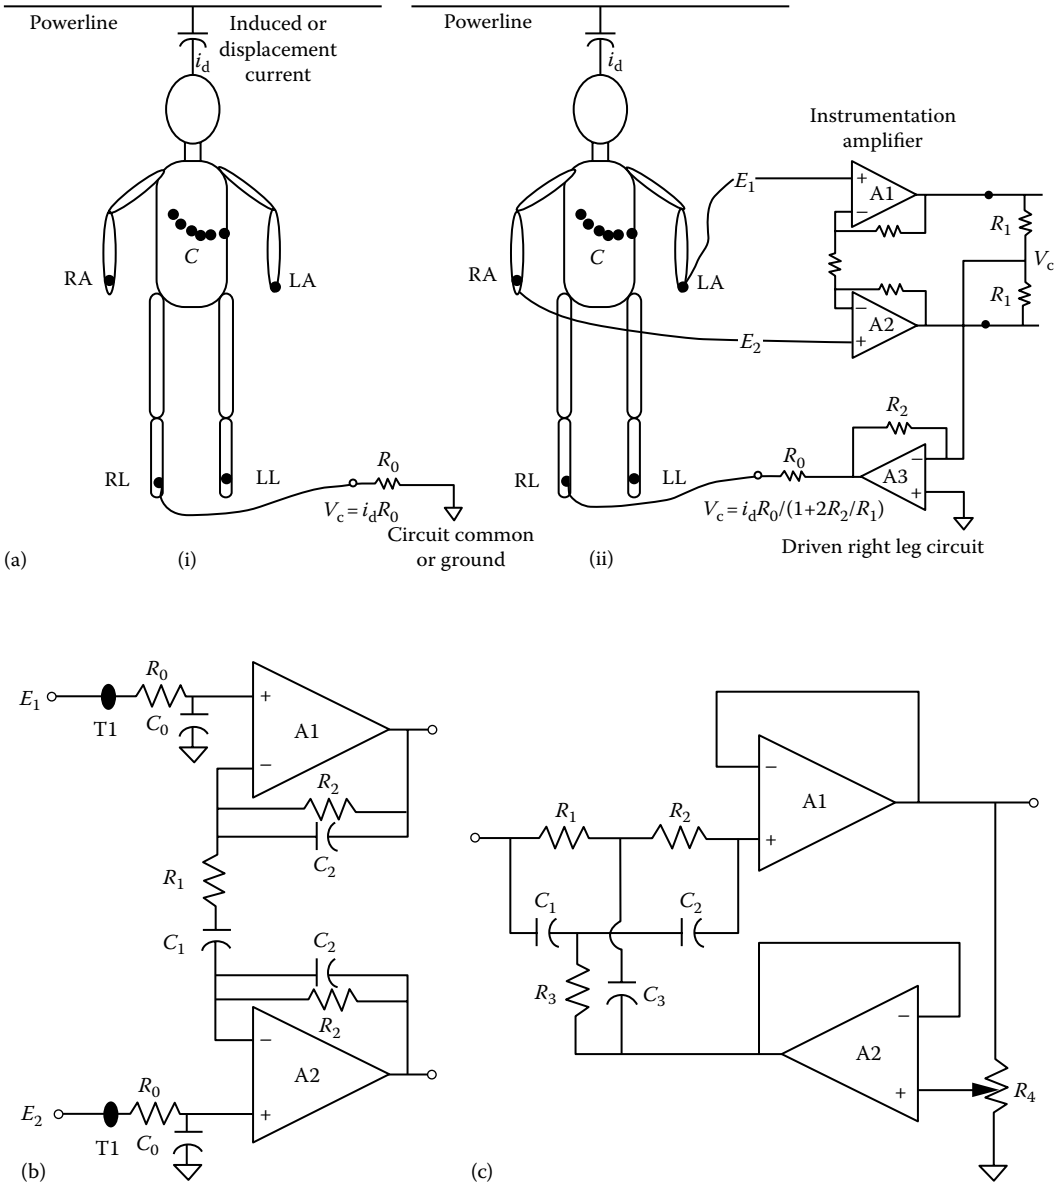

FIGURE 64.6 Circuit enhancements for biopotential measurements. (a) The schematic on the left shows electric interference induced by the displacement current i_d from the power line. This current flows into the ground electrode lead generating common-mode voltage V_c. The driven right leg circuit on the right uses negative feedback into the right leg electrode to reduce the effective common-mode voltage. (b) Amplifier front end filters—T1: RF choke; R_0 and C_0: RF filter; R_1 and C_1: high-pass filter; R_2 and C_2: low-pass filter. (c) Notch filter for power line interference (50 or 60 Hz): twin T notch filter in which notch frequency is governed by R_1, R_2, R_3, C_1, C_2, and C_3 and notch tuning by R_4.

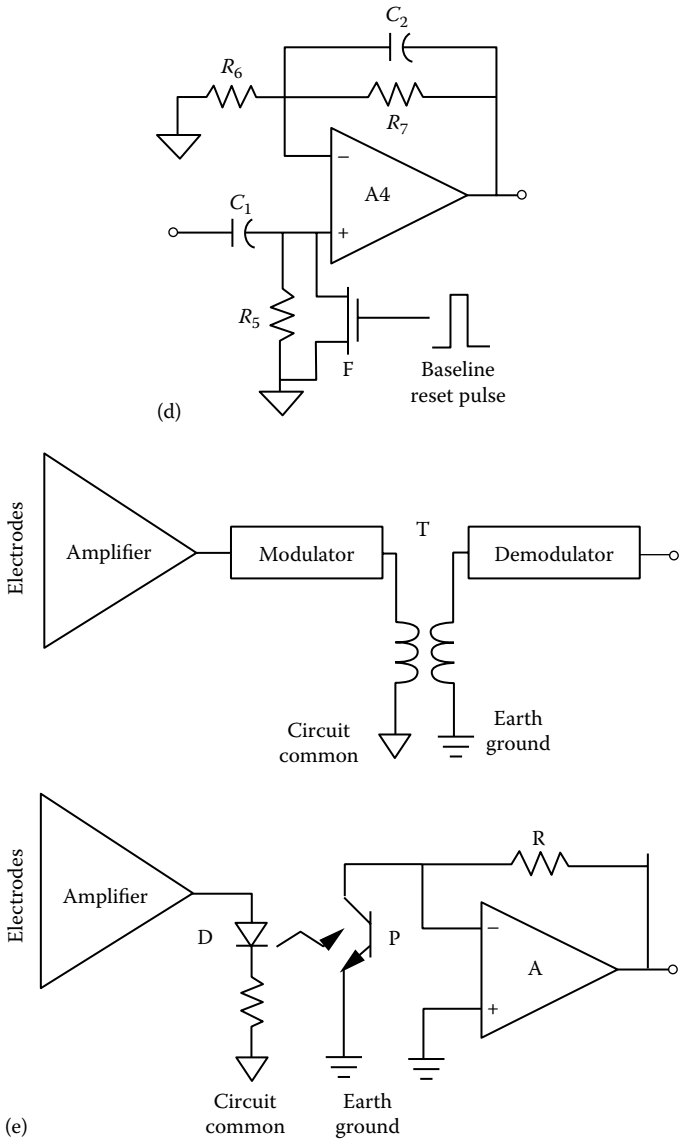

FIGURE 64.6 (continued) Circuit enhancements for biopotential measurements. (d) Baseline restoration circuit: the high-pass filter capacitor C1 is discharged by field effect transistor F when activated manually or automatically by a baseline restoration pulse. (e) Electrical isolation: transformer coupled using the transformer T (top) or optical using the diode D and the photodetector P (bottom). Note that the isolator separates circuit common on the amplifier side from the earth ground on the output side.

(*continued*)

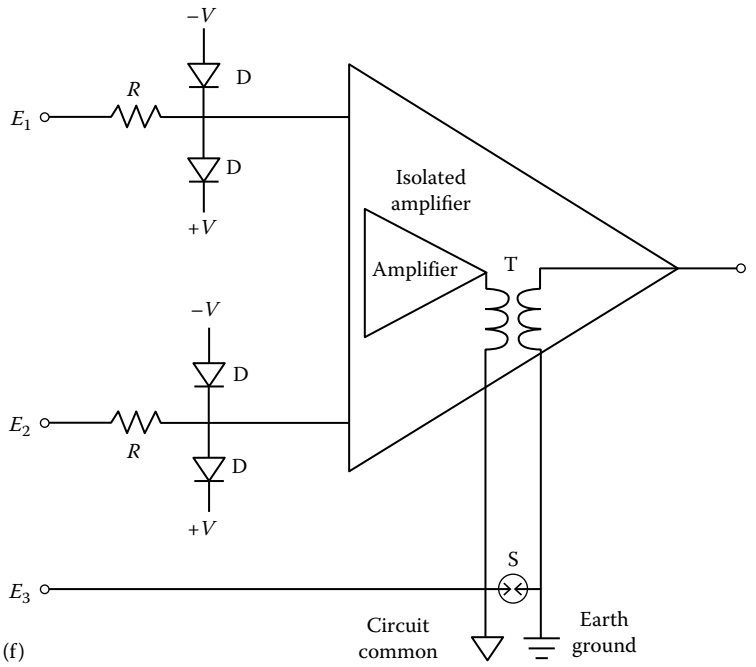

FIGURE 64.6 (continued) Circuit enhancements for biopotential measurements. (f) Electrical protection circuit: resistance R limits the current, reverse-biased diodes D limit the input voltage, and the spark gap S protects against defibrillation pulse-related breakdown of the isolation transformer T.

64.7.2 Filtering

After following the precautions described earlier, filtering at the front end of the amplifier and limiting the bandwidth of the biopotential amplifier can further help to reduce the interference (Figure 64.6b). Small inductors or ferrite beads in the lead wires help to block very high-frequency electromagnetic interference. Small capacitors between each electrode lead and ground filter the RF interference. Bandwidth limitation can be imposed at each stage of the amplifier. Because dc potentials arising at the electrode–skin interface must be blocked well before the biopotential is amplified greatly (otherwise, the amplifier could saturate), use of high-pass filtering in the early stages of amplification is recommended. Low-pass filtering at several stages of amplification is recommended to attenuate residual RF interference as well as muscle signal interference. Power line interference at 50 or 60 Hz and their harmonics clearly pose the biggest problem in biopotential measurement [11,13]. Sometimes it may be desirable to provide a 50 or 60 Hz notch filter to remove the power line interference (Figure 64.6c), an option that is often available with low-level signal (EEG, EOG) measuring instruments. The risk of a distorted biopotential signal arises when a notch filter is used and this may affect diagnosis. Filtering should, therefore, be used selectively.

64.7.3 Artifact Reduction

One principal source of artifact is the potential arising at the electrode–skin interface [11]. Slow changes in the baseline can arise due to changes in the junction potential at this interface and, in some instances, can cause a temporary saturation of the amplifier [9]. This event is detected manually or automatically (by quickly discharging the high-pass capacitor in the amplifier to restore the baseline; Figure 64.6d). Movement of the subject or disturbance of the electrode can produce motion artifacts [11], which can be reduced by filtering the signal, but as suggested earlier, such filtering, typically high pass, can severely distort the biopotential being measured. Alternatively, computerized processing may be necessary to

identify an artifact and delete it from display and processing. Of note, a biopotential source could be the desired one in one case but an unwanted artifact in another case. For example, EOG signal resulting from blinking of eyes can produce a rather significant artifact in EEG recordings. Similarly, EMG signals become unwanted artifacts in all other non-EMG biopotential measurements. ECG monitoring must especially account for EMG artifact for high-fidelity recording. Another example is the pacemaker pulse. Since a pacemaker pulse can be detected and amplified as a short (about 2 ms) pulse preceding a QRS complex, it can be mistakenly interpreted as a heartbeat by some circuits for automatically determining heart rate. Special circuits must be designed to identify and delete this artifact [9].

64.7.4 Electrical Isolation

Electrical isolation limits the possibility of the passage of any leakage current from the instrument in use to the patient [22]. Conversely, patient safety must be ensured by electrical isolation to reduce the prospect of leakage of current from any other sensor or instrument attached to the patient to the earth ground of the instrument being tested [8]. Passage of leakage current through the patient could be harmful or even fatal if this current were to leak to the heart via a catheter or intravenous line. Electrical isolation can be done electrically by inserting a transformer in the signal path or optically by introducing an optical coupler (Figure 64.6e). Since the primary and the secondary of the transformer remain electrically isolated, no direct path to ground can exist. One problem with this approach is that the transformer is inherently an ac high-frequency device. Therefore, a suitable solution is to modulate the biopotential signal using a high-frequency carrier preferred by the transformer. An alternative solution is to use optical isolation. The electric signal from the amplifier is first converted to light by a light-emitting diode (LED). This optical signal is modulated in proportion to the electric signal and transmitted to the detector. A photodetector (photodiode or a phototransistor) then picks up the light and converts it into an electric signal, which is then demodulated to recover the original signal. The optical signal is typically pulse code modulated to circumvent the inherent nonlinearity of the LED–phototransistor combination.

64.7.5 Defibrillation Protection

Biopotential measuring instruments can encounter very high voltages, such as those from electric defibrillators that can damage the instrument [9]. For example, electric shocks in the order of 1500–5000 V may be produced by an external defibrillator [1]. Other high-voltage sources are electrocautery (used in surgery) and power lines (inadvertent short circuits in the instrument). Therefore, the front end of the biopotential instrument must be designed to withstand these high voltages (Figure 64.6f). Use of resistors in the input leads can limit the current in the lead and the instrument. Protection against high voltages is achieved by the use of diodes or Zener diodes. These components conduct at 0.7 V (diode conduction voltage) or 10–15 V (depending on the Zener diode breakdown voltage), thus protecting the sensitive amplifier components. Since it is more likely that protection against higher voltages will be needed, low-pressure gas discharge tubes such as neon lamps are also used. They break down at voltages on the order of 100 V, providing an alternative path to ground for the high voltages. As a final line of protection, the isolation components (optical isolator or transformer) must be protected by a spark gap that activates at several thousand volts. The spark gap ensures that the defibrillation pulse does not breach the isolation.

64.8 Measurement Practices

Biopotential measurements are made feasible, first of all, by good amplifier designs. High-quality biopotential measurements require use of good electrodes and their proper application on the patient, along with good laboratory or clinical practices. These practices are summarized later.

64.8.1 Electrode Use

Various electrodes best suited for each biopotential measurement were described earlier. First, different electrodes by virtue of their design offer distinguishing features: more secure (use of strong but less-irritant adhesives), more conductive (use of noble metals such as silver and gold), and less prone to artifact (use of low-junction-potential materials such as Ag–AgCl). Electrode gel can be of considerable importance in maintaining a high-quality interface between the electrode metal and the skin. High-conductivity gels, in general, help reduce the junction potentials along with the resistance (they tend, however, to be allergenic or irritating and hence a practical compromise in terms of electrolyte concentration must be found) [20]. Movement of the electrode with respect to the electrode gel and the skin is a potential source of artifact (Figure 64.7a). Such movements can change the electrode junction to skin potentials, producing motion artifacts [21]. Placement above bony structures where there is less muscle mass can reduce unwanted motion artifact and EMG interference (Figure 64.7b). Electrodes must be securely attached, for example, with stress loops secured away from the electrode site, so that motion artifact can be reduced. In certain instances, the electrodes may be essentially glued to the skin, as in the case of EEG measurements.

64.8.2 Skin Preparation

The potentials existing at the skin surface, attributable to potentials at the membranes of cells in the epidermal layers of the skin, can result in a large dc potential (which can be a significant problem in EOG measurements). Any disturbance of the skin by motion, touching, or deformation can cause this potential to change and result in motion artifacts (Figure 64.7a). Sweat glands in the epidermis can also contribute varying extents of skin resistance and skin potential. Such potentials and artifacts can be reduced by abrading the epidermal skin. A mild abrasion by sandpaper or its equivalent can significantly reduce skin resistance and skin potential and thereby reduce artifact [26]. A less traumatic but somewhat less effective approach is to use an alcohol swab or similar skin-cleansing solution to wet and clean the skin surface to remove debris, oils, and damaged or dead epidermal cells. Sometimes, as with EEG measurements where very low signals are recorded and very low noise is permitted, skin resistance must be significantly lowered, perhaps to below 2 kΩ [18]. Obviously, reduced motion or muscle activity while measurement is carried out also helps.

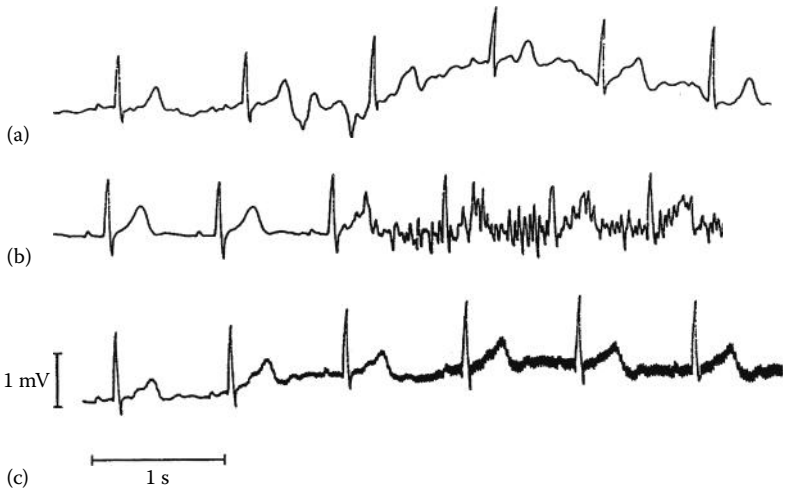

FIGURE 64.7 Examples of electric interference in biopotential recordings: (a) ECG signal with baseline changes and motion artifacts, (b) muscle signal interference, and (c) electromagnetic interference (60 Hz power line and RF).

64.8.3 Reduction of Environmental Interference

Electromagnetic interference radiated from the power lines, RF interference from machines, induced magnetic field in the leads, and electric currents induced on to the body are all potential sources of environmental interference (Figure 64.7c). Shielding of the amplifier along with the electrode and the lead, and in certain extreme conditions shielding of the subject (e.g., when taking magnetic field measurements from the body), can greatly help reduce the signals picked up by or induced into the amplifier. The electrode leads can be shielded or at the very least twisted together to reduce induced electromagnetic interference.

The amplifier circuit should also have extensive filtering of unwanted electromagnetic interference. To eliminate RF interference, filter capacitors should be used in the front end of the amplifier as well as at various stages of the amplifier. Very high frequencies can be blocked by the use of a choke or an inductor at the input leads. The effect of electrostatic interference can be minimized or eliminated by grounding the instrument.

Electric interference in the environment induces current into the body, which is then picked up by the biopotential amplifier as a common-mode voltage [27]. The CMRR property of the amplifier is essential for reduction of the common-mode voltage [24]. Finally, the driven right leg design [27], described earlier, can be optionally used to reduce further the common-mode voltage and the effective interference.

64.9 Conclusions

Biopotential acquisition is a well-developed science, and acceptable engineering design solutions do exist. It is apparent that each biopotential source presents its own distinct challenge in terms of electrode interface, amplifier design, pre- or postprocessing, and practical implementation and usage. ECG signals can be best acquired using Ag–AgCl electrodes, although good experimental/clinical practice is needed to reduce biological and environmental interference. Further circuit protection and isolation are necessary in clinical usage. EEG signals are distinguishable by their very low amplitude, and hence EEG electrodes must be securely attached via a very small electrode–skin resistance and the amplifier must exhibit exceptionally low noise. For EMG acquisition, electrodes are needed that can be attached for long periods of time to the muscle groups under study. The EMG signal inevitably needs postprocessing, such as integration, to derive a measure of muscle activity. EOG signals have small amplitudes and are characterized by dc or low frequencies. Skin–electrode potentials and dc drift of the amplifier are, therefore, important considerations.

These biopotential measurement principles are applicable to a variety of conventional as well as emerging applications. For example, although ECG acquisition is used mainly in cardiac monitors, it is also of interest and importance in implantable pacemakers and defibrillators. EEG acquisition is useful in the detection of seizure spikes and study of sleep patterns and it may also be used to identify cortical dysfunction after trauma or stroke. EMG acquisition is used in diagnosing neuromuscular diseases. Interesting attempts have been made to use EMG for controlling prostheses. EOG has been helpful in diagnosing vestibuloocular disorders and also has been studied as a way of operating communication devices (pointing) used by quadriplegics. The measurement and instrumentation principles described in this chapter would be applicable, with some modifications, to these emergent applications.

Blood Pressure Measurement

65.1 Introduction

Blood pressure measurements have been part of the basic clinical examination since the earliest days of modern medicine. The origin of blood pressure is the pumping action of the heart, and its value depends on the relationship between cardiac output and peripheral resistance. Therefore, blood pressure is considered as one of the most important physiological variables with which to assess cardiovascular hemodynamics. Venous blood pressure is determined by vascular tone, blood volume, cardiac output, and the force of contraction of the chambers of the right side of the heart. Since venous blood pressure must be obtained invasively, the term *blood pressure* most commonly refers to arterial blood pressure, which is the pressure exerted on the arterial walls when blood flows through the arteries. The highest value of pressure, which occurs when the heart contracts and ejects blood to the arteries, is called the systolic pressure (SP). The diastolic pressure (DP) represents the lowest value occurring between the ejections of blood from the heart. Pulse pressure (PP) is the difference between SP and DP, that is, PP = SP–DP. The period from the end of one heart contraction to the end of the next is called the cardiac cycle. Mean pressure (MP) is the average pressure during a cardiac cycle.

Mathematically, MP can be decided by integrating the blood pressure over time. When only SP and DP are available, MP is often estimated by an empirical formula:

$$\mathrm{MP} \approx \mathrm{DP} + \frac{\mathrm{PP}}{3} \tag{65.1}$$

Note that this formula can be very inaccurate in some extreme situations. Although SP and DP are most often measured in the clinical setting, MP has particular importance in some situations because it is the driving force of peripheral perfusion. SP and DP can vary significantly throughout the arterial system, whereas MP is almost uniform in normal situations.

The values of blood pressure vary significantly during the course of 24 h according to an individual's activity [1]. Basically, three factors, namely, the diameter of the arteries, the cardiac output, and the state or quantity of blood, are mainly responsible for the blood pressure level. When the tone increases in the muscular arterial walls so that they narrow or become less compliant, the pressure becomes higher than normal. Unfortunately, increased blood pressure does not ensure proper tissue perfusion, and in some instances, such as certain types of shock, blood pressure may seem appropriate when peripheral tissue perfusion has all but stopped. Nevertheless, observation or monitoring of blood pressures affords dynamic tracking of pathology and physiology affecting the cardiovascular system. This system in turn has profound effects on the other organs of the body.

65.2 Measurement Techniques

The basis of any physiological measurement is the biological signal, which is first sensed and transduced or converted from one form of energy to another. The signal is then conditioned, processed, and amplified. Subsequently, it is displayed, recorded, or transmitted (in some ambulatory monitoring situations). Blood pressure sensors often detect mechanical signals, such as blood pressure waves, to convert them into electric signals for further processing or transmission. They work on a variety of principles, for example, resistance, inductance, and capacitance. For accurate and reliable measurements, a sensor should have good sensitivity, linearity, and stability [2].

65.3 Indirect Blood Pressure Measurement

Indirect measurement is often called noninvasive measurement because the body is not entered in the process. The upper arm, containing the brachial artery, is the most common site for indirect measurement because of its closeness to the heart and convenience of measurement, although many other sites may have been used, such as forearm or radial artery and finger. Distal sites such as the wrist, although convenient to use, may give much higher SP than brachial or central sites as a result of the phenomena of impedance mismatch and reflective waves [3]. An occlusive cuff is normally placed over the upper arm and is inflated to a pressure greater than the systolic blood pressure. The cuff is then gradually deflated, while a detector system simultaneously employed determines the point at which the blood flow is restored to the limb. The detector system does not need to be a sophisticated electronic device. It may be as simple as manual palpation of the radial pulse. The most commonly used indirect methods are auscultation and oscillometry, each is described later.

65.3.1 Auscultatory Method

The auscultatory method most commonly employs a mercury column, an occlusive cuff, and a stethoscope. The stethoscope is placed over the blood vessel for auscultation of the Korotkoff sounds, which defines both SP and DP. The Korotkoff sounds are mainly generated by the pulse wave propagating through the brachial artery [4]. The Korotkoff sounds consist of five distinct phases. The onset of phase I Korotkoff sounds (first appearance of clear, repetitive, tapping sounds) signifies SP, and the onset of phase V Korotkoff sounds (sounds disappear completely) often defines DP [5].

Observers may differ greatly in their interpretation of the Korotkoff sounds. Simple mechanical error can occur in the form of air leaks or obstruction in the cuff, coupling tubing, or Bourdon gage. Mercury can leak from a column gage system. In spite of the errors inherent in such simple systems, more mechanically complex systems have come into use. The impetus for the development of more

elaborate detectors has come from the advantage of reproducibility from observer to observer and the convenience of automated operation. Examples of this improved instrumentation include sensors using plethysmographic principles, pulse-wave velocity sensors, and audible as well as ultrasonic microphones [6].

The readings by auscultation do not always correspond to those of intra-arterial pressure [5] The differences are more pronounced in certain special occasions such as obesity, pregnancy, arteriosclerosis, and shock. Experience with the auscultation method has also shown that determination of DP is often more difficult and less reliable than SP. However, the situation is different for the oscillometric method where oscillations caused by the pressure pulse amplitude are interpreted for SP and DP according to empirical rules [7].

65.3.2 Oscillometric Method

In recent years, electronic pressure and pulse monitors based on oscillometry have become popular for their simplicity of use and reliability. The principle of blood pressure measurement using the oscillometric technique is dependent on the transmission of intra-arterial pulsation to the occluding cuff surrounding the limb. An approach using this technique could start with a cuff placed around the upper arm and rapidly inflated to about 30 mmHg above the systolic blood pressure, occluding blood flow in the brachial artery. The pressure in the cuff is measured by a sensor. The pressure is then gradually decreased, often in steps, such as 5–8 mmHg. The oscillometric signal is detected and processed at each step of pressure. The cuff pressure can also be deflated linearly in a similar fashion as the conventional auscultatory method.

Figure 65.1 illustrates the principle of oscillometric measurement along with auscultatory measurement. Arterial pressure oscillations are superimposed on the cuff pressure when the blood vessel is no longer fully occluded. Separation of the superimposed oscillations from the cuff pressure is accomplished by filters that extract the corresponding signals. Signal sampling is carried out at a rate determined by the pulse or heart rate [7]. The oscillation amplitudes are most often used with an empirical algorithm to estimate SP and DP. Unlike the Korotkoff sounds, the pressure oscillations are detectable throughout the whole measurement, even at cuff pressures higher than SP or lower than DP. Since many oscillometric devices use empirically fixed algorithms, variance of measurement can be large across a wide range of blood pressures [8]. Significantly, however, MP is determined by the lowest cuff pressure of maximum oscillations [9] and has been strongly supported by many clinical validations [10,11].

65.3.3 Self-Measurement

From the growing number of publications on the topic in recent years, it is evident that the interest in self-measurement of blood pressure has increased dramatically. There is also evidence that the management of patients with high blood pressure can be improved if clinic measurements are supplemented by home or ambulatory monitoring. Research has shown that blood pressure readings taken in the clinic can be elevated, by as much as 75 mmHg in SP and 40 mmHg in DP, when taken by a physician. The tendency for blood pressure to increase in certain individuals in the presence of a physician due to stress response is generally known as "white-coat" hypertension [12]. When reasonably priced and easy to use, oscillometric devices became commonly available in the early 1970s, public interest in the self-measurement of blood pressure increased, and this has made it possible for greater patient involvement in the detection and management of hypertension [13]. Health-care costs may also be reduced by home monitoring. Indeed, a recent study found that costs were almost 30% lower for patients who measured their own blood pressure than those who did not [14]. Measurements taken at patient's home are more highly correlated to 24 h blood pressure levels than clinic readings are. It has also been shown that most patients are able to monitor their blood pressure and may be more relaxed as well as assured by doing so, particularly when experiencing symptoms [15].

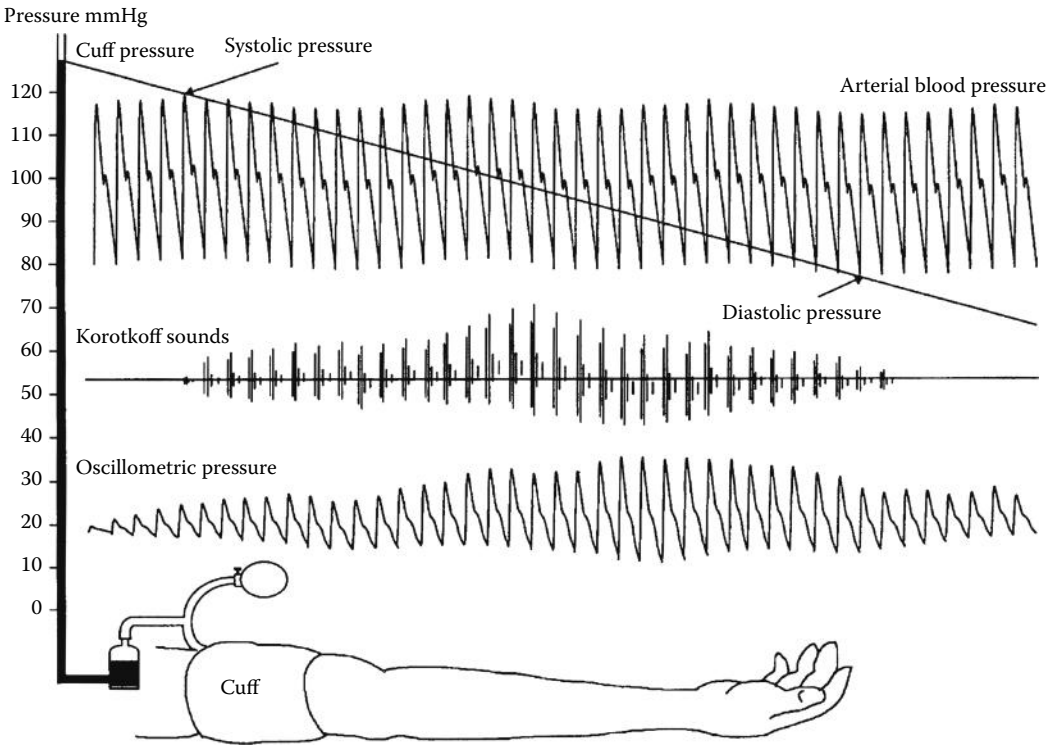

FIGURE 65.1 Indirect blood pressure measurements: oscillometric measurement and auscultatory measurement. (Adapted from Current technologies and advancement in blood pressure measurements—review of accuracy and reliability, *Biomed. Instrum. Technol.*, AAMI, Arlington, VA. With permission.)

65.3.4 Ambulatory Monitoring

There is great significance for ambulatory monitoring of blood pressure. Over a period of 24 h, blood pressure is subject to numerous situational and periodic fluctuations [1]. The pressure readings have a pronounced diurnal rhythm in an individual, with a decrease from 10 to 20 mmHg during sleep and a prompt increase on getting up and walking in the morning. Readings tend to be higher during working hours and lower at home, and they depend on the pattern of activity. After a bout of vigorous exercise or strenuous work, blood pressure may be reduced for several hours. The readings may be raised if the patient is talking during the measurement period. Smoking a cigarette and drinking coffee, especially if they are combined, may both raise the pressure [16]. When assessing the efficacy of antihypertensive drugs, ambulatory blood pressure monitoring can provide considerable information and validation of the drug treatment [17].

Although the technique of noninvasive ambulatory blood pressure monitoring was first described more than three decades ago, it has only recently become accepted as a clinically useful procedure for evaluation of patients with abnormal regulation of blood pressure. It gives the best evaluation for patients who have white-coat hypertension. Technical advances in microelectronics and computer technology have led to the introduction of ambulatory monitors with improved accuracy and reliability, small size, quiet operation, and reasonable low price. They can take and store several hundred readings over a period of 24 h while patients may not be compromised with their normal activities, thus becoming usable for purposes of clinical diagnosis [18]. Theoretically, ambulatory monitoring can provide information about the level and variability covering the full range of blood pressure experienced during day-to-day activities. It is now recognized to be a very useful procedure in clinical

practice since blood pressure varies significantly during the course of 24 h, especially useful in detecting white-coat hypertension. However, many studies have found that accuracy of monitoring using current ambulatory monitors is acceptable only when patients are at rest but not during physical activity [19] or under truly ambulatory conditions. Report of error codes during operation in the latter situations is much higher [20].

65.3.5 Cuff Size

Both the length and width of an occluding cuff are important for accurate and reliable measurement of blood pressure by indirect methods. A too-short or too-narrow cuff results in false high blood pressure readings. Several studies have shown that a cuff of inappropriate size in relation to the patient's arm circumference can cause considerable error in blood pressure measurement [21]. The cuff should also fit around the arm firmly and comfortably. Some manufacturers have designed cuffs with a fastener spaced so that a cuff of appropriate width only fits an arm of appropriate diameter. With this design, the cuff will not stay on the arm during inflation unless it fits accordingly.

According to the American Heart Association (AHA) recommendations [5], the width of the cuff should be 40% of the midcircumference of the limb and the length should be twice the recommended width. Table 65.1 presents the AHA cuff sizes covering from neonates to adults.

65.3.6 Recommendations, Standards, and Validation Requirements

The AHA has published six editions of the AHA recommendations for indirect measurement of arterial blood pressure. The most recent edition [5] included the recommendations of the joint national committee on the diagnosis, evaluation, and treatment of hypertension for classifying and defining blood pressure levels for adults (age 18 years and older) [22], as shown in Table 65.2. The "Report of the Second Task Force on Blood Pressure Control in Children" [23] offered classification of hypertension in young age groups from newborns to adolescents, as shown in Table 65.3.

The AHA recommendations provide a systemic step-by-step procedure for measuring blood pressure, including equipment, observer, subject, and technique. It extends considerations of blood pressure recording in special populations such as infants and children, elderly, and pregnant and obese subjects.

TABLE 65.1 AHA Acceptable Bladder Dimensions for Arm of Different Sizes[a]

Cuff	Bladder Width (cm)	Bladder Length (cm)	Arm Circumference Range at Midpoint (cm)
Newborn	3	6	≤6
Infant	5	15	6–15[b]
Child	8	21	16–21[b]
Small adult	10	24	22–26
Adult	13	30	27–34
Large adult	16	38	35–44
Adult thigh	20	42	45–52

Source: Adapted from the *Recommendations for Human Blood Pressure Determination by Sphygmomanometers*, American Heart Association, Dallas, TX, 1993. With permission.

[a] There is some overlapping of the recommended range for arm circumferences in order to limit the number of cuffs; it is recommended that the larger cuff be used when available.

[b] To approximate the bladder width/arm circumference ratio of 0.40 more closely in infants and children, additional cuffs are available.

TABLE 65.2 Recommendations of the Joint National Committee on the Diagnosis, Evaluation, and Treatment of Hypertension for Classifying and Defining Blood Pressure Levels for Adults (Age 18 Years and Older)[a]

Category	SP (mmHg)	DP (mmHg)
Normal[b]	<130	<85
High normal	130–139	85–89
Hypertension[c]		
Stage 1 (mild)	140–159	90–99
Stage 2 (moderate)	160–179	100–109
Stage 3 (severe)	180–209	110–119
Stage 4 (very severe)	≥210	120

[a] Not taking antihypertensive drugs and not acutely ill. When SPs and DPs fall into different categories, the higher category should be selected to classify the individual's blood pressure status. For instance, 160/92 mmHg should be classified as stage 2, and 180/120 mmHg should be classified as stage 4. Isolated systolic hypertension is defined as a systolic blood pressure of 140 mmHg or more and a diastolic blood pressure of less than 90 mmHg and staged appropriately (e.g., 170/85 mmHg is defined as stage 2 isolated systolic hypertension). In addition to classifying stages of hypertension on the basis of average blood pressure levels, the clinician should specify presence or absence of target-organ disease and additional risk factors. For example, a patient with diabetes and a blood pressure of 142/94 mmHg plus left ventricular hypertrophy should be classified as having "stage 1 hypertension with target-organ disease (left ventricular hypertrophy) and with another major risk factor (diabetes)." This specificity is important for risk classification and management.

[b] Optimal blood pressure with respect to cardiovascular risk is less than 120 mmHg systolic and less than 80 mmHg diastolic. However, unusually low readings should be evaluated for clinical significance.

[c] Based on the average of two or more readings taken at each of two or more visits after an initial screening.

It also provides recommendations of self-measurement or home measurement of blood pressure, as well as ambulatory blood pressure measurement.

The Association for the Advancement of Medical Instrumentation (AAMI) and American National Standard Institute (ANSI) published and revised a national standard [24,25] for evaluating electronic or automated sphygmomanometers. This standard established labeling requirements, safety and performance requirements, and referee test methods for electronic or automated sphygmomanometers used in indirect measurement of blood pressure. Specific requirements for ambulatory blood pressure monitors were also included. Recently, AAMI/ANSI amended this SP10 standard to include neonatal devices as well [26]. Some of the specific requirements, procedures, and limits were modified to fit neonatal applications, such as the maximum cuff pressure, ranges of age and weight, reference standards for validation, and minimum sample size of data. The overall system efficacy for both neonatal and adult devices requires that for SPs and DPs treated separately, the mean difference between the paired measurements of the test system and the reference standard shall be ±5 mmHg or less, with a standard deviation of 8 mmHg or less.

For manual or nonautomated indirect blood pressure measuring devices, ANSI/AAMI SP9 standard [27] applies.

The British Hypertension Society (BHS) also published and revised a protocol for assessing accuracy and reliability of blood pressure measurement using automatic and semiautomatic devices [28,29]. Many automatic and semiautomatic devices, including ambulatory devices, have been evaluated according to the BHS protocol. Such evaluation provided a quality-control mechanism for manufacturers and an objective comparison for customers. However, there are many more devices available on the market,

TABLE 65.3 Classification of Hypertension in the Young by Age Group

Age Group	High Normal (90th–94th Percentile) (mmHg)	Significant Hypertension (95th–99th Percentile) (mmHg)	Severe Hypertension (>99th Percentile) (mmHg)
Newborns (SBP)		96–105	≥106
7 days	—	104–109	≥110
8–30 days	—		
Infants (≥2 year)			
SBP	104–111	112–117	≥118
DBP	70–73	74–81	82
Children			
3–5 year			
SBP	108–115	116–123	≥124
DBP	70–75	76–83	≥84
6–9 year			
SBP	114–121	122–129	≥130
DBP	74–77	78–85	≥86
10–12 year			
SBP	122–125	126–133	≥134
DBP	78–81	82–89	≥90
13–15 year			
SBP	130–135	136–143	≥144
DBP	80–85	86–91	≥92
Adolescents			
16–18 year

SBP, systolic blood pressure; DBP, diastolic blood pressure.

which have not been accordingly evaluated. Different from the AAMI SP10 standard in which either indirect or direct blood pressure may be used as a reference standard, the BHS protocol relies exclusively on references of sphygmomanometric blood pressure measurement and does not recommend comparison with intra-arterial blood pressure values [30]. This could make accurate validation of ambulatory devices difficult because sphygmomanometric measurements during exercise and under ambulatory conditions are not accurate [31].

Significantly, the BHS protocol emphasized the need on special-group validation, such as children, pregnancy, and the elderly for the intended use. It also emphasized the need for validation under special circumstances, such as exercise and posture. The accuracy criteria use a grading system based on the percentages of test instrument measurements differing from the sphygmomanometric measurements by ≤5, ≤10, and ≤15 mmHg for systolic and diastolic blood pressure, respectively, as shown in Table 65.4.

65.3.7 Manufacturer, Product, Price, Efficacy, and Technology

The annual publication of the *Medical Device Register* is a comprehensive reference work that provides a wealth of detailed information on U.S. and international medical devices, medical device companies, OEM suppliers, and the key personnel in the industry. Blood pressure devices are listed in the sphygmomanometer directory. Price information of specific models for some providers is also published. For example, A&D Engineering, Inc. listed price from $51.95 (model UA701) to $179.95 (model UA-751) for a

TABLE 65.4 Grading Criteria of the 1993 BHS Protocol[a,b]

Grade	Absolute Difference between Standard and Test Device (mmHg)		
	≤5	≤10	≤15
	Cumulative Percentage of Readings		
A	60	85	95
B	50	75	90
C	40	65	85
D	Worse than C

[a] Grades are derived from percentages of readings within 5, 10, and 15 mmHg. To achieve a grade, all three percentages must be equal to or greater than the tabulated values.

[b] Grading percentages changed from the 1990 BHS protocols due to changes in sequential assessment of blood pressure references. See original publications for details (1990, 1993).

whole line of sphygmomanometers in the 1997 *Medical Device Register* [32]. Since technology and market can change rapidly, models, features, specifications, and prices may change accordingly. More specific and updated information may be available by contacting the manufacturers or distributors directly.

Table 65.5 lists only a limited number of indirect blood pressure devices from a literature review. Many of the listed blood pressure devices have multiple evaluation studies, and only a few study results are presented here. In view of reference standards for comparison, although direct and indirect methods yield similar measurements, they are rarely identical because the direct method measures pressure and the indirect method are more indicative of flow [5]. Egmond et al. [33] evaluated the accuracy and reproducibility of 30 home blood pressure devices in comparison with a direct brachial arterial standard. They found average offsets of all tested devices amounted to –11.7 mmHg for systolic and 1.6 mmHg for diastolic blood pressure, which were close to those of the mercury sphygmomanometer (–14.2 mmHg for SP and –0.1 mmHg for DP), indicating a significant difference between the two assessment standards. When selecting a blood pressure device for a specific application, the evaluation using the reference that is of a common practice in the intended population or environment may be practically more informative, since that reference has been the common basis for decision making in blood pressure diagnosis and treatment.

Different evaluation results for the same brand product can also be due to different versions of a model used for validation, where a later version may have performance improvement over the earlier one [34]. Another source of discrepancies can come from utilizing different study protocols or only partially following the same protocols. It is recommended that the original clinical evaluation report be carefully examined in determining the desired efficacy that may meet the users' requirements. If the devices were FAD approved for marketing in the United States, one may request a copy of their clinical validation report directly from the manufacturer.

In addition to the fundamental categories such as intended use, efficacy, and acquisition technology, listed in Table 65.5, many other categories are also very important in evaluating, selecting, purchasing, using, and maintaining blood pressure devices. These include but are not limited to the following items: measurement range of each pressure (systolic, diastolic, and mean) for each mode of intended use (i.e., neonates, children, adults); maximum pressure that can be applied by the monitor and cuff for each

65.3.8 Advancement of Indirect Blood Pressure Measurement

Since the introduction of Dinamap™, an automated blood pressure monitor based on the oscillometric principle [9], many variants of oscillometric algorithms were developed. However, the fixed or variable fractions of the maximum oscillations are still the fundamental algorithms of the oscillometry [10,53,54]. Typically, mean blood pressure was determined by the lowest cuff pressure with greatest average oscillation [11]. Systolic and diastolic blood pressure was determined by the cuff pressure with the amplitude of oscillation being a fixed fraction of the maximum. Performance of the algorithms may be improved by introducing a greater level of complexity or variables into considerations. The Dinamap 1846SX (Critikon, Tampa, FL) oscillometric device offered two measurement modes. The normal mode uses two matching pulse amplitudes at each cuff pressure step to establish an oscillometric envelope or curve. Therefore, measurement time is heart rate dependent. The second mode, which the manufacturer refers to as "stat mode," is capable of faster determination by disabling the dual pulse-matching algorithm that was designed for artifact rejection. The stat mode does not appear to compromise accuracy in anesthetized patients [55], in which rapid measurement of blood pressure is often more desirable, particularly during induction and management of anesthesia.

Another variant of the oscillometric algorithm was developed by Protocol Systems [56]. In addition to using pulse amplitude for primary artifact rejection, it further calculated impulse value, a principal area of pulse waveform, in constructing an oscillometric curve. This curve is smoothed by employing a Kalman filter that also provides an expected mean and acceptable upper and lower bounds of prediction for the principal area of subsequent pulse waveform. Smoothing of the oscillometric curve is accomplished by using the difference between the predicted and calculated area data of pulse waveform for each cuff pressure step. Blood pressures are derived from the final smoothed oscillometric curve.

In more recent study, oscillometric algorithms using an artificial neural network have been reported to produce better estimates of reference blood pressures than the standard oscillometric algorithm [57]. By using neural network training and processing, subtle features and nonlinear relationships of the oscillometric envelope have been modeled. Empiricism of the oscillometric fixed fraction criteria is overcome, and variances of measurements are greatly reduced.

Because of its low risk and cost, noninvasive continuous blood pressure monitoring represents another need in critical-care monitoring to supplement invasive arterial catheterization. A significant development in this field is the arterial counterpulsation principle, proposed by Penaz [58] and further developed by two major groups of people [59,60]. Finapres™, a continuous finger arterial blood pressure monitor, was engineered and developed by Ohmeda, Denver, CO. Many clinical evaluation reports of these devices have been published since then.

Recently, a number of other continuous blood pressure monitors have been made commercially available. Examples of these are Cortronic APM770 [61], which monitors pulsation of the brachial artery with a slightly pressurized arm cuff and calibrates it to a continuous pressure waveform; Sentinel ARTRAC 7000 [62], which monitors pulse transit time and correlates that to pressure change; and Colin CBM-3000 and Jentow (Colin Electronics, Komaki, Japan) [63,64] and Nellcor NCAT N-500 (Nellcor, Hayward, CA) [65], which are tonometric devices monitoring the radial artery pulse waveform by a matrix pressure sensor. All of these monitors require a frequent calibration reference. Except for a few favorable reports with the tonometric method and devices, many reports so far are unfavorable. Nevertheless, noninvasive continuous monitoring represents an important and growing field of biomedical sensor and instrumentation research and development. Continuous monitors, which maintain cuff pressure, must periodically relieve pressure to prevent the risk of venous congestion, edema, swelling, and tissue damage.

65.4 Direct Blood Pressure Measurement

Direct measurement is also called invasive measurement because bodily entry is made. For direct arterial blood pressure measurement, an artery is cannulated. The equipment and procedure require proper setup, calibration, operation, and maintenance [66]. Such a system yields blood pressures dependent upon the location of the catheter tip in the vascular system. It is particularly useful for continuous determination of pressure changes at any instant in dynamic circumstances. When heavy blood loss is anticipated, powerful cardiovascular medications are suddenly administered, or when a patient is induced to general anesthesia, continuous monitoring of blood pressure becomes vital.

Most commonly used sites to make continuous observations are the brachial and radial arteries. The femoral or other sites may be used as points of entry to sample pressures at different locations inside the arterial tree, or even the left ventricle of the heart. Entry through the venous side of the circulation allows checks of pressures in the central veins close to the heart, the right atrium, the right ventricle, and the pulmonary artery. A catheter with a balloon tip carried by blood flow into smaller branches of the pulmonary artery can occlude flow in the artery from the right ventricle so that the tip of the catheter reads the pressure of the left atrium, just downstream. These procedures are very complex and there is always concern of risk of hazard as opposed to benefit [67].

Invasive access to a systemic artery involves considerable handling of a patient. The longer a catheter stays in a vessel, the more likely an associated thrombus will form. The Allen's test can be performed by pressing on one of the two main arteries at the wrist when the fist is clenched and then opening the hand to see if blanching indicates inadequate perfusion by the other artery. However, it has proved an equivocal predictor of possible ischemia [68]. In the newborn, when the arterial catheter is inserted through an umbilical artery, there is a particular hazard of infection and thrombosis, since thrombosis from the catheter tip in the aorta can occlude the arterial supply to vital abdominal organs. Some of the recognized contraindications and complications include poor collateral flow, severe hemorrhage diathesis, occlusive arterial disease, arterial spasm, and hematoma formation [69].

In spite of well-studied potential problems, direct blood pressure measurement is generally accepted as the gold standard of arterial pressure recording and presents the only satisfactory alternative when conventional cuff techniques are not successful. This also confers the benefit of continuous access to the artery for monitoring gas tension and blood sampling for biochemical tests. It also has the advantage of assessing cyclic variations and beat-to-beat changes of pressure continuously and permits assessment of short-term variations [70,71].

65.4.1 Catheter–Tubing–Sensor System

A large variety of vascular catheters exist. Catheter materials have undergone testing to ensure that they have a minimal tendency to form blood clots on their surface. The catheter chosen may be inserted percutaneously over a hollow stylet into the blood vessel. Guide wires can be useful to facilitate longer or larger-diameter catheters into vessels, after the guide wires have been placed through a smaller catheter or needle. Less often, entry to a vessel requires a "cutdown," a direct exposure of the vessel after a skin incision. Ultrasonic devices may assist locating the vessels not readily apparent at the skin surface.

Although pressure sensors can be located at the catheter tip, this presents a problem for calibration if left in place and a clot forms near the tip of the catheter, damping the pressure signal. Instead, most catheters connect to an external pressure sensor via fluid-filled low-compliance tubing. The signal from the sensor then undergoes transformation for display or recording. The sensor may take one of several forms, from a variable resistance diaphragm to a silicon microchip. A basic system can consist of an intravascular catheter connected to a rigid fluid-filled catheter and tubing that communicates the pressure to an elastic diaphragm, the deflection of which is detected electrically. There is a direct relationship between the deflection of the diaphragm and the voltage.

The higher the voltage is the greater the pressure. Continuous low-rate infusion of heparinized saline is carried out to keep the catheter patent or free from coagulation. The advent of disposable sensor kits has greatly simplified the clinical use of intravascular monitoring [72]. With the cost continually being lowered with the development of semiconductor industry, disposable sensors become more and more cost-effective.

Although direct recording is considered the most accurate method, its accuracy may be limited by variations in the kinetic energy of the fluid in the catheter or dynamic frequency response of the measurement system. The hydraulic link between the patient and the sensor is the major source of potential errors and hazard for the monitoring. Damping and degrading the system's natural frequency, caused by trapped air bubbles, small catheters, various narrow connections, compliant and too long tubing, and too many components connected, are the two characteristic problems with a pressure sensor system. Extreme care should be exercised to eliminate all air bubbles from the fluid to provide adequate dynamic response. The sensor should be zeroed at the level of the heart to eliminate hydrostatic error [73]. A fast flush testing is easy to use for inspection of the dynamic response of the whole system of catheter–tubing–sensor. It can also help direct adjustments for the system to minimize dynamic artifacts [74,75].

65.5 Reproducibility, Accuracy, and Reliability Issues and Recommendations for Corrective Measures

For each blood pressure assay technique, there is an issue of reproducibility of measurements given approximately similar conditions. Reproducibility quantifies the internal uncertainty of an individual method and instrument, whereas accuracy quantifies the external uncertainty when compared with a reference. Table 65.6 presents estimated uncertainties of reproducibility for three blood pressure measuring techniques: auscultation, oscillometry, and umbilical arterial catheter [50]. When dealing with blood pressure measurement, it is important to bear in mind that even for standard methods, there is a certain amount of nonrepeatable random error. Consequently, taking the average of repeated measurements or multiple readings is always advised before any serious recommendation or management is made.

Table 65.7 presents a review of common problems associated with accuracy and reliability in both indirect and direct blood pressure measurements. Consequences of these problems are analyzed and recommendation of preventive action or alternative solutions is provided. Hazard or safety analyses and review are also very important.

TABLE 65.6 Estimated Uncertainties of Reproducibility for Blood Pressure Measuring Techniques of Auscultation, Oscillometry, and Umbilical Arterial Catheter

	Auscultation	Oscillometry[a]	Umbilical Arterial Catheter

TABLE 65.7 Common Issues of Accuracy and Reliability in Blood Pressure Measurement and Recommendations of Preventive Action or Alternative Solution in Both Indirect and Direct Measurements

	Problem	Result	Recommendation
Source	Indirect Measurement		
Subject	Obesity, peripheral edema, peripheral vascular disease	Weak Korotkoff sounds and diminished sound transmission may reduce the accuracy and reliability of auscultatory measurement; oscillometric measurement may also be affected	Verify with a second indirect method such as oscillometry; direct blood pressure measurement may be elected to use in severe conditions that indirect measurement does not warrant sufficient accurate and reliable measurement
	Shock, severe peripheral vasoconstriction, diminished peripheral circulation resulting from shunting of blood to central organs; the Korotkoff sounds and pulses may be absent even in the presence of normal pressure [76]	Any of the indirect methods, including auscultatory, oscillometric, and Doppler techniques, may not provide accurate and reliable reading; indirect measurement may be impossible or may give misleading results	Direct measurement should be considered
	Arrhythmias, respiratory effect	Pronounced variation in beat-to-beat blood pressure and waveform	Take multiple measurements and average
	Subject shivering, pain, anxiety, discomfort, motion artifact	Shivering and motion artifact may cause either false high or false low reading, whereas pain, anxiety, and discomfort may cause false high reading	Minimize pain, anxiety, and discomfort; reduce shivering and movement
	Physical activity within 5 min of measurement; talking, moving, arm unsupported, back unsupported, legs dangling, and any other isometric activities	False high reading that does not reflect subject's resting blood pressure	Subject should rest at least 5 min in the same position that blood pressure is going to be taken; subject should not talk and involve any isometric activities during measurement; arm should be supported at heart level
	Arm supported at above heart level	Hydrostatic pressure causes false low reading by 0.78 mmHg for each centimeter of offset [77]	Support the arm with midpoint of upper arm at heart level
	Arm supported at below heart level	Hydrostatic pressure causes false high reading by 0.78 mmHg for each centimeter of offset	Support the arm with midpoint of upper arm at heart level
	White-coat hypertension during clinical measurement	Psychological or stress response causes blood pressure temporarily elevated and unrepresentative of subject's true condition	Take multiple self-measurements at home or ambulatory monitoring as desired, and provide record to care providers
	"Pseudohypertension" with calcified or stiffened arteries	Reduced arterial compliance, often occurring in the elderly, causes cuff blood pressure falsely too high or unable to be measured accurately	Use Osler maneuver for screening; direct method is recommended for those who test positive [78,79]

(*continued*)

TABLE 65.7 (continued) Common Issues of Accuracy and Reliability in Blood Pressure Measurement and Recommendations of Preventive Action or Alternative Solution in Both Indirect and Direct Measurements

	Problem	Result	Recommendation
Source	Indirect Measurement		
Operator	Hose kinked	Will cause reading error or operation failure	Rearrange hose to avoid kink
	Cuff used too narrow for arm	Will cause false high reading	Select appropriate cuff size that its width encircles 40% of arm circumference
	Cuff used too wide for arm	May cause false low reading; may not fit on arm	Select appropriate cuff size that its width encircles 40% of arm circumference
	Cuff wrapped too loosely	Will cause false high reading; may introduce artifact of inter cuff-arm abrasion if placed for long-term monitoring	Cuff should be snugly applied; one should not be able to insert two fingers between the cuff and arm for adult
	Cuff wrapped too tightly	May cause false low reading; will restrict and impair limb circulation if placed for long-term monitoring	Cuff should be snugly but not restrictively applied; one should be able to insert one finger between the cuff and arm for adults
	Cuff pressure inflated too high	Patient discomfort; may induce increase in systolic blood pressure during inflation period, so-called cuff-inflation hypertension [80]	Inflate cuff pressure to 30 mmHg above palpatory blood pressure
	Cuff pressure inflated too low	Will either miss or have false low SP reading	Inflate cuff pressure to 30 mmHg above palpatory blood pressure
	Cuff pressure deflated too fast	May degrade the accuracy of the reading	Deflate cuff pressure at 2–4 mmHg per heart beat or 3 mmHg/s
	Cuff pressure deflated too slow	May cause discomfort or forearm congestion	Deflate cuff pressure at 2–4 mmHg per heart beat or 3 mmHg/s
	Repeated cuff pressure measurement too frequently	May cause discomfort and forearm congestion	A sufficient time should lapse (at least 60 s) before the next reading to allow the return of normal circulation
	Miss identifying auscultatory gap between SP and DP	Will cause false low SP or false high DP	Listen to the Korotkoff sounds carefully for a wide pressure deflation range or use oscillometric method
	Stethoscope head or sensor not over the brachial artery	Will not hear clear sounds or detect sufficient signal for blood pressure determination	Place the stethoscope head or sensor over the brachial artery at least 1.5 cm above the antecubital fossa
	Noise and artifact created by accidentally touching or bumping the cuff, hose, stethoscope, or sensor	May cause inaccurate reading or failure of reading	Avoid incidence of extraneous noise and artifact
Equipment	Leaky hose, bladder/cuff, or pneumatic components	Will cause inaccurate reading or failure in operation	Require service or replace equipment
	Faulty valves	Will cause inaccurate reading or failure in operation	Require service or replace equipment
	Limited selection for different size of cuffs	Will cause false low or false high reading if cuff is too large or too small, respectively	Manufacturer should provide appropriate label/labeling for the intended use and arm size; blood pressure measurement beyond the intended use of the device should be warned against and prohibited
	Device zero-shifted, out of calibration	Will create systematic bias or uncertainty in blood pressure reading	Require routine calibration and maintenance

TABLE 65.7 (continued) Common Issues of Accuracy and Reliability in Blood Pressure Measurement and Recommendations of Preventive Action or Alternative Solution in Both Indirect and Direct Measurements

	Problem	Result	Recommendation
Source	Direct Measurement		
Subject	Subject position change (e.g., body position change and bed lowered or elevated) in relation to pressure sensor	Subject heart level change in relation to pressure sensor will introduce bias of hydrostatic pressure in blood pressure recording	Move the sensor zero port to the heart level, and zero the sensor/monitor
	Catheter whip in pulmonary artery, catheter impact in aorta or ventricle	Catheter whip can result in superimposed waves of ±10 mmHg; catheter impact can cause high-frequency transients to occur in waveform [81]	Catheter whip and catheter impact are difficult to prevent; evaluation of pressure waveform and reading should consider the effect of these events
	Subject severe shivering, pain, anxiety, discomfort, moving	Severe shivering and moving may cause artifact on blood pressure waveform, whereas pain, anxiety, and discomfort may elevate blood pressure	Minimize pain, anxiety, and discomfort, and reduce shivering and moving
Operator	Tubing kinked	Will change dynamic response of tubing system and distort pressure waveform	Use short and low compliant tubing, and place tubing appropriately to avoid kink
	Sensor zero port higher than heart level when zeroing	Hydrostatic pressure causes false low pressure measurement by 0.78 mmHg for each centimeter of offset	Move the sensor zero port to heart level, and zero the sensor/monitor
	Sensor zero port lower than heart level when zeroing	Hydrostatic pressure causes false high pressure measurement by 0.78 mmHg for each centimeter of offset	Move the sensor zero port to heart level and zero the sensor/monitor
	Air bubbles entrapped in the tubing system	Air bubbles will decrease natural frequency and increase damping coefficient; therefore they damp and distort the waveform, causing high-frequency components to loss in pressure waveform	Eliminate air in both tubing system and flush solution bag; light tapping while fluid is filling the tubing system is an effective method for removing air
	Tubing too long, too thin, and with too many components	All of these will degrade the system dynamic response and result in distorted waveform and erroneous reading	Use tubing of large inner diameter and short length, and reduce the number of components as much as possible
	Connectors not tightly connected	Will decrease natural frequency of tubing system and cause pressure waveform to be distorted	Check loose luer-lock connection and cracked connection; replace cracked components and secure tight connection of all components
	Failure to flush the arterial line adequately after blood draw	May cause the catheter tip partially clotted by the blood and pressure waveform over damped and distorted	Flush the arterial line adequately; may need to replace with a new catheter if dynamic response cannot be improved to meet the minimum requirement
	Failure to zero the sensor/monitor after subject position change in relation to pressure sensor	Subject heart level change in relation to pressure sensor will introduce bias of hydrostatic pressure in blood pressure recording	Move the sensor zero port to the heart level and zero the sensor/monitor

(*continued*)

TABLE 65.7 (continued) Common Issues of Accuracy and Reliability in Blood Pressure Measurement and Recommendations of Preventive Action or Alternative Solution in Both Indirect and Direct Measurements

Source	Problem	Result	Recommendation
	Direct Measurement		
	Failure to provide constant infusion of anticoagulation/saline solution	May cause catheter tip partially clotted by the blood and pressure waveform overdamped and distorted	Check the constant infusion device to have sufficient flow rate; flush the arterial line adequately; may need to replace with a new catheter if dynamic response cannot be improved to meet the minimum requirement
	Failure to test dynamic response at least once a shift and anytime after blood draw or component change	This leaves the system dynamic performance unknown, which may affect the accuracy of SP the most and DP the second; MP is hardly affected	Routinely perform the fast flush test to evaluate the dynamic response visually according to Gardner's chart of natural frequency vs. damping coefficient [73]
Equipment	Not equipped with an appropriate flush device	May not be able to generate quality test waveform to evaluate the adequacy of dynamic response of the catheter–tubing–sensor system	Select appropriate flush device that permits fast flush test for the system dynamic response
	Tubing or component not transparent	Unable to see entrapped air bubbles	Use transparent tubing and components
	Tubing, sensor, or constant flush device too compliant	Will decrease natural frequency of the system and cause pressure waveform to be distorted	Use only high-quality and low-compliance tubing, sensor and constant flush device
	Stopcocks not tightly sealed	Will decrease natural frequency of the system and cause pressure waveform to be distorted	Replace with tightly sealed, high-quality stopcocks
	Monitor failure to zero the sensor electronically, sensor zero drift, or pressure amplifier zero drift	Will introduce unknown offset or bias in pressure measurement	Require service or replacement of the equipment
	Natural frequency and damping coefficient of the catheter–tubing–sensor system failure to meet minimum dynamic response requirement	Fidelity of pressure waveform recording suffers and accuracy of SP and DP measurement degrades	Need to optimize the catheter–tubing–sensor system by replacing part or all of the components; use low-compliance pressure sensor, tubing, and all other components; use short and large tubing and reduce the number of components as much as possible
	Blood pressure monitor failure to identify special events such as sensor zeroing, fast flush testing, blood drawing, as well as artifacts	Blood pressure monitor displays false digital reading of blood pressure without warning sign or error message	Health-care provider needs to exercise care in viewing the digital results with waveform display; quality-control or screening process is needed in dealing with monitoring database

65.6 Blood Pressure Impact, Challenge, and Future

Hypertension is one of the most common and important risk factors of health in industrialized countries [82]. It is the leading cause of death in the United States. It is treatable by a variety of effective medications. It can cause serious damage to the heart and arteries leading to cardiac infarct, stroke, or renal failure. Significant sudden changes in blood pressure may also precede a major physiological catastrophe such as cardiac arrest. There is now almost universal acceptance that basic physiological parameters such as blood pressure should always be monitored in the clinical setting.

There has been increasing interest in automatic blood pressure monitoring devices in recent years, and some clinicians are now advising patients to record their blood pressure at home over a period of up to 3 months before starting antihypertensive medication [83]. Self-monitoring of blood pressure has become very common with the development of microchip technology and oscillometric monitors. The patients no longer have to learn how to listen for the Korotkoff sounds. This has also removed bias and observer errors, allowing more accurate measurement than by conventional techniques using a stethoscope and a mercury sphygmomanometer [84].

Special populations have unique blood pressure assessment requirements. Newborns require miniaturized equipment. The act of taking a blood pressure in a newborn may stimulate a series of movements causing motion artifact. The very obese may be hard to fit properly with a cuff at the upper arm, if the upper arm is too conical rather than cylindrical. In pregnancy, auscultatory and oscillometric methods, although useful to follow trends, may correspond poorly with central pressures [85], and even the proper Korotkoff sound (IV or V) to designate as DP is uncertain [86].

Observing blood pressures has limitations. It may suggest what is happening with blood volume, but sometimes does not reveal that blood volume has become inadequate until circulatory collapse has occurred. Venous and left atrial pressures are often used in an attempt to clarify blood volume problems but with uncertain results [87]. Similarly, a satisfactory blood pressure does not always indicate adequate tissue perfusion. Some medications that increase blood pressure can do so at the expense of general perfusion. Since blood pressure is measured at specific sites in the arterial tree, if circulation has become nonhomogeneous (such as what can happen in arteriosclerosis) the region distal to the arteriosclerosis can be compromised without warning from blood pressure readings sampled at another site. Even mean blood pressure, so useful otherwise, can fail in these circumstances.

In spite of inherent problems, observation of blood pressure through both old and new technologies retains more than enough usefulness to have remained an essential aspect of patient care. The promise of improved technology to solve problems such as those of motion artifacts, noninvasive continuous monitoring, long-distance telemetry, rapid analysis of accumulated or concurrent data, and assessment of new inaccessible regions of blood flow represents continued challenges for future biomedical research and development.

Recently, exciting research has revealed that comparing pressures taken at the arm and the ankle results in a simple but extremely useful index for assessment of lower extremity vascular disease, with implications for general cardiovascular risk factors [88]. The possibility of obtaining noninvasive blood pressures from arteries in the forehead by stick-on oscillometric patches has also been proved. At least in anesthetized patients, the forehead noninvasive blood pressure corresponded reasonably well with central arterial pressures [89]. Finger blood pressure monitors have found some applications in continuous ambulatory and sleep blood pressure assessments [90]. A technology that is capable of continuously monitoring brachial or even central blood pressure continues to be a clinical demand and future challenge.

66.1 Doppler Measurements

66.1.1 Ultrasound Doppler

The ultrasound Doppler measurements [1,2] are based on a principle discovered by the Austrian physicist Christian Doppler in 1842 [3], who theoretically predicted that a wave backscattered from a moving object will be shifted in frequency. The principle was verified by two hornblowers, one aboard a moving train and the other standing still, with the ability to assess the pitch of the sound.

To obtain a Doppler signal from a fluid, the fluid must contain scattering particles, which in the case of blood are the blood cells. The size of a red blood cell is about 2 × 7 μm, which means that the scatterers are much smaller than the wavelength of the ultrasound. Hence, a diffuse scattering of the ultrasound will occur (Rayleigh scattering). The scattering from tissues surrounding the heart and vessels usually gives a much larger signal (20–40 dB) than that from blood in motion. The velocity of tissue motion is usually much lower than that of blood. This contribution can therefore be suppressed by high-pass filtering. In recent years, ultrasound contrast agents (consisting of gas-filled shells) have been introduced to increase the blood flow signal. Figure 66.1 illustrates the ultrasound Doppler principle. An ultrasound beam is sent toward a moving object. The beam hits the object and returns to the receiver with a Doppler-shifted frequency carrying information about the velocity of the object.

The Doppler shift f_d of an ultrasound signal with the nominal frequency f_c is given by

$$f_d = 2f_c \cdot \frac{v}{c} \tag{66.1}$$

where

v is the velocity component in the direction of the ultrasound beam

c is the speed of sound in the medium that is in the range of 1500–1600 m s^{-1} in soft tissue and usually set to 1540 m s^{-1}

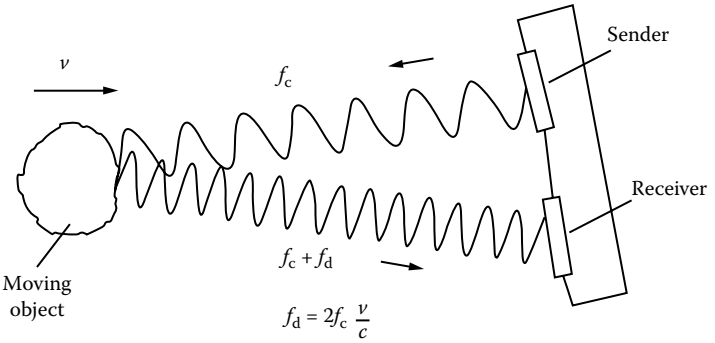

FIGURE 66.1 For Doppler ultrasound, the moving object shifts the received frequency.

The frequency f_c is in the range of 2–10 MHz, which gives a wavelength between 0.15 and 0.77 mm.

The peak systolic flow velocity in the heart and larger vessels is normally 0.5–1 m s^{-1}, resulting in a Doppler shift in the range of 1.3–13 kHz (depending on the ultrasound frequency f_c). The Doppler sound is therefore audible, which is helpful for the investigator in identifying vessels and phenomena of interest.

The most straightforward ultrasound investigation is to use a continuous wave system. The ultrasound beam is focused by suitable ultrasound transducer geometry and by a lens. By this arrangement, a narrow beam can be arranged and the backscattered information can come from any section along the beam.

In order to know from where along the beam the blood flow data are collected, a pulsed Doppler system has to be used. The transducer sends four to eight cycles of the ultrasound signal; at a specified time later a gate is opened and the transducer will act as a receiver. By using a preset time delay between the sending and the receiving signal, only flow information from a certain depth will be collected. The depth is obviously determined by the delay time and the propagation velocity in the tissue. Flow velocity information is obtained by spectral estimation of the Doppler signal.

By multirange gating, blood flow at various points along the ultrasound beam can be measured. By scanning with an ultrasound beam within a sector, a 2D velocity field can be presented. By color coding the information, a color Doppler flow image can be obtained. By scanning in one additional orthogonal plane, a 3D flow image can be created.

An important medical application of the ultrasound Doppler is in the study of heart valve flow when one might suspect stenosis or leaking flow in the valves. The pumping ability of the heart can be assessed from the general flow patterns. Regions with arteriosclerotic obstructions can be localized in the peripheral vessels.

66.1.2 Laser Doppler Flowmetry

The Doppler principle is also utilized in blood flow measurements in the microcirculatory bed in which laser Doppler flowmetry measures the blood perfusion. Laser light from a gas or semiconductor laser is launched into an optical fiber that leads the light to the tissue (Figure 66.2). Photons are reflected, scattered, and absorbed in the tissue matrix, and those that hit moving red blood cells become Doppler shifted, whereas those that are reflected in stationary structures are refracted without any change in frequency. A part of the photons returning to the fiber-optic system will be conducted by the pickup fiber to the detector. Shifted and nonshifted photons are mixed at the surface of a square-law photodetector. According to elementary wave mechanics, this type of mixing (coherent detection) results in the sum and difference frequencies. The frequency of the "difference wave" is proportional to the average velocity of the red blood cells. The amplitude of the same signal is proportional to the number of moving scatterers in the tissue volume. A velocity distribution will result in a Doppler spectrum, usually in the range of 30–12,000 Hz.

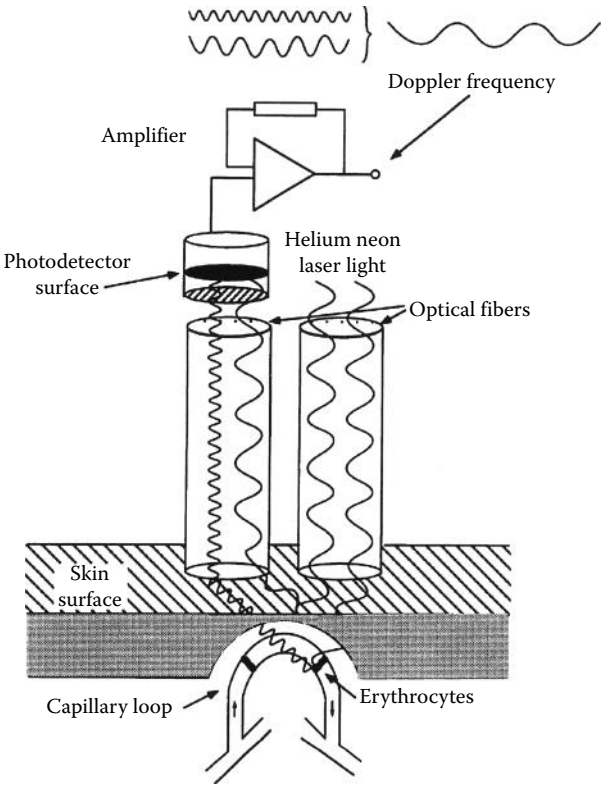

FIGURE 66.2 For laser Doppler flowmetry, the moving blood cells shift the received frequency.

Variants of the method utilizing fiber optics, airborne beams, microscope-based setups, and color-coded imaging scanners are described in the literature. For a review, see Shepherd and Öberg [4].

66.2 Indicator Dilution Methods

Cardiac output measurement is one of the most essential heart performance measures. The rest and exercise flows carry important diagnostic information. The monitoring of cardiac output is very important for the critically ill patient.

The principle is that an indicator is injected upstream in the circulation. Mixing with the circulating blood volume occurs and the indicator concentration is detected downstream. By knowing the added quantity of indicator and the time integral of the detected indicator concentration, the flow can be determined (Figure 66.3).

We can subdivide the indicator dilution methods into dye dilution and thermal dilution methods. See Webster [5] and Bronzino [6].

66.2.1 Dye Dilution Method

To determine the cardiac output (1/min), a known quantity (mass m) of a dye indicator such as Evans Blue is injected into the right heart, and a concentration of the indicator $c(t)$ is detected in the pulmonary artery. At the time t an indicator quantity Δm passes the detector at a time interval Δt. If F is the blood flow,

$$\Delta m = F\, c(t)\Delta t \tag{66.2}$$

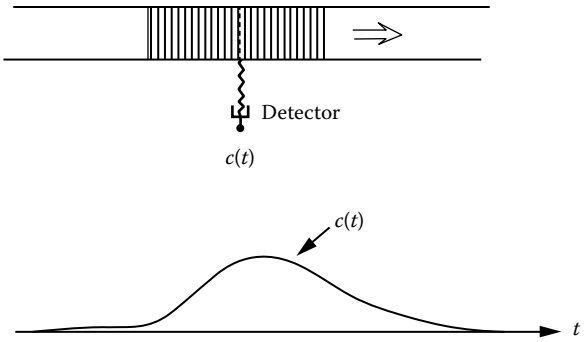

FIGURE 66.3 Indicator dilution measurements. The flow can be calculated if the amount of indicator and the time course of its concentration are known.

or by integration

$$F = \frac{m}{\int c(t)dt} \tag{66.3}$$

Thus, only the amount of indicator added and the time integral of the downstream concentration, assuming good mixing, have to be known to be able to calculate the flow, that is, the cardiac output.

66.2.2 Thermal Dilution Method

The thermal dilution method is a variant of the indicator dilution method family. A thermal dilution catheter is placed with the injection outlet in the right atrium of the heart and with a temperature sensor in the pulmonary artery (Bronzino [6] and Weissel et al. [7]).

A chilled solution of dextrose in water or saline solution is used for the injection and causes transient decrease in the pulmonary artery temperature $T(t)$. The blood flow (cardiac output) can be calculated from

$$F = \int T(t)dt\rho_b c_b = V(T_b - T_i)\rho_i c_i K \tag{66.4}$$

or

$$F = \frac{V(T_b - T_i)}{\int T(t)dt}\left(\frac{\rho_i c_i}{\rho_b c_b}\right)K \tag{66.5}$$

where

V is the injected volume
T_b is the undisturbed temperature in the pulmonary artery
T_i is the temperature of the indicator
ρ_i and ρ_b are the density of the indicator and the blood
c_i and c_b are the specific heat of the indicator and the blood
K is a correction factor that takes heat transfer along the catheter into account

The thermodilution technique is the standard technique for the monitoring of cardiac output in critically ill patients.

66.3 Plethysmography

The word *plethysmography* means methods for recording volume changes of an organ or a body part. Depending on the technique used, strain gage, impedance, and optical techniques can be used for the volume determination. See Webster [5] and Figure 66.4.

66.3.1 Strain Gage Plethysmography

The classical strain gage plethysmography is used to study circulation in the lower extremities from changes in the circumference of the legs.

Small-diameter silicone rubber tubes, filled with mercury or other types of conductive liquids, are placed around the circumference of the leg. Changes in the latter can be directly related to electric impedance changes of the silicone rubber tube. If a cylindrical cross section of the leg is assumed, volume changes should be proportional to the total circumference, times the change in impedance.

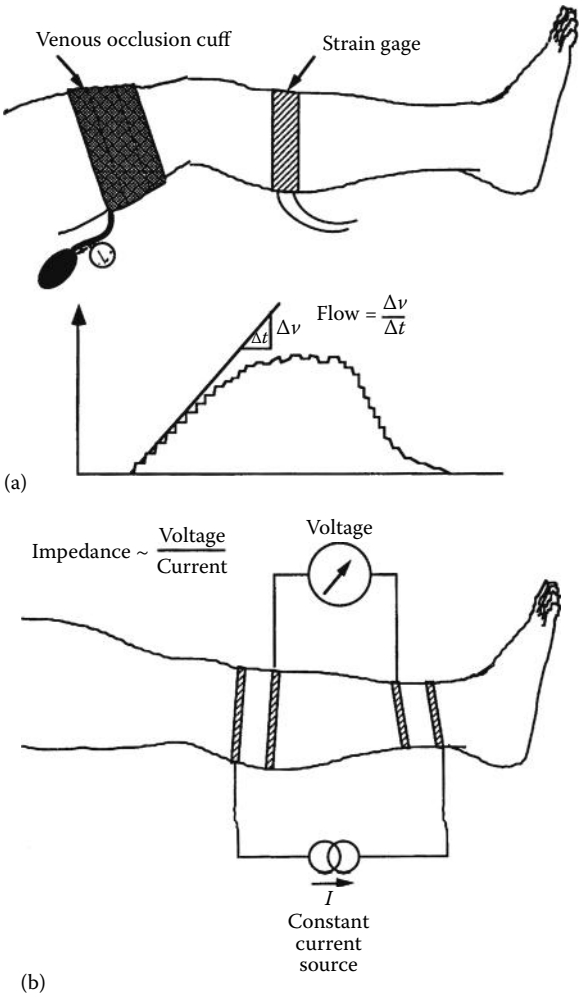

FIGURE 66.4 For occlusion plethysmography, increased volume stretches the strain gage (a) and decreases the impedance (b).

The strain gage tubes (Figure 66.4) are positioned around the lower part of the leg; an inflatable cuff is placed around the upper part (above the knee) and inflated to 40–50 mmHg, that is, above the venous pressure that will cause the outflow of blood to cease. The increased volume of the leg is therefore proportional to the arterial inflow. The latter is determined from the initial slope. Flow is volume increase per time unit.

When the cuff pressure is released, blood will flow out from the leg via the veins. The time course of the volume change will be related to venous function. If there is venous thrombosis, the decline in the volume curve will be slower.

66.3.2 Impedance Plethysmography

Bioelectric impedance measurements have a history dating back to the 1940s. The reason why impedance is useful for detection of volume changes is that different tissues in the body have different resistivity. Blood is one of the best conductors among the tissues of the body.

Impedance plethysmography has its most established applications in respiratory monitoring in newborn infants and for detection of venous thrombosis. Less-established applications are cardiac output measurements, peripheral blood flow studies, and body composition assessments.

A constant current with a frequency of 50–100 kHz and amplitude of 0.5–4 mA rms is applied via skin electrodes (Figure 66.4). Influences from skin impedance are eliminated by the use of the four-electrode technique.

The measurement object can be described with a conduction object with the constant impedance Z_0 in parallel with a time-varying impedance ΔZ. The impedance ΔZ is represented with a column of a conducting media with resistivity ρ and the length L. If the changes in ΔZ are small in comparison to those of Z_0, the volume changes can be obtained as

$$\Delta V \approx \rho \frac{L^2}{Z_0^2} \Delta Z \tag{66.6}$$

This technique can be used in the same way as the strain gage plethysmographic method to study circulation in the leg.

For the measurement of cardiac output, Equation 66.6 or a modified formula can be used [8]. The method seems to work rather well in normal persons for relative change, but for patients with cardiac disease, the cardiac output estimation might be poor.

66.3.3 Photoelectric Plethysmography

Hertzman and Spealman [9] and Hertzman [10] were the first to use the descriptive term *photoelectric plethysmography* (PPG). The first reports on the successful use of the principle were published in the middle of 1930 by Molitor and Kniazuk [11]. The principle on which PPG is based is simple, although the underlying detailed optical mechanisms remain unknown. A beam of light is directed toward the part of the tissue in which blood flow (or volume) is going to be measured (Figure 66.5). Reflected, transmitted, and scattered light leaving this volume is collected and focused on a photodetector. A signal modulated by the attenuation or scattering of light in the blood volume can be recorded. Two different components can be derived from the detector. One is pulsatile and synchronous with the heartbeat (the ac component), and the other is a constant voltage (the dc component). The physiological significance of the two signals is still under debate, but they reflected the blood volume and the orientation of erythrocytes during the cardiac cycle.

PPG has been used mainly for monitoring blood perfusion in skin, venous reflux conditions, and skin flaps during plastic surgery. Challoner [12], Roberts [13], and Bernstein [14] have reviewed the methodology and applications of PPG.

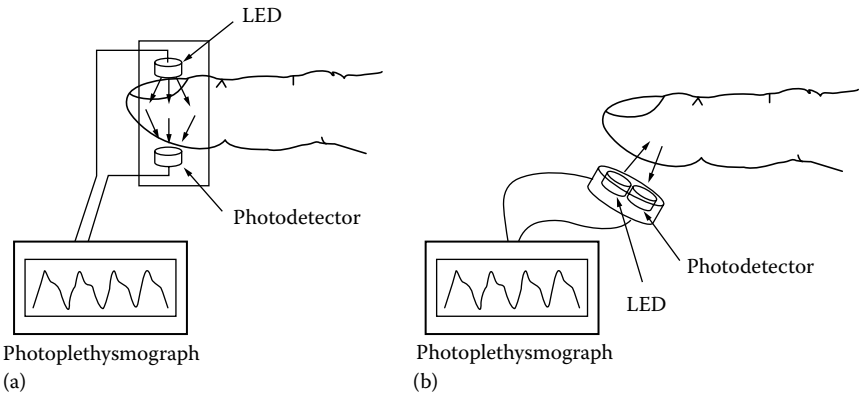

FIGURE 66.5 For photoplethysmography, increased blood decreases received light in (a) transmission mode and (b) reflection mode.

66.4 Radioisotopes

Kety [15] introduced the principle of tissue clearance of rapidly diffusing inert isotopes for blood flow measurements. An extensive theoretical treatment is given by Zierler [16]. In most applications, lipid-soluble gases like ^{133}Xe and ^{85}Kr have been used. These isotopes rapidly diffuse from blood to tissue and a rapid equilibration of the isotope concentration within a tissue volume takes place. Figure 66.6 illustrates the measurement principle. Their elimination from a microcirculatory bed is related to the blood flow rate. If the tissue is uniformly and constantly perfused, the activity of the isotope decays monoexponentially with time. The elimination of the isotope can be described by the equation

$$C(t) = C_0 \exp(-kt) \tag{66.7}$$

where

$C(t)$ and C_0 are the tissue concentrations at times t and at the onset of the injection C_0

k is the clearance constant related to the local blood flow by the relation

$$k = \frac{\ln 2}{t_{1/2}} \tag{66.8}$$

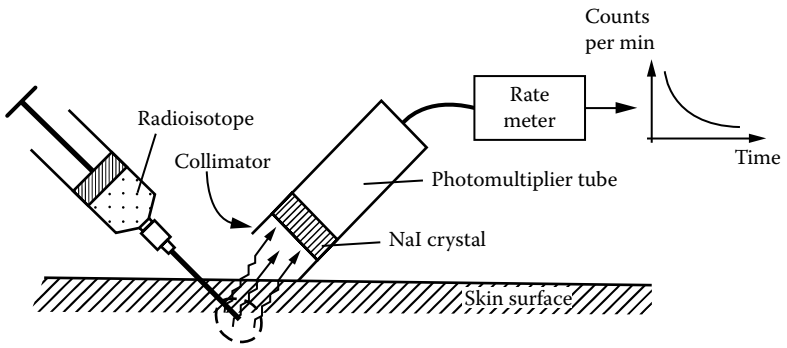

FIGURE 66.6 For isotope measurement of microcirculatory blood flow, the radioactivity decreases with washout.

in which $t_{1/2}$ is half the time of decay. Blood flow Q (in $k\ s\ 100$ mL $min^{-1} \cdot 100\ g^{-1}$) can then be derived from the formula

$$Q = k\ s\ 100 \tag{66.9}$$

where s denotes the tissue–blood partition coefficient. The indicator is administered via an injection into the tissue volume or through passive diffusion after deposition on the surface of the tissue volume under study.

The advantage of clearance methods is that they can be applied to the study of all kinds of tissue blood flow problems. One of the disadvantages is that the method does not give a continuous measurement of flow. In addition, the clearance curves are sometimes difficult to interpret. The trauma caused by injection of the isotope into the tissue seriously disturbs the flow, as shown by Holloway [17] and Sejrsen [18]. In spite of these shortcomings, the isotope clearance method has been applied extensively to the study of skin and tissue blood flow in experimental as well as clinical problem areas.

66.5 Thermal Convection Probes

Thermal convection probes have been developed specifically for skin blood flow measurements. Gibbs [19] pioneered the field by describing a probe in the form of a needle. Hensel and Bender [20] and van de Staak et al. [21] developed noninvasive variants by designing probes that can be positioned at the surface of the tissue.

All methods measure the rate of removal of heat from the tissue volume under the probe. A relation exists between the blood flow rate and the rate by which heat dissipates from the tissue volume under study. The sensing unit is usually designed around a central metal disk and a concentric outer ring between which a temperature difference is established (Figure 66.7). The two rings are thermally and electrically isolated from each other and both are in contact with the tissue. The temperature difference between the two rings is a measure of the blood flow under the probe.

A temperature difference of 2 °C–3 °C is usually established between the inner disk and the outer annulus. The central disk is heated with an electric current and kept at a constant temperature that only by 1°C or 2°C exceeds the resting temperature of the tissue under study. Thermal probes have not been extensively used because of their extreme nonlinear properties and the difficulties in their practical use, that is, the contact pressure sensitivity. Another difficulty is the highly variable thermal characteristics of the skin.

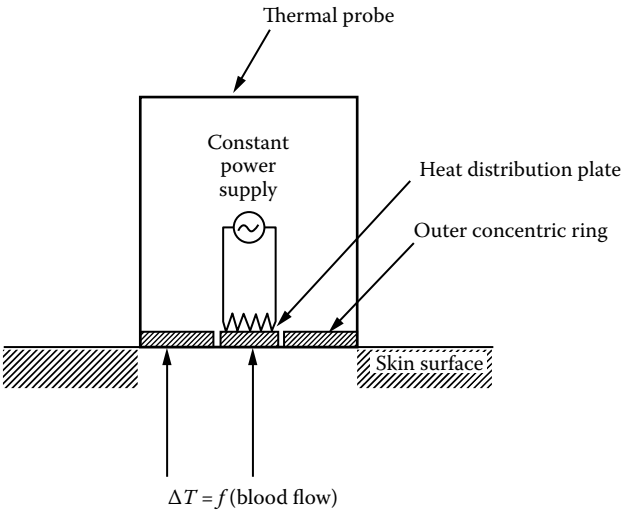

FIGURE 66.7 For thermal convection measurement of blood flow, heat dissipation increases with blood flow.

67.1 Introduction

Medical imaging has advanced considerably since the discovery of x-rays by Wilhelm Conrad Röntgen in 1895. Today, in addition to the continued use of x-rays for medical diagnosis, there are imaging methods that use sound (ultrasound), magnetic fields and radio waves (magnetic resonance imaging [MRI]), and radionuclides (nuclear medicine). Both projection imaging and cross-sectional imaging are routinely used clinically. This chapter will describe the principles behind the various imaging modalities currently in use and the various measurements routinely made with them.

67.2 Image Information Content

The vast majority of imaging procedures are qualitative in nature, where it is the visual presentation of anatomy that is the measurement outcome. There are also some quantitative measurements, which will be discussed in Section 67.5. However, since most imaging is concerned only with the qualitative nature of the image, a description of the salient features of image content follows.

There are three primary physical parameters of interest in image content: contrast, noise, and resolution. If these three features are known for a given image (or imaging system), then the entire

physical nature of the image has been characterized. There are also psychovisual effects, such as conspicuity [1], which affect the ability of the observer to detect a particular feature, but these issues are difficult to quantitate and are outside the scope of this handbook.

The first of the physical image features, contrast, is defined as the fraction of the total image signal occupied by a particular object:

$$C = \frac{B - S}{B} \tag{67.1}$$

where

S is the signal in the area of interest
B is the background signal

Contrast is determined by the properties of the object being imaged, the imaging modality, the properties of the image detector, postprocessing of the image (such as by digital processing), and the contrast of the display device.

Image noise is a measure of the stochastic nature of the image. All physical measurements, including medical images, contain a certain degree of uncertainty. In x-ray imaging, for example, the physics of x-ray production dictates that the number of x-rays incident on a unit area per unit time is random and given by a statistical distribution known as the Poisson distribution. The greater the image noise, the less likely it is that one will observe a given object. There is a relationship between the image noise, the contrast and area of an object, and its likelihood of being observed. This is summarized in the Rose model:

$$N = \frac{k^2}{C^2 A} \tag{67.2}$$

where N is the number of quanta (such as x-rays) per unit area needed to discern an object of contrast C and area A; assuming a signal to noise of k, Rose found that a signal-to-noise ratio of 5 is typically required to detect a visual object reliably [2].

Resolution is the ability of an imaging system to record faithfully the range of spatial detail in an object. Recording objects with finer spatial detail requires "sharper" imaging detectors. The resolving ability of a detector is largely determined by its point-spread function. The point-spread function describes how well the imaging apparatus can record an infinitesimal point object. No detector is perfectly sharp, and some spread of the infinitesimal dot occurs—the worse the spread, the less resolving the system.

67.2.1 Measurement of Imaging Performance

A linear-systems approach is typically used to quantify the performance of an imaging system. The relations among contrast, noise, and resolution of an imaging system are customarily described by two functions: the modulation transfer function (MTF) and the noise power spectrum (NPS), both of which are functions of spatial frequency. The MTF is the Fourier transform of the point-spread function and describes the inherent deterministic frequency response of the system. The NPS (also referred to as the Wiener spectrum) is proportional to the square of the Fourier transform amplitude at each frequency and represents the variance associated with noise in the system at each particular spatial frequency. The ratio of MTF and NPS, properly normalized, is the noise equivalent quanta (NEQ), which is the square of the maximum available signal to noise at each spatial frequency u:

$$\mathrm{NEQ}(u) \equiv \frac{(\text{Large area signal})^2 \cdot \mathrm{MTF}^2(u)}{\mathrm{NPS}(u)} \tag{67.3}$$

If the NEQ is divided by the number of incident quanta per area (e.g., the number of x-ray photons incident on the detector in x-ray imaging), the result is the detective quantum efficiency (DQE). The zero-frequency DQE is a measure of the fraction of incident quanta effectively used by the system. Alternatively, the DQE may be viewed as the efficiency with which the system utilizes the available signal to noise at each spatial frequency.

The actual measurement of MTF, NPS, and DQE is quite tedious and will be only briefly summarized here. The interested reader is encouraged to consult the suggested references for the appropriate detail on these measurements. Examples of these measurements will be given for x-ray imaging.

The MTF is typically measured by imaging either a very fine slit (typically 10–20 μm) [3–6] or an edge [7]. The profile across the slit image is called the line-spread function (LSF). The Fourier transform of the LSF gives the MTF in the direction perpendicular to the slit. The derivative of values along the edge-response function also gives the LSF. Detector response typically varies with energy so it is important to specify the conditions under which MTF is measured. With x-ray imaging it is typical to use a tube voltage of 70 kV with 0.5 mm Cu filtration placed in the beam to simulate the filtering of the x-ray spectrum expected from a patient, although other measurement techniques are also found in the literature.

The NPS is measured by taking an image of a flat field, where there is no structure in the image other than noise. Contemporary methods of NPS measurement on digital systems perform a 2D Fourier transform on the flat-field image [6], although when measuring the NPS of film, a scanning slit is used to generate a 1D NPS parallel to the direction of slit movement [8–10]. After appropriate scaling, the square of the amplitude of the 2D Fourier transform is the NPS. There are many details related to measuring the NPS properly, including eliminating background trends and the size of the region over which the Fourier transform is taken. These are all covered in detail in Refs. [6,8–18].

Measurement of imaging properties is easier on digital imaging systems than on film, since film must first be digitized at appropriately fine sampling intervals or else corrected for the use of 1D slits [19]. However, the effects of aliasing (fictitious frequency response in a digital system due to limited sampling) make the interpretation of MTF and NPS in digital systems more difficult than with film [11,12,20].

67.3 X-Ray Imaging

X-ray imaging requires an x-ray-generating apparatus (tube, high-voltage supply, and controls) and an appropriate x-ray detector. Typical x-ray detectors include photographic film (almost always used in concert with a fluorescent screen), image intensifiers, computed radiography phosphor plates, and newer dedicated digital detectors.

The x-ray generator is basically a high-voltage step-up transformer with appropriate rectification and control circuitry. Most contemporary generators are three-phase 12-pulse, full-wave rectified to give a very low-voltage ripple (3%–10%) [21]. For procedures requiring very fast pulses of several milliseconds or less (such as coronary angiography), a tetrode-based constant-potential generator is used. The operator selects the tube kilovoltage, tube current, and exposure time appropriate for the examination of interest.

X-ray tubes contain a heated filament (which serves as the cathode) and an anode made of a tungsten/rhenium combination for conventional use or molybdenum for mammography. With the exception of dental tubes, modern clinical x-ray tubes almost always contain a rotating anode to spread the heat out over a larger area, allowing for a greater tube output without damaging the anode. Many tubes contain two filaments, a large one and a small one, depending on tube output and resolution requirements of a particular exam. Measurements on x-ray tubes and generators involve calibrations to assure that kilovoltage, tube output, and exposure time are in good agreement with the control console settings [21]. Calibration of the high voltage is done by commercially available voltage dividers or by specially designed x-ray film cassettes with calibrating filters inside. Tube output is measured by ion chambers, and exposure time is measured either by a rotating-arm timer test tool placed over a film cassette during an x-ray exposure or by direct plotting of the exposure versus time output of an ion chamber.

67.3.1 X-Ray Imaging Detectors

The most common detector for x-ray imaging was film. X-ray film was typically placed in a sandwich between two fluorescent screens (or one screen in mammography for improved visibility of small detail). Contemporary screens were made of rare earth compounds such as Gd_2O_2S and served to convert the x-rays to visible light that exposed the film more efficiently than x-rays alone, thus reducing patient radiation dose. The response of these screen–film combinations had good contrast at intermediate exposure ranges (as given by the film γ, or contrast ratio), but poor contrast at low or high exposures. The contrast and latitude of films are described by the characteristic curve (often referred to as the Hurter–Driffield [HD] curve). Appropriate screen–film combinations were chosen based on the anatomy to be imaged, since screen–film combinations were designed with different contrast, latitude, and exposure sensitivity characteristics [22].

A second type of x-ray detector is the image intensifier, which is used with fluoroscopy. Fluoroscopy uses a low-exposure-rate x-ray output to image a patient continuously, typically to properly position the patient for a subsequent high-exposure film image. The image intensifier (Figure 67.1) comprises a cylindrical glass enclosure, inside of which are an input screen, photocathode, focusing electrodes, accelerating anode, and output screen [21]. The x-rays are absorbed in the input screen (typically CsI), giving off light that liberates electrons from the photocathode. The photoelectrons are then accelerated

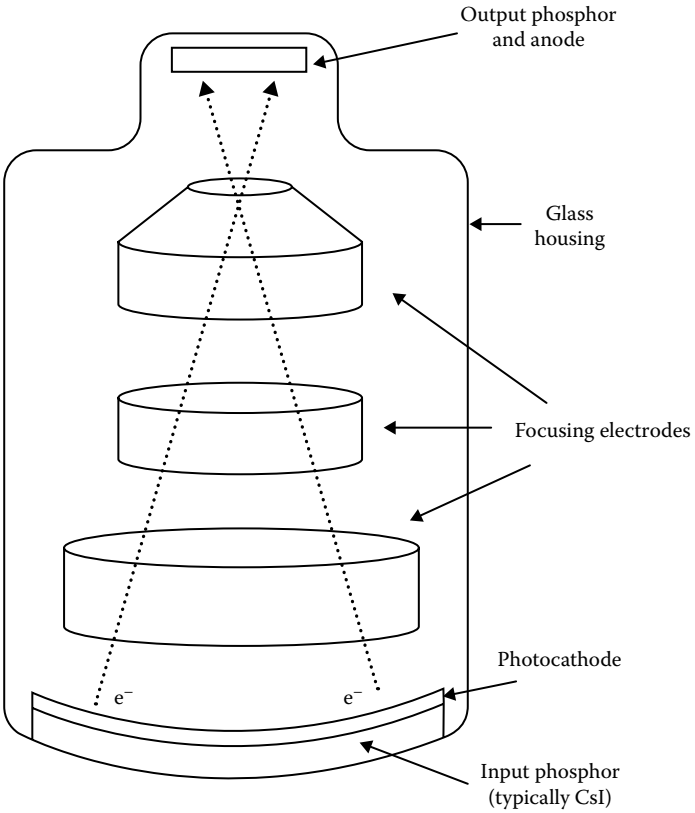

FIGURE 67.1 Schematic diagram of the major components of an image intensifier. The anode is typically at about 30 kV, and the three annular electrodes focus the beam and determine the usable area of the input surface for intensifiers having multiple formats.

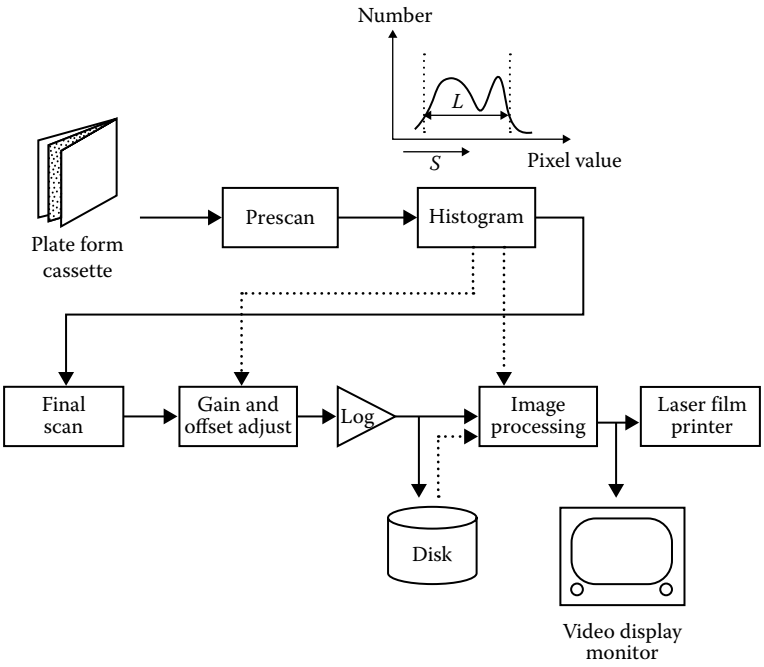

FIGURE 67.2 Schematic diagram of a typical photostimulable phosphor computed radiography system.

to the output screen where they strike the output phosphor screen with high energy (~30 keV), giving off a bright light, which is viewed by either a video camera or motion-picture (cineradiographic) camera.

A recently developed digital x-ray detector is the photostimulable phosphor, which is referred to commonly as computed radiography [23–25]. This detector uses a special type of phosphor that stores about half of the absorbed x-ray energy in metastable states, which are read out later by laser scanning. The laser light stimulates the phosphor to emit ultraviolet light in proportion to the original x-ray exposure. The photostimulated light is then detected with a photomultiplier tube (PMT) or solid-state photodetector and digitized. The clinical apparatus (Figure 67.2) first does a prescan of the imaging plate to adjust the input range of the analog-to-digital converter based on the image histogram; the digitized signal is then logarithmically transformed and stored, displayed on a video monitor, or printed on film following optional spatial filtering and contrast adjustment.

There are also currently available or in development a variety of other digital x-ray detectors, including selenium plate detectors [26], CCD-camera detectors with fluorescent screens [27], and flat-panel arrays with amorphous silicon [28] or amorphous selenium [29] detector elements. Computed radiography cassette scanners scan a storage phosphor screen mounted in a cassette of the same dimensions as a conventional x-ray cassette. This has replaced the use of film and permitted digital images for medical information systems.

67.4 Computed Tomography

A diagnostic computed tomography (CT) scanner comprises an x-ray tube with collimation to provide the slice thickness, a linear array of detector elements, and a reconstruction computer. The x-ray tube and the detectors typically rotate in a gantry. The number of detectors used depends on the generation of the scanner. First-generation scanners had only one detector that was translated across the patient with the tube for each projection, and then the entire assembly was rotated to acquire the next projection view.

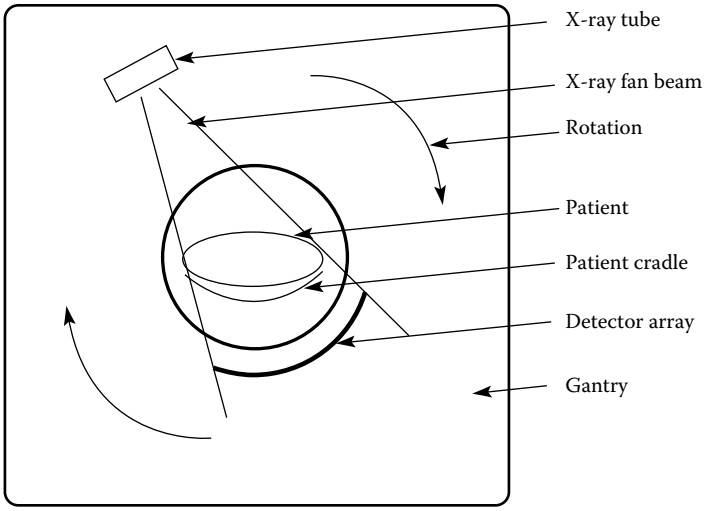

FIGURE 67.3 Orientation of components in a typical third-generation CT scanner.

To increase acquisition speed, second-generation scanners used several detectors in limited fan-beam geometry. Third-generation CT scanners, which are the most common in use today, utilize a large fan array of detectors (852 elements in a current scanner), which completely encompasses the patient and allows slice acquisition times of about 1 s [21]. The x-ray tube and the detector fan array are mechanically coupled and rotate together at high speed (Figure 67.3).

The implementation of electronic slip rings, which allow continuous electric contact, has removed the physical restriction imposed by the high-voltage cables of earlier scanners. Fourth- and fifth-generation scanners have a stationary, complete ring of detectors (typically 1200–4800 detectors). In fourth-generation scanners the x-ray tube is rotated alone, while the fifth-generation scanner design has a focused electron beam that traverses multiple target rings. Fifth-generation scanners can acquire a slice fast enough (50 ms per slice and 17 slices per second) to stop cardiac motion [30,31]. These last two generations are not in common use, primarily due to high cost. In recent years, a helical-scan adaptation of third-generation scanners, allowing continuous acquisition of data over a large patient volume, has become clinically popular [32,33].

While the x-ray tubes used for CT (tube potential range of 80–140 kV) are very similar to general radiographic tubes, the detectors are quite different from conventional radiographic detectors. Detectors used in CT are 1D photon counters that must be efficient and fast. Early CT devices used scintillation detectors, which converted the x-ray energy into light photons that were counted by PMTs. Originally, single-crystal NaI was used, but it proved to be insufficient in dynamic range and had too much afterglow of scintillation light. High-pressure (25 atm) xenon gas later replaced NaI as the detector. Currently, many CT scanners use scintillating ceramics (e.g., $CdWO_4$, $(Y,Gd)_2O_3$:Eu, and Gd_2O_2S:Pr,Ce) coupled to photodiodes, due to the high bulk density of the ceramics.

67.4.1 Reconstruction of an Object from Projections

CT is based on the image reconstruction theorem, which states that if one measures enough projections of an object, the 2D distribution of that object may be reconstructed from the projection data. In CT, the quantity of interest is the linear attenuation coefficient, μ, at each point in the object. The transmission of x-rays through an object of thickness x can be stated as

$$I(x) = I(0)e^{-\mu x} \tag{67.4}$$

where $I(0)$ is the incident intensity. Each ray from the focal spot of the tube to a discrete detector element is a measure of the line integral of the attenuation coefficient through the patient:

$$\lambda(x_r) = -\ln \frac{I(x_r)}{I(0)} = \int_{\ell} \mu(x_r, y_r) dy_r \tag{67.5}$$

where r represents the reference frame of one of the many projections through the patient.

Image reconstruction requires a method to invert Equation 67.5, in order to extract $\mu(x,y)$ of the object from the measured projection views, λ. The mathematical principles of image reconstruction from an infinite number of projections through an object were developed by Radon in 1917 [34]. An approximate solution to the Radon inversion, known as back projection, was later developed because of the need for rapid computation of images in clinical CT. Back projection involves smearing the data from each projection through the 2D space of the patient and summing overall projections. Simple back projection yields an estimate of the patient structures, but is plagued by artifacts due to the approximate nature of the reconstruction procedure. These artifacts are successfully removed, however, by prefiltering the projection data before back projecting. The 1D prefiltering is typically performed in frequency space by multiplying by a ramp function. This technique is known as filtered back projection and results in more accurate reconstructions of patient anatomy [35].

There are several conditions that can reduce the quality of image reconstruction. First, an insufficient number of angular projections or incomplete sampling of the object can lead to aliasing in the reconstructed view. Second, partial volume effects occur when the object is not of homogeneous composition in a particular voxel, causing the reconstructed pixel value (CT number) to be not representative of the tissue. Third, if the acquisition is not fast enough, patient motion leads to a ghosting artifact in the reconstructed image. Last, beam hardening occurs when a high-density structure, such as the skull, significantly changes the beam energy spectrum. The result is reduced intensity of adjacent structures. Beam hardening can be reduced by slightly altering the shape of the reconstruction filter to improve the reconstruction for a particular tissue type.

To present the reconstructed data in digital format, the CT number (also known as the Hounsfield unit [HU]) was developed.

$$\text{CT number} \equiv 1000 \times \frac{\mu_{\text{pixel}} - \mu_{\text{water}}}{\mu_{\text{water}}} \tag{67.6}$$

Using this normalization, pixel values in a CT image are stored as 12-bit integers between –1000 and 3095. A pixel containing only water would have a CT number equal to 0, while one containing bone or muscle would have a positive value, and one with only fat or air would have a negative value.

67.4.2 Clinical Measurements

The reconstructed images are only as accurate as the data input to the algorithm; therefore, a rigorous calibration and quality assurance program is vital to the performance of a diagnostic CT scanner. Calibration generates a baseline reference in air for the scanner and calibration values for every possible scan parameter. Detector channel variation and interaction along with x-ray tube focal spot size and position are quantified. A phantom is used to measure detector response for typical beam widths (1, 3, 5, 7, and 10 mm) and tube potentials (80, 100, 120, and 140 kV). The positioning accuracy of the scanner is also checked.

Quality assurance seeks to establish and maintain consistent image quality [36,37]. A specialized Plexiglas phantom is used to monitor the low-contrast detectability and high-contrast resolution and noise characteristics of the system. The low-contrast portion of the phantom consists of a set of holes of

different diameter in a thin polystyrene slab. The 0.75 mm thick polystyrene, when submerged in water and scanned with a 10 mm slice thickness, yields low contrast in the holes of about 1% (10 HU). The minimum detectable diameter is then found. The high-contrast resolution part of the phantom contains several repeating, equally sized bar/space patterns (spaces filled with water, contrast ~12% or 120 HU) with bar widths from 0.5 to 1.6 mm. The MTF is computed as a plot of the high-contrast frequency response [38]. The noise and uniformity of the scan are assessed with a homogeneous section of the phantom. An ROI is placed in the homogeneous area and the standard deviation is calculated, which should be approximately 3 HU.

67.5 Nuclear Medicine

Nuclear medicine techniques [39,40] use radiopharmaceuticals that are injected into the body to monitor or measure physiological function. Central to nuclear medicine is the role of the radiopharmaceutical as a tracer, that is, an agent with a predictable physiological action that is introduced without perturbing the function of the system. An external detector is used to record radioactivity emanating from the patient to determine the spatial distribution (and often temporal changes in concentration) of the radiopharmaceuticals in specific organs or tissues. Each radiopharmaceutical has an expected bio-distribution that a radiologist evaluates to diagnose the medical status of a patient. The radiopharmaceutical can be labeled either with positron-emitting radionuclides, which produce annihilation photons, or with "single-photon" radionuclides that emit γ-rays (or sometimes x-rays). This section considers only single-photon-emitting radionuclides, examples of which are given in Table 67.1.

TABLE 67.1 Examples of Tracers Used in Nuclear Medicine

Process	Tracer	Refs.
Blood flow		
Diffusible	^{133}Xe	[57]
	[^{99m}Tc]-HMPAO	[58]
Diffusible (trapped)	[^{123}I]IMP (brain)	[58]
	^{201}Tl (heart)	[44,59]
	[^{99m}Tc]-MIBI	[47]
Nondiffusible (trapped)	[^{99m}Tc]macroaggregated albumin, labeled microspheres	—
Effective renal plasma flow	[^{123}I]Hippuran	—
Blood volume		
Red blood cells (RBCs)	[^{99m}Tc]-RBC	[45,46]
Plasma	[^{125}I]-albumin	—
Transport and metabolism		
Free fatty acids	[^{123}I]-hexadecanoic acid	[44]
Bile	[^{99m}Tc]-HIDA	—
Osteoblastic activity	[^{99m}Tc]-MDP	[43]
Glomerular filtration rate	[^{99m}Tc]-DPTA	[60]
Molecular diffusion	[$^{99m}TcO_4$]	[58]
Receptor systems		
Dopaminergic	[^{123}I]-IBZM	[61]
Cholinergic	[^{123}I]-QNB	[62]
Adrenergic	[^{131}I]-MIBG	[63,64]
Somatostatin	[^{111}In]-octreotide	[65,66]

The scintillation camera [41,42] is the most common device for imaging the distribution of single-photon-emitting radionuclides in vivo (Figure 67.4). The scintillation camera incorporates a large-field (e.g., 40 cm × 50 cm) position-sensitive photon detector with a collimator having a large number of small parallel holes (1–2 mm diameter, 4 cm length) so that only photons traveling perpendicular to the detector surface are recorded. Photons emitted by the patient and passing through the collimator are absorbed by a 1 cm thick sodium iodide scintillator coupled to an array of PMTs. The PMT signals are processed to generate signals proportional to the (*x,y*) coordinates of the interaction site of the photon in the crystal. In addition, the PMT signals are integrated to calculate the photon energy. Events falling within a specified range (typically ±7.5%) around the expected radionuclide photon energy are recorded, whereas those outside of this range are rejected as unwanted scatter or background events. An image is integrated from individual events at the calculated position and specified energy, representing detected photons emitted by the radiopharmaceutical. The camera acquires a planar projection image of the radiopharmaceutical distribution in the patient with a spatial resolution of about 1 cm. The image also can be acquired tomographically by rotating the scintillation camera around the axis of the patient.

This technique is called single-photon emission computed tomography (SPECT) and produces cross-sectional images representing the radiopharmaceutical concentration within the patient.

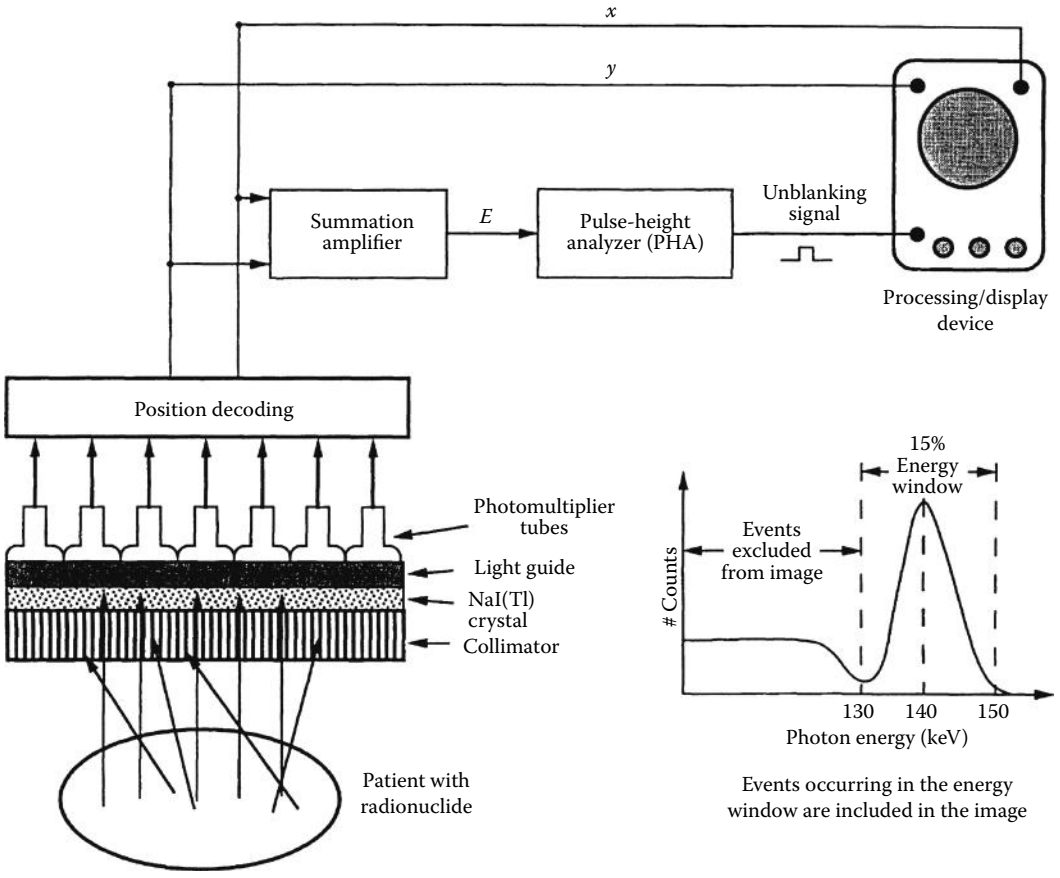

FIGURE 67.4 Scintillation camera incorporates collimator, scintillation crystal, PMTs, and electronic circuitry to generate position (*x,y*) and energy (*E*) of photons emitted by radiopharmaceutical distribution in patient. Only events falling within a specified energy window are recorded by the processing or display device to form the nuclear medicine image.

67.5.1 Measurement of Physiological Function

Radionuclide images can be interpreted visually or quantitatively. For example, the radiopharmaceutical [^{99m}Tc]-methylene diphosphonate (MDP) is incorporated into the bone matrix by osteoblastic activity [43]. A radiologist will inspect a nuclear medicine image for sites demonstrating focal uptake of ^{99m}Tc-MDP to determine the extent and degree of trauma, inflammation, degeneration, metastatic disease, or other skeletal disease processes. Typically, ^{99m}Tc-MDP images are interpreted visually but are not analyzed to determine the quantity of radiotracer incorporated into the skeleton.

Other nuclear medicine studies are assessed quantitatively in the sense that values extracted from the image represent the radioactivity concentration (and physiological function) in a specific organ or tissue region. Myocardial perfusion imaging with [^{99m}Tc]-hexatris-2-methoxyisobutylisonitrile (MIBI) is an example of one such "quantitative" nuclear medicine study for assessing a patient suspected of having coronary artery disease [44–46]. [^{99m}Tc]-MIBI is a lipophilic cation that accumulates in myocardial tissue roughly in proportion to blood flow [47]. Image data are acquired using SPECT to reconstruct tomograms of the myocardial concentration of [^{99m}Tc]-MIBI that are analyzed to assess regional myocardial blood flow. Although absolute measurements (μCi/g) of tissue activity are difficult (if not impossible) to obtain with SPECT, the images are interpreted "quantitatively" by extracting pixel values from the image to derive diagnostic information [48], rather than relying on "qualitative" visual interpretation of the images. Typically, ^{99m}Tc-MIBI is imaged in the "short-axis" view that presents the left ventricular myocardium in a series of annuli (or "doughnuts"). The image is analyzed using a "circumferential profile" representing the radionuclide concentration at 6° angular increments around each annular slice of the myocardium [49]. The extracted values are compared with standard values obtained from patients, in whom atherosclerotic disease has been excluded by coronary angiography, thereby allowing the nuclear cardiologist to assess both the presence as well as the regional extent of coronary artery disease.

67.5.2 Measurement of Technical Performance

Several parameters generally are measured to assess the performance of the scintillation camera [50–56]. *Spatial resolution* represents the precision with which the position of an event is localized and can be assessed from the full width at half maximum (FWHM) of a profile taken across the image of a point or linear radioactive object having small dimensions in comparison to the resolution of the system. *Spatial linearity* is quantified as the accuracy with which the position of an event is localized and represents the ability of a scintillation camera to produce a straight image of a straight object. Spatial linearity is measured as the deviation about the best-fit line in an image of a parallel line phantom or an orthogonal hole phantom, expressed as a percentage (ideally less than 1%) of the detector diameter. *Energy resolution* represents the precision with which the energy of a photon is recorded and generally is measured as the FWHM of the photopeak in an energy spectrum (number of detected photons recorded as a function of photon energy) of the radioactive source. *Flood field uniformity* assesses the ability of the camera to record a spatially uniform image when presented with a spatially uniform distribution of photons. An intrinsic measurement is performed by irradiating the uncollimated detector with the point source placed at a distance equal to at least five times the field of view of the detector. The system uniformity can be checked by irradiating the entire surface of a collimated detector with an extended source of uniform radioactivity. Sensitivity represents the number of photons recorded per unit of source radioactivity when the detector is operated either without (intrinsic sensitivity) or with (extrinsic sensitivity) a collimator. *Count-rate linearity* represents the ability of the camera to record a count rate proportional to the photon event rate received by the detector. At low event rates, the measured count rate increases linearly with the actual photon event rate. Because the scintillation camera acts as a paralyzable system, at higher event rates, the measured count rate is lower than that

predicted from linear response. At sufficiently high event rates, the measured count rate actually can decrease with increasing photon event rate and eventually can be extinguished when imaging radioactive sources of sufficiently high activities.

67.6 Positron Emission Tomography

Positron emission tomography (PET) involves a physiological administration of a positron-emitting radiopharmaceutical into the human body. The principal advantage of PET over single-photon imaging is the availability of a number of physiologically relevant radiotracers that are labeled with the short-lived positron-emitting radionuclides ^{11}C ($T_{1/2}$ = 20.4 min), ^{13}N (9.96 min), ^{15}O (2.04 min), and ^{18}F (109.8 min). A typical PET center consists of a cyclotron for on-site isotope production, a radiochemistry laboratory for synthetic incorporation of the isotopes into organic molecules, and a PET scanner. PET instrumentation is described in detail in several review articles [67,68].

67.6.1 Principle of Coincidence Detection

The proton-rich radioisotopes used with PET imaging undergo β-decay and emit positrons (anti-electrons). A positron travels a short distance and combines with an electron from the surrounding medium. The masses of the positron and electron are converted to electromagnetic radiation in the form of two γ-rays of energy 511 keV, which are emitted at nearly 180° to each other. The PET scanner utilizes multiple opposing γ-detectors that surround the positron emitter, each defining a linear volume of response between the detectors. Coincidence timing circuitry enables effective localization of the decay events occurring between detector pairs, rejecting events in each detector that originate from outside the volume of response. A typical modern PET scanner employs tens of thousands of small detectors (or analogous position-coded larger detectors), yielding as many as tens of millions of such volumes of response. The coincidence principle is also utilized to measure and correct for attenuation of photons within the body, allowing the measurement of radioactivity concentration in absolute terms (i.e., Bq/mL). In this case, a separate "transmission" measurement scan is performed, using an external positron-emitting source placed adjacent to the subject yet within the volume of response. A "blank" scan is similarly acquired but without the subject in the field of view. The ratio of coincident count rates in the blank/transmission scans multiplies the corresponding coincidence counts in the emission scan to correct for attenuation along each coincidence line of response.

67.6.2 Detector Composition

The choice of detector material for PET scanners is influenced by a number of considerations, including scanner geometry, detection efficiency (stopping power), output signal strength (energy resolution), signal decay time (count rate capability), physical stability (i.e., hygroscopicity), availability, and cost. Inorganic scintillators are best suited for detection of the 511 keV photons. The physical properties of the two most widely used scintillators, NaI(Tl) and bismuth germanate (BGO), are shown in Table 67.2. NaI(Tl) has found application in position-sensitive detector systems that utilize a small number of large crystals observed by multiple PMTs. NaI(Tl) offers the advantages of (1) good energy resolution for effective rejection of scattered radiation, (2) good timing resolution for minimizing the coincidence-resolving time window, (3) availability of large crystals, and (4) relatively low cost. The higher stopping power of BGO is advantageous for detector designs that use smaller crystals with one-to-one PMTs or position-encoded matrices of crystals [69]. The recently identified lutetium oxyorthosilicate (LSO) is a potential successor to BGO in detector block designs. LSO has a density of 7.4 g/mL, an effective atomic number of 59, a photofluorescent decay time of 40 ns, and light outputs that are 3/4 that of NaI(Tl) [70].

TABLE 67.2 Physical Properties of Scintillators Commonly Employed in PET Scanners

	NaI(Tl)	BGO
Density (g/cm^3)	3.67	7.13
Effective atomic number	51	75
Index of refraction	1.85	2.15
Relative emission intensity	100	15
Peak wavelength (nm)	410	480
Decay constant (ns)	230	300

67.6.3 PET Scanners

PET scanners use a number of different detector compositions and gantry configurations, each with its unique advantages and disadvantages [68]. Figure 67.5 shows two of the most common designs that are currently employed. At present, the majority of commercial designs employ a cylindrical geometry with individual BGO detector blocks arranged to form contiguous rings of detectors, each defining an image plane [71,72]. Most of these scanners have retractable lead (or tungsten) septa that are positioned between detector rings to attenuate photons that are emitted at angles not contained in the image plane. This minimizes the effect of out-of-plane scattered radiation, allowing accurate quantitation of the radioactivity distribution in each image plane by 2D (tomographic) image reconstruction. With the septa retracted, all axial angles are accepted, allowing true 3D volume imaging. Another scanner design uses large-area position-encoded NaI(Tl) detectors, allowing 3D volume imaging [73]. In all cases, computer-assisted image reconstruction is used to produce quantitative images of radiotracer concentration in the body.

The spatial resolution of the radioactivity distributions seen in the PET image is primarily determined by the size of the detector elements. In scanners employing cylindrical detector geometry, the in-plane spatial resolution is highest in the center of the field of view (typically 4–5 mm FWHM of the point source response for present state-of-the-art scanners). The spatial resolution slowly degrades as the radius increases due to inadequate stopping of photons within incident detectors for nonperpendicular entrance angles. Likewise, the resolution in the axial direction is determined by the axial dimension of the detector elements.

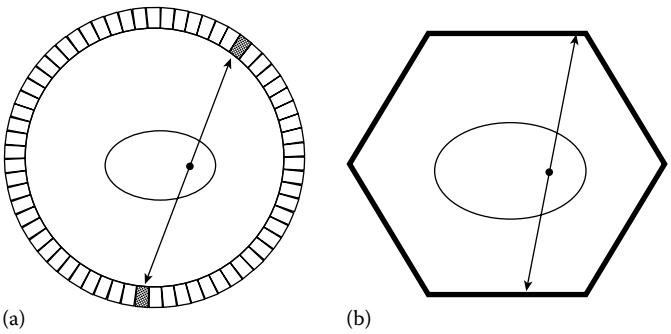

FIGURE 67.5 Representation of PET scanner geometries for typical scanners employing (a) multiple rings of small BGO scintillators and (b) six large NaI(Tl) position-sensitive planar detectors. The arrows represent positron annihilation photons that are emitted 180° from each other and detected in opposing detectors. (Courtesy of Dr. T. Turkington.)

67.7 Ultrasound Imaging

Ultrasound scanning provides a safe and noninvasive way to image the body. With this modality, brief pulses of sound are emitted by a transducer coupled to the skin surface. The sound pulse propagates through tissue at a fixed speed. Interfaces and other objects reflect portions of the acoustic energy back to the transducer, where they are detected as echoes. The ultrasound scanner forms 1D, or more commonly 2D, images of anatomic structures from the reflected echo patterns. In general imaging applications, ultrasound imaging uses frequencies in the 2–10 MHz range. Some newer ultrasound devices, for example, those used in emerging ophthalmology applications, use frequencies as high as 50 MHz [74,75].

67.7.1 Characteristics of Sound Waves in Tissue

The speed at which sound waves propagate through a medium depends on the density and compressibility of the medium. At 22 °C, the speed of sound in air is around 300 m/s, while in freshwater it is 1480 m/s. Human soft tissues behave somewhat like water, with speeds of sound ranging from 1460 m/s for fat to 1620 m/s for muscle. The average speed of sound in tissue is taken to be 1540 m/s (1.54 mm/μs) [76,77].

Any interface, large or small, can reflect a fraction of the ultrasound energy and produce an echo. The relative amount of energy reflected depends on the change in density and compressibility at the interface; the greater the change in these properties of the materials forming the interface, the greater the amplitude of an echo. Examples of reflectors include organ boundaries, blood vessels, and small scatterers distributed more or less randomly throughout most organs. The majority of the echo data displayed on images can be attributed to this scattering process [77]. Shung [78] has reviewed experimental work on ultrasonic scattering versus frequency in biological tissues.

As ultrasound pulses travel through tissue, they lose their strength due to attenuation. Attenuation is caused by scatter and reflection at interfaces and by absorption. For typical tissues, the amplitude of a 5 MHz beam decreases by about 50% for each centimeter traveled. The attenuation per unit distance is approximately proportional to the ultrasound frequency, so lower-frequency waves propagate greater distances through tissues than higher-frequency waves [79].

67.7.2 B-Mode Imagers

Figure 67.6 illustrates a typical configuration for an ultrasound imager. The operator places a handheld transducer on the skin surface of the patient. Early instruments utilized "single-element" transducers, but the majority of systems now use transducer arrays [80]. Acoustic pulses emitted by the transducer travel in well-defined beams. This beam can be "steered" in different directions, either mechanically with motors or electronically by using transducers arrays.

The same transducer detects echoes that arrive from interfaces in the body and applies them to the receiver, where they are amplified and processed for display. The instrument converts each echo signal into a dot on the display, the brightness of the dot being proportional to the echo amplitude at the transducer. The "scan converter" memory places dots in a location that corresponds to the reflector locations; information required to do this is the return time for each echo and the beam axis direction when the echo is detected.

The scanner constructs a cross-sectional image by sending out 100–200 such ultrasound beams, each in a slightly different direction, somewhat like a searchlight scanning the night sky. Echoes received from each beam direction are placed in the image memory using the scheme mentioned earlier. The entire image is updated at rates of 15–30 scans per second, producing a real-time image on the display monitor. This technique is referred to as B-mode imaging because echo signals simply modulate the intensity, or brightness, of the display at locations corresponding to their anatomic origin.

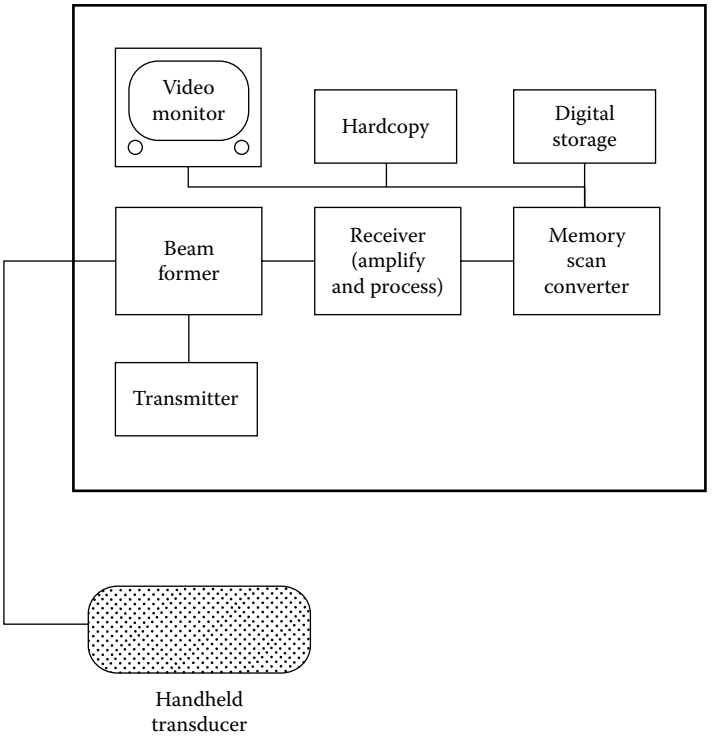

FIGURE 67.6 Components in a typical B-mode ultrasound device.

67.7.3 Doppler Techniques

Ultrasound instruments commonly provide Doppler records as well as B-mode images. Fundamentally, the Doppler effect is a change in the frequency of reflected waves when there is relative motion between the transducer and reflector. For motion directly toward or directly away from the transducer, the Doppler signal frequency f_d is given by

$$f_d = \frac{2 f_0 v}{c} \tag{67.7}$$

where

f_0 is the frequency of the transmitted ultrasound
v is the velocity of the reflector
c is the speed of sound

Thus, the Doppler signal frequency provides information on reflector velocity.

Continuous wave (CW) Doppler instruments consist of a transducer with separate transmitting and receiving elements, a transmitter–receiver unit, and a signal display. They extract a Doppler signal from the complex echo pattern, usually by heterodyning the echo signal with a signal that is coherent with the transmitted wave and then low-pass filtering. The most common applications are to detect and measure blood flow. With a 5 MHz ultrasound frequency and blood velocity of 50 cm/s, the Doppler signal frequency is 3.25 kHz, that is, in the audible frequency range. A simple loudspeaker may be all that is necessary for interpreting the Doppler signal, but very often a real-time spectral analyzer is available.

Pulsed Doppler instruments are a bit more complicated, but allow the operator to define precisely the distance from the transducer from which Doppler signals are selected. In pulsed Doppler, an acoustic

pulse is transmitted along a fixed beam line. Resultant echo signals are amplified and subjected to Doppler processing methods, similar to those outlined for the CW instrument. An operator-adjusted gate captures the waveform from the depth of interest, and a sample-hold device retains the value of this waveform until a subsequent pulse–echo sequence. Because the phase of the echo signal from moving reflectors changes from one pulse–echo sequence to the next, a Doppler signal can be constructed from the behavior over time of the sample-hold value.

67.7.4 Color Doppler Imaging

Color flow imagers may be thought of as extensions of pulsed Doppler machines. Rather than detecting Doppler signals from a single location, color flow imagers detect signals from all depths covered by the ultrasound beam and for many beam directions. Most instruments extract and display the mean Doppler signal frequency for each location throughout the scanned field [81,82]. A color Doppler image is almost always combined with a B-mode image to provide both anatomic and flow data from the scanned plane.

67.7.5 Measurement of Ultrasound Instrument Performance

Defining "image quality" in ultrasound, and specifying quantifiable factors that relate to optimal B-mode imaging, is controversial to say the least. Important factors that are considered include spatial and contrast resolution, sensitivity, penetration depth, and geometric accuracy.

High-quality ultrasound imagers interrogate the scanned field using a sufficient number of individual beam lines (more than 100) such that gaps between lines can be ignored in resolution considerations. An exception may be in color flow imaging, where sparse line densities are needed for sufficient frame rates [77]. Thus, spatial resolution is dictated by the volume of the ultrasound pulse propagating through the tissue. The dimension of this pulse volume in the direction the pulse travels, that is, the axial resolution, is determined by the duration of the pulse emitted by the transducer, while the dimension perpendicular to the beam axis or the "lateral resolution" is determined by the beam width. Although ultrasound beam energy is concentrated near the axis, it is the nature of beams from finite-sized apertures that the intensity falls off gradually with increasing distance from the beam axis. Finally, the size of the ultrasound beam perpendicular to the image plane determines the "slice thickness," the width of the volume of tissue contributing to the echo data viewed in the image plane.

A variety of methods have been used for determining in-plane resolution. The lateral and axial dimensions of a reflector whose size is small enough that it can be considered a pointlike object are frequently used [83]. For a 3.5 MHz transducer, this "spot size" can be as small as 0.7 mm in the axial dimension and 1–2 mm laterally. Smaller spot sizes are found with higher-frequency imagers, such as those using 10 MHz scan heads. Also, larger spot sizes are obtained with scanners that use fixed-focus, single-element transducers.

Slice thickness has been measured using a planar sheet of scatterers scanned with the ultrasound scanning plane intersecting the sheet at a 45° angle [83]. If the slice thickness were negligible, the image of the sheet in this projection would be a straight, horizontal line. The finite thickness of the scanned slice causes a thickening of the line; in fact, for the 45° orientation the vertical size of the image of the sheet corresponds to the slice thickness. For all ultrasound imaging systems, except annular array transducers, the slice thickness is the worst measure of spatial resolution, ranging from the 10 to 2 to 3 mm, depending on depth, for a 3.5 MHz transducer.

Physicians commonly use ultrasound imagers to detect cancerous tumors, for which the echoes are slightly stronger or weaker than the surrounding region. "Contrast-detail" tests [84,85] measure the smallest object that can be visualized at a fixed backscatter difference. Spherical mass detectability [86] assesses capabilities to visualize realistic focal lesions. Masses in the latter detection test are characteristic of actual tumors; furthermore, they are easily distributed throughout the scanning plane, assessing resolution at all depths.

Scanner sensitivity is an important performance feature, especially because spatial resolution can be enhanced with higher-frequency transducers. However, this is at the expense of increased ultrasound beam attenuation and poorer penetration. Although absolute measurements of sensitivity of scanners have been done [87], most centers rely upon clinically meaningful "maximum visualization distances" [83,88] for estimating and comparing sensitivity. Geometric accuracy also is important, as images frequently are used to determine structure dimensions, such as fetal head size when determining gestational age [89]. Calibration of distance measurements is done following standard protocols [83,90]; fortunately, modern scanners with digitally based image formation maintain their accuracy much better than previous systems, and many physicists maintain that tests for geometric accuracy are not crucial in routine performance assessments.

67.8 Magnetic Resonance Imaging

MRI is a new medical imaging modality that uses magnetic fields and radio-frequency (RF) energy to produce images of the body. This technique is based on nuclear magnetic resonance (NMR) [91], which is a quantum mechanical phenomenon exhibited by atoms having an odd number of either protons or neutrons. Such atoms have a nonzero nuclear magnetic moment, μ, and will precess (or rotate) about an external magnetic field ($\mathbf{B}_0$) with a frequency of $\omega_0 = \gamma \mathbf{B}_0$, where γ is the gyromagnetic ratio that for H is 42.57 MHz/T. A number of isotopes (including ^{1}H, ^{31}P, ^{23}Na, ^{2}H) exhibit the NMR phenomena; however, the majority of magnetic resonance (MR) scanners image ^{1}H. This is because, relative to other isotopes, ^{1}H has a high inherent sensitivity and abundance in tissue. Therefore, the following discussion is limited to ^{1}H MRI. When placed in a $\mathbf{B}_0$ field, ^{1}H nuclei align their spins either parallel or antiparallel to $\mathbf{B}_0$, with a slight excess in the lower-energy parallel state. At $T = 25$ °C and $|\mathbf{B}_0| = 1.5$ T, an excess of ~5 in 10^6 atoms is in the parallel state (this excess increases with $\mathbf{B}_0$ and T^{-1}). Because there are $\sim 10^{23}$ ^{1}H per milliliter of tissue, this excess, when summed over even a small volume, results in a net magnetization, $\mathbf{M} = \Sigma\mu$.

67.8.1 MR Imaging Techniques

The Bloch equations [91,92] are a set of phenomenological equations that succinctly describe the evolution of the net magnetization $\mathbf{M}(\mathbf{r},t)$ during an MRI experiment:

$$\frac{\partial \mathbf{M}(\mathbf{r},t)}{\partial t} \gamma \mathbf{M}(\mathbf{r},t) \times \mathbf{B}(\mathbf{r},t) - \frac{M_x(t)\hat{x} + M_y\hat{y}}{T2} + \frac{(M_z(t) - M_0)\hat{z}}{T1} \tag{67.8}$$

where $\mathbf{M}(\mathbf{r},t) = (M_x(t), M_y(t), M_z(t))$; M_0 is the initial (or equilibrium) magnetization, $\mathbf{B}(\mathbf{r},t) = \mathbf{B}_0 + \mathbf{G}(\mathbf{r},t)\ \mathbf{r} + \mathbf{B}_1(t)$ is the total applied magnetic field and includes terms representing the static field, $\mathbf{B}_0$, the field gradients, $\mathbf{G}(\mathbf{r},t)\ \mathbf{r}$, and the magnetic field component of any applied RF excitation, $\mathbf{B}_1(t)$; and $T1$ and $T2$ are the characteristic relaxation times of the tissues being imaged. The coordinate system is described in Figure 67.7. The $\mathbf{B}_0$ and $\mathbf{G}(\mathbf{r},t)\ \mathbf{r}$ fields are parallel to z, and the $\mathbf{B}_1$ field is orthogonal to z. Every MRI experiment consists of an excitation phase, in which the equilibrium magnetization is tipped away from z (the longitudinal axis) and into the transverse (x–y) plane. This is followed by a detection phase, in which the signal emitted by the excited spins is manipulated so that an echo forms. The echo time (TE) and the repetition time (TR) denote the time between excitation and echo formation and the time between successive excitation phases, respectively. Starting at equilibrium, RF energy at ω_0 is applied to create an oscillating $\mathbf{B}_1$(t) field that tips $\mathbf{M}$ toward the transverse plane, at which time it begins to precess about z (Figure 67.7a). Viewed in a frame of reference rotating at $-\omega_0$ about $z(x', y', z')$, the RF excitation corresponds to tipping $\mathbf{M}$ through an angle α from z (Figure 67.7b). Gradients, $\mathbf{G}(\mathbf{r},t)$, are then applied so that spatial information is encoded into the precessional frequency of $\mathbf{M}$, $\omega = \gamma\ [\mathbf{B}_0 + \mathbf{G}(\mathbf{r},t) \cdot \mathbf{r}]$. Additional gradients and/or RF-excitation pulses are used to refocus the magnetization into an echo (Figure 67.7c through f).

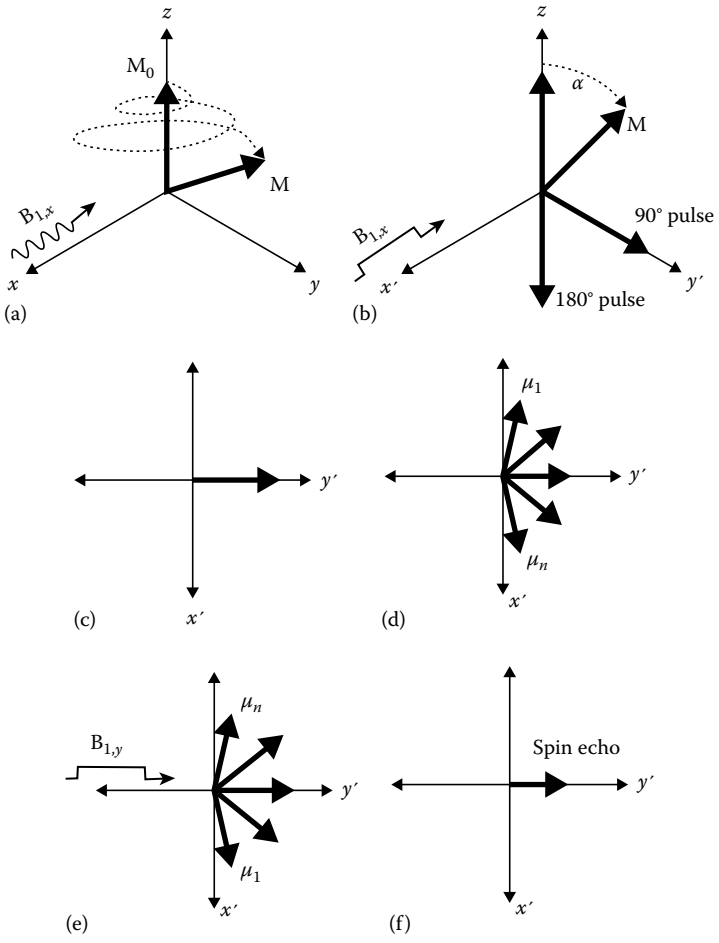

FIGURE 67.7 Graphical depiction of the MRI process showing the effect of the $\mathbf{B}_1$-excitation pulse (a–b) and formation of a spin-echo (c–f). In (a) an RF pulse, $\mathbf{B}_1$, is applied along the x-axis causing the net magnetization to tip away from equilibrium, $\mathbf{M}_0$, as it precesses about z. Viewed in the rotating frame of reference, this corresponds to a nutation by some angle α in the y'–z plane. After application of an $\alpha = 90°$ pulse, $\mathbf{M}$ lies in the x'–y' plane (c) and is subject to variations in the local magnetic field that cause the individual spins to precess at different frequencies, that is, μ_1 and μ_n in (d). The local field variations could be due to gradients or field inhomogeneity, the latter effect leading to $T2^*$ signal loss. By applying an $\alpha = 180°$ RF pulse along y', the spins are rotated about y' (e) and are refocused into an echo (f).

The precessing transverse component of the magnetization ($M_{xy} = M_x + jM_y$) induces a signal (EMF) in the receiver coil, and this is recorded during echo formation. The experiment is repeated many times (normally 128–256) using predetermined gradient strengths [93] so that a complete data set is collected. These data are in spatial-frequency space (known as **k**-space), and images are reconstructed after taking the multidimensional Fourier transform of **k**-space [94]. Gradients can be used to encode spatial information along all axes, so either 2D (planar) or 3D (volume) imaging is possible with MR.

67.8.2 MR Image Contrast

Excited spins undergo two principal relaxation processes: spin–lattice and spin–spin relaxation. Spin–lattice relaxation occurs when spins lose energy to surrounding molecules and return to the equilibrium position, M_0. Spin–spin relaxation is due to local interactions that cause spins to precess at different rates, resulting in

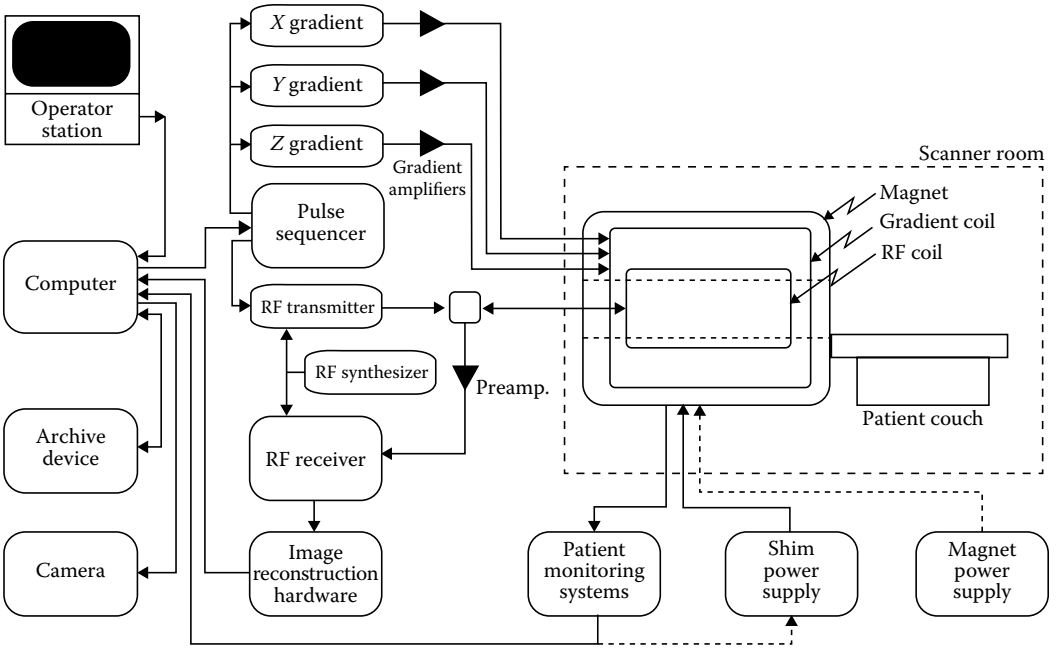

FIGURE 67.8 Overview of an MR scanner showing key components.

a reduction in $\mathbf{M}_{xy}$ (Figure 67.7d). Field inhomogeneity due to an imperfect magnet is reversible ($\delta\mathbf{B}(\mathbf{r})$), while inhomogeneity due to variations in local chemical structure is not. The relaxation times $T1$ and $T2$ characterize spin–lattice and spin–spin relaxation processes, respectively, and from the Bloch equation (Figure 67.8) the following equations can be derived for the relaxation of spins tipped by $\alpha = 90°$ at $t = 0$:

$$M_z(t) = M_0(1 - e^{-t/T1}) \quad \text{and} \quad M_{xy}(t) = M_{xy}(t = 0)e^{-t/T2} \tag{67.9}$$

Together with the differences in the inherent proton density between tissues, differences in $T1$ and $T2$ are the basis of the contrast seen in MR images. A spin-echo (SE) acquisition uses one or more additional RF excitations with $\alpha = 180°$ to refocus the reversible component of spin–spin relaxation so that one or more echoes are formed. Equation 67.9 shows that images with primarily $T1$ weighting, $T2$ weighting, or proton density weighting result when relative to $T1$ and $T2$: TR and TE are short, TR and TE are long, and TR is long and TE is short, respectively. In practice, images with a pure weighting are not obtainable because image contrast is due to a mixture of these contrast mechanisms. Gradient-recalled echo (GRE) imaging uses additional gradients, instead of an $\alpha = 180°$ pulse, to produce echoes and results in images with significantly shorter TR and TE than SE techniques. GRE images, however, do not refocus the reversible component of spin–spin relaxation and are thus susceptible to $T2^*$ signal loss, where $1/T2^* = 1/T2 + 2\pi\gamma|\delta\mathbf{B}(r)|$. This leads to lower signal to noise in GRE images compared with SE images. Since TR is short compared with $T1$, GRE images tend to have $T1$ weighting. If TE approaches $T2^*$, then the $T2^*$ weighting becomes significant.

67.8.3 MR Instrumentation

The key components of a modern MRI system include a magnet, a pulse sequencer, gradient and shim coils, and an RF transmitter/receiver—the function of which are controlled by a host computer (Figure 67.8). To obtain the $\mathbf{B}_0$-field, most commercial scanners use superconducting magnets, although some special-purpose (and often lower-cost) scanners may use resistive magnets. Superconducting magnets generally

have field strengths between 0.5 and 4.0 T, while resistive magnets normally have field strengths <0.3 T. The improved signal-to-noise ratio obtained with superconducting designs is offset by the need for periodic cryogen replacement. More modern magnets, however, minimize this cost by including a cryogen reliquefier. Two sets of auxiliary gradient coils are located within the main magnet to provide spatially varying fields, $\mathbf{G}(\mathbf{r},t)$, and to allow shimming of the $\mathbf{B}_0$-field. Current gradient coil hardware can generate maximum gradients of up to 40 mT/m with rise times of 120 μs and allow fields of view from 4 to 48 cm. Shim coils improve the homogeneity of the $\mathbf{B}_0$-field by decreasing $\delta\mathbf{B}(r)$ to a few parts per million in order to minimize $T2^*$ effects and spatial distortions. Modern scanners incorporate a digital RF subsystem that excites the spins and then records the emitted signals via one or more RF coils within the magnet. An RF synthesizer is coupled to both the RF transmitter and receiver, so that synchronous detection is possible. The RF system is connected either to separate transmit and receive coil(s) or to a combined transmit/receive coil(s).

To acquire an MR image, the host computer interacts with the operator who defines the imaging parameters (such as α, TR and TE, slice location, and field of view). The parameters are then translated into instructions that are executed on a synchronous state machine known as a pulse sequencer. This device provides real-time control of the gradient and RF waveforms as well as other control functions, such as unblanking the RF receiver and enabling the ADC during an echo. Data are collected and demodulated by the receiver, and then images are reconstructed using specialized hardware built normally around a fast-array processor. The images are sent to the host computer for operator station display, archival, or filming. In addition, many MR scanners incorporate devices for monitoring heart and respiration rate and allow these signals to trigger or gate image acquisition. Future MRI systems will probably include higher $\mathbf{B}_0$-field and gradients and faster data processing/reconstruction hardware. In addition to current imaging apparatus, it is likely that dedicated instruments will be increasingly used to study the heart and for performing neurofunctional imaging and MR-guided interventional procedures.

Blood Chemistry Measurement

Terry L. Rusch
Douglas Scientific

Ravi Sankar
University of South Florida

68.1 Introduction

The study of blood and its effects on sustaining life dates back to the start of understanding human anatomy. There is a diverse background associated with blood chemistry, and knowledge of the makeup and purpose of blood and its components is growing by leaps and bounds. The typical discussion and history of blood chemistry relate to oxygen transport and its effects. This chapter will deal mainly with the measurement of oxygen related to health and critical-care applications, with limited descriptions of noncritical health status measurements. The beginning of blood analysis and the measurement of a person's health status were not practically and conveniently performed until technology advanced. It has been within the last 50 years that routine monitoring began in critical care. Critical-care health monitoring is the focus of this discussion because it has been one of the main motivations for developing analytical measurements. However, most critical-care monitoring has led to diagnostic tools and functional assessment of blood and its components.

Current healthcare professionals use a variety of common analytical measurements to assess and maintain a person's health. The measurements of interest include hemoglobin, hematocrit (Hct), blood gases (O_2 and CO_2), pH, glucose, and concentrations of electrolytes. Blood gas analysis is divided into a wide variety of specific tests. The tests include arterial, mixed venous, and transcutaneous oxygen tension; carbon dioxide tension; oxygen and carbon dioxide concentration; and oxygen saturation. Each test has a specific purpose in diagnostics. Continuous real-time monitoring of oxygen saturation by pulse oximetry measurements is routinely used in anesthesia and critical-care settings. However, to determine heart and lung efficiency or true tissue oxygenation, other measurements are required. Different measurements are required because of the complex nature of the human body, and no one measurement gives a complete picture of overall status. For example, arterial oxygen saturation does not give true cardiac output efficiency nor does it give a true tissue

oxygenation state. Measurements can also be very misleading. During normal conditions, the measured values correspond very well. For example, under a given temperature and pH, oxygen saturation corresponds to oxygen tension. A fixed relationship occurs under these conditions. This does not mean the same relationship applies to all circumstances. A change in temperature or pH will shift the oxygen tension to a saturation relationship.

68.2 Background

Most blood chemistry measurements have a long history. In the late 1800s, the hydrogen (H^+) electrode was used to measure pH and, in 1925, John Peters at Yale showed a relationship between pH and CO_2 content. The measurement of blood gas started in the early 1920s with *in vitro* analysis of oxygen saturation. It was not until much later, however, that common patient care measurements were accepted. For example, it was not until 1952 in Copenhagen that pH monitoring was performed on artificially ventilated patients. The monitoring of pH was the start of the clinical use of blood gas monitoring. Until that time, physiological measurements were performed only in the laboratory setting. Electrochemical measurements were more common and performed with a Clark electrode or similar electrode arrangement. Leland Clark made a working model of an oxygen electrode around 1950, which introduced a practical method of measuring oxygen tension. The probe was originally developed to aid in heart bypass instruments. Not long after the Clark electrode was developed, optical transmission analysis tools were developed. The measurement of oxygen saturation, called oximetry, was one of the early optical measurements. Oximetry has a long history dating back more than 70 years to the 1930s. Matthes and Millikan recorded the earliest noninvasive reading around 1935, and Glen Millikan introduced the name *oximetry* in 1942. A real research effort was started during World War II as a part of military aviation. It took almost 70 years for pulse oximetry to become a standard piece of equipment in operating rooms, critical-care units, and emergency health care. On January 1, 1990, the American Society of Anesthesiologist (ASA) made intraoperative monitoring with pulse oximetry a standard [1]. Despite the acceptance of pulse oximetry and its benefits, there still has been little change in pulse oximetry techniques. A good historic perspective on most blood gas analysis is written in a series of articles in the *Journal of Clinical Monitoring* and in *International Anesthesiology Clinics* [2–7].

68.2.1 Oxygen Delivery

As Severinghaus and Astrup [6] note in the history of blood gas analysis, nothing is more important than oxygen supply for life. Therefore, it can be argued that oxygen content and consumption should be one of the most important things to monitor in critical and unconscious patients. It is important to look at the mechanisms for oxygen transport. All human tissue needs oxygen to function, and it is therefore critical to understand how oxygen is delivered. *Hemoglobin* is the binding agent for oxygen in blood, but it is necessary to oxygenate the blood and move it to the tissue that uses the oxygen. A simple explanation is as follows. Oxygen is diffused into blood via the lungs. Blood is then circulated by a system of *arteries, veins*, and *capillaries* where the oxygen is diffused to tissue. The tissue also diffuses carbon dioxide to blood in the capillaries, which transports back to the lungs, where the carbon dioxide is diffused to the lungs for expiration. Figure 68.1 shows a diagram of the general makeup of the components of interest. This is a very simplistic view of blood and oxygen transport. There are many other regulatory factors, such as sodium, potassium, calcium, pH, and glucose, but this simplistic view is a good starting point to understand the measurements that follow. It is also important to note that several measurement options and locations exist for gathering the same or similar data. This makes understanding the interaction and importance of different measurements difficult. For example, arterial and venous blood oxygen tensions are interdependent but have different readings. Different physical states and health problems cause varying interdependence. A simple requirement to identify whether or not cell tissue is

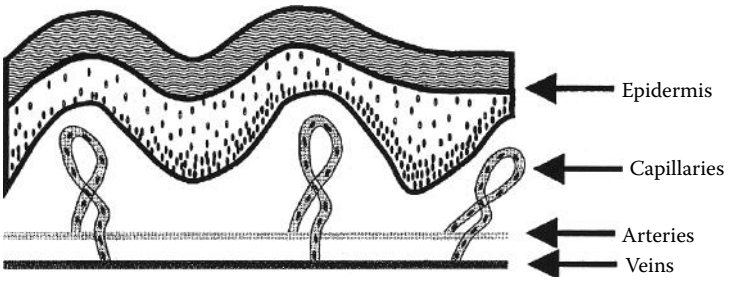

FIGURE 68.1 Components involved in oxygen transport. Oxygen is delivered to the epidermis by arteries and exchanged through the capillaries. Veins return the by-product.

being properly oxygenated becomes very complex. Oxygen delivery to tissue is determined by the differential in partial pressure between cell tissue and capillaries. The partial pressure difference determines the rate and efficiency of diffusion. However, the rate is also dependent on blood flow, concentration of hemoglobin (CtHb), and the saturation of oxygen. No individual parameter or measurement gives a complete picture of cell oxygen consumption.

68.2.2 Blood Hemoglobin

Blood contains many components, but hemoglobin is the main transporter of oxygen (O_2) to tissue. In addition, blood is responsible for removing the by-product of oxygen expenditure, carbon dioxide (CO_2). Hemoglobin is a good binding agent for oxygen, producing oxyhemoglobin (O_2Hb), also called oxygenated hemoglobin. Hemoglobin is a combination of four peptide chains, each containing several hundred amino acids. Hemoglobin is composed of two elements, heme and globin. Heme is the iron pigment of the electrolytes, and globin is a simple protein. Hemoglobin contains about 6% heme and 94% globin. Hemoglobin is the principal component of red blood cells. Unbound hemoglobin is called deoxyhemoglobin (RHb) or reduced hemoglobin. Hemoglobin also binds to produce additional components, such as carboxyhemoglobin (COHb) and methemoglobin (MetHb). MetHb is a result of oxidation of ferrous iron in hemoglobin [8]. There are other compounds that are found in blood, but they are usually in very low concentrations and are of interest in more specialized cases.

68.2.3 Measurement Methods

Most blood chemistry analysis measurements are derived from one of two methods: electrochemical and optical. There are other specific measurement techniques, such as gas chromatography, but they are more of a specialized measurement and will not be addressed. Electrochemical measurements are based on the Clark electrode with the blood component or electrolyte of interest using a different ion-specific electrode. The Clark electrode consists of an electrode in a medium. The first electrode for oxygen tension measurements was a platinum electrode and a silver anode. The current or voltage generated at the electrode is measured and is proportional to the amount of that component. The relationship is usually a calculated concentration derived from empirical data. For optical measurements, there are many approaches, but all are based on absorption, reflection, scattering, and fluorescence techniques. One optical probe has been called an optode. The optode is a cross measurement of optical fluorescence and electrochemical measurement. Figure 68.2 shows a diagram of one configuration for an optode arrangement. In an optode, an ion-selective membrane is used to diffuse an ion or compound into the fluorescent dye measurement chamber. The ion is associated with a fluorescent dye, excited with a light source, and the emitted fluorescent light is measured. Many measurements can be obtained, such as oxygen tension, carbon dioxide tension, pH, potassium concentration, calcium concentration, and chloride concentration.

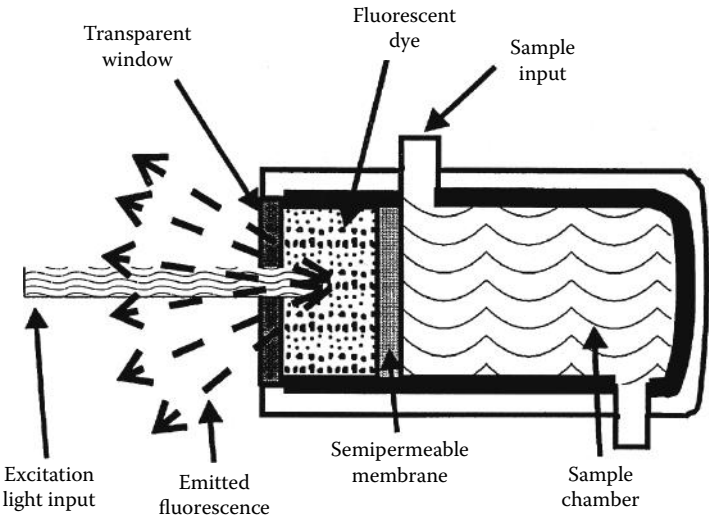

FIGURE 68.2 Chemical fluorescent optode for oxygen tension measurements. Light input through a window excites encased dye. The sample interacts with the dye through a semipermeable membrane. The sample is introduced to the dye via a flow-through chamber.

Measurements are listed in one of four categories, (1) invasive or (2) noninvasive measurements and (3) continuous or (4) periodic measurements. *Invasive* measurements can be continuous or periodic and can be performed *in vivo* or *in vitro*. Invasive *catheter* sensors can record real-time data continuously with no loss of blood sample. *Intra-arterial* measurements can be drawn periodically for minimally invasive measurements with no sample loss, or samples can be withdrawn and discarded. Periodic samples can also be drawn for analysis and measured in a physically different location at a later time. Noninvasive measurements can also be continuous or periodic but are generally on patient, real-time measurements. Noninvasive measurements are always preferred over invasive measurements, because invasive measurements increase risk of infection and usually mean some delay between the time of acquisition and the time results are available. However, noninvasive measurements are not always as accurate as invasive measurements.

68.3 Measurements and Techniques

There are typically several measurement techniques that yield the same or similar data. Each technique will give information about different physical states, such as cardiac efficiency or tissue oxygenation state. For example, oxygen saturation and partial pressure of oxygen are related. However, the exact relationship is dependent on pH and temperature. A text by Kenneth McClatchey on *Clinical Laboratory Medicine*, the International Federation of Clinical Chemistry (IFCC), and instrument operator's manuals are good references for laboratory protocols relating to invasively drawn samples [9,10]. Sample preparation and handling protocols, as well as standard measurement levels and physical states relating to excess or deficient readings, are detailed. The range, price, and suppliers for instrumentation are extensive. A standard midrange laboratory blood gas analyzer can cost from $5,000 to $50,000. The more common measurements are described in the following text.

68.3.1 Hemoglobin and Hematocrit Concentration

The total CtHb or Hct indicates the oxygen-carrying potential of blood. The combination of amount of hemoglobin, partial pressure of oxygen or percent oxygen saturation, and rate of flow

of hemoglobin determines the amount and efficiency of tissue oxygenation. Invasively drawn samples are typically used to measure hemoglobin and Hct values.

68.3.1.1 Hemoglobin

The total hemoglobin concentration is not the same as the red blood cell count, because red blood cells have different amounts of hemoglobin. The total hemoglobin concentration is measured optically by absorptive intensity at the isosbestic point. The Beers–Lambert law, also referred to as Beer's law, shown in Equation 68.1 regulates the absorptive property of a substance:

$$I_t = I_0 e^{-DC\alpha_e} \tag{68.1}$$

where

I_t is the transmitted intensity
I_0 is the incident intensity on the sample
D is the distance light travels through the substance
C is the concentration of the solution
α_e is the extinction coefficient at a specified wavelength

The isosbestic point is the crossover point in extinction curves for oxyhemoglobin and RHb. The wavelength of 805 nm is an isosbestic point, and at this wavelength the absorption is independent of hemoglobin type. If blood is assumed to be composed of only O_2Hb and RHb, then the absorbance at the isosbestic point determines the total concentration of Hb. The most common error in assuming only O_2Hb and RHb is during elevated COHb. COHb, however, generally is optically indistinguishable from O_2Hb for absorption. An alternative approach to isosbestic measurement is to calculate CtHb. Assuming only O_2Hb and RHb, the total Hb concentration is simply the sum of the two concentrations. A more accurate sum is shown in Equation 68.2:

$$\text{CtHb} = \text{O}_2\text{Hb} + \text{RHb} + \text{COHb} + \text{MetHb} \tag{68.2}$$

Here, the four most common Hb derivatives are used to calculate a more accurate CtHb. The individual Hb derivatives are measured as outlined later.

68.3.1.2 Hematocrit

Hct is the volumetric fraction occupied by red blood cells and is generally measured by conductivity. Hct is also referred to as the packed cell volume (PVC). Hct can be determined by conductivity based on the plasma ion content. Hct does not contribute to the conductivity and therefore is inversely proportional to the conductivity. Hct can also be determined optically in various ways. One way is through optical density measurements, where the total optical density is the sum of optical absorbance and optical scattering density. The total optical density is linearly proportional to Hct, and, at clinically relevant Hct levels of 20%–40%, scattering is dominant over absorption. One optimization study showed that an optimum wavelength of 624 nm, at a measured angle of 90° from the incident light, gave an inverse linear intensity to the Hct level [11].

68.3.2 Oxygen Tension

Oxygen tension or the partial pressure of oxygen (PO_2) is a common measure of oxygenation states. The partial pressure of oxygen in hemoglobin determines how well oxygen is delivered to the cell tissue of the body. The more common partial pressure reference is arterial partial pressure of oxygen (PaO_2). If the partial pressure of oxygen is higher than the surrounding tissue, oxygen is diffused to the tissue.

If the partial pressure is lower than the tissue partial pressure, no oxygen is diffused to the tissue, and tissue damage can start to occur. Equation 68.3 shows Henry's law:

$$C = \alpha_s * PO_2 \tag{68.3}$$

where
C is the concentration of oxygen (O_2)
α_s is the solubility coefficient
PO_2 is the partial pressure of oxygen

In diffusion, a partial pressure between the tissue and blood supply is trying to maintain equilibrium. Diffusion will occur until the two partial pressures are equal. Equation 68.4 shows diffusion equilibrium:

$$PO_2 = \frac{C_1}{\alpha_{s1}} = \frac{C_2}{\alpha_{s2}} \tag{68.4}$$

The rate of oxygen diffusion is dependent on the difference in partial pressure. The larger the difference in partial pressure, the faster the diffusion rate.

The partial pressure difference is partially determined by the oxygen delivery (D_o) rate. Oxygen delivery can be identified as the concentration of arterial oxygen minus the concentration of venous oxygen times the rate of blood flow (R), as shown in Equation 68.5:

$$D_o = (C_aO_2 - C_vO_2) * R \tag{68.5}$$

where
C_aO_2 is the arterial oxygen concentration
C_vO_2 is the venous oxygen concentration

The oxygen delivered, however, is not the oxygen delivered to the tissue. Some oxygen is transpired through the skin. The transpired oxygen allows an alternative approximation measurement of arterial oxygen tension. The more common oxygen tension measurement is arterial oxygen tension. Oxygen tension can be measured electrochemically, transcutaneously, or optically. The techniques are listed in the following text.

68.3.2.1 Electrochemical PO_2 Measurements

Electrochemical measurements of PO_2 are obtained using a basic Clark electrode with a platinum electrode and a silver/silver chloride reference electrode. Figure 68.3 shows a diagram of one type of Clark electrode. The electrode provides a path for the reduction in Equation 68.6:

$$O_2 + 4e^- \rightarrow 2O^- \tag{68.6}$$

The platinum electrode has an affinity with oxygen. If a reference PO_2 at the electrode is known, preferably zero, then the current depends only on the oxygen tension variations of the sample. Early electrodes were consumption measurements where the oxygen is removed and the sample is altered. Oxygen was attracted to the electrode and a current proportional to the oxygen content was observed. Improved electrodes use a semipermeable, constant diffusion membrane. An electrolyte is used with the membrane to improve response, longevity, and stability. An exposed electrode will become coated in whole blood

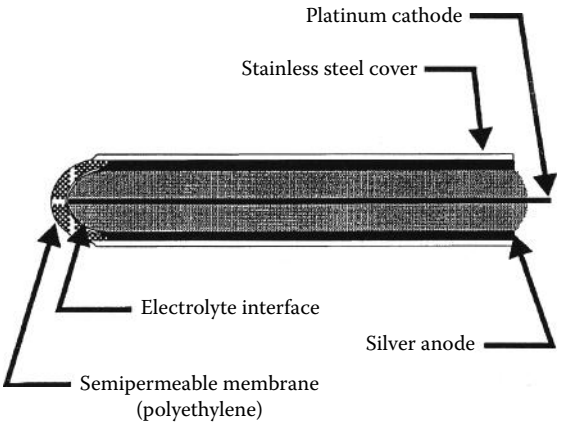

FIGURE 68.3 Clark-type needle electrodes for PO_2 measurements. Oxygen ion interaction through the membrane tip allows the ion concentration to be measured by dissimilar metals.

and the sensitivity will degrade. The membrane and electrolyte allow the diffusion of oxygen without the sample directly contacting the electrode. In addition, a properly designed membrane reduces the stirring effect noted by Clark and others using an exposed electrode. The size and location of electrodes have been extensively studied. The exact setup for the electrode can be varied for optimum performance in different areas. For example, a less permeable diffusion layer reduces the stirring effect and makes the probe more stable, but the result is a slower response time [3,6,12,13].

68.3.2.2 Transcutaneous Partial Pressure of Oxygen

Partial pressure and oxygen saturation are not always true indicators of actual tissue oxygen consumption. It has been known since 1851 that oxygen is respired from living tissue. A combination of heat and optical means can be used to determine the amount of oxygen expired and correlated to arterial partial pressure under controlled conditions. This method of measuring arterial oxygen partial pressure is called transcutaneous oxygen partial pressure ($P_{tc}O_2$). There are, however, many complications in the measurement of $P_{tc}O_2$. Many studies have tried to correlate arterial oxygen saturation with the measured expired oxygen. The most accurate measurements are made by maintaining a constant temperature as high as 45 °C, to assure perfusion. This causes the complication of burns to skin, and sensors need to be moved on a regular basis.

Measurements can be performed polarographically using Clark electrodes or alternatively by mass spectroscopy. Because of the nature of $P_{tc}O_2$, adult measurements are not common, but premature infant hemoglobin and skin are more responsive to $P_{tc}O_2$ measurements, which have had a place in monitoring neonatal oxygenation [7,14].

68.3.2.3 Optical-Based PO_2

There are many variations on optical-based blood gas measurements. The basic optical measurement for PO_2 is a *fluorescent* measurement. A fiber-optic cable is used to excite a fluorescent dye remotely. The excited dye emits a higher-wavelength signal, known as Stokes shift. The emitted signal is measured and is correlated to the PO_2 value. Figure 68.4 shows a configuration for a fluorescent sensor. Oxygen is used as a fluorescence quencher. Oxygen has a fluorescence-quenching property and attenuates the fluorescent intensity. A zero state can be measured by filling the sample chamber with a zero oxygen concentration mixture. The measured intensity is compared with the incident light source and is used to calculate the concentration of the sample. For oxygen tension, the measurement is done by a fluorescent electrochromic dye, such as pyrenebutyric acid, with an ion-selective membrane such as silicone rubber.

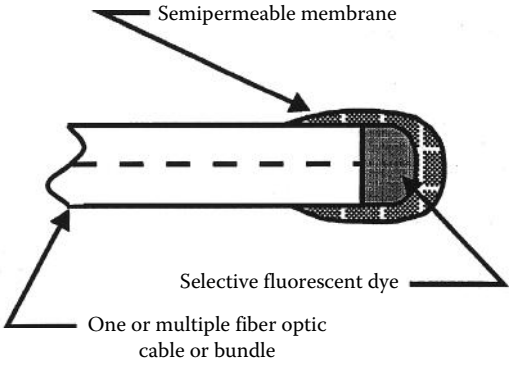

FIGURE 68.4 Chemical fluorescent fiber-optic probes. Dye is encased on a fiber tip by a membrane. Light enters the dye through the fiber and the emitted fluorescence is returned via the fiber. The amount of fluorescence is an indication of the interaction between the dye and the substance in which the fiber tip is placed.

The oxygen tension is then calculated using the Stern–Volmer quenching formula, shown in Equation 68.7, and the PO_2 value is calculated empirically:

$$\frac{I_0}{I} = 1 + K * PO_2 \quad \text{or} \quad I(PO_2) = \frac{I_0}{(1 + K * PO_2)} \tag{68.7}$$

where

$I(PO_2)$ and I_0 are the relative fluorescence intensities in the presence of oxygen and in the absence of oxygen, respectively

K is the overall quenching constant and is given in Equation 68.8:

$$K = k^+ * \alpha_O * \tau_0 \tag{68.8}$$

where

k^+ is the collisional quenching constant

α_O is the oxygen solubility coefficient

τ_0 is the mean lifetime of the excited state at zero PO_2

The ratio of I to I_0 is then plotted against the PO_2 value. This plot is used to calibrate the sensor empirically for different PO_2 values. $1/I_0$ is the intercept, and the slope is K/I_0. The system is empirically derived and errors can occur with varying excitation intensity. One way to correct for intensity variations is to use a reference fluorescence dye that is not affected by oxygen quenching. The same procedure can be used to calculate the percent oxygen concentration [15,16].

68.3.3 Oxygen Saturation

There are several readings that are interrelated regarding oxygen saturation. The most common measurements are arterial blood saturation (S_aO_2), mixed venous blood saturation (S_vO_2), and *photoplethysmogram* arterial blood saturation (S_pO_2). S_pO_2 measurements, also called pulse oximetry measurements, are arterial measurements but are only related to true arterial saturation. Care must be taken in knowing which measurements are actually taken, because of inaccuracies in various measurements. Saturation measurements can be performed invasively using reflectance or fluorescence oximetry or noninvasively by transmission or reflectance photoplethysmogram readings.

There is an important relationship between oxygen saturation and partial pressure. A plot shown in Figure 68.5 of arterial oxygen saturation vs. arterial partial pressure is called the oxygen–hemoglobin

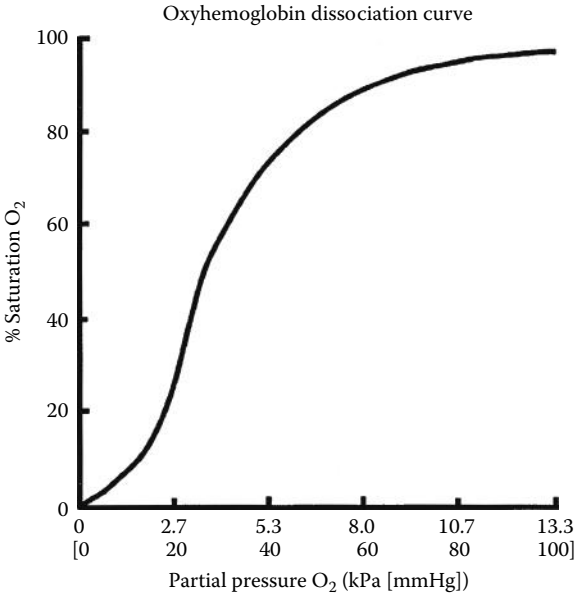

FIGURE 68.5 Oxygen saturation versus PO_2 oxygen–hemoglobin dissociation curve. The partial pressure shows a sigmoidal relationship to the percent oxygen saturation.

dissociation curve. Partial pressure falls at a linear rate and is a good indicator of changing oxygen delivery to cell tissue. The percent oxygen saturation is nonlinear with respect to partial pressure in a sigmoidal relationship. A partial pressure of 13.3 kPa (100 mmHg) is effectively 100% saturation. An increase in partial pressure above 13.3 kPa (100 mmHg) indicates free oxygen not bound to hemoglobin and in that state does not contribute much to tissue oxygenation. This means the percent saturation gives a delayed notice of desaturation. In a patient with healthy lungs, partial pressure values of greater than 24.0 kPa (180 mmHg) can be measured. A 50% decrease in partial pressure could go undetected using the percent oxygen saturation. The oxygen dissociation curve, as mentioned previously, is dependent on pH and temperature. Under normal conditions, the relationship between partial pressure and saturation is maintained, but under altered conditions, such as low perfusion, the relationship can deviate.

Roughton and Severinghaus [18] describe a computation to approximate the dissociation curve based on the Hill equation. The Hill equation is given in Equation 68.9:

$$Y = \frac{(PO_2/P_{50})^n}{1 + (PO_2/P_{50})^n} \tag{68.9}$$

where

Y is the oxygen saturation
PO_2 is the oxygen partial pressure
P_{50} is the partial pressure at 6.7 kPa (50 mmHg)

The P_{50} point is determined by the temperature and pH of the sample. Temperature and pH correction equations are also presented in Refs. [5,7,17–19].

68.3.3.1 Transmission Oximetry

Continuous S_aO_2 and S_vO_2 measurements are used to help evaluate whether oxygen is being adequately delivered to tissue. Oxygen is either consumed or expired. If oxygen is delivered to tissue and not consumed, then tissue oxygenation is not adequate. Early oximeters used invasively drawn samples and

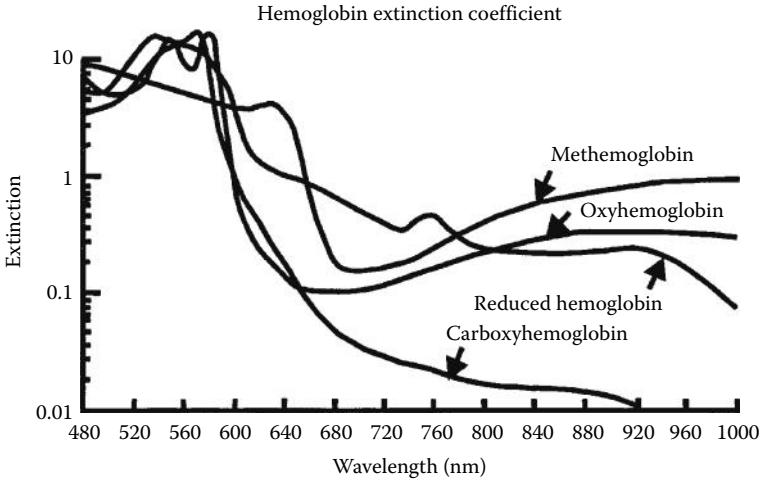

FIGURE 68.6 Hemoglobin extinction coefficients plotted by wavelength. The light extinction coefficient varies by wavelength and type of hemoglobin.

light transmission to measure oxygenation. The basic concept in oximetry is to transmit light through a blood sample, and blood absorbs a determined amount of light according to Beer's law, shown in Equation 68.1. For oximetry applications, hemoglobin is assumed to be composed of only two substances, oxygenated hemoglobin or oxyhemoglobin (O_2Hb) and deoxygenated or RHb. This is a very simplistic approach, but it is the basis for most oximetry measurements. For *in vivo* measurements, the path length for the light is constant and known. Both the O_2Hb and RHb can be measured simultaneously by using two separate wavelengths. Flash lamps and filter wheels were originally used to illuminate blood samples, and the transmitted signals were measured. Current technology uses light-emitting diodes (LEDs) and alternate on and off cycles.

If two light wavelengths are used and the two substances have different extinction coefficients (α_e), or equivalently attenuation coefficients (σ), then the percentage of each substance can be calculated. The extinction coefficients of hemoglobin are well documented. Figure 68.6 is a plot of the extinction coefficients for oxyhemoglobin, RHb, COHb, and MetHb. The two wavelengths of light yielding good results for oximetry are the red (660 nm) and infrared (940 nm) wavelengths. Red has the largest difference between the two extinction curves, and infrared has maximal difference after the isosbestic point where the two extinction curves cross. The functional arterial oxygen saturation (S_aO_2) is calculated using Equation 68.10 given the concentration of O_2Hb and RHb:

$$\text{Functional } S_aO_2 = \frac{C_o}{(C_o + C_r)} * 100 \tag{68.10}$$

The concentration of oxyhemoglobin is given by C_o and the concentration of deoxygenated hemoglobin is given by C_r. This formula must be adjusted for other contents in blood that influence measurements if present, such as COHb and MetHb. The more accurate fractional saturation is given as the total hemoglobin concentration (tHb) in Equation 68.11:

$$\text{Fractional } S_aO_2 = \frac{C_o}{(\text{tHb})} * 100 = \frac{C_o}{(C_o + C_r + C_c + C_m)} * 100 \tag{68.11}$$

where

C_c is the COHb saturation

C_m is the MetHb concentration

To account for COHb and MetHb accurately, four transmission wavelengths would be required, or for accurate S_aO_2 readings the total Hb concentration needs to be known or measured [5,7,20].

68.3.3.2 Pulse Oximetry

Pulse oximetry is based on the transmission, absorption, and dispersion of light as it passes through hemoglobin. Beer's law, as stated in Equation 68.1, determines the transmission of light through a substance. For pulse oximetry, the light illuminates both arterial and venous blood and the light must traverse all tissue between light source and receiver. Figure 68.7 represents the light path and indicates a variable (ac) path length as well as a constant (dc) path length.

To calculate the pulse oximetry digital photoplethysmogram (DPP) oxygen saturation (S_pO_2), two equations are used. An example of a DPP signal is shown in Figure 68.8 and it indicates the ac and dc DPP components. The first step is to use the red and infrared time signal to calculate an R value.

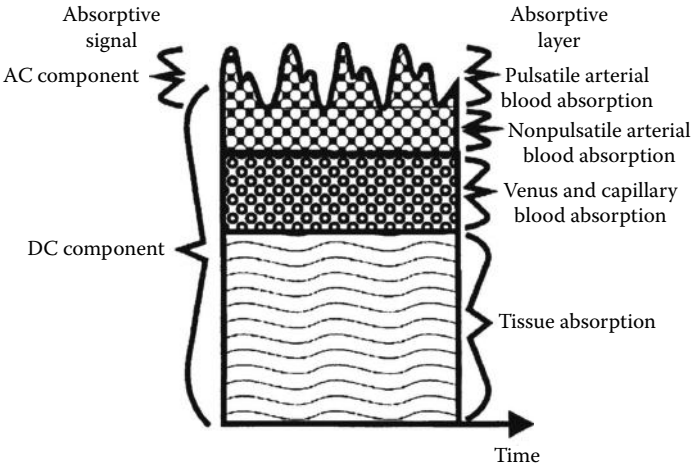

FIGURE 68.7 Absorption components encountered during transmission oximetry. The arteries, veins, capillaries, and tissue absorb light. The total light absorbed has a steady state (dc) and a varying (ac) signal component. The varying signal is due to the pulsatile arterial volume change.

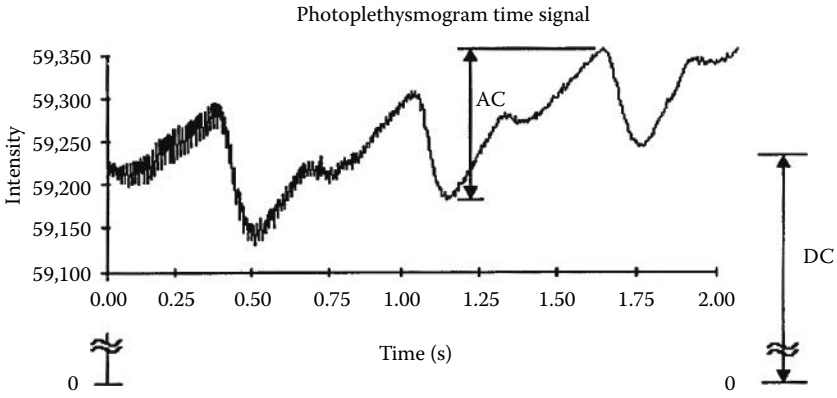

FIGURE 68.8 Photoplethysmogram with ac and dc components labeled. The light intensity transmitted through the finger varies with time. The signal contains a constant (dc) component and a varying signal (ac) component. The varying signal is due to the pulsatile arterial volume change.

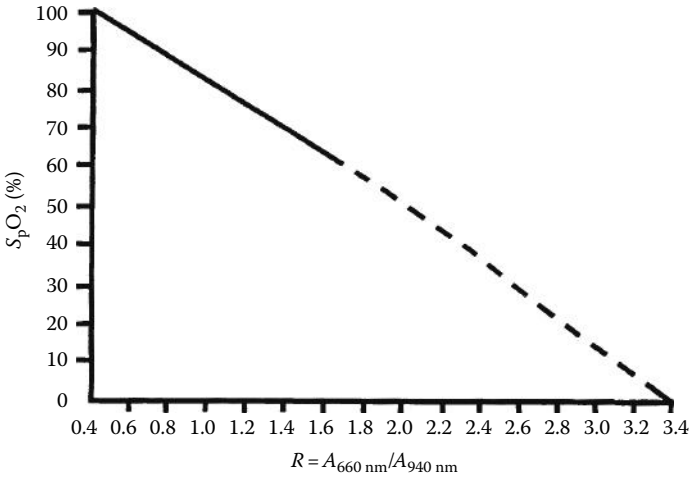

FIGURE 68.9 Measured oxygen saturation vs. *R* value. Empirically derived 660–940 nm ratio oxygen saturation. The values are used to formulate a first-order equation to calculate the pulse oximetry saturation.

The *R* value is the normalized ratio of the red to infrared transmitted light intensity and is shown in Equation 68.12:

$$R = \frac{(ac_r/dc_r)}{(ac_i/dc_i)} \tag{68.12}$$

The *R* value for two specific light wavelengths can be plotted against a measured S_aO_2 value, as shown in Figure 68.9. A linear approximation can then be used to calculate a S_pO_2 value. The empirical linear approximation for Figure 68.9 is listed in Equation 68.13:

$$S_pO_2 = 110 - 25R \tag{68.13}$$

The empirical approximation is used to correct for errors in the measured values. Pulse oximeters on the market traditionally used weighted moving average (WMA) techniques to identify the transmitted ac and dc DPP components. The dc component is the averaged signal intensity. The ac signal is computed using the WMA as a band-pass filter to single out only the ac cardiac signal.

There are many areas where pulse oximetry has limitations. One limitation was already mentioned, and that is the assumption of only two substances in hemoglobin. For most measurements, the percentage of these substances is small enough not to affect the pulse oximetry measurements. There are cases in emergency care when these substances may be present and do affect readings. At present, the user must be aware of the limitations and not use the pulse oximetry reading if the person has any of the additional substances. The solution to this problem is to use additional light sources to calculate the additional substance. The first pulse oximeters tested used a multiple-wavelength light source and could easily be implemented in new instruments.

A second limitation of pulse oximetry is background light. Because pulse oximetry currently uses transmitted light, the photodiode receiver is susceptible to ambient light. Ambient light can be from indoor lighting, sunlight, or phototherapy lights. To correct for this problem, a third light measurement can be collected with no light source and subtracted from the transmitted intensity. Using a digital microprocessor, the subtraction can be easily performed.

A third limitation is called low *perfusion*. Pulse oximetry is based on having a pulsatile signal. If the pulsatile signal is small compared with the dc signal, usually 1 count in 1000, the *R* value calculation becomes inaccurate. There are two reasons for the inaccuracy, roundoff error and resolution. The roundoff error can be compensated for by using more precision during the *R* value calculations.

Another limitation, which is difficult to eliminate, is motion artifact and autonomic nervous system response. Whenever there is an autonomic nervous system action, there is a transition or movement in the pulse oximetry signal. The most common technique to correct for motion artifact is averaging of consecutive measurements. Averaging works, but it slows the response time and lengthens the processing time. Another improvement would be to identify and eliminate inaccurate readings. This approach, however, is difficult to implement [7,21–23].

68.3.3.3 Reflectance Oximetry

An alternative technique to consider for DPP is reflectance probe measurements, as shown in Figure 68.10. Reflectance pulse oximetry has been addressed for *in vivo* studies by Mendelson and Ochs [24]. Because reflectance probes can be placed flat on the measurement area, they provide better shielding than a probe placed across a finger. However, reflectance measurements have less intensity than transmission measurements. Reflectance probe location and temperature effects have been analyzed. Increased temperature results in perfusion and increased signal intensity.

Schmidt et al. [25] reported an integrated circuit-based optical sensor for *in vivo* surface measurements. A set of equations was derived to estimate the amount of reflectance at a given intensity. The solution is a three-wavelength reflectance probe, with a red LED wavelength emission of 660 nm and a near and far infrared LED. The reflectance depth was calculated to be within 2 mm of the surface of the probe. The third wavelength is used to eliminate errors in measurement due to additional hemoglobin derivatives. The third wavelength was used to calculate a Hct value. The saturation was calculated using Equation 68.14:

$$SO_2 = A - B\left(\frac{R_{805}}{R_{660}}\right) \tag{68.14}$$

where A and B are constants empirically derived for a specific light source and detector under specific physiological conditions.

A current method to measure S_vO_2 is by reflectance oximetry methods. A bundled fiber-optic cable is placed through a catheter. Light enters by a fiber or fibers and the reflected light is analyzed for oxygen content using spectrophotometry. The probe is similar to the fluorescence probe shown in Figure 68.4 with no chemistry envelope. The reflectance is used to determine the oxygen concentration empirically [24–26].

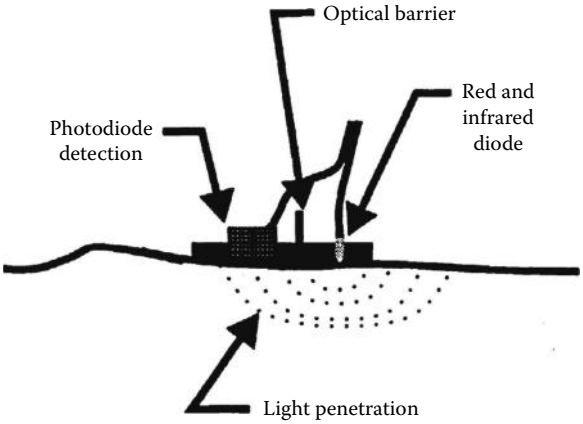

FIGURE 68.10 Reflectance oximetry probe. Red and infrared diodes illuminate the surface alternately and the reflected light is detected in close proximity by a photodiode. An optical barrier is required to eliminate direct light detection.

68.3.4 pH Measurements

Blood pH is very important in sustaining life. There is a small range of values allowable to maintain life, and pH is one of the most tightly regulated parameters in the body. Typical pH measurements are taken invasively either through a catheter probe or as a blood sample measurement. pH is noted as the negative decade logarithm of the molal activity of hydrogen ions. The acid and alkaline hydrogen reactions are given in Equations 68.15 and 68.16, respectively:

$$O_2 + 4H^+ + 4e^- \rightarrow 2H_2O \tag{68.15}$$

$$O_2 + 2H_2O + 4e^- \rightarrow 4OH^- \tag{68.16}$$

The pH level can be determined by electrochemical means. The original pH measurements were performed using hydrogen electrodes after the oxygen (O_2) was eliminated. Current electrochemical measurements use a glass electrode sensitive to hydrogen and a concentrated KCl bridge.

Optical measurements of pH are performed fluorescently. It was determined that pH corresponds to CO_2 tension. Both PCO_2 and pH can be measured using a dye sensitive to hydrogen ions and using a variant of the Henderson–Hasselbalch equation, shown in Equation 68.17:

$$\frac{I_0}{I} = 1 + K * H^+ \tag{68.17}$$

where
- I is the relative fluorescence intensity
- H^+ is the hydrogen ion concentration
- I_0 and K are calibration constants

pH fluorescence measurements can be obtained using a pH-sensitive dye, such as phenol red. The basic form of phenol red is green absorbing, and the acidic form is blue absorbing. Exciting the phenol red buffer with a green 560 nm and red 600 nm light, the ratio of intensities can be used to calculate the pH according to Equation 68.18:

$$R = k * 10^{[-C/(10^{-\delta}+1)]} \tag{68.18}$$

where
- k is the system optical constant
- C is the green base form intensity
- δ is the difference between the pH and pK of the dye

Intensity shifts are accounted for by measuring the difference in intensity of two different excitation wavelengths. An alternative two-wavelength approach using hydroxypyrene trisulfonic acid (HTA) can be used. The basic form of HTA has a maximum excitation at a wavelength of 460 nm and an acidic maximum excitation wavelength of 410 nm. The ratio of the two fluorescent intensities at 520 nm is used to calculate the pH value [2,6,16,27].

68.3.5 Glucose Measurement

A common glucose measurement technique is by enzymatic amperometric measurements. Through selective binding, glucose and other compounds can be measured. The bound glucose changes the conductance and the glucose concentration can be determined.

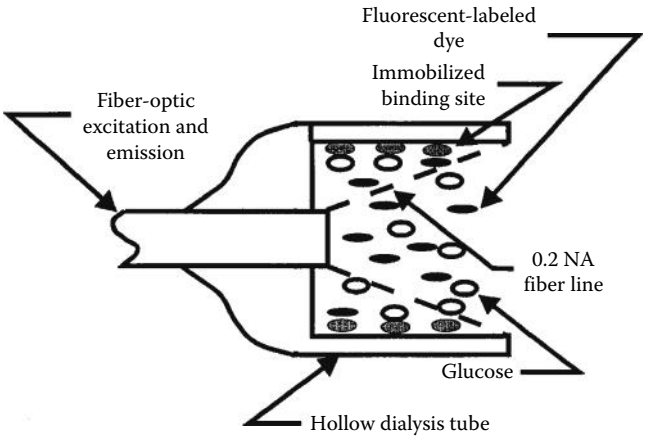

FIGURE 68.11 Optical glucose probe. A hollow tube is used to localize fluorescent dye outside the numerical aperture of the fiber. The fiber is used both to introduce excitation light and to collect emitted fluorescent levels. Only dye in the fiber view is illuminated. Dye bound to the hollow tube is not illuminated and is not detected.

Another more recent and interesting measurement technique is enzymatic optical measurements. Competitive binding between glucose and a fluorescein-labeled analog is used to determine glucose concentrations. An immobilized binding site is used to bind a fluorescent material, such as fluorescein-labeled dextran. A diagram of a glucose sensor is shown in Figure 68.11. The binding sights are fixed outside the excitation illumination. As the glucose concentration increases, the bound fluorescent material is released into the optical path. As the concentration of glucose increases, the viewed fluorescence increases and the reflected intensity increases. The reflected intensity will follow the concentration of glucose, and the actual response is measured empirically. The probe operation is reversible, allowing the probe to be reused. Reversibility is a requirement for implantable probes, which is the intended application for the optical glucose probe [27,28].

68.3.6 Electrolyte Concentration Measurements

In the clinical setting, it is important to monitor the concentration of various *electrolytes*. Typical measurements include sodium (Na^+), calcium (Ca^{++}), potassium (K^+), chloride (Cl^-), and magnesium (Mg^{++}). The concentrations are typically invasively drawn samples measured in a clinical laboratory. The measurement is performed using an ion-specific electrode, which is similar to the Clark electrode described previously. The clinical significance of different electrolytes is outlined in the text by McClatchey, *Clinical Laboratory Medicine* [9]. Optical measurement techniques have been performed but are not typically used in the clinical setting and are not covered here.

68.4 Combined Analysis Techniques

There are many combinations of instruments available. As instruments become more accurate and smaller, the trend is to simplify measurements and increase usefulness of equipment. Several selected instruments are described that have combined blood chemistry measurements into one unit.

68.4.1 CO-Oximetry

CO-oximetry has been noted for some time as the gold standard for oximetry readings. The more typical CO-oximeter does not measure just oxygen saturation but several hemoglobin concentrations.

For example, the Instrumentation Laboratory, Inc., IL 282 CO-oximeter uses an invasively drawn sample and measures total hemoglobin, oxyhemoglobin, COHb, MetHb, and oxygen content in blood. The measurement technique is optical absorption. Four wavelengths at 535, 585.2, 594.5, and 626.6 nm are generated using a hollow cathode lamp. The extinction coefficients are used to calculate the concentration of RHb, O_2Hb, COHb, and MetHb. The total hemoglobin (tHb) concentration is calculated as the sum of the individual hemoglobin groups. The oxygen saturation (S_aO_2) is calculated as the concentration of oxyhemoglobin divided by the total CtHb. The total hemoglobin concentration, however, is usually noted as only the oxyhemoglobin concentration divided by the concentration of RHb and oxyhemoglobin. Therefore, care must be used in comparisons, because variations in S_aO_2 calculations can occur. The oxygen content is calculated as 1.39 times the concentration of oxyhemoglobin [29].

68.4.2 Intra-Arterial Probes

Intra-arterial probes have drawn much interest. They allow continuous or periodic measurements in the clinical setting in real time. These probes also offer minimally invasive measurements. The intent is to use intra-arterial measurements on patients who require catheterization. The goal is a small probe that can be inserted into a catheter and not interfere with administering therapies or blood sampling. An optode-type probe is described by Shapiro et al. [30,31]. A fiber-optic probe is described by Gehrich et al. [15] for blood gas monitoring. The probe is designed to measure pH, PCO_2, and PO_2. In addition, a thermocouple is used to adjust for temperature variations, and values are normalized to standard temperatures. The sample drawing of the probe is shown in Figure 68.12. A set of chemical optical fluorescent probes is used.

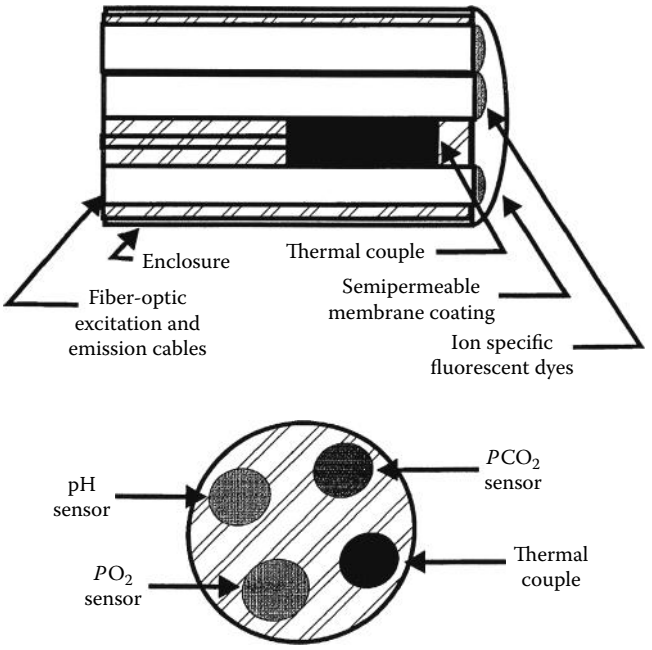

FIGURE 68.12 Combined fiber-optic sensor for pH, PCO_2, PO_2, and temperature correction measurements. Each sensor is bundled into a single enclosure and has separate detection areas.

68.5 Evaluation of Technology

There have been numerous measurement types and techniques used in developing an understanding of blood chemistry. The diverse background has resulted in very good indicators of how blood is used to sustain life. Despite the diverse background, many changes and advances are occurring at an impressive rate. Immediate improvements are being tested and implemented on a regular basis, and novel approaches will be seen in the near future. In addition, there is an explosion of studies being performed to understand how the body works and is put together. A brief overview of some improvements that can be expected follows.

Some basic engineering changes could be performed to enhance accuracy. Oximetry measurements could easily see engineering improvements. New techniques have been tested, but approval and acceptance are slow. There has been progress made in size, with new oximeters that can clip on the finger. The accuracy has seen only moderate improvement. Alternative probes and algorithms have been tested and even patented but have not been marketed. One example of a patent is for Fourier analysis of pulse oximetry signals for arterial saturation measurements. The spectral analysis would allow the possibility to implement some novel filter and analysis routines. This would improve stability from motion artifact. Hardware changes could also bring changes. Resolution could be improved by using more accurate photodiodes and A/D converters or by using laser diodes for more intense and accurate light illumination. Reflectance probe advances would improve versatility.

The future of blood chemistry should see continued miniaturization. Fiber optics have been a major research direction. Fiber optics allow remote sensing and have reduced the possibility of electrical and magnetic complications for patient monitoring. Miniature fiber-optic sensors are being developed for numerous applications, and the improvement and developments can be applied to biological readings. Miniaturization not only reduces size but can also improve stability. Small probes also allow multiple readings in one sensor. This trend has already started with blood gas probes being used for intravascular and extravascular measurements. The next trend envisioned is nanoprobes. Implantable glucose probes are already being tested. Sensor and light sources can be implemented on an integrated circuit and continue to shrink. Microsensors are already being used in biomedical application, such as blood pressure sensors and single-cell neural stimulators. Miniature chemistry and thermal-cycling laboratories are being developed into single integrated chips. The same chemical and optical arrangements can be performed for blood chemistry analysis. A complete laboratory measurement system could be at the patient location for continuous monitoring [28–30,32].

The other major anticipated change is the trend for additional and more accurate noninvasive readings. Invasive measurements can mean delays and noncontinuous monitoring, as well as increased possibility of infection. Given equal measurement accuracy, noninvasive measurements are an obvious choice over invasive readings.

It is important to note that measurement techniques will continue to improve, but the rate of growth and utilization will not grow as fast. Acceptance and utilization are dependent on cost and the effort involved in using the instruments. Cost can slow or even eliminate instrumentation from being used. However, with the increasing cost of medical care, there is interest in providing fast diagnosis and recovery for patients. This will provide incentive for improving measurement technique and accuracy.

Defining Terms

Artery: Vessel used to carry blood away from the heart.

Capillary: Semipermeable membrane used to exchange oxygen and other substances with tissue.

Catheter: Surgical instrument inserted into the body for drawing or administering fluids.

Electrolyte: A substance that dissolves into ions, becoming capable of conducting electricity.

Fluorescence: The property of emitting light when exposed to an excitation light.

Glucose (dextrose): Substance found in normal blood, which is the main source of energy in living tissue.

Hematocrit: The total CtHb, or packed red cells, in blood.

Hemoglobin: Oxygen-carrying pigment found in blood, which has the property of reversible oxygenation.

Intra-arterial: Within the artery.

Invasive: Pertaining to the insertion of an instrument into the body.

Oximetry: Photoelectric determination of arterial blood oxygen saturation (S_aO_2).

Perfusion: Pertaining to the passage of fluid through vessels. Low perfusion refers to reduced blood flow.

Photoplethysmogram: Chart of the volume change in an organ or limb. In oximetry it is the chart of the light passed through an ear, nose, or digit. The light intensity varies with the arterial pulse, which is related to the arterial volume.

Transcutaneous: Pertaining to entering through the skin.
Vein: Vessel used to return blood to the heart.

Human Occupancy Detectors

Jacob Fraden
Fraden Corporation

69.1 Introduction

September 11 has changed the way people think about the airport, aviation, and security in general. The threat is expanding interest in more reliable systems to detect presence of people within the protected perimeters. All sensors that respond to a human body are divided on the occupancy and motion detectors. The *occupancy* detectors detect the presence of people (and sometimes animals) in a monitored area. The *motion detectors* respond only to moving objects. A distinction between the two is that the occupancy detectors produce signals whenever an object is stationary or not, while the motion detectors are selectively sensitive to the moving objects. The applications of these sensors include security, surveillance, energy management (electric lights control), personal safety, friendly home appliances, point-of-sale advertisements, interactive toys, and novelty products. Depending on the applications, presence of humans may be detected through any means that is associated with some kind of a human body's property or body's actions [1]. For instance, a detector may be sensitive to body weight, heat, sounds, dielectric constant, etc. The following is a nonexhaustive list of the types of detectors that are presently used for the occupancy and motion sensing of people:

1. *Air pressure sensors*—detect miniscule changes in air pressure resulted from opening doors and windows or movement of an intruder
2. *Capacitive*—detectors of human body capacitance
3. *Acoustic*—detectors of sound produced by people
4. *Photoelectric*—interruption of light beams by moving objects
5. *Optoelectric*—detection of variations in illumination or optical contrast in the protected area

6. *Pressure mat switches*—pressure-sensitive long strips or pressure sensors imbedded into floors to detect weight of an intruder
7. *Stress detectors*—strain gauges imbedded into floor beams, staircases, and other structural components
8. *Switch sensors*—electrical contacts connected to doors and windows
9. *Magnetic switches*—a noncontact version of switch sensors
10. *Vibration detectors*—react to the vibration of walls or other building structures. Also, may be attached to doors or windows
11. *Glass breakage detectors*—sensors reacting to specific vibrations produced by shattered glass
12. *Infrared (IR) motion detectors*—devices sensitive to heat waves emanated from warm or cold moving bodies
13. *Microwave detectors*—active sensors radar-type devices responsive to microwave electromagnetic signals reflected from objects
14. *Ultrasonic detectors* (USDs)—devices similar to microwave detectors except that instead of electromagnetic radiation, ultrasonic waves are used
15. *Video motion detectors*—video equipment that compares a stationary reference image with the current image of a protected area. May operate in visible or IR spectral ranges
16. *Facial recognition*—the image analyzers that compare facial features with a database
17. *Laser system detectors*—similar to photoelectric detectors, except that they use narrow light beams and combinations of reflectors
18. *Triboelectric detectors*—sensors capable of detecting static electric charges carried by moving objects

One of the major aggravations in detecting occupancy or intrusion is a *false-positive* detection. The term "false positive" means that the system indicates an intrusion when there is none. In some noncritical applications where false-positive detections occur once in a while, for instance, in a toy or switch controlling electric lights in a room, this may be not a serious problem: the lights will be erroneously turned on for a short time, which unlikely do any harm.* In other systems, especially used for the security and military purposes, false-positive detections, while generally not as dangerous as false negative ones (missing an intrusion), may become a serious problem. While selecting a sensor for critical applications, considerations should be given to its reliability, selectivity, and noise immunity. It's often a good practice to form a multiple sensor arrangement with the symmetrical interface circuits. It may dramatically improve a reliability of a system, especially in the presence of the external transmitted noise. Another efficient way of reducing the erroneous detections is to use in concert the sensors operating on different physical principles [2], for instance, combining the capacitive and IR detectors is an efficient combination as they are receptive to different kinds of transmitted noise. In the following, we proved overview of the most popular or promising detectors of people.

69.2 Ultrasonic Detectors (USD)

These devices are based on transmission to the object and receiving the reflected acoustic waves. A transmission and reception of the ultrasonic energy is the basis for very popular ultrasonic range meters and velocity detectors. The USDs for humans are employed for the automatic door openers and security sensors. Ultrasonic waves are mechanical compressions and rarefaction of air covering the frequency range well beyond the capabilities of human ears, that is, over 20 kHz. However, these frequencies may be quite perceptive by smaller animals, like dogs, cats, rodents, and insects. Indeed, the USDs are the biological ranging devices for bats and dolphins.

* Perhaps just steering up some suspicion about living in a haunted house.

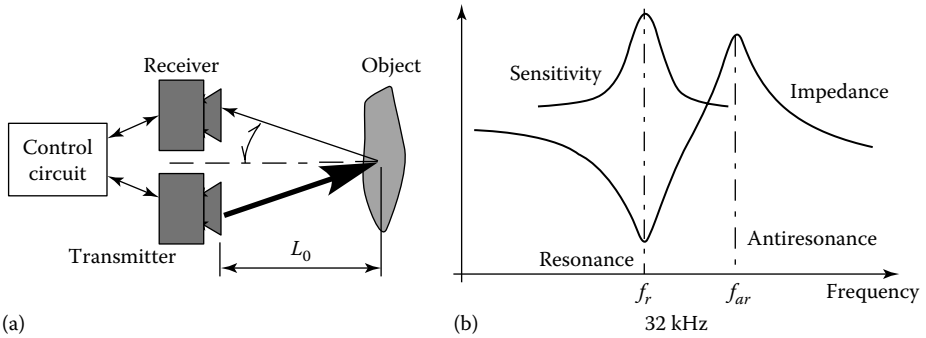

FIGURE 69.1 Ultrasonic distance measurement: (a) basic arrangement and (b) impedance characteristic of a piezoelectric transducer.

When the waves are incident on an object, part of their energy is reflected. In many practical cases, the ultrasonic energy is reflected in a diffuse manner. That is, regardless of the direction where the energy comes from, it is reflected almost uniformly within a wide solid angle, which may approach 180°. If an object moves, the frequency of the reflected wavelength will differ from the transmitted waves. This is called the Doppler effect.

A distance L_0 to the object can be calculated through the speed v of the ultrasonic waves in the media and the angle Θ (Figure 69.1a):

$$L_0 = \frac{vt\cos\Theta}{2} \tag{69.1}$$

where t is the time for the ultrasonic waves to travel to the object and back to the receiver (thus 2 in the denominator).

If transmitter and receiver are positioned close to each other when compared with the distance to the object (which usually is the case), then $\cos\Theta \approx 1$. The ultrasonic waves have an obvious advantage over the microwaves: they propagate with the speed of sound, which is much slower than the speed of light at what the microwaves propagate. Thus, time t is much longer and its measurement can be accomplished easier and cheaper.

To generate any mechanical waves, including ultrasonic, the movement of a surface is required. This movement creates compression and expansion of medium (air). The most common type of the excitation device that can generate surface movement in the ultrasonic range is a piezoelectric transducer operating in the so-called *motor* mode. The name implies that the piezoelectric device directly converts electrical energy into mechanical energy.

Figure 69.2a shows that the input voltage applied to the ceramic element causes it to flex and transmit ultrasonic waves in air. Because piezoelectricity is a reversible phenomenon, the ceramic generates voltage when incoming ultrasonic waves flex it. In other words, the element may work as both the sonic transmitter and receiver (a microphone). A typical operating frequency of the transmitting piezoelectric element is near 32 kHz. For better efficiency, frequency of the driving oscillator should be adjusted to the resonant frequency f_r of the piezoelectric ceramic (Figure 69.1b) where the sensitivity and efficiency of the element is the best. When the measurement circuit operates in a pulsed mode, the same piezoelectric element is used for both transmission and receiving. If the system requires continuous transmission of ultrasonic waves, separate piezoelectric elements are employed for the transmitter and receiver. Typical design of air-operating sensors is shown in Figures 69.2b and 69.3b. A directional sensitivity diagram (Figure 69.3b) is important for a particular application. The narrower the diagram is the more sensitive the transducer.

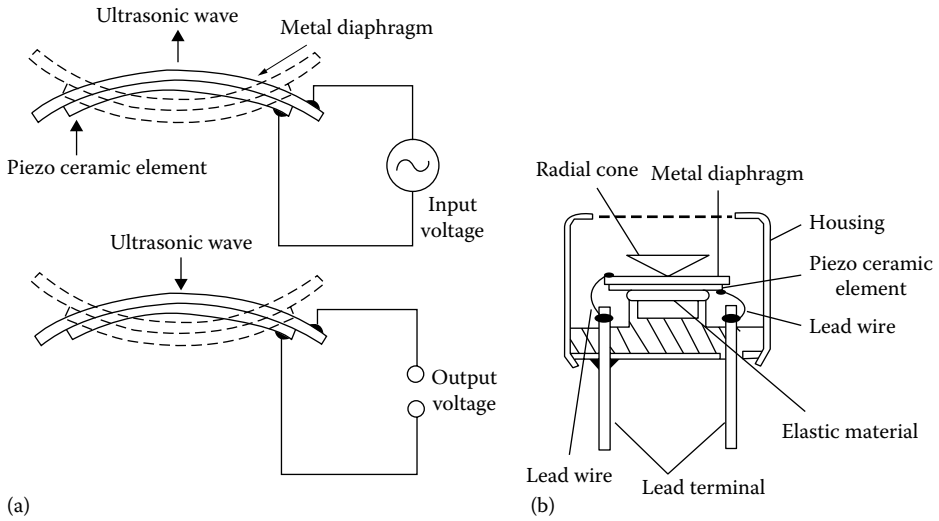

FIGURE 69.2 Piezoelectric ultrasonic transducer: (a) input voltage flexes the element and transmits ultrasonic waves, while incoming waves produce output voltage and (b) open aperture type of ultrasonic transducer for operation in air. (Courtesy of Nippon Ceramic, Japan.)

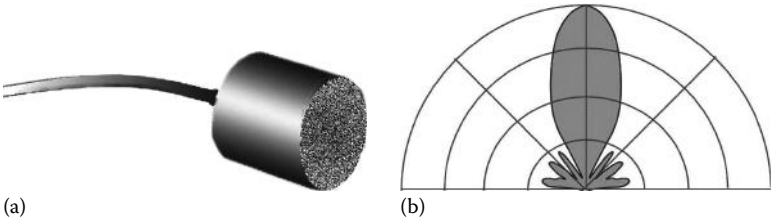

FIGURE 69.3 (a) Ultrasonic transducer for air and (b) directional diagram.

69.3 Microwave Motion Detectors

The microwave detectors offer an attractive alternative to other detectors when it is required to cover large areas and to operate over an extended temperature range under the influence of strong interferences, such as wind, acoustic noise, fog, dust, and moisture. Just like the USDs, these detectors belong to the active sensors as they generate an excitation signal. That is, they emit pulses of the electromagnetic energy and can operate at day or night. The operating principle of a microwave detector is based on radiation of electromagnetic radio-frequency (RF) waves toward a protected area. The electromagnetic waves backscattered (reflected) from objects whose sizes are comparable with or larger than the wavelength of the excitation signal. The reflected waves are received, amplified, and analyzed. A time delay between the sent (pilot) signal and received reflected signal is used to measure distance to the object, while the frequency shift is used to measure speed of motion of the object.

The microwave detectors belong to the class of devices known as *radars*. Radar is an acronym for *radio detection and ranging*. The radar frequencies are shown in Table 69.1.

The name *microwave* is arbitrarily assigned to the wavelengths shorter than 4 cm (K_a, K, and X bands). They are long enough ($\lambda \approx 3$ cm at X band) to pass freely through most contaminants, such as fog and airborne dust, and short enough for being reflected by humans.

The microwave part of the detector consists of a Gunn oscillator, an antenna, and a mixer diode. The Gunn oscillator is a diode mounted in a small precision cavity that, upon application of power, oscillates at microwave frequencies. The oscillator produces electromagnetic waves (frequency f_0), part of which

TABLE 69.1 Radar Frequencies Various Bands

Band	Frequency Range (GHz), f	Wavelength Range (cm), λ
K_a	26.0–40.0	0.8–1.1
K	18.0–26.5	1.1–1.67
X	8.0–12.5	2.4–3.75
C	4.0–8.0	3.75–7.50
S	2.0–4.0	7.5–15
L	1.0–2.0	15–30
P	0.3–1.0	30–100

is directed through an iris into a waveguide and focusing antenna that directs the radiation toward the object. Focusing characteristics of the antenna are determined by the application. As a general rule, the narrower the directional diagram of the antenna, the more sensitive it is (the antenna has a higher gain). Another general rule is that a narrow-beam antenna is much larger, whereas a wide-angle antenna can be quite small. The typical radiated power of the transmitter is 10–20 mW. A Gunn oscillator is sensitive to the stability of applied dc voltage and, therefore, must be powered by a good quality voltage regulator. The oscillator may run continuously, or it can be pulsed, which reduces the power consumption from the power supply.

A smaller part of the microwave oscillations is coupled to the Schottky mixing diode and serves as a reference signal (Figure 69.4a). In many cases, the transmitter and the receiver are contained in one module called a transceiver. The target reflects some waves back toward the antenna, which directs the received radiation toward the mixing diode whose current contains a harmonic with a phase differential between the transmitted and reflected waves. The phase difference is in a direct relationship to the distance to the target. The phase-sensitive detector is useful mostly for detecting the distance to an object. However, in a motion sensor, movement, not distance, should be detected. Thus, for the occupancy and motion detector, the Doppler effect is the basis for operation of microwave and USDs. It should be noted that the Doppler effect device is a true motion detector because it is responsive only to moving targets. Here is how it works.

An antenna transmits the frequency f_0 that is defined by the wavelength λ_0 as

$$f_0 = \frac{c_0}{\lambda_0} \tag{69.2}$$

where c_0 is the speed of light in air.

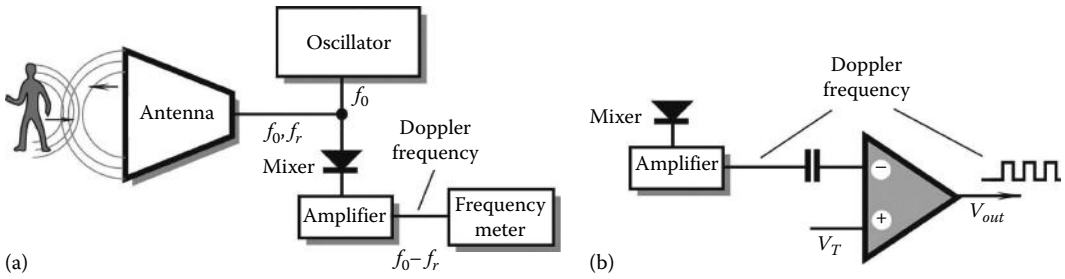

FIGURE 69.4 Microwave occupancy detector: (a) a circuit for measuring Doppler frequency and (b) circuit with a threshold detector.

When the target moves toward or away from the transmitting antenna, the frequency of the reflected radiation will change. Thus, if the target is moving away with velocity v, the reflected frequency will decrease and it will increase for the approaching targets. This is called the Doppler effect, after the Austrian scientist Christian Johann Doppler (1803–1853).* Although the effect first was discovered for sound, it is applicable to electromagnetic radiation as well. In contrast to sound waves that may propagate with the velocities dependent on movement of the source of sound, electromagnetic waves propagate with the speed of light, which is an absolute constant, independent of the light source movement. The frequency of reflected electromagnetic waves can be predicted by Einstein's special theory of relativity as

$$f_r = f_0 \frac{\sqrt{1-(v/c_0)^2}}{1+(v/c_0)} \tag{69.3}$$

For practical purposes when detecting a relatively slow moving objects, the quantity $(v/c_0)^2$ is very small as compared with unity; hence, it can be ignored. Then, the equation for the frequency of the reflected waves becomes identical to that for the acoustic waves:

$$f_r = f_0 \frac{1}{1+(v/c_0)} \tag{69.4}$$

As follows from Equation 69.4, due to a Doppler effect, the reflected waves have a different frequency f_r. The mixing diode combines the radiated (reference) and reflected frequencies and, being a nonlinear device, produces a signal that contains multiple harmonics of both frequencies. The electric current through the diode may be represented by a polynomial:

$$i = i_0 + \sum_{k=1}^{n} a_k (U_1 \cos 2\pi f_0 t + U_2 \cos 2\pi f_r t)^k \tag{69.5}$$

where

i_0 is a dc component
a_k are the harmonic coefficients that depend on a diode operating point
U_1 and U_2 are amplitudes of the reference and received signals, respectively
t is time

The current through a diode contains an infinite number of harmonics, among which there is a harmonic of a differential frequency: $\Delta f = a_2 U_1 U_2 \cos 2\pi (f_0 - f_r)t$, which is called a Doppler frequency.

The Doppler frequency in the mixer can be found from Equation 69.4:

$$\Delta f = f_0 - f_r = f_0 \frac{1}{1+(c_0/v)}, \tag{69.6}$$

and since $c_0/v \gg 1$, the following holds after substituting Equation 69.2:

$$\Delta f \approx \frac{v}{\lambda_0} \tag{69.7}$$

* During Doppler times, the acoustical instruments for precision measurements were not available yet. To prove his theory, Doppler placed trumpeters on a railroad flatcar and musicians with a sense of absolute pitch near the tracks. A locomotive engine pulled the flatcar back and forth at different speeds for two days. The musicians on the ground "recorded" the trumpet notes as the train approached and receded. The equations held up.

Therefore, the signal frequency at the output of the mixer is proportional to the velocity of a moving target. For instance, if a person walks toward the detectors with a velocity of 0.6 m/s, a Doppler frequency for the *X*-band detector is $\Delta f = 0.6/0.03 = 20$ Hz.

Equation 69.6 holds true only for movements in the normal direction. When the target moves at angles Θ with respect to the detector, the Doppler frequency is

$$\Delta f \approx \frac{v}{\lambda_0}\cos\Theta \tag{69.8}$$

This implies that Doppler detectors theoretically become insensitive when a target moves at angles approaching 90°.

In the velocity meters, to determine velocity of a target, it is required to measure the Doppler frequency and phase to determine direction of the movement (Figure 69.5a). This method is used in police radars. For the supermarket door openers and security alarms, instead of measuring frequency, a threshold comparator is used to indicate the presence of a moving target (Figure 69.5b). It should be noted that though Equation 69.8 predicts that the Doppler frequency is near zero for targets moving at angles $\Theta = 90°$, the entering of a target into a protected area at any angle results in an abrupt change in the received signal amplitude, and the output voltage from the mixer changes accordingly. Usually, this is sufficient to trigger the response of a threshold detector.

A signal from the mixer is in the range from μV to mV, so amplification is needed for the signal processing. Because the Doppler frequency is in the audio range, the amplifier is relatively simple. However, it generally must be accompanied by the so-called notch filters that reject a power line frequency and the main harmonic from full-wave rectifiers and fluorescent light fixtures: 60 and 120 Hz (or 50 and 100 Hz). For the normal operation, the received power must be sufficiently high. It depends on several factors, including the antenna aperture area A, target area a, and distance to the target r:

$$P_r = \rho\frac{P_0 A^2 a}{4\pi\lambda^2 r^4} \tag{69.9}$$

where P_0 is the transmitted power.

For effective operation, the target's cross-sectional area a must be relatively large, because for $\lambda^2 \le a$, the received signal is drastically reduced. Further, the reflectivity ρ of a target in the operating wavelength is also very important for the magnitude of the received signal. Generally, conductive materials and objects with high dielectric constants are good reflectors of electromagnetic radiation, whereas

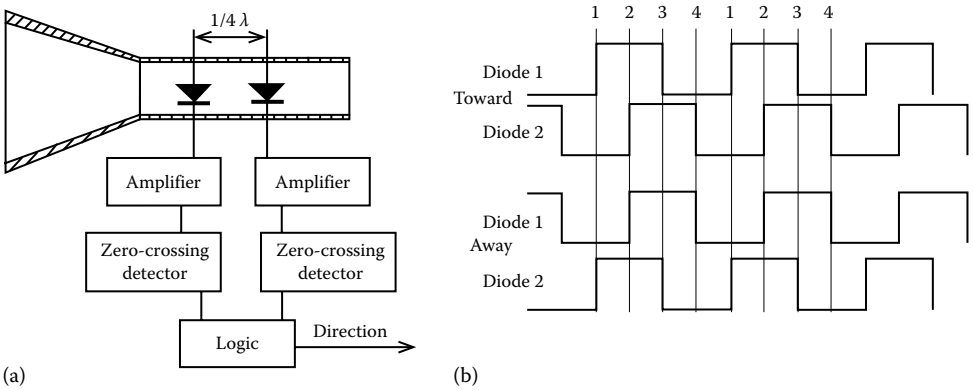

FIGURE 69.5 Block diagram (a) and timing diagrams (b) of a microwave Doppler motion detector with directional sensitivity.

many dielectrics absorb energy and reflect very little. Plastics and ceramics are quite transmissive and can be used as windows in the microwave detectors.

The best target for a microwave detector is a smooth, flat conductive plate positioned normally toward the detector (doesn't look like a human, does it?). A flat conductive surface makes a very good reflector; however, it may render the detector inoperable at angles other than 0°. Thus, an angle of $\Theta = 45°$ can completely divert a reflective signal from the receiving antenna. This method of diversion, along with other techniques, was used quite effectively in designs of the stealth bombers and fighters that are virtually invisible on radar screens. Nevertheless, at relatively short distances, signals reflected from the human bodies are still sufficiently strong for many practical purposes because they are scattered rather than reflected.

To detect whether a target moves toward or away from the antenna, the Doppler concept can be extended by adding another mixing diode to the transceiver module. The second diode is located in the waveguide in such a manner that the Doppler signals from both diodes differ in phase by one-quarter of wavelength or by 90° (Figure 69.5a). These outputs are amplified separately and converted into square pulses that can be analyzed by a logic circuit. The circuit is a digital phase discriminator that determines the direction of motion (Figure 69.5b). The door openers and traffic control devices are two major applications for this type of a module. Both applications need the ability to acquire a great deal of information about the target for discrimination before enabling a response. In door openers, limiting the field of view and transmitted power may substantially reduce the number of false-positive detections. Although discrimination is optional for the door openers direction, for traffic control it is a necessity to reject signals from the vehicles moving away. If the module is used for intrusion detection, the vibration of building structures may cause a large number of false-positive detections. A direction discriminator will respond to vibration with an alternate signal, and it will respond to an intruder with a steady logic signal. Hence, the direction discriminator is an efficient way to improve reliability of the detection.

Generally, the transmission and reception are alternated in time. That is, the receiver is disabled during the transmission; otherwise, a strong transmitted energy not only will saturate the receiving circuitry but may damage its sensitive components. In Nature, bats use ultrasonic ranging to catch their small prey. The bats become deaf for the short time when the ultrasonic burst of energy is transmitted. This temporary blinding of the receiver is the main reason why radars and acoustic rangers are not effective for short distances—it's just not enough time to disable and enable the receiver.

Whenever a microwave detector is used in the United States, it must comply with the strict requirements (e.g., MSM20100) imposed by the Federal Communication Commission. Similar regulations are enforced in many other countries. Also, emission of the transmitter must be below 10 mW/cm^2 as averaged over any 0.1 h period, as specified by OSHA 1910.97 for the frequency range from 100 MHz to 100 GHz.

69.4 Capacitive Occupancy Detectors

Being a conductive medium with a high dielectric constant, a human body develops a coupling capacitance to its surroundings.* This capacitance greatly depends on such factors as body size, clothing, materials, type of surrounding objects, and weather. However wide the coupling range is, the capacitance may vary from few pF to several nF. When a person moves, the coupling capacitance changes, thus making it possible to discriminating static objects from moving objects.

All objects form some degree of a capacitive coupling with respect to one another. If a human moves into vicinity of the objects whose coupling capacitance with each other has been previously established, a new capacitive value arises between the objects as a result of presence of an intruding body. Figure 69.6 shows that the capacitance between a test plate and earth† is equal to C_1. When a person moves into

* At 40 MHz, the dielectric constant of muscle, skin, and blood is about 97. For fat and bone, it is near 15.

† Here, by "earth" we mean any large object, such as the earth, lake, metal fence, car, ship, and airplane.

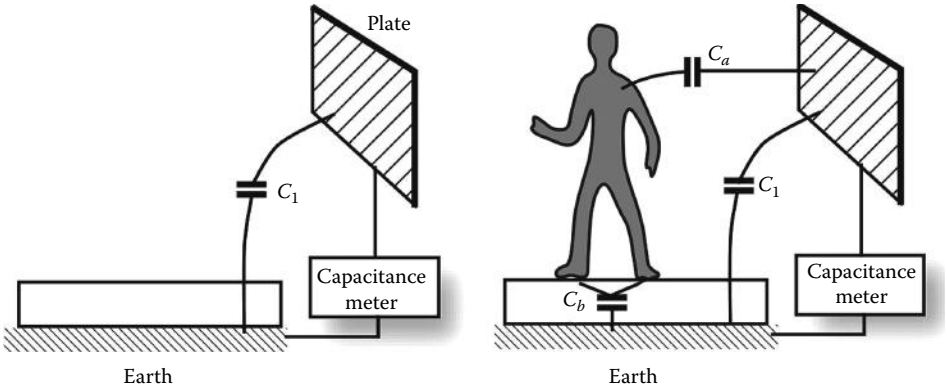

FIGURE 69.6 An intruder brings in an additional capacitance to a detection circuit.

vicinity of the plate, it forms two additional capacitors: one between the plate and its own body, C_a, and the other between the body and the earth, C_b. Then, the resulting capacitance C between the plate and the earth becomes larger by the incremental capacitance ΔC:

$$C = C_1 + \Delta C = C_1 + \frac{C_a C_b}{C_a + C_b} \tag{69.10}$$

With the appropriate apparatus, this phenomenon can be used for occupancy detection. What is required is to measure capacitance between a test plate (the probe) and a reference plate (the earth).

Figure 69.7 illustrates a capacitive security system for an automobile [3]. A sensing probe is imbedded into a car seat. It can be fabricated as a metal plate, metal net, a conductive fabric, etc. The probe forms one plate of a capacitor C_p. The other plate of the capacitor is formed either by a body of an automobile or by a separate plate positioned under a floor mat. A reference capacitor C_x is composed of a simple fixed or trimming capacitor that should be placed close to the seat probe. The probe plate and the reference capacitor are, respectively, connected to two inputs of a charge detector (resistors R_1 and R_2). The conductors preferably should be twisted to reduce the introduction of spurious signals as much as possible. For instance, strips of a Twinflex cabling were found quite adequate. A differential charge detector is

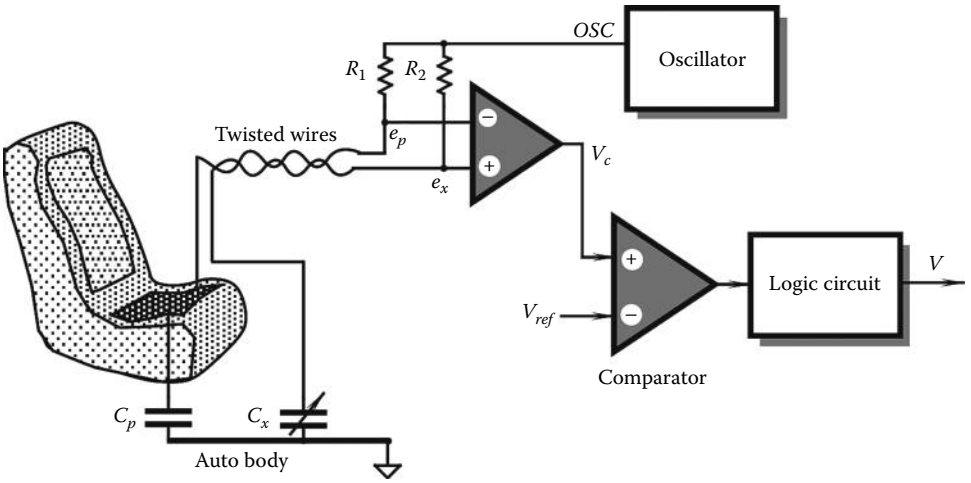

FIGURE 69.7 Capacitive intrusion detector for automotive applications.

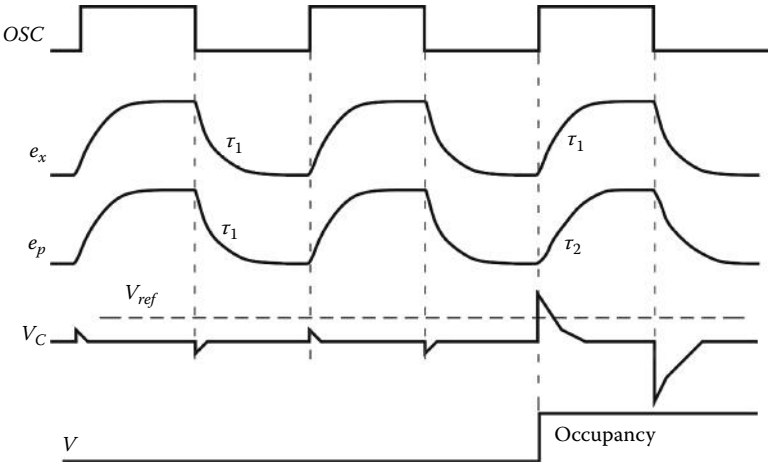

FIGURE 69.8 Timing diagrams for a capacitive intrusion detector.

controlled by an oscillator that produces square pulses (Figure 69.8). Under a no-seat-occupied condition, the reference capacitor is adjusted to be approximately equal to C_p. Resistors and the corresponding capacitors define time constants of the networks. Both *RC* circuits have nearly equal time constants τ_1. Voltages across the resistors are fed into the inputs of a differential amplifier, whose output voltage V_c is near zero. Small spikes at the output are the result of some unavoidable imbalance. When a person is positioned on the seat, her body forms an additional capacitance in parallel with C_p, thus increasing a time constant of the R_1C_p network from τ_1 to τ_2. This is indicated by the increased spike amplitudes at the output of a differential amplifier. The comparator compares V_c with a predetermined threshold voltage V_{ref}. When the spikes exceed the threshold, the comparator sends an indication signal to the logic circuit that generates signal V manifesting the car occupancy.

When a capacitive occupancy (proximity) sensor is used near or on a metal device, its sensitivity may be severely reduced due to a capacitive coupling between the electrode and the device's metallic parts. An effective way to reduce that stray capacitance is to use driven shields. Figure 69.9a shows a robot with a metal arm. The arm moves near people and other potentially conductive objects with which it could collide if the robot's control computer is not provided with advance information on proximity to the obstacles. An object, while approaching the arm, forms a capacitive coupling with it, which is equal to C_{so}. An arm is covered with an electrically isolated conductive sheath that is called an *electrode*. The nearby massive metal arm (Figure 69.9b) forms a much stronger capacitive coupling

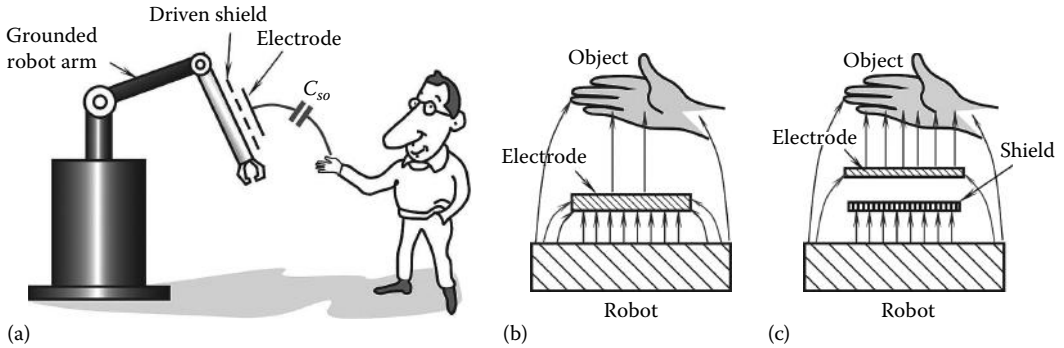

FIGURE 69.9 Capacitive proximity sensor: a driven shield is positioned on the metal arm of a grounded robot (a). Without the shield, the electric field is distributed between the electrode and the robot (b), while a driven shield directs electric field from the electrode toward the obstacle (c).

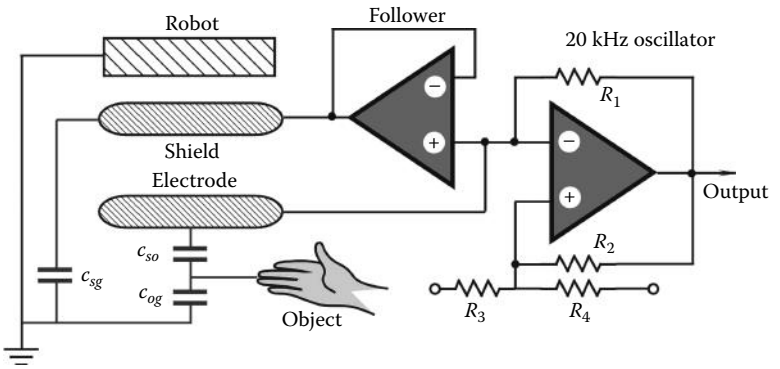

FIGURE 69.10 Simplified circuit diagram of a frequency modulator controlled by the input capacitances.

with the electrode that drugs the electric field from the object. An elegant solution is to shield the electrode from the arm by an intermediate shield as shown in Figure 69.9c. The sensor's assembly is a multilayer cover for the robotic arm, where the bottom layer is an insulator, then there is a large electrically conductive shield, then another layer of insulation, and on the top is a narrower sheet of the electrode. To reduce a capacitive coupling between the electrode and the arm, the shield must be at the same potential as the electrode, that is, its voltage must be driven by the electrode voltage (hence the name is a *driven shield*). As a result, no electric field is formed between them. Yet, a strong electric field will exist between the shield and the arm. The electric field is squeezed out from beneath the electrode and distributed toward the object.

Figure 69.10 shows a simplified circuit diagram of a square-wave oscillator whose frequency depends on the net input capacitance, comprised of C_{sg} (sensor to ground), C_{so} (sensor to object), and C_{og} (object to ground). The electrode is connected to the shield through a voltage follower. A frequency-modulated signal is fed into the robot's computer for controlling the arm movement. This arrangement allows detecting proximity to conductive objects over the range of 30 cm.

69.5 Triboelectric Detectors

Any object can accumulate, on its surface, static electricity. These naturally occurring charges arise from the triboelectric effect, which is a process of charge separation due to object movements, friction of clothing fibers, air turbulence, atmosphere electricity, etc. Usually, air contains either positive or negative ions that can be attracted to the human body, thus modifying its charge. Under the idealized static conditions, an object is not charged—its bulk charge is equal to zero. In reality, any object that at least temporarily is isolated from the ground can exhibit some degree of its bulk charge imbalance. In other words, it becomes a carrier of electric charges.

Any electronic circuit is made of conductors and dielectrics. If a circuit is not shielded, all its components exhibit a certain capacitive coupling to the surrounding objects. A pickup *electrode* can be added to the circuit's input to increase its coupling to the environment, very much like in the capacitive detectors. The electrode can be fabricated in form of a conductive surface that is well isolated from the ground. The difference between the triboelectric and capacitive sensors is that in the former no capacitance is being measured but rather an electric charge that is accumulated on the capacitance.

Electric field is established between the surrounding objects and the electrode whenever at least one of them carries electric charges. In other words, all distributed capacitors formed between the electrode and the environmental objects are charged by static or slow-changing electric fields resulted from a triboelectric effect. Under a no-occupancy condition, electric field in the electrode vicinity is either constant or changes relatively slow.

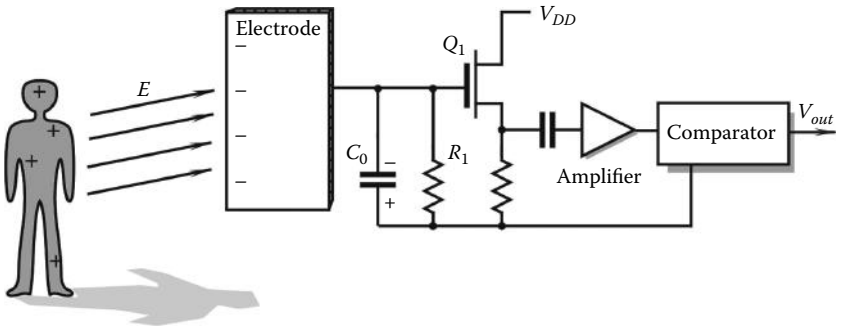

FIGURE 69.11 Monopolar triboelectric motion detector.

If a charge carrier (an intruder) changes its position, moves away, or a new charge-carrying object enters into the vicinity of the electrode, a static electric field is disturbed. This results in a redistribution of charges between the coupling capacitors, including those that are formed between the input electrode and the surroundings. The charge depends on the atmospheric conditions and nature of the objects. For instance, a person in dry manmade clothes walking along a carpet carries a million times stronger charge than a wet intruder who has come from the rain. An electronic circuit can be adapted to sense these variable charges at its input. In other words, it can be made capable of converting the induced variable charges into electric signals that may be amplified and further processed. Thus, static electricity that is a naturally occurring phenomenon can be utilized to generate alternating signals in the electronic circuit to indicate the movement of objects.

Figure 69.11 shows a monopolar triboelectric motion detector [4]. It is comprised of a conductive electrode connected to an analog impedance converter made with a MOS transistor Q_1, a bias resistor R_1, an input capacitance C_0, a gain stage, and a window comparator [5]. While the rest of the electronic circuit may be shielded, the sensing electrode is exposed to the environment and forms a coupling capacitor C_p with the surrounding objects. Being a charge carrier, the intruder becomes a source of an electric field, having intensity E. The field induces a charge of the opposite sign in the electrode. Under the static conditions, when the person doesn't move, the field intensity is constant and the input capacitance C_0 is discharged through a bias resistor R_1. To make the circuit sensitive to relatively slow motions, the resistor R_1 should be selected of a very high value: on the order of 10^{10} Ω or higher. When a person moves, the intensity, E, of the electric field changes. This induces a corresponding variable electric charge in the input capacitor C_0 and results in appearance of a variable electric voltage across the bias resistor. That voltage is fed through the coupling capacitor into the gain stage whose output signal is applied to a window comparator. Note that contrary to a capacitive motion detector that is an active sensor, a triboelectric detector is passive. That is, it does not generate or transmit any signal that makes it more difficult to detect. This detector may be hidden in or behind nonmetallic objects such as wood and bricks.

There are several possible sources of interferences that may cause spurious detections by the triboelectric detectors. The detector may be subjected to a transmitted noise resulting in false-positive detection. Among the noise sources are 60 or 50 Hz power line signals, electromagnetic fields generated by radio stations, power electric equipment, lightnings, etc. Most of these interferences generate electric fields that are distributed around the detector quite uniformly and can be compensated for by employing a symmetrical input circuit with a significant common mode rejection ratio.

69.6 Optoelectronic Motion Detectors

By far, the most popular intrusion sensors are the optoelectronic motion detectors. They rely on electromagnetic radiation in the optical range, specifically having wavelengths from 0.4 to 20 μm. This covers the visible, near, and part of the far-IR spectral ranges. The detectors are primarily used for indication of

movement of people. They operate over distances ranging up to several hundred meters and, depending on the particular need, may have either a narrow or wide field of view.

The operating principle of the optical motion detectors is based on detection of light (either visible or IR) reflected or passively emanated from surface of a moving object into the surrounding space. Such radiation may be originated either by an external light source and then reflected by the object, just like the microwave or ultrasonic waves, or it may be produced by the object itself in form of a natural IR emission. The former case is classified as an active detector and the latter—a passive. Hence, an active detector requires an additional light source, for instance, daylight, electric lamp, IR LED projector, and laser. The passive detectors detect mid- and far-IR natural emission from objects having temperatures that are different from the surroundings.

First, we shall consider limitations of the optoelectronic detectors as opposed to such devices as microwave, ultrasonic devices, and laser detectors. Presently, optoelectronic detectors are used almost exclusively to detect the presence or absence of movement qualitatively rather than quantitatively. In other words, the optoelectronic detectors are very useful to indicate whether an object moves or not, while they cannot distinguish one moving object from another and they can't be utilized to accurately measure distance to a moving object or its velocity. The major application areas for the optoelectronic motion detectors are in security systems (to detect intruders), in energy management (to turn lights on and off), and in the so-called "smart" homes where they can control various appliances, such as air conditioners, cooling fans, and stereo players. They also may be used in robots, toys, point-of-sale advertisements, and novelty products. The most important advantage of an optoelectronic motion detector is simplicity and low cost.

69.6.1 Sensor Structures

A general structure of an optoelectronic motion detector is shown in Figure 69.12a. Regardless of what kind of sensing element is employed, the following components are essential: a focusing device (a lens or curved mirror), a light detecting element, and a threshold comparator. An optoelectronic motion detector resembles a photographic camera. Its focusing component creates on a focal plane an image of the field of view. Instead of an imaging sensor, a "single-pixel" light-sensitive element is used. The element converts the focused light into an electric signal.*

Let's assume that the motion detector is mounted in a room. A focusing lens creates an image of the room on a focal plane where the light-sensitive element is positioned. If the room is unoccupied, the image is static and the output signal from the element is steady/stable. When an "intruder" enters the room and keeps moving, her image on the focal plane also moves. In a certain moment, the intruder's body is displaced for an angle α and the image overlaps with the light sensing element. This is an important point to understand—the detection is produced only at the moment when the object's image either coincides with the detector's surface or clears it. That is, no crossing—no detection. Assuming that the intruder's body creates an image whose photon flux is different from that of the static surroundings, the light-sensitive element responds with a deflecting voltage V. To cause detection, a moving image shall have a certain degree of an optical (or thermal) contrast with its surroundings.

Figure 69.12b shows that the output signal is compared with two thresholds in a window comparator. The purpose of the comparator is to convert the analog signal V into two logic levels: 0—no motion detected and 1—motion is detected. In most cases, signal V from the element first must be amplified and conditioned before it becomes suitable for the threshold comparison. The window comparator contains both the positive and negative thresholds, while signal V is positioned in between. Whenever an image of a moving object overlaps with the light-sensitive element, voltage V deflects from its steady-state position and crosses one of two thresholds. The comparator generates a positive voltage (1), thus indicating

* In a differential sensor, as described in the following text, two "pixels" are employed.

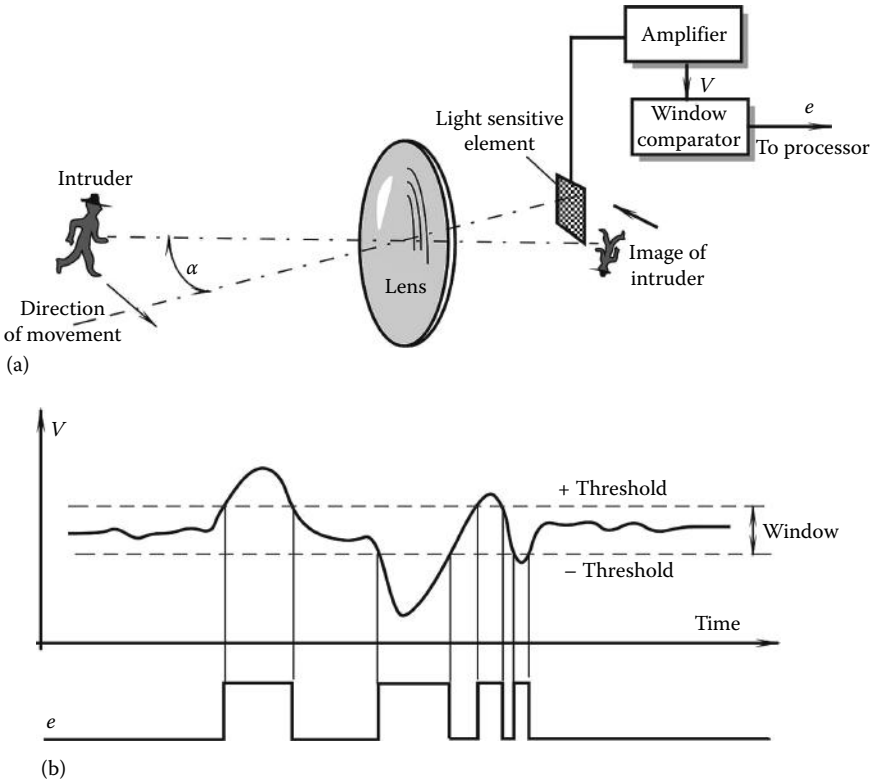

FIGURE 69.12 General arrangement of an optoelectronic motion detector. A lens forms an image of a moving person (intruder). When the image crosses the sensor's optical axis, it covers the sensitive element (a). The element responds with a signal that is amplified and compared with a window threshold in a comparator (b).

detection of movement in the field of view. The operation of this circuit is identical to the threshold circuits described earlier for other types of occupancy detectors.

Note from Figure 69.12 that the detector has quite a narrow field of view: if the intruder keeps moving, her image will overlap with the sensor only once. After that the window comparator output will produce steady zero. This is the result of a small area of the sensing element. In some instances, when a narrow field of view is required, it is quite all right; however, in the majority of cases, a much wider field of view is desirable. This can be achieved by several methods described later.

69.6.2 Multiple Detecting Elements

An array of detecting elements (multiple pixels) may be placed in the focal plane of a wide-angle focusing mirror or lens. Each individual element covers a narrow portion of the field of view, while in combination they encompass a larger area. All detectors in the array either shall be multiplexed or otherwise interconnected to produce a composite detection signal.

69.6.3 Complex Sensor Shapes

If the detecting element's surface area is sufficiently large to cover the entire angle of view, the sensor's surface may be optically broken into smaller elements, thus creating an equivalent of a multiple detector array. To break up the surface area into several parts, one may shape the sensing (detecting) element in an odd pattern like that shown in Figure 69.13a. Each part of the element acts as a separate light detector.

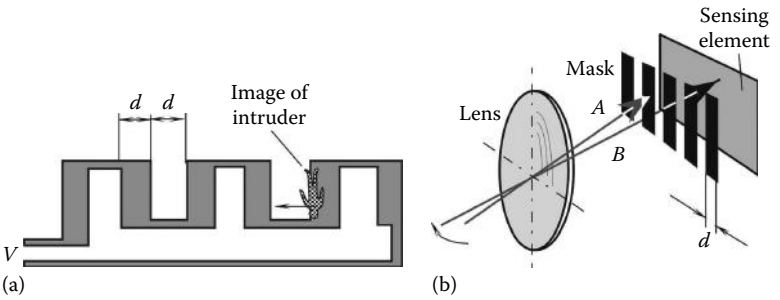

FIGURE 69.13 (a) Complex shape of a sensing element and (b) image distortion mask.

All such detectors are electrically connected either in parallel or in series, being arranged in a serpentine pattern. The parallel or serially connected detectors generate a combined output signal, for instance, voltage *V*, when image of the object moves along the element surface crossing alternatively sensitive and nonsensitive areas. This results in an alternative signal *v* at the detector terminals. For a better sensitivity, such sensitive and nonsensitive areas should be sufficiently large to overlap with most of the object's image.

69.6.4 Image Distortion

Instead of making the detector in a complex shape, an image of an entire field of view may be broken into several parts. This can be done by placing a distortion mask [6] in front of the detector having a sufficiently large area as it is depicted in Figure 69.13b. The mask is opaque and allows formation of an image on the detector's surface only within its clearings. The mask operation is analogous to the complex sensor's shape as described earlier.

69.6.5 Facet Focusing Device

A more popular way of broadening the field of view while employing a small area light detector is to use multiple focusing devices. A focusing mirror or a lens may be divided into arrays of smaller mirrors or lenses called *facets*, resembling an eye of an insect. Each facet works as an individual lens (mirror) thus creating its own image on a common focal plane. The optical axis of each facet is shifted with regard to its neighbor to project an image of an adjacent area of the field of view. All facets together form multiple images as shown in Figure 69.14a. When the object moves, the multiple images also move across the

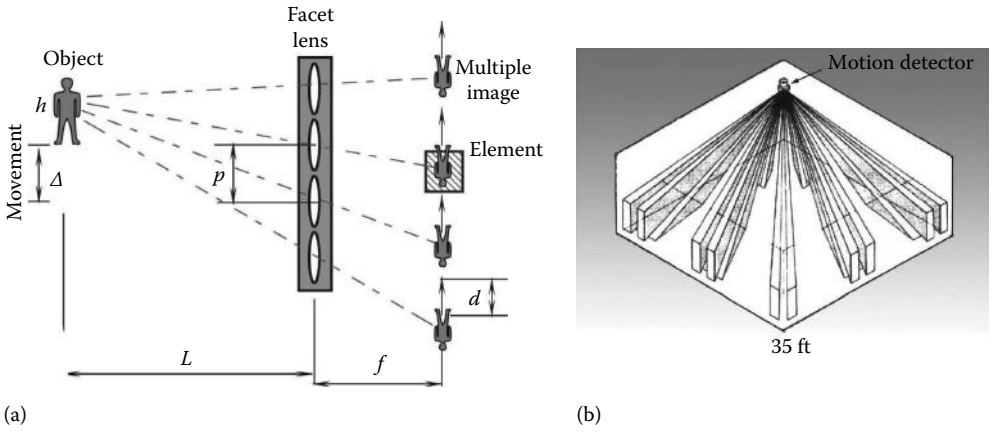

FIGURE 69.14 (a) A facet lens creates multiple images near the sensing element and (b) sensitive zones created by a complex facet lens.

FIGURE 69.15 Example of curved IR faceted Fresnel lens molded of HDPE.

sensing element causing it to produce an alternative signal every time at least one of the images crosses the sensing element. By combining multiple facets, it is possible to shape any desirable detecting pattern in the field of view, in both horizontal and vertical planes. Positioning of the facet lens, focal distances, number, and a pitch of the facets (a distance between the optical axes of two adjacent facets) may be calculated in every case by applying rules of geometrical optics. The following practical formulas may be applied to find the focal length of a facet:

$$f = \frac{Ld}{\Delta} \tag{69.11}$$

and the facet pitch (a distance between their optical axes) is

$$p = 2nd \tag{69.12}$$

where

L is distance to the object
d is width of the sensing element
n is number of the sensing elements (evenly spaced)
Δ is the object's minimum displacement that must result in detection

By combining facets, one may design a lens that covers a large field of view (Figure 69.14b)—up to 180°—where each facet creates a relatively narrow angle sensitive zone. Currently, the facet lenses are primarily used in the mid- and far-IR spectral ranges. These lenses are molded of high-density polyethylene, HDPE (Figure 69.15), and quite inexpensive.

69.6.6 Visible and Near-IR Light Motion Detectors

Most of objects (apart from very hot) radiate electromagnetic waves only in the mid- and far-IR spectral ranges. Hence, visible and near-IR light motion detectors have to rely on additional sources of light that illuminate objects. The light is reflected by the object's surface toward the focusing device for a subsequent detection. The light sources may be the sun, lamps, or invisible near-IR light-emitting diodes (LEDs). The use of visible light for detecting moving objects goes back to 1932 [6] when in the pre-radar era, inventors were looking for ways of detecting moving cars and flying airplanes. In one invention, an airplane detector was built in form of a photographic camera where the focusing lens made of glass was aimed at the sky. A moving plane's image was focused on a selenium photodetector that reacted to a changing contrast in the sky image. Naturally, such a detector could operate only at a daytime to detect planes flying below clouds. Obviously, those detectors were not too practical.

Another version of a visible range light motion detector was patented and produced for less demanding applications: controlling lights in a room [5] and to make interactive toys [7].

To turn the lights off in a nonoccupied room, the visible range motion detector was combined with a timer and a solid-state relay. The detector was activated when the room is illuminated. Visible light photons carry a relatively high energy and may be detected by quantum photovoltaic or photoconductive cells whose detectivity is quite high. Thus, the optical system may be substantially simplified. In the motion switch, the focusing device was built in form of a pinhole lens (Figures 69.16b and 69.17a). Such a lens is just a tiny hole in an opaque foil. To avoid a light diffraction, a hole diameter must be substantially larger than the longest detectable wavelength (red). The motion switch had a three-facet pinhole lens with apertures of 0.2 mm in diameter (Figure 69.16c). A pinhole lens has a theoretically infinite depth of focusing range; hence, a photodetector can be positioned at any distance from the lens. For practical reasons, that distance was calculated for the object's displacement, view angle, and the photoresistor dimensions used in the design. The CdS (cadmium sulfide) photoresistor was selected with a serpentine pattern of a sensing element (Figure 69.16a) and connected into a low frequency ac amplifier. When the

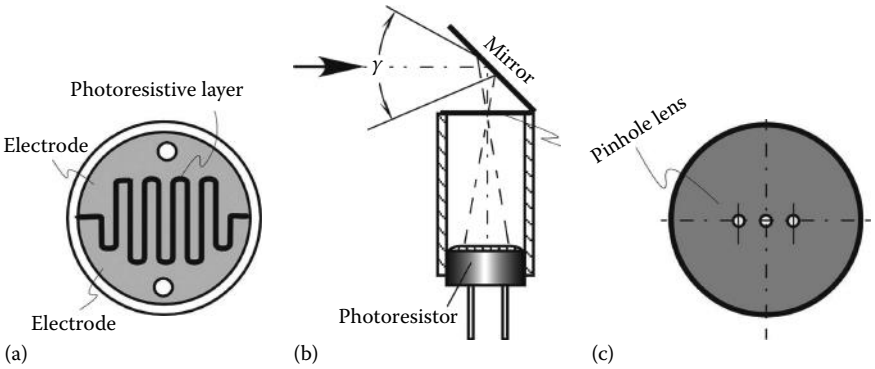

FIGURE 69.16 Simple optical motion detector for a light switch and toys: (a) a sensitive surface of a photoresistor forms a complex sensing element, (b) a flat mirror and a pinhole lens form an image on a surface of the photoresistor, and (c) a triple-pinhole lens.

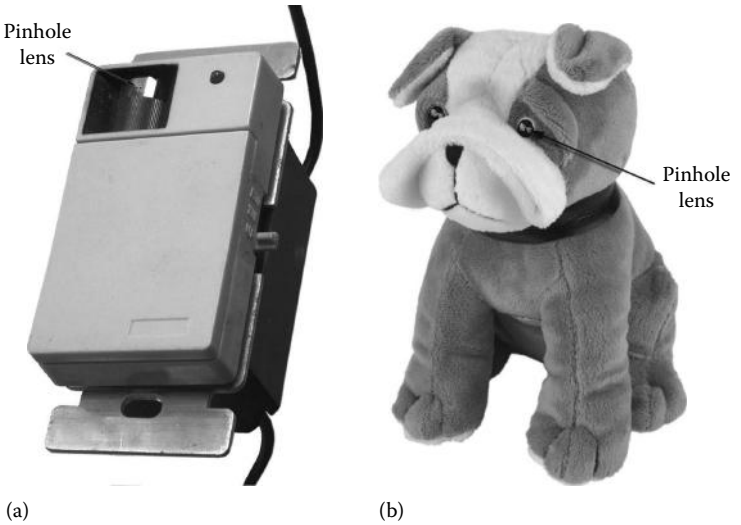

FIGURE 69.17 Motion-controlled light switch with a photoresistor and pinhole lens (a). Interactive toy (b) that reacts to a child's movement—the dog barks when motion is detected.

room was illuminated, the motion sensor acted as a miniature photographic camera: an image from the lens' field of view was created on a surface of the photoresistor. Moving people in the room caused the image to change in such a way as the optical contrast changed across the serpentine pattern of the photoresistor (see Figure 69.13a). In turn, its resistive value was changing, resulting in modulation of the electric current passing through the photoresistor. This signal was further amplified and compared with a predetermined threshold. Upon crossing that threshold, the comparator generated electric pulses that reset a 15 min timer. If no motion was detected within 15 min from the last movement, the timer disabled the solid-state relay to turn lights off. Then, light could be turned on back only manually, because this motion detector can't function in darkness. Thanks to its very low cost, this type of a motion sensor was used in interactive toys that react to movement of children [7]. An example of such a toy is shown in Figure 69.17b where a pinhole lens was built into an eye of a mechanized barking dog. Normally the dog was sitting quietly but when motion in its vicinity was detected, the dog started moving and barking. If you pet it on the back, the barking stopped and the dog wagged the tail (a tactile sensor was installed on the back under the coat).

69.6.7 Far Infrared Motion Detectors

Another version of a motion detector operates in the optical range of thermal radiation, the other name for which is mid- and far IR. Such detectors are responsive to radiative heat exchange between the sensing element and moving object [9–11].

The principle of thermal motion detection is based on the physical theory of natural emission of electromagnetic radiation from any object whose temperature is above absolute zero.

For motion detection, it is essential that surface temperature of an object be different from that of the surrounding objects, so a thermal contrast would exist, just as a visible contrast in the sensors described earlier. All objects emanate thermal radiation from their surfaces and intensity of that radiation is governed by the Stefan–Boltzmann law. If the object is warmer than the surroundings, its thermal radiation is shifted toward shorter wavelengths and the intensity becomes stronger. Most objects whose movement is to be detected are nonmetals; hence, they radiate thermal energy quite uniformly within a hemisphere. Moreover, the dielectric objects generally have high emissivity of thermal radiation. Human skin is a quite good emitter of thermal radiation. Its emissivity is well over 90%. Most of natural and synthetic fabrics also have high emissivities between 0.74 and 0.95.

There are two types of the IR motion detectors: passive and active. Here we briefly overview the passive passive infrared (PIR) detectors as most popular for the security and energy management systems. The PIR sensing element is responsive to mid- and far-IR radiation within a spectral range from approximately 4 to 20 μm where most of the thermal power emanated by humans is concentrated (body surface temperatures ranging from about 28°C and up). There are three types of the sensing elements that are potentially useful for that detector: bolometers, thermopiles, and pyroelectrics; however, the pyroelectric elements are used almost exclusively for motion detection thanks to their simplicity, low cost, high responsivity, and broad dynamic range. Let's see how a pyroelectric may be employed in a practical motion sensor design.

A pyroelectric material generates an electric charge in response to a thermal energy flow through its body. In a very simplified way, it may be described as a secondary effect of a thermal expansion (Figure 69.18). Since all pyroelectrics are also piezoelectrics, absorbed heat causes the front side of the sensing element to expand. This miniscule thermally induced stress leads to development of a piezoelectric charge on the element electrodes. The charge is manifested as voltage across the electrodes deposited on the opposite sides of the material. Unfortunately, the piezoelectric properties of the element have also a negative effect. If the sensor is subjected to a minute mechanical stress due to any external force, like sounds or structural vibrations, it also generates a charge that in many cases is indistinguishable from that caused by the IR heat waves. This would cause a false-positive detection.

To separate thermally induced charges from the piezoelectrically induced charges, a pyroelectric sensor is usually fabricated in a symmetrical form (Figure 69.19a), as a two-pixel element. Two identical

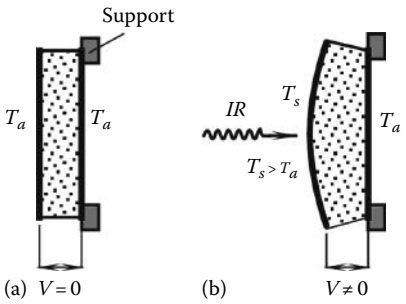

FIGURE 69.18 Simplified model of a pyroelectric effect as a secondary effect of piezoelectricity. Initially, the element has a uniform temperature (a); upon exposure to thermal radiation, its front side warms up and expands, causing a stress-induced charge (b).

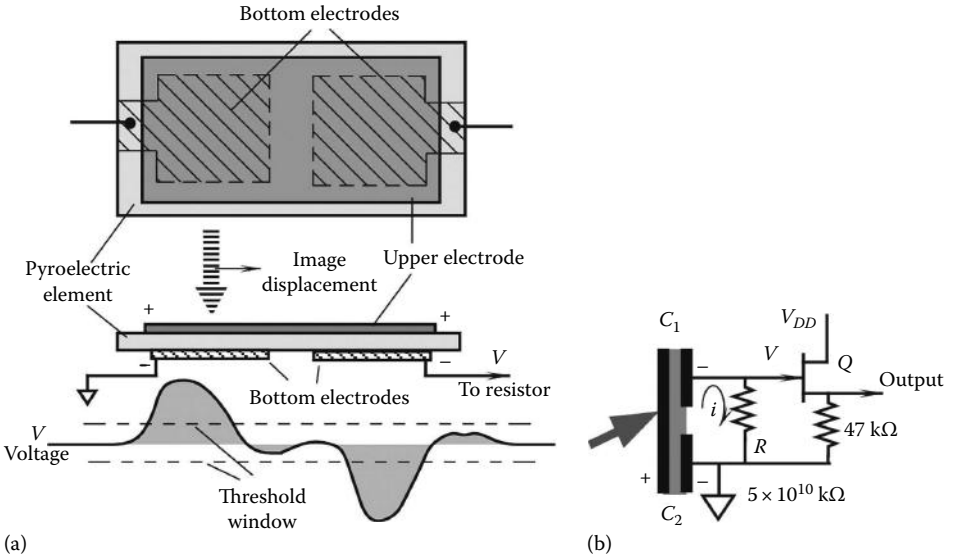

FIGURE 69.19 Dual pyroelectric sensor: sensing element with a front (upper) electrode and two bottom electrodes deposited on a common crystalline substrate (a). A moving thermal image travels from left part of the sensor to the right generating an alternate voltage across the bias resistor, *R* (b).

elements are positioned inside the sensor's housing. The IR radiation is focused on the element by a faceted Fresnel lens, such as depicted in Figure 69.15. The pixels are connected to the electronic circuit in such a manner as to produce the out-of-phase signals when subjected to the same in-phase inputs. The idea is that interferences that are produced by the piezoelectric effect or spurious signals are applied to both electrodes equally (in phase) and thus cancelled at the input of the electronic circuit, while the variable thermal radiation thanks to a correctly designed faceted lens will be absorbed by only one element at a time, thus avoiding a cancellation. This arrangement is called a differential sensor.

One way of fabricating a differential sensor is to deposit two pairs of electrodes on both sides of the pyroelectric element. Each pair forms a capacitor that may be electrically charged either by heat or by a mechanical stress. The electrodes on the upper side of the sensor are connected together forming one continuous electrode, while the two bottom electrodes are separated, thus creating the opposite serially connected capacitors. Depending on the side where the electrodes are positioned, the output signal will have either a positive or negative polarity for a thermal influx. In same applications, a more complex pattern of the sensing electrodes may be required (for instance, to form predetermined detection zones), so that more than one pair of the electrodes are needed. In such a case, for better rejection

of the in-phase signals (common mode rejection), the sensor still should have an even number of pairs where positions of the pairs alternate for a better geometrical symmetry. Sometimes, such an alternating connection is called an interdigitized electrode [8].

A symmetrical sensing element should be mounted in a way assuring that both parts of the element generate the same in-phase signals if subjected to the same external factors. At any moment, the optical component (e.g., a Fresnel lens) must focus a thermal image of a target on the surface of one part of the sensor only, otherwise signals from the thermal image will be cancelled. The element generates a charge only across the electrode pair that is subjected to a heat flux. When a thermal image moves from one electrode to another, the current i flowing from the sensing element to the bias resistor R (Figure 69.19b) changes from zero, to positive, then back to zero, then to negative, and again back to zero. A field-effect transistor Q is used as an impedance converter. Resistor R value must be very high. For example, a typical alternate current generated by the element in response to a moving person is on the order of 1 pA (10^{-12} A). If a desirable output voltage for a specific distance is v = 50 mV, according to Ohm's law, the resistor value should be $R = v/I$ = 50 GΩ (5×10^{10} Ω). Such a resistor cannot be directly connected to a regular electronic circuit; hence, transistor Q serves as a voltage follower (the gain is close to unity). Its typical output impedance is on the order of several kilohm.

69.7 Optical Presence Sensors

A reflection of light is the optical phenomenon that is used quite extensively in detecting not only motion but a mere presence of a human in a monitored area. The operating principle is very simple. The sensor contains two key components: a source of light (usually a near-IR LED) and a photodetector. The LED emits a light beam that illuminates surroundings in the field of view of a photodetector. First, the background reflection from the surrounding objects is established in terms of the output voltage from the photodetector V_0. A new object that appears in a foreground either absorbs more light or reflects more. In most cases it alters the background signal by the increment ΔV that can be detected by a threshold detector in the electronic processor. This sensor is a reflectance monitor. It will not measure a distance to the object because the value of ΔV depends on many factors, such as size of the object, its shape, material, surface finish, and distance to the sensor. The sensor is merely a presence detector, yet in many practical cases it's just what's needed. An example of the sensor application is a presence detector for a bathroom faucet that is used to control flow of water when hands are placed under the water outlet [11,12]. Placement of hands under the faucet controls the actuator of water flow (a solenoid-valve assembly). A similar detector is frequently employed in hand dryers, toilet tanks, light switches, robotic vacuum cleaners, and many other products.

Figure 69.20a and b show two possible locations of the sensor in a water fixture. One location is on the spout while in the other the sensor is built in directly into the faucet. It's important to make sure that the

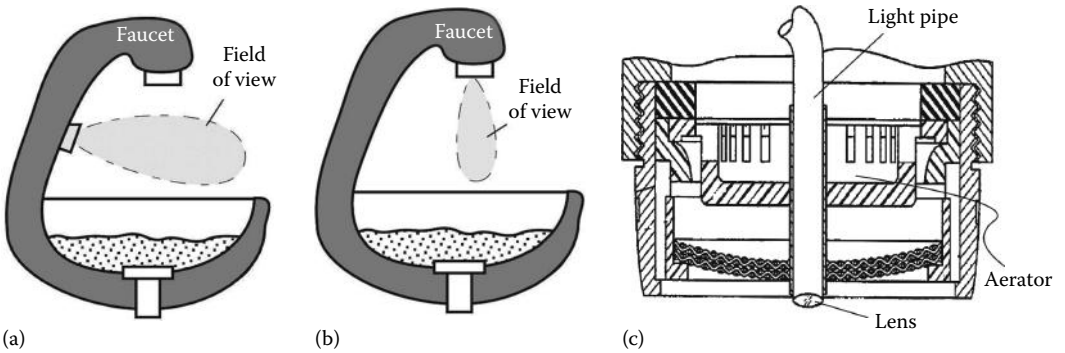

FIGURE 69.20 Installation of the optical presence detector into a spout (a) and faucet (b). Cross-sectional view (c) of the faucet with a light pipe. (Adapted from Parsons, N.E. et al. Passive sensors for automatic faucets and bathroom flushers, U.S. Patent No. 7,396,000, 2008.)

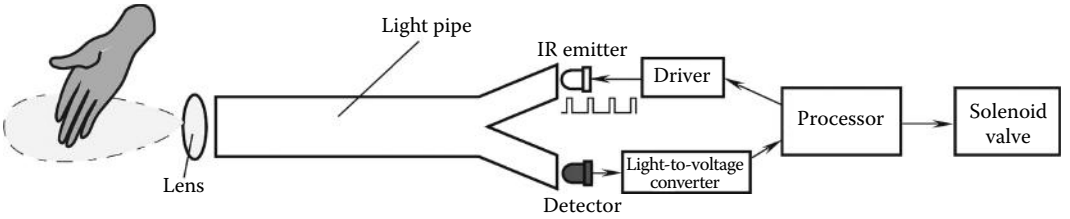

FIGURE 69.21 Block diagram of a water flow controller with the optical presence detector.

detection area is situated where the hands are normally being placed. Figure 69.20c illustrated the faucet having a light pipe and the parts that are normally needed for dispensing water. Figure 69.21 shows a block diagram of the water flow control system. The light pipe can be a bundle of the optical fibers or a solid translucent rod molded of polycarbonate resin. Usually, the emitted light is modulated by pulses. This helps to separate the reflected light signals into a background (ambient) component and that controlled by the pulsing LED driver, since the ambient light is a dc or slow-changing signal. Note that the background component also may contain a pulsing signal since some light will be constantly reflected from it, for example, from a sink surface. This can be taken care of by both the sensitivity adjustment and by detecting only a variable component of signal ΔV. It is possible to eliminate the pilot light LED and entirely rely on the ambient illumination by independent light sources [13]; however, this design may be not as robust as the one with a modulated LED.

69.8 Pressure-Gradient Sensors

An efficient sensor can be designed to detect intrusion into a closed room by monitoring small variations in the atmospheric air pressure resulting from opening doors and windows or movement of people. In general, variations in air pressure can be monitored by a conventional air pressure sensor. However, this is not an efficient solution. A conventional air pressure sensor is designed for a relatively large span of the input pressures, while the peak amplitudes of the pressure variations that are associated with intrusion are very small—over three orders of magnitude smaller than a conventional pressure sensor's span. In fact, these variations approach the noise floor of stress-sensitive membrane pressure sensors. Besides, such a sensor is just not sensitive enough for them. Appending the sensor with a high-gain amplifier is not a solution because noise will be amplified as well. The solution would be to design a sensor having a narrow pressure span but high sensitivity. It is also desirable to make the sensor responsive only to the pressure changes rather than to an absolute value of pressure. Preferably the sensor should produce a signal similar to a first derivative of the air pressure. Since the only purpose of the sensor is to detect intrusion and not measure the actual air pressure, accuracy requirements can be significantly relaxed. This sensor produces a qualitative rather than quantitative output.

High sensitivity can be achieved by making the sensing membrane very thin with a relatively large area. An example of the intrusion air pressure sensor design [14] is shown in Figure 69.22. The main part of the sensor is an enclosed chamber. The left wall of the chamber is covered with a thin stretched membrane made of a plastic or metal foil having thickness on the order of 25 μm. The membrane area should be relatively large—about 200 mm^2 or larger. The right side of the chamber is a rigid backplate with a small venting hole whose purpose is to equalize static air pressures inside and outside of the chamber. The distance d from the membrane to the backplate is monitored by a built-in displacement detector (sensor). All exterior surfaces of the sensor are exposed to ambient air. When all doors and window in the monitored room are closed, the ambient air pressure is either static or changes slowly. Thanks to the vent in the backplate, pressures P_h inside and outside of the sensor's chamber are equal. When the door or window opens, the ambient air pressure changes slightly but rapidly. Because the vent is very narrow and air has a finite viscosity, air pressure P_h inside the chamber can't change instantly; thus, any changes inside the chamber will lag behind the outside changes. The phase lag creates a temporary air pressure

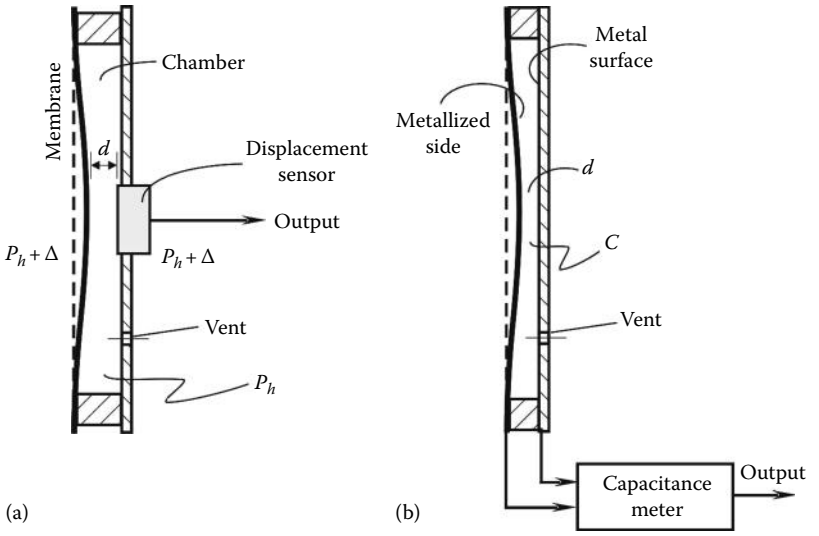

FIGURE 69.22 Air pressure-gradient sensor (a) and the sensor with a capacitive displacement detector (b).

differential across the membrane that deflects it to or from the backplate in relation to the differential amplitude and sign. The distance *d* from the membrane to the backplate is measured by a displacement sensor and is used as an indication of the intrusion. When the differential pressure is small, the membrane remains substantially flat and the distance *d* is at its base level. Figure 69.23 illustrates the timing diagrams of air pressures inside and outside of the sensing chamber and the differential pressure across the membrane. Note that the signal representative of the displacement *d* is compared with a threshold to detect an intrusion.

There are numerous ways of designing a displacement senor for monitoring the membrane deflection [15]. As an example, Figure 69.22b illustrates a capacitive displacement sensor, where the sensing chamber was built in form of a flat capacitor with two plates. The first plate of a capacitor is a metal foil (or metalized plastic membrane) and the other plate is a metal layer on the backplate. The baseline gap *d* between the membrane and backplate should be rather small—a few millimeters maximum. A value

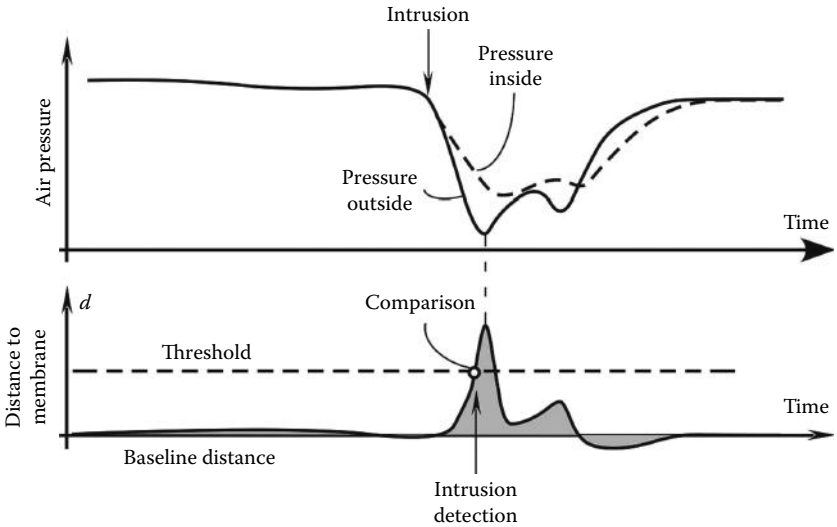

FIGURE 69.23 Timing diagrams for the pressure-gradient detector.

of the capacitance C will change when distance d varies according to the air pressure differential. The capacitance variations are measured and converted into a useful signal.

An alternative design of the earlier approach may include a solid-state MEMS sensor with a thermo-anemometer as a flow sensor [16]. Such sensors can detect pressure gradients as low as a few Pa (pascal) or mm of H_2O. This is a sufficient sensitivity to detect minute air movements in a room. However, unlike the sensor of Figure 69.22 that outputs the signal proportional to the rate of change in differential pressure, to detect changes in air pressure, the flow sensor would require a differentiator as part of the signal processing.

GPR Principles and Applications

Jan Francke
International Groundradar Consulting, Inc.

70.1 Introduction

Ground-penetrating radar, also known as surface-penetrating radar, geo-radar, or more commonly by the abbreviation GPR, has seen significantly increased acceptance as a viable near-surface geophysical technique in recent years. The practice of employing radio waves to image the subsurface dates to work conducted on glaciers in the Austrian Alps in the 1920s (Stern, 1929). Research on the ice-penetrating capabilities of radio waves languished until the late 1950s, when it was noted that newly installed radar altimeters on aircraft could penetrate through the Greenland icecap and display the aircraft's height above the underlying bedrock, which led to a number of mishaps (Waite and Schmidt, 1961). Although the ability to penetrate ice was a limitation for the reliance on radar altimetry for low-altitude flying in Polar regions, agencies such as NASA took an interest in the ability of radar to penetrate the ground in suitable environments. A rudimentary GPR system was launched onboard Apollo 17 in an attempt to determine surface conditions prior to a manned mission to the moon (Simmons et al., 1972).

Stemming from NASA's requirements for instrument portability and miniaturization and research conducted by the Atomic Energy Commission, the technology was commercialized in the mid-1970s, initially for archaeological investigations (Morey, 1974). However, GPR's potential to locate discrete targets in the ground, such as buried pipes, cables, tunnels, or land mines, was quickly realized. It was also found that low-frequency radar waves (10–100 MHz) could image geological contacts in some environments to depths of dozens of meters (Clough, 1976; Thierbach, 1974). Sedimentologists, geologists, groundwater hydrologists, and the mineral exploration sector all experimented with the technology in various environments. This research was assisted by work conducted to better understand the

electrical properties of geological materials at radio frequencies as well as the relationship between electrical conductivity and dielectric polarization of such media (Olhoeft, 1975, 1987).

By the late 1980s, the major restrictions on the further use of GPR as a geophysical tool were the bulkiness and power requirements of the instrumentation. Furthermore, data were generally recorded on electrostatic plotters, limiting the geophysicist's ability to employ advanced seismic processing techniques, which were keeping pace with the rapidly developing power of desktop computing.

The advent of portable computing and fast A/D microchips in the late 1980s led to a significant reduction in power requirements, more portable instrumentation, and the ability to digitally capture radar data for subsequent processing.

Since the early 1990s, the possible applications for GPR have burgeoned to include the mapping of pavement thickness and cracks at highway speeds (Saarenketo and Scullion, 2000; Spagnolini and Rampa, 1999), network-wide mapping of utilities in full 3D imaging (Eide and Hjelmstad, 2002), and the detection of movement in collapsed buildings (Sachs et al., 2008; Zaikov et al., 2008). GPR has also led to the development of subtechnologies such as wall-penetrating radar (Nag et al., 2001), which is used for the detection of live targets through nonmetallic walls by law enforcement of military personnel, and pipe-penetrating radar (Ariaratnum et al., 2005), which is employed within pipes to detect variations in wall thickness and adjacent voids.

Regardless of the application, all penetrating-radar technologies rely on electromagnetic (EM) fields to probe lossy dielectric materials to image variations in material properties. In most geological material, as well as manmade media such as concrete and asphalt, EM fields will penetrate some distance before being attenuated. This depth could range from many kilometers through Antarctic ice sheets to a few centimeters in some concretes.

70.2 Radar Wave Propagation in the Subsurface

The radar signals are emitted by a transmitter and penetrate into the subsurface as nondispersive waves. When the signals encounter a variation in the subsurface material's impedance, the signals are scattered or reflected, with some of the energy returning back to the surface, where it is captured and digitized by a receiver. Due to the nondispersive nature of radar, the returned reflections are similar to the transmitted signal, making signal recognition and interpretations simple. The frequency range of GPR signals is generally between 1 MHz and 2 GHz. Below the MHz range, the EM fields become dispersive, whereas higher frequencies are limited in their practical application because several factors increase attenuation to a degree where penetration would be limited to a few millimeters.

Maxwell's equations mathematically describe the physics of the EM theory and thus GPR energy propagation as a 3D polarized vector field. In geological media, the waves travel at velocities lower than the speed of light and are scattered by variations in the electrical and magnetic properties of the subsurface. The subsurface media through which GPR energy must penetrate are referred to as semiconductors, or dielectrics, and are characterized by three EM properties: electrical conductivity, electrical permittivity, and magnetic permeability.

Electrical conductivity, σ, is the measure of a material's ability to transmit a direct current, which results in energy dissipation through the conversion of electrical energy to heat. Dielectric permittivity, ε, refers to the degree to which a geological medium resists the flow of electrical charge divided by the degree to which free spaces resists the same charge. The dielectric permittivity is thus defined as the ratio of the electric displacement to the electric field strength and is an important quantity for GPR. Most often, the terms *relative permittivity* or *dielectric constant* are used, which may be defined as the ratio of $\varepsilon/\varepsilon_0$, where ε_0 is the permittivity of a vacuum. The velocity of an EM wave propagating through a medium is the reciprocal of the square root of the dielectric permittivity.

Magnetic permeability, μ, is the result of electron spin and motion in atomic orbits and also results in energy loss and storage. In most GPR applications, the effect of magnetic permeability is negligible and is often excluded from calculations.

GPR is most effective in environments with low electrical loss media. If the media through which GPR is imaging had $\sigma = 0$, the radar system would be able to image great depths, limited only by the power of the radar transmitter and the sensitivity of the receiver. However, neither geological material nor manmade media are perfect insulators, and their semiconductive nature is highly variable and often unpredictable.

One of the greatest determinant factors of the GPR range in most media is the concentration of both pore and bound water. Generally, bulk minerals are good GPR targets with low pore water content and thus exhibit low dielectric permittivities. Conversely, sands and soils have pore spaces filled with air, water, and other minerals. Furthermore, the water within the pores can often contain ions from dissolved minerals, with the ionic mobility within the water being the dominant contributor to bulk electrical conductivity.

A number of factors control the maximum range of a radar system. As a radar wave field encounters a discontinuity in impedance, a portion of the energy is returned, while the remainder continues on to greater depths. In an environment with a large number of impedance changes with depth, there is a decrease in the portion of the original imparted energy that is still available to continue deeper. Since the radar energy path is generally two-way, these losses, known as reflection losses, are doubled due to the return journey to the surface. Although this describes a simple layered model, the effects on penetration of which may be modeled easily, most GPR environments also include scattering effects from unwanted targets such as gravels and boulders. Scattering losses cause the incident radar energy to reflect in multiple directions, with only a portion aimed back toward the receiving antenna.

The electrical conductivity of the media being propagated through leads to material losses, which have a significant effect on the maximum range of a GPR system. With increasing conductivity, the radar energy is attenuated more quickly, thereby restricting the effective penetration depths.

The final common type of loss is due to the geometric spreading of the radar energy. Although generally difficult to quantify in real-world complex geologies, these losses are exponentially proportional to the range being imaged. The maximum range of a GPR system can be generally estimated by summing these losses along with the losses encountered within the instrument itself.

70.3 GPR Instrumentation

A generalized radar block diagram is shown in Figure 70.1. The transmitted energy may be a waveform modulated in frequency, amplitude, or phase, as well as random noise. The amount of power, the pulse rate, and the bandwidth will depend on the lossiness of the subsurface media and the target dimensions. The transmitting and receiving antennas are usually matched and are also designed with target dimensions and signal polarization taken into account, as well as practical size and weight limitations. The receiver must be designed to capture the returned signals quickly and at a sufficient dynamic range to overcome the losses encountered by the radar signals on their two-way journey from the surface to the target and back to the surface.

Of the possible modulation techniques, amplitude modulation, commonly referred to as impulse radar, is most commonly employed for GPR instrumentation. Presently, there are over a dozen manufacturers of commercial GPR systems worldwide, with all but two employing impulse transmitters. In such systems, a train of impulses are applied to a transmitting antenna. The impulse sequence may have amplitudes ranging from 20 to 400 V, a width of a few nanoseconds, and a pulse repetition frequency (PRF) in the range of 100–800 MHz. The signals returned from the ground are applied to a flash A/D converter or, more commonly, to a sequential-sampling receiver with a high-speed sample-and-hold circuit. The requirement for ultrafast sampling generally restricts impulse radars to the range of 10 MHz to 1 GHz.

For radar frequencies greater than 1 GHz, frequency-modulated continuous wave (FMCW) radar architectures become more suitable. Thus, such systems are generally employed for shallow,

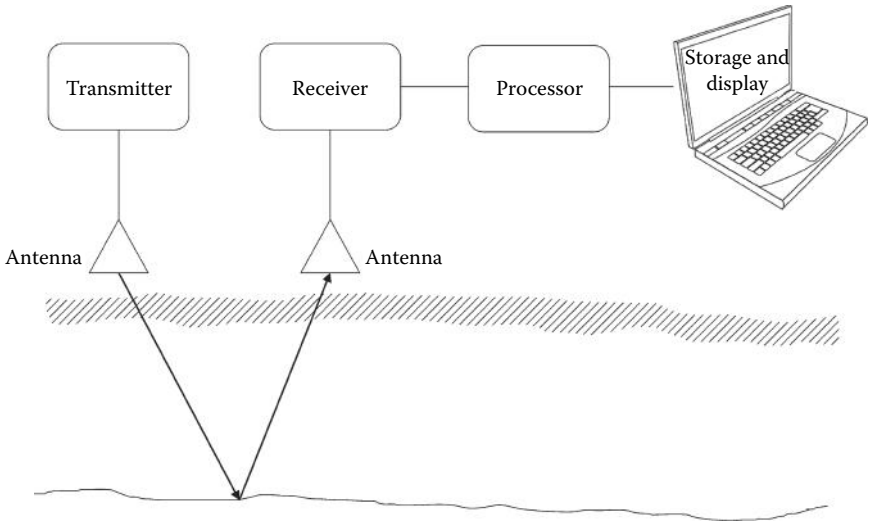

FIGURE 70.1 General radar block diagram.

high-resolution applications such as pavement analysis and landmine detection. In an FMCW system, a continuously changing carrier frequency is repeatedly transmitted using a voltage-controlled oscillator over a range of frequencies. The returned signal is combined with a sample of the original transmitted waveform, which produces a difference frequency related to the phase of the received signal and thereby a different time delay and range in relation to the target reflector. To produce a radar signal similar in the time domain, the difference frequency must be derived from an *I*/*Q* mixer pair (Daniels, 2004).

70.4 Commercial Radar Systems

As of 2012, it is estimated that there are between 10,000 and 20,000 GPR systems in existence worldwide. Although the majority of these are used on rare occasion for research purposes, many thousand systems are employed regularly for commercial surveys. The first commercial manufacturer of GPR systems, Geophysical Survey Systems, Inc., of Salem, NH, United States (www.geophysical.com), remains the world leader in terms of sales volumes, followed closely by Sensors and Software, Inc., of Mississauga, ON, Canada (www.sensoft.ca), and Malå Geosience of Malå, Sweden (www.malags.se). In addition, over the last decade, Ingegneria dei Sistemi SpA of Pisa, Italy, has become known for their multichannel GPR systems. More recently, researchers from the former Eastern Bloc countries and from China and South Korea have also begun to commercialize GPR systems.

Each of these manufacturers tends to focus on the lucrative civil infrastructure market, which includes rebar detection in concrete, road, and railbed analysis, utility mapping, and void identification. Although the instrumentation is packaged differently and the robustness and flexibility of the design vary greatly, all systems generally employ impulse transmitters with shielded bowtie antennas and sequential-sampling receivers. Figure 70.2 shows a typical commercial cart-mounted GPR system employed for utilities detection.

For low-frequency radar applications (10–200 MHz), manufacturers rely on resistively loaded dipoles for the transmitter and receiver antennas, as depicted in Figure 70.3. Such antennas can be unwieldy in difficult terrain, such as in forests, where cut lines up to 4 m wide are required. Alternatively, dipole antennas may be placed collinearly, allowing the radar system to be housed within a long "snake" and towed easily along a trail. The Malå Geoscience's RTA system and the UltraGPR from Groundradar, Inc., in Vancouver, Canada (www.groundradar.com), both employ such a design with real-time radar receivers for long-range imaging of mineral deposits (Figure 70.4). Such a collinear orientation of

FIGURE 70.2 Typical cart-mounted utility-detection GPR.

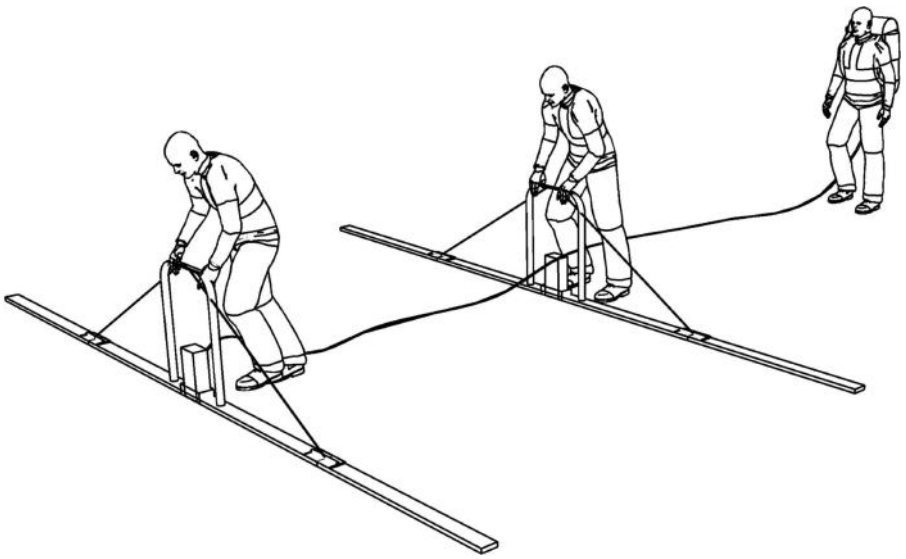

FIGURE 70.3 Low-frequency dipole antennas.

radar antennas often produces clutter patterns on the received radar profiles due to the end fire from the antennas reflecting off of aboveground targets such as trees.

In recent years, the availability of large array radar systems for 3D mapping of wide swaths has grown significantly (Figure 70.5). One of the pioneers in the field, 3D-Radar AS of Trondheim, Norway (www.3d-radar.com), has commercialized large radar arrays for pavement and utility mapping using FMCW radar architecture. Radar Portal, Pty., of Brisbane, Australia (www.radarportal.com.au), specializes in integrating large radar arrays using noise-modulated FMCW radars with complementary sensors such a high-speed falling weight deflectometers, panoptic cameras, and laser profilometers to comprehensively map road surfaces and structures at highway speeds.

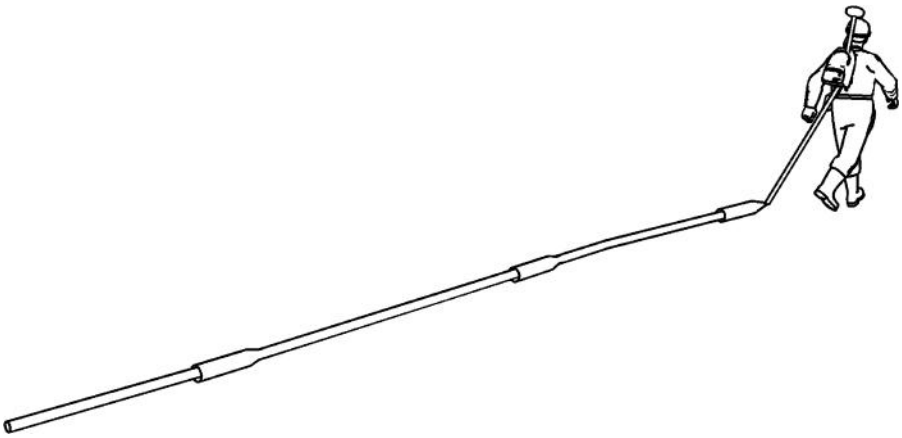

FIGURE 70.4 Low-frequency collinear towed dipole antennas.

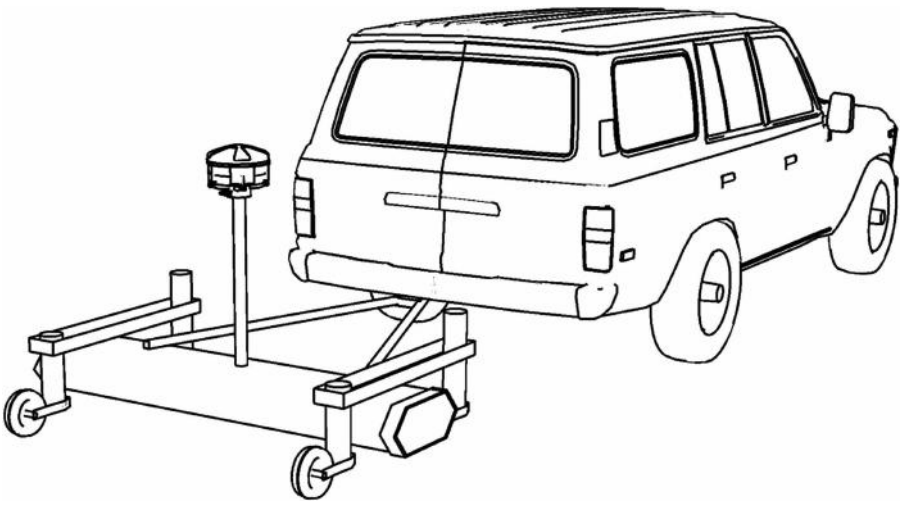

FIGURE 70.5 Array of GPR antennas for pavement and utility surveys.

70.5 Typical Commercial Applications

A review of GPR manufacturers' websites would suggest that GPR is a panacea to all near-surface imaging problems. What are often neglected or downplayed are the inherent limitations of GPR in many, if not most, environments. These limitations are governed by the laws of physics, and no degree of advanced radar design, virtual-reality 3D software, or high instrument price can circumvent them. Listed in the following text are the most common applications for GPR technology for commercial surveying. A myriad of other applications are possible, ranging from tree root imaging and the detection of wood rot and landmine detection.

70.5.1 Utilities Detection

Perhaps the first substantial commercial application of GPR technology was the mapping of buried utilities. With many urban areas, "as-planned" maps are often unrelated to "as-is" conditions underground. The severing of a sewer or natural gas line can have disastrous consequences. Traditional methods such

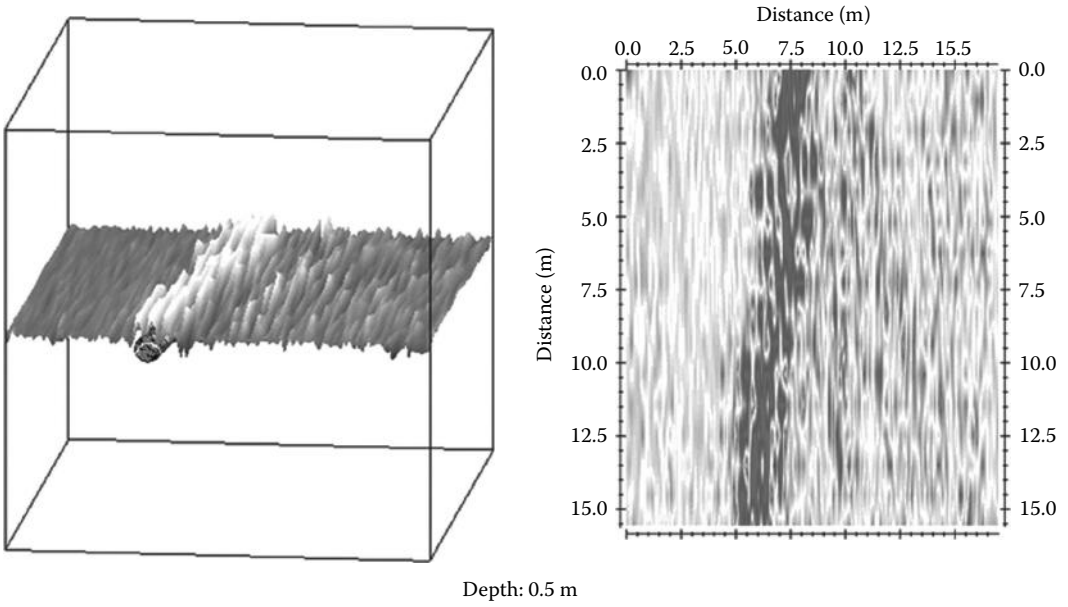

FIGURE 70.6 3D and plan view representation of radar-detected pipe. (Courtesy of Malå Geoscience.)

as radiodetection can yield ambiguous depths or inaccurate results in clustered pipes. While disruptive trenching has given way to trenchless technology such as horizontal directional drilling, which enables far more rapid installations in urban settings, engineers still rely on a degree of chance to avoid collateral damage to preexisting plants. As existing plants age and cities expand, the need for a tool to rapidly and accurately map existing utilities has become critical.

Although seemingly an ideal solution, particularly for metal pipes and cables, GPR suffers from some limitations. The most common is due to signal attenuation in the subsurface. Many cities built along floodplains or in coastal zones are situated atop clay units, which significantly restrict radar suitability to as shallow as a few decimeters. It has been estimated that in the United Kingdom, only 60%–70% of the total land area may be suitable for GPR surveying (Daniels, 2004). A further limitation is that in a situation where radiodetection is ambiguous and GPR is most useful, such as clusters of pipes and cables, radar is generally ineffective without extreme care in sensor positioning and complete high-density 3D imaging by surveying the region in perpendicular directions. Such surveys are time-consuming with single antennas, often require positioning accuracies not practical in urban settings, and generally still produce data volumes subject to ambiguous interpretations.

Nevertheless, a significant portion of the commercial GPR market is aimed at utilities detection. In many environments, such as parking lots and open fields with uncluttered pipe layouts, GPR can be a highly effective tool at mapping utilities. Figure 70.6 shows a typical radar cross section of a series of utilities, each shown a characteristic hyperbolic reflection signature.

70.5.2 Pavement and Railbed Analysis

Traditionally, the health of a road or highway has been measured using methods such as falling weight deflectometers to determine dynamic moduli and coring to measure the thickness of various construction layers. Together with other sensors such as surface roughness, profilometers, and data on traffic flow, estimates of the residual life of the road can be determined. These approaches are time-consuming and costly and also interrupt traffic flow during surveys. Furthermore, coring disturbs the road surface and provides information only at disparate points.

This was one of the first commercial applications for GPR, as radar can be used to determine the thickness of asphalt layers and concrete slabs, the spacing and location of slab reinforcement, their depth of cover, dowel bars, joining slabs, and cracking. Compared to traditional methods, GPR can provide continuous coverage at a fraction of the cost (Noureldin et al., 2003). Modern systems operate at highway speeds, eliminating the disruption of traffic flow (Maser, 2001). Although depth measurements generally have a 90%–95% accuracy rate, variations in radar velocity due to differing moisture contents both across a lane and along a stretch of road can lead to inaccuracies in layer depths (Saarenketo, 1997). In addition, the construction layers of the roadbed must have sufficient variation in impedance to create radar reflections.

A similar application of radar in the area of transport infrastructure is the rapid surveying of rail ballast conditions. GPR is regularly used on railway tracks to provide continuous measurements of the track substructure to assist in maintenance decision making. The track substructure consists of the ballast, the subballast, and subgrade layers, each having a significant influence on track performance. Designed to facilitate water drainage and distribute load, a deterioration of these layers or an accumulation of moisture forces trains to slow down or, at worst, can cause derailments. A significant portion of operating expenses for a rail company is the correction of rough track caused by shifting or mixing of these layers under repeated heavy loads. Standard monitoring methods include trenching, cone penetrometer tests, and core drilling, all of which cause traffic delays and further disrupt the integrity of the layers.

GPR has been applied to provide a continuous profile of the track substructure to characterize layer thicknesses and degree of mixing as well as accumulations of moisture (Al-Nuaimy, 2004a; Gallagher et al., 1999). Often employing radar antennas in a range of 800 MHz to 1.5 GHz, there is generally sufficient variation in the impedance between the substructure layers to produce radar reflections. While layer thicknesses can be mapped by tracking these reflections, the amplitude of the reflections can provide some indication of variations in moisture content (Olhoeft and Selig, 2002). In regions where water is trapped in the substructure, the higher dielectric contrast produces stronger radar reflections. The texture of the radar data can also be analyzed to produce a relative indication on the coarseness of the ballast.

Antennas may be either ground coupled or air coupled. Ground-coupled antennas on roads are designed to handle rough road conditions, whereas such antennas on railbeds must be able to cope with frequent obstructions higher than the sleepers (Figure 70.9). High-frequency air-coupled horn antennas have been used for both road and rail applications (Selig et al., 2008). Often, an array of antennas is used to provide maximum coverage across a lane or railbed (Al-Nuaimy, 2004b).

70.5.3 Concrete and NDT

The advent of high sampling rate A/D converters for high-frequency radar receivers and the further miniaturization of electronics have led to the proliferation of relatively low-cost concrete radar systems. Radar now forms an important role in the nondestructive testing (NDT) of in situ concrete. In many jurisdictions, standard practices for GPR use in concrete NDT have been published (American Concrete Institute, 1998; Concrete Society, 1997; Texas Transportation Institute, 2001). Products such as the Hilti PS 1000 X-Scan (www.hilti.com) have moved concrete GPR from the exclusive realm of geophysics to a consumer product on par with inspection cameras. The acquisition of accurate 3D grids for rebar mapping is now a trivial task using adhesive templates (Figure 70.7). Applications for these systems include the location of rebar and posttensioning cables as well as metal and plastic conduits and voids, with the former being the most common. The optimization of antenna orientation to maximize the effect of signal polarization is important for both the imaging of rebar and for attempting to image through them to deeper targets (Annan et al., 2002).

Recent research in this field has focused on determining the size and shape of voids (Pollock et al., 2008), the location of honeycombing and cracking (Beutel et al., 2008), and the estimation of rebar size and corrosion (Lai et al., 2010). Each of these subjects has been studied extensively through numerical modeling and laboratory measurements, although practical applications have remained elusive.

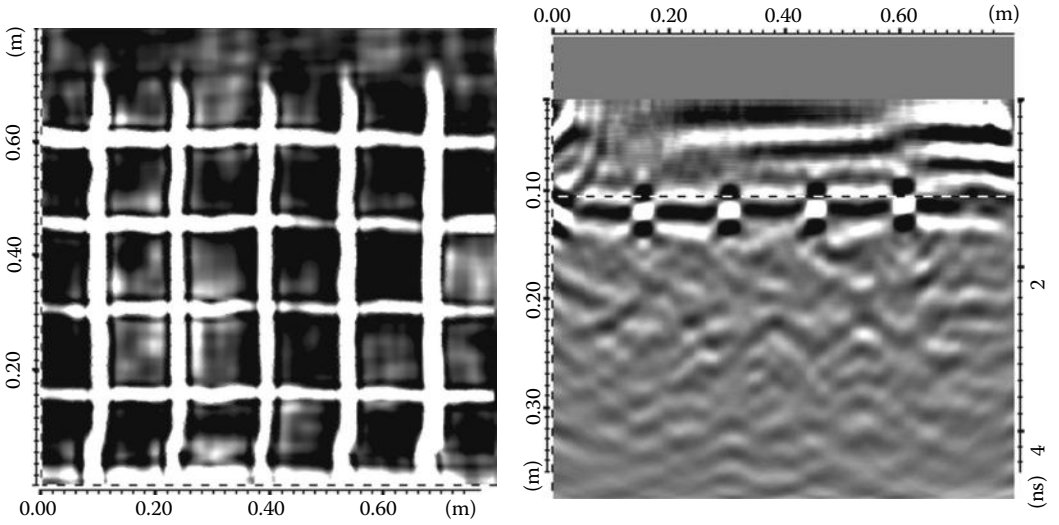

FIGURE 70.7 Plan view and radar cross section of rebar in concrete. (Courtesy of Malå Geoscience.)

70.5.4 Snow and Ice

The original applications of GPR, snow and ice, provide the ideal environment for radar penetration. Extremely low conductivity, low dielectric permittivity, and no magnetic relaxation processes combine to permit penetration to many kilometers. Spurred by an interest in climate change, ground-based, as well as increasingly airborne, GPR surveys are being regularly conducted by researchers over glaciers with impressive results (Arcone, 1996; Arcone et al., 2000; Maijala at al., 1998). Such data are of use in the examination of ice structures and paleoclimatic studies.

Common commercial applications include the delineation of ice thickness for ice roads and runways as well as the creation of snow thickness maps on ski slopes. Recent discoveries of major oil and diamond resources in the Arctic have created the need for an extensive network of seasonal ice roads and runways. Ice thickness is traditionally controlled by manual auger coring, a process that is both slow and inherently inferential due to practical limitations on hole spacing. Furthermore, as weather conditions change, it is critical the ice roads and runways be monitored regularly in order to ensure that minimum ice thicknesses are maintained. High-frequency antennas (500 MHz–1 GHz) are often used for this application. Water lenses in the ice may cause significant distortion in the radar profiles or inhibit further radar penetration altogether (Galley et al., 2009). The ideal radar velocity of ice is approximately 0.17 m/ns, while water has a velocity of 0.03 m/ns. Not compensating for this significant variation in velocity will lead to inaccurate depth maps.

Recent developments have included the use of multichannel radar systems designed for roadbed surveys to automatically collect radar velocity information. While allowing for more precise ice depth maps, the dielectric permittivity variations, calculated from the radar velocities, may also yield information on the load-bearing characteristics of the ice (Proskin et al., 2011).

GPR is now a common tool used for monitoring snow depth at ski resorts (Heilig, 2008). The optimal distribution of natural snow and the creation of manmade snow are reliant on accurate and dense snow depth data, which have been traditionally measured by probing. GPR systems fitted with GPS can be easily mounted on hand-towed sleds to rapidly provide snow maps with 3D depth. When mounted on groomers, GPR can provide a real-time display of snow thickness, allowing the operator to redistribute the snow evenly over a run. Such radar systems eliminate the need for an expert interpretation of a GPR profile by automatically interpreting the depth of snow and storing only these depths and GPS locations for subsequent mapping.

70.5.5 Archaeology and Forensics

Archaeologists were among the first to realize the potential benefits of the rapid subsurface imaging that GPR made possible in the 1970s. Early surveys were conducted to search for buried foundations and stone walls (Bevan and Kenyon, 1975). In addition, extensive surveys were conducted during the 1980s in Japan for burial mounds and ancient pit dwellings (Imai et al., 1987).

Although hundreds of successful surveys have been performed and the technique has been well established as a viable tool for both archaeology and forensics, these surveys are often conducted by untrained users in environments unsuitable for GPR. As the intended targets for such GPR investigations are often discrete objects buried among other radar reflections from geological features, the results of a "radar search" often produce ambiguous anomalies. Prior to the ability to integrate high-precision GPS positioning to track the radar antennas, surveys only relied on widely spaced 2D cross sections to map targets. Modern GPR systems with integrated RTK-DGPS allow the user to traverse a search site rapidly in a random semigrid pattern, often with lines spaced decimeters apart (Nuzzo, 2002). These data may then be input into a gridding algorithm to produce a 3D voxel cube, which may subsequently be sliced both vertically and horizontally to discriminate a potential investigation dig site from background clutter.

Regardless of these advancements in the 3D visualization of archaeological GPR data, the inherent ambiguity of the technique in all but the most ideal environments suggests that GPR is best considered in tandem with another sensing tool such as magnetics and/or EMs.

70.5.6 Tunnel Detection

Concurrent with the development of radar for lunar exploration and monitoring nuclear test explosions, the US military experimented with early radar systems to detect tunnels beneath the DMZ along the 38th parallel (Kim and Ra, 1993). Tunnel detection, whether for security or geotechnical applications, has always been an important application of GPR.

While manufacturers often display images of clear radar profiles across large highway tunnels through solid bedrock, the most practical applications for tunnel detection are situated in areas of significant subsurface and aboveground clutter and involve relatively small tunnels at significant depths. Research on the use of GPR to monitor tunneling beneath sensitive borders such as the US–Mexico frontier and the West Bank and the Gaza Strip has yielded moderate results due to the generally conductive nature of the soils in these locations (Cechak, 2007; Mahrer and List, 1995). Furthermore, due to the ambiguous nature of radar targets, security personnel are often reluctant to rely solely on the technique due to the costly implications of false anomalies (Pappalardo, 2009).

Similarly, in the geotechnical community, GPR has found mixed success at locating abandoned mine workings (Duff, 1983; Fenner, 1995; Leggo and Leech, 1983). Perhaps the most crucial need for the remote sensing of tunnels is that of abandoned coal mines. Often, urbanization has encroached on historical mining areas, raising the risk of ground subsidence or collapse. Such applications generally require shielded antennas to minimize the effects of interference from aboveground reflectors and other EM signal sources. Due to size limitations, the lowest frequency shielded antenna commercially available is 100 MHz, which restricts the practical search depths to less than 8 m in most environments. Recently, a partially shielded 40 MHz system has become commercially available for tunnel detection (Francke, 2012).

70.5.7 Sedimentary Geology

Geologists have long employed radar imaging to past depositional environments and the nature of sedimentary processes in a variety of settings, particularly in describing unconsolidated recent and Quaternary fluvial deposits both above and below the water table. Numerous studies dating to the early 1990s provide excellent examples of fluvial stratiforms (Jol and Smith, 1991, 1992; Vandenberghe and van Overmeeren, 1999).

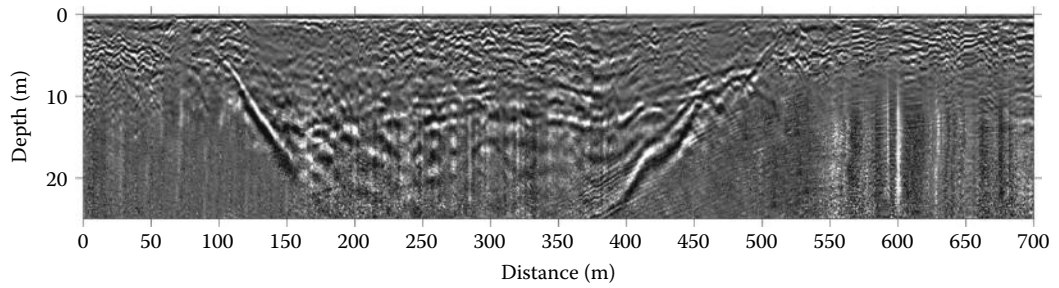

FIGURE 70.8 GPR cross section of a paleochannel in Brazil.

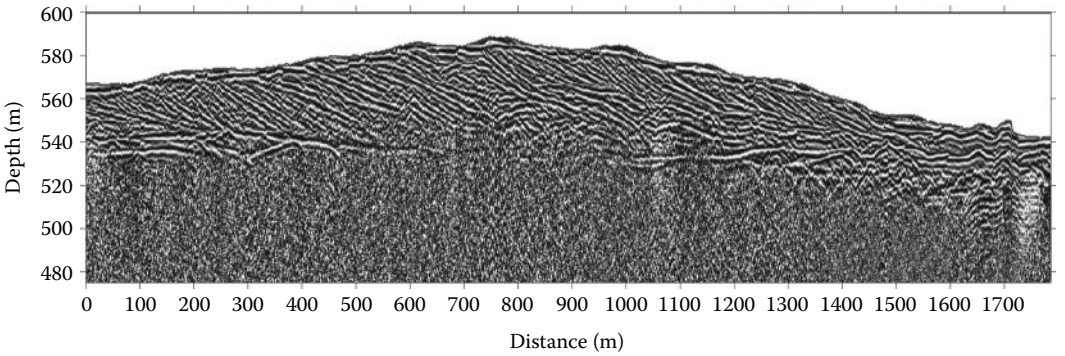

FIGURE 70.9 GPR profile through a Saharan sand dune in Libya.

An associated commercial application of sedimentary geology studies is the mapping of paleochannels for alluvial gold and diamond exploration. A complete understanding of the paleofluvial environment is critical to resource exploration and project economics. Exploration is normally conducted using drill holes and trenching, with seismic or EM geophysical surveying occasionally employed. GPR is increasingly being trialled in suitable environments where the in-filled sediments consist of course-grained sands and gravels in order to map the ore-rich basal gravels. Figure 70.8 shows an example of a radar-imaged paleochannel from an alluvial project in Guyana.

Given the low electrical conductivity and dry nature of the environment, desert sand dunes are often ideal radar settings. Studies of the internal structure of dunes are useful for studying desertification and climate change processes as well as for constructing petroleum reservoir analogies. While studies of sand dunes with GPR have been conducted over the last two decades (Bristow and Jol, 2003; Bristow et al., 1996, 2000), recent advances in rapid long-range radar have enabled the deep profiling and 3D surveying of sand dunes (Tatum and Francke, 2012). The example shown in Figure 70.9 demonstrates the suitability of radar in mapping the complex sedimentary bedding features of large duneforms.

70.5.8 Tropical Weathering Environments

One of the most common applications for GPR technology in mineral exploration is in tropical weathering environments with residual enrichments of either nickel (nickel laterites) or aluminum oxide (bauxites) (Francke, 2012). Both environments pose particularly challenging problems for traditional resource definitions that use drill holes alone, due to the extreme lateral variability in weathering thicknesses. Radar penetration depths of up to 70 m have been recorded in these weathering environments, with many tropical types of clay exhibiting unexpectedly low electrical resistivities. Although the clay-rich limonite and saprolite contain high bound water and thus are characterized by relatively slow radar

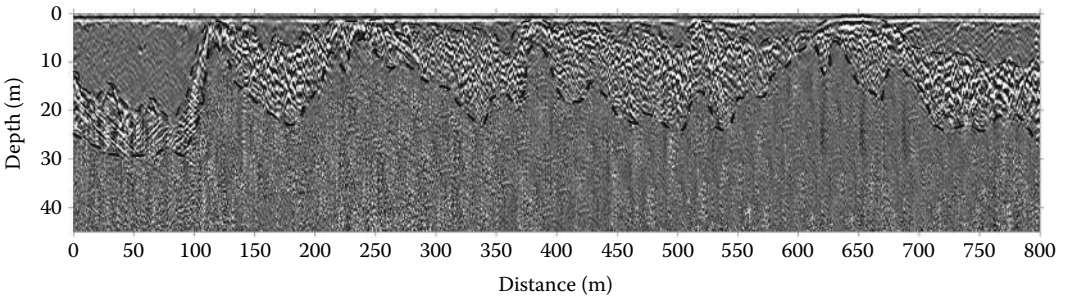

FIGURE 70.10 GPR profile of a lateritic weathering sequence in Indonesia, with dashed lines indicating the top of saprolite (upper line) and bedrock (lower line).

velocities, the lateritization process, with its repeated seasonal groundwater fluctuation, effectively leaches most of the conductive mineralogy from the profile.

The primary objective of nickel laterite and bauxite exploration is the mapping of the contact between weathered materials with the underlying bedrock, which commonly defines the limit of mining. Radar reflections from this interface are due to the dramatic change in water saturation between the moist weathered zone and the dry solid parent rock beneath. Similarly, the boundary between weathered soil and the interstitial rocky saprolite is well imaged with radar as a region of superimposed hyperbolic reflections. Figure 70.10 shows an example of GPR data acquired over a nickel laterite deposit.

In some lateritic bauxite deposits, particular challenges are faced due to the thin ore zone and the undulating nature of the underlying ferricrete. Seasonal fluctuations in the water table result in regions of diffuse bauxite to ironstone transitional zones, whereas a static water table produces a more abrupt transition. Resource exploitation consists of a large earth-moving operation, wherein the avoidance of bauxite ore contamination by the silica in the underlying ferricrete is critical while still maximizing the tonnage of extracted bauxite. GPR has been used to accurately map the depth of bauxite and the texture of the underlying horizon with high accuracy, with the intention of eventually using a GPR-generated digital surface model to form a "mine to" surface for semiautomated excavators (Francke and Yelf, 2003).

70.6 Future Advancements in GPR

70.6.1 Depth Range

With the ongoing development of faster processors and A/D converters, the future of long-range radar is seemingly limitless. However, both the laws of physics and practical limitations will significantly inhibit deeper radar systems in the future. In the realm of impulse radars, to double the penetration of an existing GPR transmitter in a given geological environment, an increase of 30 dB in system performance would be required, which in turn requires an increase in peak transmitter voltage of 1000 times. Generating hundreds of kilovolts in a portable instrument is not practical. Furthermore, the PRF of the transmitter would need to be lowered substantially to avoid saturation of the components.

An alternative approach to increasing penetration in environments where the radar range is limited by the noise floor is through stacking or averaging of radar signals at colocated positions, thereby increasing the signal-to-noise ratio. Stacking 1000 times would theoretically double the penetration over a single-stack system. The sequential sampling used in most radar systems limits the practical number of stacks to approximately 32. Technologies such as UltraGPR employ real-time sampling to effectively stack 32,000 times in the same amount of time that it takes a sequentially sampled system to stack 32 times. In addition, the latest GPR systems employ completely wireless designs and use PDAs or mobile phones as data acquisition computers.

Even further depth penetration may be achieved by using pulse compression techniques, which refer to the wave-shaping process that is produced as a propagating waveform is modified by the properties

of the transmission system (Utsi, 2007). Pulse compression combines the high energy of a long pulse width with the high resolution of a short pulse width. Since each part of the pulse has a unique frequency, the resultant returns can be completely separated. A GPR system developed for extreme penetration in suitable radar environments using pulse compression has imaged to 200 m through Libyan sand dunes. This penetration through dunes demonstrates the possible applicability of radar techniques to seismic static correction problems in deserts. A thorough understanding of the variations in the shallow low seismic velocity (LVL) zones in these environments is critical for seismic processing. Accepted approaches of up-hole surveys and drilling are costly and time-consuming and provide only point data over a large concession. GPR is showing promise of being able to penetrate to sufficient depths to image the base of the LVL.

70.6.2 Rapid 3D Surveys

The proliferation of multichannel array radar systems over the past 5 years foretells the future of GPR surveying for shallow civil infrastructure surveys through the use of instruments that can survey wide swaths of ground at once and often at high speeds. These systems are linked to RTK-DGPS or robotic theodolites to provide accurate positions for each of the antennas. The latest radar processing software, Reflex (www.sandmeier-geo.de) and GPR-Slice (www.gpr-survey.com), are capable of importing and manipulating these large data volumes to visualize buried targets. However, such systems are an order of magnitude more costly than single-channel radar units, suggesting that most future GPR surveys will be conducted by large companies capable of the required capital investment.

70.7 Conclusion

Four decades after commercialization, GPR has gained acceptance as a mature geophysical method. While the rapid growth in the number of manufacturers has yet to lower equipment prices, the increased competition in commercial systems appears to have split the market into two approaches to instrumentation. Systems intended for small-scale utilities detection, pavement studies, and concrete NDT are no longer designed as high-level geophysical instrumentation but as standard job site tools to be used by untrained workers. Conversely, large-scale surveys conducted by multichannel radar arrays and long-range GPR systems designed for mineral exploration have become increasingly expensive and complex, relegating their use to the largest and most experienced service providers. This bifurcation of the radar instrumentation market is likely to continue for the foreseeable future, with more manufacturers being spun off from university research laboratories. Eventually, competition should drive down the cost of single-channel units.

Although new uses for GPR appear in the literature each year, they are generally ancillary to those that have been well established over the past decades. What appears to be the future is the incorporation of GPR as a complementary tool in a suite of sensors, such as those used for roadbed analysis. EM sensors, magnetometers, precision positioning and guidance sensors, and LIDAR (light detection and ranging) all have applicability when fused with subsurface radar for use in many different scenarios.

Airborne Radiometers to Measure Electromagnetic Radiation in the Earth's Atmosphere: Mature and Emerging Technologies

Manfred Wendisch
University of Leipzig

71.1 Introduction

71.1.1 Importance of Airborne Measurements of Electromagnetic Radiation in the Atmosphere

Electromagnetic (EM) radiation is important for many atmospheric and oceanic processes. The solar radiative energy reaching the top of atmosphere (TOA) is the major source of energy feeding weather and climate phenomena on Earth (Sellers, 1965). All biological life depends on the energy provided by solar radiation. Almost every motion of air in the atmosphere or of water in the oceans and numerous chemical processes within the atmosphere are powered by solar radiative energy. If the Sun would hypothetically be switched off, then plants would die within several weeks, and animals would lose food and would die shortly after plants have disappeared. Within about one year, no more higher life would be possible on Earth, and ice and snow would cover the continents. After roughly 15 years, the Earth would be a snowball.

Within the atmosphere and at the Earth's surface, solar radiation is scattered (redistributed in direction) and absorbed (transformed into other forms of energy, mainly heat or chemical energy). As a result of absorption, the temperatures of the atmospheric components (gases, aerosol particles, clouds) and the Earth's surface rise.

Earth's terrestrial radiation is emitted corresponding to the atmospheric and Earth's surface temperatures and respective emissivities. The radiation emitted by the Earth's surface is partly reabsorbed and reemitted by the atmospheric components whereby the atmospheric reemission takes place at mostly lower temperatures compared to the Earth's surface temperature, which causes the atmospheric greenhouse effect; a phenomenon of fundamental importance for life on Earth.

Globally and averaged over long time periods, the climate system is in energetic equilibrium (balanced net radiation, i.e., downward minus upward radiative energy at TOA equals zero) (see Trenberth and Fasullo, 2012). However, on a local and short time scale, there is no such energetic equilibrium. As a result, thermal meridional gradients develop, which are causing compensating dynamic processes, such as atmospheric air motions or oceanic water circulations in the vertical or horizontal directions, thermodynamic processes like evaporation or condensation initiating clouds and precipitation, and chemical reactions. Thus, all processes modifying solar and terrestrial radiation within the atmosphere and at the Earth's surface are crucial for the energy budget of the global climate systems. For this purpose, airborne measurements of atmospheric EM radiation are of highest importance.

Additionally, airborne observations of EM radiation are fundamental to develop, test, and apply remote sensing techniques to retrieve atmospheric and Earth's surface properties. In order to characterize the global climate system, satellites comprise an essential tool of observations. All satellite techniques are based on measuring radiative energy in different wavelength ranges. Therefore, the transfer of atmospheric radiative energy through the atmosphere and its interactions with the Earth's surface needs to be measured by airborne techniques and modeled by radiative transfer simulations in order to interpret the radiation data received by the satellite instruments.

71.1.2 Quantitative Description of Electromagnetic Radiation

The following definitions of quantities to describe the atmospheric radiation field follow Wendisch and Yang (2012) and Wendisch et al. (2013).

71.1.2.1 Angular Coordinates

In order to describe direction, spherical polar coordinates are applied. The zenith angle θ represents the planar angle from local vertical; it is measured in units of radian (rad) or degrees (°). Overhead means $\theta = 0$ rad or 0° (zenith direction), and the horizon corresponds to $\theta = \pi/2$ rad or 90°. $\theta = \pi$ rad or 180° denotes the nadir direction. Often instead of the zenith angle, the quantity $\mu = \cos\theta$ is used. The azimuth angle φ measures the horizontal angle in units of rad or °. φ is counted counterclockwise from a reference point such that 0 rad < ϕ < 2π rad. Often, the projection of the direction of the Sun with respect to the horizontal plane is defined as reference. For the direction of the Sun, the subscript "0" is applied.

Furthermore, the solid angle Ω is introduced, which is something like "square degrees" and carries the unit of "steradian" (sr). If an observer is situated at the center of a sphere of unit radius, then the total surface area of the sphere is 4π square radius units. Thus, the total solid angle is defined as 4π sr. The surface area of one-half of the sphere is 2π square radius units; the angle is 2π sr. This holds for the upper and lower hemispheres separately. For the assumed unit sphere with radius of 1 m, the solid angle of 1 sr is bordered by a surface of 1 m^2 on the unit sphere. The incremental solid angle dΩ is defined by:

$$\mathrm{d}\Omega := \sin\theta\,\mathrm{d}\theta\,\mathrm{d}\varphi = \mathrm{d}\mu\;\mathrm{d}\varphi = \frac{\mathrm{d}A}{a^2}, \tag{71.1}$$

with dA the enclosed area on the surface of the sphere with radius a. Integration over all directions yields 4π sr:

$$\iint_{4\pi}\mathrm{d}\Omega = \int_0^{2\pi}\int_0^{\pi}\sin\theta\,\mathrm{d}\theta\,\mathrm{d}\varphi = 2\pi\ \mathrm{rad}\int_0^{\pi}\sin\theta\,\mathrm{d}\theta = 4\pi\,\mathrm{sr}. \tag{71.2}$$

71.1.2.2 Vertical Coordinate: Optical Depth

We define the vertical spectral optical depth $\tau(\lambda, z)$ at the given wavelength λ as a transformed vertical coordinate:

$$\tau(\lambda, z) = \int_{z}^{z_{\mathrm{TOA}}} b_{\mathrm{ext}}(\lambda, z')\,\mathrm{d}z'. \tag{71.3}$$

The volume extinction coefficient, $b_{\mathrm{ext}}(\lambda, z)$, quantifies the extinction (sum of absorption and scattering) by atmospheric constituents (gases, aerosol particles, clouds), see Wendisch and Yang (2012). If τ is used to characterize the extinction properties of a layer, it is called the optical thickness instead of depth.

71.1.2.3 Radiant Energy Quantities

The radiant energy E_{rad} in units of Joule (J) is the basic quantity to describe the EM radiation field in the atmosphere. It can be measured using first principles. From the differential radiant energy E_{rad} per time increment $\mathrm{d}t$, the radiant energy flux (or radiant power) ϕ in units of Watt (W) is derived:

$$\phi(\tau) = \frac{\mathrm{d}E_{\mathrm{rad}}}{\mathrm{d}t} \tag{71.4}$$

The radiant energy flux density F (often wrongly quoted as flux) in units of W m^{-2} is given by the incremental radiant flux $\mathrm{d}\phi$ per incremental area element $\mathrm{d}A$ (with no preferred orientation):

$$F(\tau) = \frac{\mathrm{d}\phi}{\mathrm{d}A} = \frac{\mathrm{d}E_{\mathrm{rad}}}{\mathrm{d}t\,\mathrm{d}A}. \tag{71.5}$$

F is a measure of total radiant flux per unit area transported by EM radiation through or deposited on a planar surface A. Finally, the radiance I in units of W m^{-2} sr^{-1} is defined as:

$$I(\tau,\theta,\varphi) = \frac{\mathrm{d}\phi}{\mathrm{d}A\,\mathrm{d}\Omega} = \frac{\mathrm{d}\phi}{\cos\theta\ \mathrm{d}A\,\mathrm{d}\Omega} = \frac{1}{\cos\theta}\frac{\mathrm{d}F}{\mathrm{d}\Omega}, \tag{71.6}$$

with $\mathrm{d}A_{\perp}$ the differential area oriented perpendicularly to the direction of propagation of the EM radiation. The integration of Equation 71.6 over the hemisphere yields the relationship between irradiance and radiance:

$$F(\tau) = \int_{2\pi} I(\tau,\theta,\varphi)\cdot\cos\theta\,\mathrm{d}\Omega. \tag{71.7}$$

In atmospheric applications, the reference unit area is usually defined as horizontal. Therefore, upward $F^{\uparrow}$ and downward $F^{\downarrow}$ irradiances are obtained from radiance I by applying Equations 71.7 and 71.1:

$$F^{\uparrow}(\tau) = \int_{0}^{2\pi}\int_{0}^{\pi/2} I(\tau,\theta,\varphi)\cdot\cos\theta\sin\theta\,\mathrm{d}\theta\ \mathrm{d}\varphi, \tag{71.8}$$

and

$$F^{\downarrow}(\tau) = \int_{0}^{2\pi}\int_{\pi}^{\pi/2} I(\tau,\theta,\varphi)\cdot\cos\theta\sin\theta\,\mathrm{d}\theta\ \mathrm{d}\varphi, \tag{71.9}$$

The dimensionless albedo α is the ratio of upward to downward irradiance:

$$\alpha(\tau) = \frac{F^{\uparrow}}{F^{\downarrow}}. \tag{71.10}$$

Actinic flux density F_{act}, sometimes called average intensity, is the integral of radiance over solid angle:

$$F_{act}(\tau) = \int_0^{2\pi}\int_0^{\pi} I(\tau,\theta,\varphi)\cdot\sin\theta\,\mathrm{d}\theta\;\mathrm{d}\varphi. \tag{71.11}$$

Like irradiance, actinic flux density has units of W m^{-2}. It represents the energy flux on a unit sphere, normalized by the cross section of the sphere, and therefore is related to flux divergence.

Irradiance (F), radiance (I), and actinic flux density (F_{act}) can be either spectral or band-integrated (broadband) quantities. For example, the spectral flux density F_λ is the irradiance per unit wavelength interval indicated by the subscript λ (λ itself is the symbol for wavelength). As a result, the units of a spectral radiant energy quantity contain an additional term nm^{-1}. The band-integrated flux density $F(\lambda_1, \lambda_2)$ includes radiant energy contributions from wavelengths within an interval (λ_1, λ_2). Here, we concentrate on spectral irradiance, radiance, and actinic flux density measurements from aircraft.

Irradiance and radiance may be divided into the contributions from scattering (diffuse) and direct transmission (direct) indicated by the subscripts "dif" and "dir," respectively (Wendisch et al., 2013). The sum of both corresponds to the total irradiance or radiance with the subscript "tot." For example, for the total irradiance, we obtain:

$$F_{tot} = F_{dir} + F_{dif}. \tag{71.12}$$

71.1.3 Solar and Terrestrial Spectra

The important spectral range for the application of airborne measurements of EM radiation in energy budget and remote sensing studies covers wavelengths between 0.3 and 100 μm. Generally, two subranges may be distinguished: The solar spectrum spans from 0.2 to 5 μm, and the terrestrial wavelength range covers wavelengths larger than 5 μm. The thermal infrared (IR) usually refers to wavelengths between 5 and 50 μm. Furthermore, the ultraviolet (UV, 10–370 nm wavelength) and microwave (MW, 0.3 mm–30 cm) spectral ranges are specified. The MW range corresponds to a frequency range of 1000–1 GHz. Frequency ν or wavenumber $\tilde{\nu}$ is sometimes used alternatively to wavelength λ. They are defined by:

$$\lambda = \frac{c}{\nu}. \tag{71.13}$$

With the speed of light in a vacuum, c is given by:

$$c = 2.997925\times10^{8}\ \mathrm{m\ s^{-1}}. \tag{71.14}$$

The wavenumber is defined as:

$$\tilde{\nu} = \frac{1}{\lambda}. \tag{71.15}$$

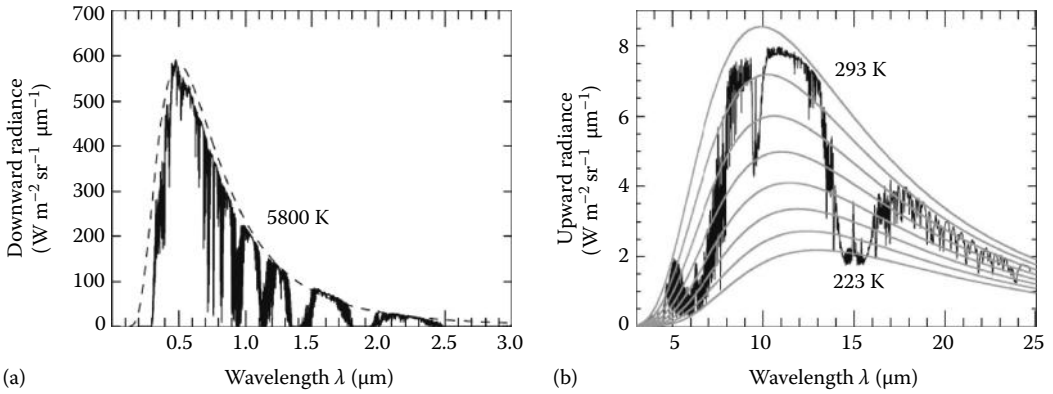

FIGURE 71.1 Black solid lines represent the spectral distribution of simulated solar downward radiances at the surface (a) and terrestrial upward radiances emitted at the TOA (b). "Tropical" profiles of atmospheric parameters have been applied from Anderson et al. (1986). The simulations were performed with MODTRAN4 (Version 3 Revision 1, MOD4v3r1) (see Berk et al. 1999), with the Sun in the zenith. The dashed line in (a) represents the Planck's function for 5800 K. The gray lines in (b) indicate Planck's functions for 293 K (upper curve) and 223 K (lower curve) in 10 K increments. (Partly adapted from Wendisch, M. and Yang, P.: *Theory of Atmospheric Radiative Transfer—A Comprehensive Introduction*. Weinheim, Germany. 2012. Copyright Wiley-VCH Verlag GmbH & Co. KGaA. Reprinted with permission.)

Figure 71.1 shows typical simulated spectra for major parts of the solar (Figure 71.1a) and the thermal IR (Figure 71.1b) spectral ranges. At the TOA, the extraterrestrial solar radiation can roughly be approximated by black-body radiation with a temperature of about 5800 K (see dashed line of Figure 71.1a). From the downward radiance reaching the ground (see the solid line of Figure 71.1a), it is obvious that the deeper the radiation penetrates into the atmosphere, the more radiation is absorbed by atmospheric gases such as ozone (O_3): <0.3 μm; oxygen (O_2): 0.76 μm; water vapor (H_2O): 0.72, 0.82, 0.94, 1.1, 1.38, 1.87, and 2.7 μm; and carbon dioxide (CO_2): 1.4, 2.0, and 2.7 μm.

The upward radiance at TOA is illustrated by the black solid line in Figure 71.1b. In selected wavelength regions, for example, the atmospheric window (8–12 μm), the upward thermal IR radiance emitted at the TOA can be approximated in most parts by black-body radiation corresponding to a temperature of about 293 K, similar to the Earth's surface temperature (see Figure 71.1b). Thus, the atmospheric window region can be used to retrieve Earth's surface parameters, for example, temperature, by remote sensing techniques. Several absorption/emission bands appear in the spectrum. For example, the wavelength of 15 μm is in the center of a strong CO_2 absorption band. Thus, the signal measured by a satellite sensor near 15 μm stems from the cold stratosphere and even higher altitudes. A narrow peak is observed in the spectra at 15 μm at the very center of the CO_2 absorption. This spike occurs where absorption (and emission) is by far the most intense of any wavelength in the thermal IR. Emission from this wavelength originates almost entirely from the relative warm stratopause. Keep in mind that the CO_2 is very well mixed in the atmosphere up to an altitude of 100 km. Further major absorption/emission bands in the TOA upward radiance correspond to carbon dioxide (CO_2): 4.3 and 15 μm; water vapor (H_2O): 6.3 μm; and ozone (O_3): 9.6 μm (within the atmospheric window).

71.2 Airborne Radiometers

In general, radiometers measure radiant energy E_{rad} directly or quantities derived from E_{rad}, such as radiance or irradiance. These are called radiometric quantities in the following text. A comprehensive overview of airborne radiometers including issues and future challenges is given in Chapter 7 of Wendisch and Brenguier (2013).

71.2.1 Instruments for Broadband Solar Radiation Measurements (Broadband Radiometers)

Instruments that measure broadband solar irradiance are often called pyranometers or broadband radiometers. Mostly, the total irradiance is measured with pyranometers; however, there are also versions that may separate direct and diffuse irradiance (Valero et al., 1989; Pilewskie and Valero, 1993). Examples of pyranometers widely used in airborne applications are those manufactured by Kipp & Zonen (http://www.kippzonen.com/) and Eppley (the Eppley Laboratory, Inc., http://www.eppleylab.com/). Here, we describe the pyranometer manufactured by Kipp & Zonen and the total ultraviolet radiometer (TUVR) from Eppley. Furthermore, pyroelectric radiometers are in use.

The pyranometer is the most common type of instrument to measure broadband solar irradiances from an aircraft, for example, Wendisch and Keil (1999). It has a circular multijunction thermopile of the plated (copper–constantan, hot and cold junction) wire wound type (Coulson, 1975). The sensitivity of the thermopile is in the range of 10 μV/(W m^{-2}); therefore, the signal needs electronic magnification in order to be logged. The temperature sensed by the detector is nearly linear with the flux density of incident radiation. The pyranometer manufactured by Kipp & Zonen is supplied with a pair of concentric hemispheres of Schott optical glass (see Figure 71.2). The inner dome is transparent to wavelengths in the range of 0.285–2.8 μm. The outer dome can be replaced by Schott glass hemispherical filters, which transmit within specified bandwidths. The outer dome is for mechanical protection of the inner dome. Furthermore, the air between the domes assures thermal insulation of the inner dome, which is then not heated by incoming solar radiation preventing emission due to solar heating. The response time of the pyranometer is in the range of 1 s. One of the advantages of the pyranometer is its mechanical robustness, which makes it well suited for airborne use. The largest problem of the pyranometer is the fact that temperature changes of the surrounding air also influence the housing and thus the temperature of the cold thermopile sensor. To mitigate this problem, thermocompensation is implemented in the pyranometer.

The Eppley TUVR measures broadband irradiance within the wavelength range from 0.295 to 0.385 μm (broadband UV) (see Wendisch et al., 1996; Wendisch and Keil, 1999). It utilizes a hermetically sealed selenium barrier-layer cell (photocell), which is protected by a quartz window. A specially designed Teflon diffuser reduces the radiant flux to acceptable levels and assures close adherence to the Lambert cosine law corresponding to Equation 71.7. An encapsulated narrow band-pass (interference) filter limits the spectral response of the photocell to the UV.

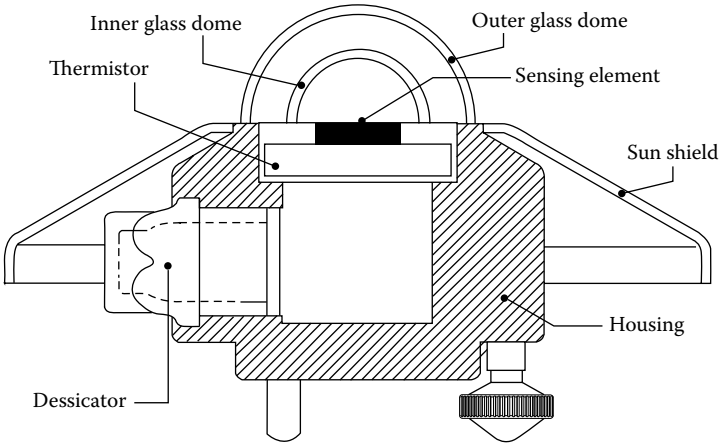

FIGURE 71.2 The Kipp & Zonen pyranometer. (Reprinted with permission from Kipp & Zonen, *CMP Series Pyranometer Instruction Manual*, The Netherlands, 2010.)

Pyroelectric solar radiometers use the temperature dependence of electric polarization in a pyroelectric crystal (Geist and Blevin, 1973; Valero et al., 1982; Hengstberger, 1989). If the temperature is changed, then the lattice spacing in the crystal also changes, which causes a change in the electric polarization of the crystal and consequently leads to a charging of the crystal surface generating a current that is used as a measure of the radiant energy. Thus, these sensors need a change in temperature to generate a signal. Therefore, they need to be equipped with a chopper, which, however, causes mechanical problems in aircraft installation. The major advantage of this type of radiometer is its fast response time (>100 Hz).

71.2.2 Spectroradiometers to Measure Spectral Solar Radiation

Spectral radiometers (also called spectroradiometers) measure radiometric quantities in narrow spectral bands as function of wavelength. In this way, spectroradiometers allow more detailed insights into the nature of solar radiation as can be achieved by broadband radiometers.

71.2.2.1 Spectral Solar Irradiance and Radiance (Spectroradiometers)

Typically, solar spectroradiometers consist of four components (Shetter and Müller, 1999; Wendisch et al., 2001; Pilewskie et al., 2003): the optical inlet, fiber optics, spectrometer (including detector), and electronics with data acquisition.

The optical inlet (fore optic) comprises either a hemispheric light collector for irradiance or a telescope for radiance observations. The hemispheric light collector is a diffuse element that transmits or reflects radiant energy flux (power) proportional to the cosine of the angle of the incident light, corresponding to Equation 71.7. For the diffusively scattering hemispheric light collector based on transmission, mostly, materials like flashed opal, Teflon, or Delrin are applied. Because scattering is wavelength dependent and mostly drops in the near IR, instead of transmitting hemispheric light collectors, an integrating sphere (using highly reflective Spectralon) can be applied (Crowther, 1997; Kindel et al., 2010).

Optical fibers transmit the light from the optical inlet (either hemispheric light collector or telescope) into the entrance slit of a spectrometer (monochromator including the detector). The wavelength dispersion within the spectrometer is often realized by gratings; sometimes also prisms or circular filter wheels are applied. The detector elements include photovoltaic and photoconductive devices, photomultiplier tubes (PMTs), photodiode, or charge-coupled device (CCD) arrays.

Solar spectroradiometers require careful calibration with regard to radiant power, as well as angular and spectral response. More details can be found in Wendisch and Brenguier (2013), Chapter 7.

71.2.2.2 Spectral Actinic Radiation

The major purpose of measuring spectral actinic flux density from aircraft is to determine the photolysis frequencies J by integrating (over wavelength) the product of spectral actinic flux density, absorption cross section of the molecular species to be photolyzed, and the quantum yield of the photoproduct. J in units of s^{-1} is given by:

$$J(\mathrm{A} \rightarrow \mathrm{B}) = \int_0^\infty \sigma_\mathrm{A}(\lambda, T, p) \cdot \phi_\mathrm{B}(\lambda, T, p) \cdot F'_{\mathrm{act},\lambda}\, \mathrm{d}\lambda, \tag{71.16}$$

where

σ_A is the absorption cross section of the molecular species A in units of cm^2

ϕ_B is the quantum yield of the photoproduct B (dimensionless)

T is the air temperature

p is the atmospheric pressure

Note that in Equation 71.16, the quantity F' (spectral photon actinic flux density) is introduced instead of the spectral actinic flux density; $F_{act,\lambda}$ is defined in Equation 71.11. $F_{act,\lambda}$ must be converted to the corresponding spectral photon actinic flux density F' applying the following relation:

$$F'_{act,\lambda} = \frac{\lambda}{h \cdot c} \times 10^{-13} F_{act,\lambda}, \tag{71.17}$$

where

λ is given in units of nm
$F_{act,\lambda}$ is given in units of W m^{-2} nm^{-1}
$F'_{act,\lambda}$ is given in units of cm^{-2} nm^{-1} s^{-1}

Two types of instruments are applied: actinic spectroradiometers and filter radiometers. Both types are described by Hofzumahaus (2006).

71.2.2.2.1 Actinic Spectroradiometers

The main setup of the spectroradiometers for actinic radiation measurements is similar to that of a spectroradiometer for irradiance measurements, except that the optical inlet has an isotropic angular response. Mainly two separate 2π optical inlets are used (one for the upper, the other for the lower hemisphere). There are two kinds of spectroradiometer for actinic radiation measurements: (a) scanning double monochromators (Shetter and Müller, 1999) and (b) single monochromators (Jäkel et al., 2005):

a. Scanning double monochromators select one wavelength band by a fixed grating position, while a second moving diffraction grating is scanning the fixed wavelength range with high spectral resolution. The spectral radiation is directed onto the detector (PMT) by moving the diffraction grating. The scanning double monochromators have the advantages of low stray light contribution and high sensitivity in the UV spectral range. However, the disadvantages in particular for airborne operation are that the wavelength scanning is time-consuming (in the order of several seconds up to minutes) and that the mechanical stability during aircraft operation is not guaranteed.
b. Therefore, in recent years, more and more single-monochromator spectroradiometers have been applied for airborne research to measure spectral actinic flux density. The multichannel spectrometer (MCS) has a photodiode array (PDA) or CCD detectors. The advantages of the single-monochromator approach are the fast time resolution of the spectra (one spectrum in less than 1 s) and the mechanical stability because of the fixed grating (no moving grating). The disadvantages are the relatively high stray light contribution (problems in the UV) and the lower sensitivity in the UV compared to scanning-monochromators with PMT detector.

71.2.2.2.2 Filter Radiometers for Actinic Radiation

Filter radiometers are designed such that the spectral response of the interference filters is close to the spectral shape of the product of the quantum yield φ_A of a specific species A and the absorption cross section σ_B. Widely used are filter radiometers for the photolysis of NO_2 and ozone (Junkermann, 1994; Volz-Thomas et al., 1996; Früh et al., 2000). The input optics (optical inlet) consists of a series of frosted hemispherical quartz domes that act as a diffuser with nearly isotropic response similar to the inlets of the actinic spectroradiometers. The photons are transferred by a pair of optical filters and detected by a photodiode. Ideally, the signal is directly proportional to J; in reality, however, the spectral response matches not exactly the spectral relative shape of the product $\varphi_A \cdot \sigma_B$. Actually, the accuracy of filter radiometers is temperature-dependent and sensitive to changes of the solar zenith angle and the total ozone column.

71.2.2.3 Direct Solar Radiation

Airborne measurements of direct solar radiation are performed to derive the optical thickness of major atmospheric constituents, mostly aerosol particles (see Equation 71.3). The optical thickness of aerosol

particles comprises one of the important input parameters for radiative transfer simulations. In general, Sun photometers are applied for this type of measurements. The direct portion of solar irradiance is measured by restricting the field of view of the instrument to the solar disc, that is, to 0.5° angular width of the Sun using a cylindrical tube (Gershun tube). Interference filters are applied for wavelength separation and photodiodes for detection. An automated drive mechanism finds and tracks the Sun (Matsumoto et al., 1987; Russell et al., 1993). Sometimes handheld Sun photometers are being used; however, the data quality in this case is not always sufficient (Porter et al., 2007). For calibration, the so-called Langley method is employed where the extraterrestrial spectral irradiance is obtained by extrapolating irradiance measurements during rising or setting Sun to a zero air mass, that is, to TOA (Langley, 1903).

71.2.3 Leveling Issues

A typical airborne irradiance sensor (broadband or spectral) is fixed with the fuselage of the aircraft. Therefore, it moves with respect to the Earth-fixed coordinate systems due to attitude changes of the aircraft during flight. However, atmospheric applications of irradiance (i.e., flux density) strictly refer to a horizontal receiving plane. If the sensor receiving plane is out of horizontal level, serious deviations compared to measurements with a horizontal sensor plane may arise (Wendisch et al., 2001). To correct for misalignments, either a software postprocessing procedure or an active, mechanical leveling of the sensor heads during the flight is required.

71.2.3.1 Software Postprocessing Correction

The following technique holds for the direct portion of solar radiation only. Although this software, past-flight procedure is not optimal, it is widely used to correct for horizontal misalignment of irradiance sensors, because the active leveling technique is technically challenging and expensive. To correct the irradiance measurements for airplane attitude deviations from the horizon, the following equation is applied (Bannehr and Schwiesow, 1993):

$$k = \frac{\sin h_0}{\cos h_0 \ \sin\phi \sin(\varphi_0 - \psi) - \cos h_0 \ \sin\Theta \cos(\varphi_0 - \psi) + \sin h_0 \ \cos\Theta \cos\phi}, \tag{71.18}$$

with the solar altitude angle $h_0 = \pi - \theta_0$; θ_0 and φ_0 are the solar zenith distance angle and the solar azimuth angles, respectively. The aircraft attitude angles (no index) are given as ψ, the true heading of the aircraft with respect to the Earth-fixed coordinate system, Θ being the aircraft pitch angle and ϕ representing the aircraft roll angle. This formula does not consider for the effects, in case the radiometer is not level with the aircraft-fixed horizontal plane.

71.2.3.2 Active Horizontal Stabilization of Sensor Heads

An active and fast horizontal stabilization technique has been developed by Wendisch et al. (2001) and Bucholtz et al. (2008). The technical challenge is to precisely measure the roll and pitch angles on an accelerated platform (aircraft) and to use these measurements to compensate for aircraft attitude changes in real time with desired final adjustment accuracy better than ±0.2°. To achieve these demands, an active horizontal stabilization involves two parts: (a) an accurate aircraft roll and pitch angle measurement unit and (b) an active horizontal mechanical adjustment system:

a. Usual inclination sensors measure the tilt of a coordinate system with respect to the Earth's gravity vector. On accelerated platforms like an aircraft, this technique does not work because the sensor cannot distinguish between the Earth's gravity and the acceleration vector of the moving platform. In this case, a so-called artificial horizon (AHZ) has to be applied. The AHZ consists of three linear servo-acceleration sensors, which deliver the aircraft velocity and position with respect to the inertial Earth-fixed coordinate system by integration of the lateral acceleration measurements and three fiber optical gyros, which measure angular rates also with respect to the inertial Earth–fixed frame. From these data, the aircraft attitude angles (i.e., roll and pitch) are derived. However, the measurements

of the acceleration sensors as well as of the fiber optical gyros are affected by temporal drifts due to sensor errors and electronic noise. These drifts are compensated by using supporting information from a Global Positioning System (GPS). The combined AHZ and GPS data are processed, and the resulting accurate position and attitude data are stored on a first data acquisition system.

b. The processor unit transfers analog output signals of the roll and pitch angles to a personal computer. This drives (after amplification) two separate 2D tilt stages, which are connected with the optical inlet systems of the radiation sensors, that is, cardianically mounted. Each of the two separate 2D tilt stages consists of two servomotors (servos), which realize the horizontal adjustment of the optical inlets. Additionally, the measured attitude data from the combined AHZ–GPS system and the signals to drive the servos are stored on a second data acquisition system.

71.2.4 Techniques to Measure Terrestrial Radiation

71.2.4.1 Broadband Thermal IR Irradiance

Terrestrial radiation can be measured with an IR thermometer or a pyrgeometer, for example, Eppley precision IR radiometer (PIR) or Kipp & Zonen pyrgeometers. The measurement principle for the pyrgeometer is based on the exchange of energy between hotter and cooler objects (Foot, 1986; Philipona et al., 1995). Assuming that the instrument is one of the objects, the instrument absorbs or emits energy if it is cooler or warmer than the object that is being sensed. A pyrgeometer is used to measure, hemispherically, the exchange of terrestrial radiation between a horizontal blackened surface (the detector) and the target viewed (i.e., the sky or the ground). The PIR has the same circular multijunction thermopile detector as the pyranometer, which is used as a method of transducing the terrestrial radiation flux into an electric response. The inner silicon dome is coated with a vacuum-deposited interference filter. Radiation at wavelengths from 0.3 to 0.4 μm to approximately 50 μm is transmitted into the sensor. The amount of radiation in the visible spectrum 0.3–4.0 μm is not significant; absorption and reemission effects are small and are compensated for in the calibration.

71.2.4.2 Spectral Thermal IR Radiance

These instruments are composed of three major parts: the optical system, a detector, and a signal processing system (electronics and data acquisition). Furthermore, calibration targets are required that are usually a hot and cold black-body target. An optical window transmits the radiation from the outside atmosphere into the instrument's optics and to the detector. Zinc selenide (ZnSe) is a common material that has a fairly flat spectral response and transmits radiation across a wide spectral range. Then a filter selects wavelengths; it consists of a narrow band-pass highly transmissive material. Some instruments have individual filters in front of a detector; others use a filter wheel to rotate a selection of filters in front of the detector. Then the light hits the detector (thermal or quantum). Thermal detectors convert the absorbed radiative energy into thermal one. Most thermal detectors do not require cooling but have slow response times and poor detection capability. Quantum detectors usually are faster but often require cooling.

71.2.5 Microwave Radiometers

The MW spectral range of terrestrial EM radiation is characterized by a typically high transmissivity of the atmosphere (>80% below 40 GHz), which allows the retrieval of surface properties by downward looking MW radiometers from aircraft. Because wavelengths are large compared to atmospheric particles, scattering of EM radiation can be ignored for most applications in the MW spectral range. This simplifies the respective equations of the radiative transfers significantly.

Some examples of scanning airborne MW radiometers are given here. The conical scanning millimeter-wave imaging radiometer (CoSSIR) (Wang et al., 2007) has a fixed angle of incidence and a vertical

axis of rotation. The polarimetric scanning radiometer (PSR) (Stankov et al., 2008) allows both cross-track and conical scanning. Similarly, the microwave airborne radiometer scanning system (MARSS) (McGrath and Hewison, 2001) is operated in an external pod.

The beam width should be limited to a few degrees. Therefore, the antenna size becomes relatively large (up to 0.5 m for <10 GHz), which often proves to be a limiting factor for the operation on a smaller aircraft. Flight altitude and antenna beam width determine the spatial resolution of the observations of the Earth's surface. For example, for a flight altitude of 6 km and a beam width of 8°, the spatial resolution at the surface of the Earth is about 2 km.

MW radiometers need to significantly amplify the signal received at the antenna. Low-noise amplifiers (LNAs) are available for frequencies up to about 100 GHz.

71.3 Examples of Applications

71.3.1 Airborne Surface Albedo Measurements

The albedo α in general is defined as the ratio of upward and downward irradiance (see Equation 71.10) at any altitude in the atmosphere. It is a nonlinear function of the vertical coordinate τ; it is wavelength-dependent and a function of the underlying atmospheric and ground properties. The spectral surface albedo at the ground is the spectral albedo at the Earth's surface, which constitutes a major input function for radiative transfer simulations. Surface albedo cannot be measured representatively at the ground. Also, it cannot be directly derived from aircraft measurements of α, because scattering and absorption processes in the atmospheric layer between the aircraft and the Earth's surface also influence the signal measured at the aircraft altitude. To correct for this so-called atmospheric masking, a nonlinear retrieval procedure has been developed by Wendisch et al. (2004) and applied over different terrains. Figure 71.3 shows some exemplary results of surface albedo measurements over water, desert, ice, and vegetation corrected for atmospheric masking by using the method of Wendisch et al. (2004). Different spectral features become obvious from Figure 71.3. Generally, low values of surface albedo are observed over water; ice surfaces exhibit high surface albedo values. The typical vegetation step around 750 nm wavelengths dominates the surface albedo spectra over planted surfaces.

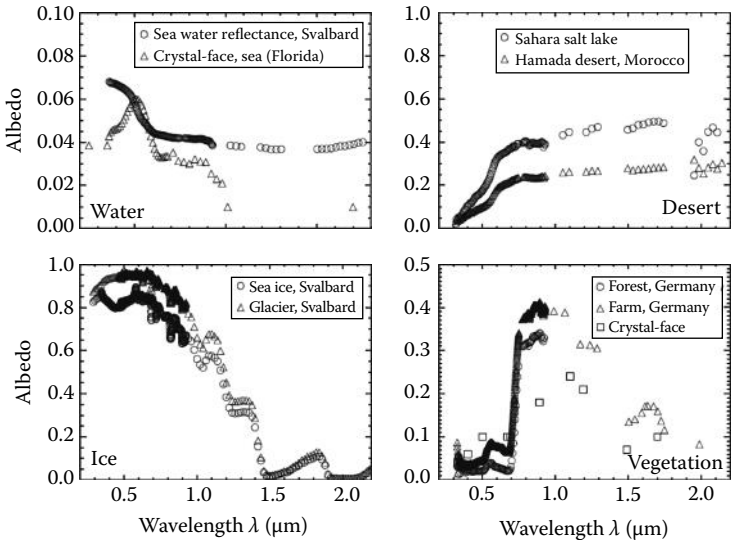

FIGURE 71.3 Different surface albedo spectra for various surface conditions. (Adapted from Wendisch, M. and Yang, P.: *Theory of Atmospheric Radiative Transfer—A Comprehensive Introduction*. 71.3.2 Impact of Crystal Shape in Cirrus on Thermal IR Irradiance

Examples of airborne pyrgeometer measurements along straight, horizontal flight paths are plotted in Figure 71.4 as open squares with horizontal lines indicating the standard deviation during the flight leg. The curve notation indicating the assumed crystal shape is given in Table 71.1.

Figure 71.4a and c show that the cirrus decreases the upward broadband thermal IR irradiance above its base height, compared to the cloudless atmosphere (greenhouse effect of cirrus). The strength

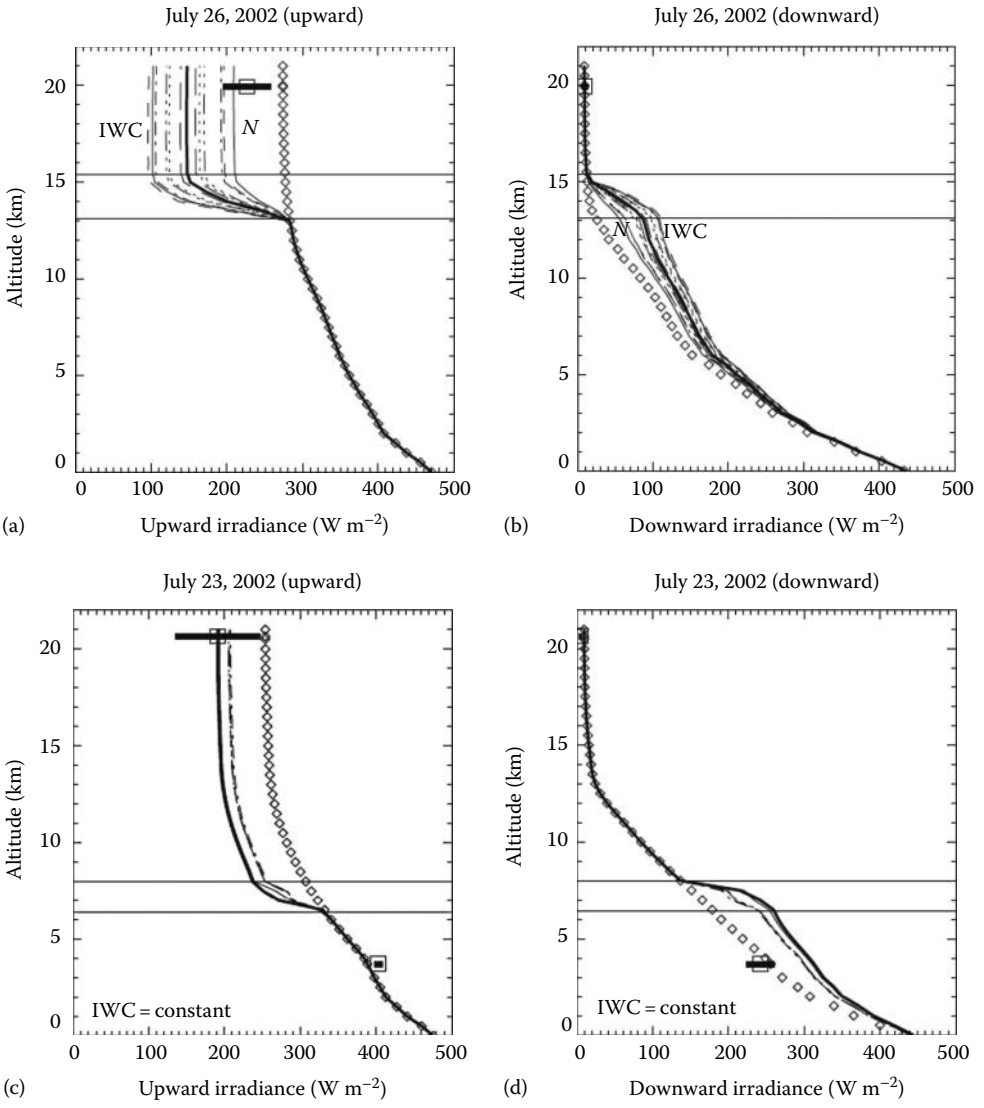

FIGURE 71.4 Vertical profiles of simulated broadband thermal IR upward and downward irradiance. The horizontal lines mark the cirrus top and bottom heights. The open diamonds indicate the simulations without cirrus (cloudless conditions). The open squares show the average of the measured irradiance, with horizontal bars representing the two-sigma standard deviations along the flight track. The first scenario is labeled by *N* (or *N* = constant), and the second scenario is marked by *IWC* (or *IWC* = constant), respectively. For details, see Wendisch et al. (2007). The curve notation is specified in Table 71.1. (Adapted from Wendisch, M., Yang, P., and Pilewskie, P., Effects of ice crystal habit on thermal infrared radiative properties and forcing of cirrus, *J. Geophys. Res.*, 112, D03202. Copyright 2007 American Geophysical Union.)

TABLE 71.1 Curve Notation Depending on Crystal Shape

Ice Crystal Shape	Curve Notation
Sphere	Thick solid lines
Droxtal	Long dashes
Solid hexagonal column	Dotted lines
Hollow hexagonal column	Dash-dot-dot-dotted lines
Solid hexagonal plate	Dash-dotted lines
Bullet rosette	Dashed lines
Aggregate	Thin solid lines

of this decrease depends on the altitude of the cirrus (i.e., its temperature) and its optical thickness. The height (temperature) dependence is because the cirrus emits less thermal IR radiation in colder environment (higher altitude). Below the cloud, there are no effects of the assumed crystal habit on the upward thermal IR irradiances. Above the cloud base, there are significant shape-related effects on upward irradiance in the cirrus case of small optical thickness. An outgoing longwave radiation (OLR) bias is seen as the difference in calculated and measured upward terrestrial irradiance in Figures 71.4a. Most probably this OLR bias is caused by the neglect of horizontal cirrus inhomogeneities. The effect is most significant for semitransparent cirrus (low optical thickness), which is located in the cold upper troposphere. For the low (warm), optically thick cirrus observed on July 23, 2002, there is no such OLR bias.

Figure 71.4b and d demonstrate that the cirrus generally increases the downward broadband thermal IR irradiance below its top height, compared to the cloudless atmosphere. This is because (due to its emission) the cirrus constitutes an additional source of thermal IR radiation, which adds to the cloud-free atmosphere emission. The cirrus has almost no impact on the downward broadband thermal IR irradiance reaching the surface; the emission source (cirrus) is too far away from the surface. The impact of crystal shape on atmospheric radiant energy budget simulations is concluded to be important for the high, optically thin cirrus only.

In Situ Sensors for Monitoring the Marine Environment

Graham A. Mills

Gary R. Fones
University of Portsmouth

Silke Kröger
Centre for Environment, Fisheries and Aquaculture Science

72.1 Introduction

The marine environment has been affected by growing population and industrial pressures in the coastal zone. Activities such as dumping of waste, construction of harbors, dredging, and extraction processes all contribute to changes in environmental quality. In order to assess the impacts of these activities and instigate appropriate remedial actions where needed, it is necessary to monitor a wide range of properties (i.e., biological, chemical, and physical) of the marine environment. Recently, such monitoring activities are becoming harmonized within regulatory frameworks and international agreements (e.g., within the Europe-specific initiatives under the Helsinki and OSPAR Commissions, the European Union's Water Framework Directive [200/60/EC], and more recently Marine Strategy Framework Directive [2008/56/EC]). The latter requires for a thematic strategy for the protection and conservation of the marine environment and mandates for the establishment of clear environmental targets and monitoring programs. Most work on developing monitoring methods has been focused on freshwater (e.g., ground and surface water) applications, but now there is an increasing demand to adapt these methods for use in the marine sector. Monitoring the marine environment, however, presents a number of problems that are not encountered with freshwaters. For example, oceans cover very large areas, and there are complex currents and, in coastal systems, tides that can cause large shifts in salinity. Large dilutions of pollutants occur, and so many contaminants can appear at very low, but often biologically significant, concentrations. Boats and ships are usually needed to reach monitoring sites, with samples of water, sediment, and biota transported back to land-based laboratories for analysis or in some cases analyzed onboard ship. The use of sampling coupled with classical biological or chemical analysis is expensive and time-consuming and often fails to provide representative information over changes in time (short term over a tidal cycle and longer term over seasons, years, and decades). An additional problem is that delays between sampling and analysis can compromise sample integrity (especially for

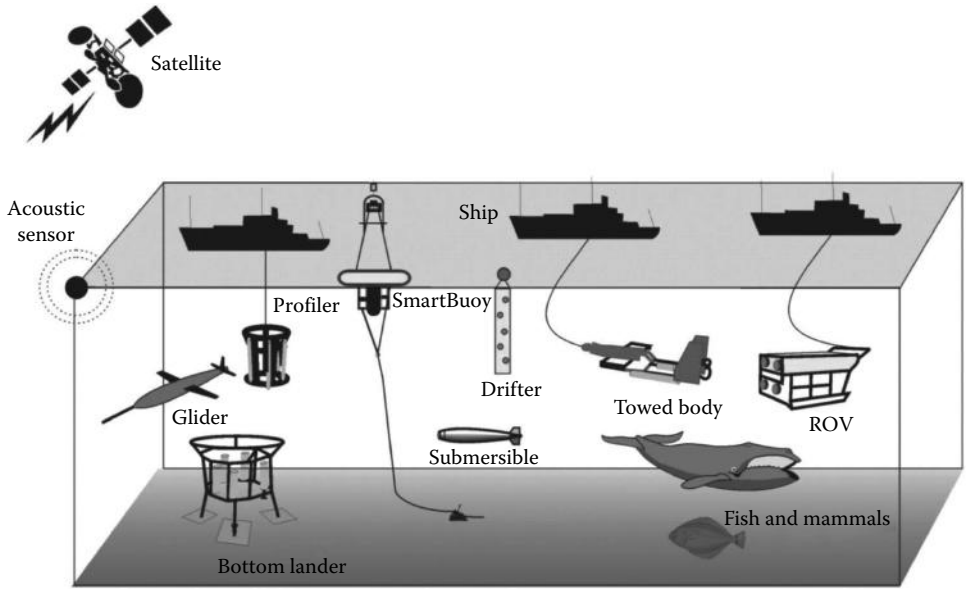

FIGURE 72.1 Schematic overview of marine observational strategies. Each of the elements shown is or could be equipped with a range of sensors.

labile compounds), while changes in temperature and pressure can also be an issue. A solution to some of the problems outlined earlier is the use of sensors that are particularly suited for making *in situ* measurements in the marine environment and can provide continuous or semicontinuous observations and transmit the information telemetrically to shore-based data-gathering facilities. Their use can overcome some of the problems of the undersampling (in both space and time) of coastal waters and the ocean. Many engineering platforms are available on which these sensors can be deployed in the environment and include APEX floats, autonomous underwater vehicles (AUVs), gliders, benthic landers, moorings, remotely operated vehicles (ROVs), nodes attached to cable networks, and even tagged live stock and wildlife (Figure 72.1). This approach thus eliminates the need for expensive (>$15–20,000 day^{-1}) sampling from ships, and there can be real-time acquisition of information where any strategic decisions can be made in a short time scale.

The first *in situ* analyzer used in the marine environment was for determining salinity on the basis of measurements of conductivity and temperature. This was reported in 1964 and is considered to represent a turning point in marine chemistry (Wangersky 2005). Today, many *in situ* techniques are used for monitoring hydrological and physicochemical variables in the marine environment. For example, a system of observational buoys (such as the Cefas "SmartBuoys" [Figure 72.2], http://www.cefas.defra.gov.uk/our-services/monitoring-and-mapping/autonomous-monitoring/smartbuoys.aspx) is in operation in European waters, and these devices house a range of measuring instruments (e.g., for monitoring pH, pO_2, turbidity, conductivity, and concentrations of nutrients such as phosphate and nitrate) (Figure 72.3). The European Marine Ecosystem Observatory (EMECO, http://www.emecogroup.org) is a consortium of European Marine Institutes that aim to integrate marine environmental monitoring, ecosystem modeling, and coastal and ocean research. But there are still significant gaps to fill, for example, there are fewer sensors in use for monitoring concentrations of heavy metals, organic pollutants, and algal toxins. Like any technology deployed in nutrient-rich environments, all these systems suffer from the problem of biofouling, which can be a factor in limiting overall deployment times. This chapter aims to provide information on the current developments in the area of *in situ* monitoring of the chemical quality of marine waters. It does not address remote sensing observations of, for example, phytoplankton blooms,

FIGURE 72.2 Cefas SmartBuoy being deployed in UK coastal waters. (Photo from The Centre for Environment, Fisheries and Aquaculture Science, http://www.cefas.co.uk.)

using satellite-based technologies. The topics covered here include physical and chemical sensors, spectroscopic and electrochemical devices, and biosensors, together with a view on the future developments and applications of these technologies to this sector. It is not the authors' aim to describe every device available or that could be potentially useful; the reader is referred for further information to other reviews cited in the bibliography and the web links.

72.2 Physical- and Chemical-Based Sensors

A sensor is defined as a device that produces a response to a change in a physical condition, such as temperature or thermal conductivity, or to a change in chemical concentration. Sensors, therefore, are particularly suited for making *in situ* measurements in the marine environment. Their use can overcome some of the problems of the undersampling (in both space and time) of coastal waters and the ocean. Currently, there is a significant research effort being undertaken to push forward the use of *in situ* sensors. An example is as follows: this is the ongoing work at the Centre for Marine Microsystems at the University of Southampton, United Kingdom (http://www.southampton.ac.uk/cmm/), for the

development of miniaturized multiparametric biogeochemical sensors. Here, they are developing a range of chemical sensors for nitrate/nitrite, phosphate, ammonia, oxygen, methane, pH, alkalinity, and iron/manganese using lab-on-a-chip technologies (Sieben et al. 2010).

In situ sensors have been used for a number of years to measure physical-based parameters such as conductivity, oxygen, pH, and carbon dioxide in seawater. The majority of these are available commercially (Table 72.1), particularly in sensor packages such as conductivity, temperature, and depth (CTD) profiling instruments. The term CTD is often used today to describe a package that includes the actual CTD as well as auxiliary sensors to measure parameters such as dissolved oxygen, pH, turbidity, chlorophyll-*a*, rhodamine, blue-green algae, ammonia, and nitrate. Often, arrays of sensors are used so that multiple parameters can be measured simultaneously, and these systems can be fully automated. These can either be deployed from a ship in the profiling mode or can be deployed on a mooring for long-term monitoring as part of an observation system.

Commercially available conductivity sensors use an ac voltage applied to nickel electrodes or graphite electrodes. The challenges are to maintain the calibration parameters during long-term deployments (Owens and Wong 2009). Oxygen sensors are also available commercially for a number of applications, such as profiling sediment–water interfaces. These can be either electrochemically or optically based systems (Glud et al. 2000). Most oxygen sensors are based on the original Clark polarographic electrode (Reimers 2007); however, there are now optical dissolved oxygen sensors that utilize luminescent technology (Glud et al. 2000; Reimers 2007), such as the AADI oxygen optode, which has been used in a number of marine applications (Körtzinger et al. 2004; Tengberg et al. 2006; Hydes et al. 2009; Queste et al. 2012).

There are numerous sensors available both commercially and as research devices for the measurement of pH and pCO_2. These parameters are important in understanding climate change and therefore need to be measured accurately in monitoring programs, ideally by *in situ* measurements. The requirements for making accurate measurements of oceanic carbonate chemistry including pH have been documented by Dickson at al. (2007). The sensors include electrochemical, potentiometric, photometric, and fiber-optic-based instruments (Cai and Reimers 2000). There are two primary techniques for measuring *in situ* pH. The first is electrochemical (potentiometric) using a hydrogen electrode and reference electrode and is the standard method. However, there is a major problem with these devices when ionic strength and composition change, such as in estuarine environments. The second approach is the photometric/fiber-optic measurement of pH (Cai and Reimers 2000). This uses an indicator dye that is added directly to the test solution or is confined within a sensing cell or matrix. These techniques have excellent precision (0.001 pH units) and accuracy (0.004 pH units) but ideally are used in flow-through systems and are therefore best suited for operation onboard research ships (Bellerby et al. 2002). Instruments for measuring pCO_2 have been used mainly as flow-through systems onboard ships (Hardman-Mountford et al. 2008); however, a pCO_2 system for deployment on ocean moorings has been developed (DeGrandpre et al. 1997). This consists of a fiber-optic pH sensor in a flow-through cell connected to a CO_2-permeable membrane equilibrator.

72.3 *In Situ* Automatic Analyzers

Another approach to achieving *in situ* measurements has been the miniaturization of existing analytical methods, such as colorimetric and spectroscopic methods. In the former, some quantitative chemical reaction that generates a colored product that can be measured spectroscopically is used; in the latter, analytes are measured directly in the water. There is considerable experience in using these methods in the laboratory and more recently online and in the field. Developments in optical fiber technology; solid-state electronics; long-life, stable power supplies; pumps; and valves have enabled the production of robust, miniaturized instruments that are portable for use at sea. An early example is the system developed to be used on research vessels to measure concentrations of hydrogen sulfide in seawater (Sakamoto-Arnold et al. 1986). The subsequent work to improve the reliability of these miniaturized

systems that are based on flow-injection analysis (FIA) methods was accompanied by developments in the design of instrument housings for deployments in robust environments such as fast-flowing water or deep water.

72.3.1 Flow-Injection Methods

Analyzers based on FIA methods for use *in situ* comprise a pump, detector, and narrow bore tube manifold (Vuillemin et al. 2009). The sample is pumped through a tube manifold where it is mixed with appropriate reagents to form a product that can be detected by a spectroscopic method. In some cases, the reaction product is colored and can be detected by visible wavelength spectroscopy; in others, it is detected by fluorimetry. A system of valves allows sample to be replaced by standard solutions from time to time to achieve an *in situ* calibration of the instrument and provide quality control information. When using such systems in the marine environment, there can be problems caused by large changes in pressure, temperature, and salinity (e.g., over a tidal cycle in inshore waters) that can lead to a significant bias in results. For example, when measuring nitrate and nitrite concentrations, the rate of formation of the colored reaction product was influenced by changes in salinity and differences in temperature with depth also affected the analysis by changing both reaction rates and the viscosity of sample and reagents (and hence flow rates and mixing times) (Daniel et al. 1995).

A number of miniaturized systems have been developed for the measurement of silicic acid (silicate), nitrate and nitrite, iron(II), total iron, phosphate, and total sulfide in the marine environment. One of the key driving forces is the need for information on the chemical quality of water in relation to the distribution of biota in the deep ocean, particularly in the region of hydrothermal vents. Some of these systems have incorporated limited temperature regulation to improve the reliability of the data. Among these is a system based on a colorimetric method (using the production of ß-silicomolybdic acid that is reduced [by tin{II}] into an intensely colored molybdenum blue) for the measurement of silicic acid (silicate) in seawater at a detection limit of 29 μg L^{-1} (Floch et al. 1998). An FIA analyzer for measuring ammonium in fresh and saline waters was developed by Aminot et al. (2001) and was based on a fluorometric method (using an orthophthaldialdehyde–sulfite reagent) since this was robust to variations in refractive index of the sample over a wide range of environmental conditions. The method gave a limit of detection in the range of 0.4–0.5 μg L^{-1}. A system with three analyzers was developed by Thouron et al. (2003) to measure the nutrients: nitrate, phosphate, and silicate. This system had a sampling rate of 2 h^{-1} and was capable of 400 autonomous measurements. The analyzers had detection limits of 6, 10, and 10 μg L^{-1} for nitrate, silicate, and phosphate, respectively. A nitrite microfluidic colorimetric sensor has been developed by Beaton et al. (2011). The low-power system is low cost, portable, and with a limit of detection of 15 nM nitrite. The device was tested in seawater over 57 h, and 375 discrete measurements were taken. Future developments include the use of on-chip valves and pumps to decrease size and operation power demands of the device.

A FIA analyzer (ALCHIMIST) was developed by IFREMER (France) to measure nitrate plus nitrite and total sulfide in deep marine locations near hydrothermal vents (Le Bris et al. 2000). The maximum sampling rate was 22 h^{-1}, and the device could take into account the effects of varying temperature and pressure. This system had detection limits of 26 and 27 μg L^{-1} for total sulfide and nitrite plus nitrate, respectively. More recently, Vuillemin et al. (2009) developed an *in situ* analyzer (the CHEMINI system) for measuring analytes at even greater depths, which demonstrated some of the latest developments in this type of technology. In this system, the reagents (up to 2 L) and standards (250 mL) are contained in flexible bags and enable 400 analyses per deployment. Prototypes of the CHEMINI have been deployed in deep-sea (1650–1750 m) hydrothermal environments for the measurement of dissolved iron and total sulfide. In this difficult environment, the analyzer gave useful spatial and temporal data by taking up to 8 measurements per day over a 6-month period. The combination of miniaturization; the availability of better protective deployment housings; stable, long-life power supplies; and advances in communications capabilities have enabled these FIA analyzer systems to be buoy based, located on robotic vehicles,

or towed by ships. However, the use of reagents sets limits on the time that instruments can be deployed and adds significantly to the bulk and weight of the analytical system. More recently, there has been a move to develop reagentless methods where possible (Lacombe et al. 2008).

72.3.2 Spectroscopic Methods

A number of spectroscopic- and spectrometric-based *in situ* devices have been developed for use in marine applications for measuring dissolved gases, nutrients, organic chemicals, and trace metals (Moore et al. 2009a). These are usually miniaturized versions of conventional laboratory analytical equipment that have been fitted with robust protective housing so as to withstand high pressures. A range of optical detectors can be used and include absorbance, reflectance, luminescence, fluorescence, refractive index, and light scattering. Underwater mass spectrometric detectors can also be employed, usually with a membrane inlet sample introduction system (Prien 2007; Moore et al. 2009b). The following provides a brief discussion of some of different optically and mass-based technologies available.

One of the simplest optical sensing systems measures changes in refractive index. These detectors can be used to measure bulk particulate loads (e.g., amounts of organic and inorganic particles in the water column). These devices work on the back scattering of light principle and can be useful in estimating phytoplankton loads and degree of sediment resuspension. Probably the most widely used method is optical absorption spectroscopy. This method is often used analytically in conjunction with FIA as described earlier. Absorption spectra (both visible and ultraviolet [UV] regions) in seawater are more complex than in pure water due to the influence of salts. The absorption peaks are broader, and this can cause overlap of spectra between different compounds making identification harder. Another interesting example is the use of flow cytometric techniques with optical sensing for the autonomous measurement of harmful algal blooms. Here, an increase in cell abundance correlated well with subsequent blooms (Campbell et al. 2008).

The ISUS is an example of a high-resolution *in situ* UV spectrophotometer that can take rapid (of the order of 1 s) direct measurements (Johnson et al. 2006). This was used to measure nitrate, bisulfide, and bromine as these species have distinctive UV absorption spectra. The device has the potential to operate at depths of 2 km and can be deployed for over 3 months without any degradation of performance due to biofouling or instrumental drift. Such *in situ* UV/visible spectrometers are frequently used to monitor surface, waste, and drinking water treatment processes. Here, light attenuation measurements are made over the whole spectrum (e.g., 200–735 nm), and over this region, it is possible to measure nitrate, chemical oxygen demand (COD), and total suspended solids (turbidity) directly in the water column (van den Broeke et al. 2006). Another deep-sea (up to 6 km) *in situ* UV spectroscopic device operating over 190–360 nm has been developed by TriOS Optical Sensors, Germany (http://www.trios.de/). The instrument was originally designed for nitrate measurements but can also be used for estimating biological oxygen demand (BOD), COD, and total organic carbon (TOC), humic acids, and some phenols. The device has "nanocoated" optical window that resists biofouling on its measurement surface.

An *in situ* dissolved manganese analyzer (Statham et al. 2003) based on the spectrophotometric detection of the 1-(2-pyridylazo)-2-naphthol (PAN)–manganese complex at 560 nm in a continuous flow system was interfaced with Autosub, which is a 7 m long AUV that is capable of carrying a wide range of instruments. The detection limit of the system was 25 nmol L^{-1}, and using 10 s averaged data, the along-track resolution of the system is about 10 m. The analyzer was successfully used with the Autosub (Figure 72.4) in Loch Etive, Scotland, to define the 3D distribution of dissolved manganese in subsurface waters (Statham et al. 2005). An *in situ* continuous flow analyzer for soluble Fe(II) species in seawater was developed by Meyer et al. (2012) and uses a colorimetric method with ferene as the spectrophotometric reagent. The method is based on the measurement of absorbance of the $[Fe^{II}(fer)_3]^{4-}$ complex at 594 nm. The method was applied *in situ*, during a cruise with the R/V "Heincke" in the central Baltic Sea and verified by concurrent analyses of discrete samples by ICP-OES. A detection limit of 20 nM L^{-1} was obtained (http://www.io-warnemuende.de/che-ag-in-situ-sensors.html).

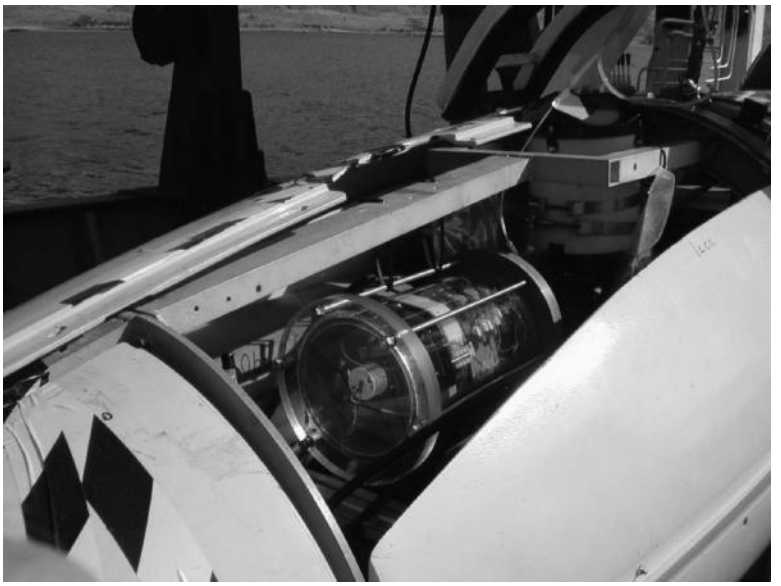

FIGURE 72.4 Manganese analyzer fitted in Autosub. (Photo by Professor Peter Statham, University of Southampton, Southampton, U.K. http://www.bodc.ac.uk/projects/uk/autosub/science_missions/mission2.html. *Source:* Copyright-Professor Peter Statham, University of Southampton, available at: http://www.bodc.ac.uk/projects/uk/autosub/science_missions/mission2.html)

In situ fluorescence spectroscopy can also be used to measure compounds that naturally exhibit this characteristic. Fluorescence spectroscopy is very sensitive; however, the drawback is the intrinsic lack of selectivity in the choice of excitation and emission wavelengths to be used. The broad character of fluorescence peaks usually prohibits finding an explicit excitation/emission wavelength combination that is unique to the analyte being measured. Due to their chemical structure, polynuclear aromatic hydrocarbons (PAHs) are inherently fluorescent. A submersible UV fluorometer has been designed for the measurement of PAHs in water and is commercially available. The enviroFlu-HC (TriOS Optical Sensors, Germany) is designed to excite compounds (using a xenon lamp) at $\lambda \approx 254 \pm 12.5$ nm and detect the emitted light at $\lambda \approx 360 \pm 25$ nm. The instrument weighs about 2 kg and is rated to 500 m depth and is hence suitable for deployment on a number of available systems (Tedetti et al. 2010). *In situ* measurements of chlorophyll are possible using fluorometers (e.g., Seapoint fluorometers used on SmartBuoys [Greenwood et al. 2010]) and can be used in the deduction of primary production rates (Kröger et al. 2009). More sophisticated, so-called fast repetition rate, PhytoFlash, and pulse-amplitude-modulation fluorometers are on the market (Table 72.1), and these can give an indication about the health of the algal population and their photosynthetic yield. With the use of the so-called saturation pulse method, the quantum yield of photosynthetic energy conversion can be derived (Kröger et al. 2009). These methods, however, still need careful calibration and checking with accepted carbon incorporation methods, but good matches between conventional and fluorescence-based production estimates have been found (Kromkamp et al. 2008). More recently, Fischer et al. (2012) developed an online, *in situ* optical fiber–based sensor to measure the growth of biofilm aquatic environments. The device is based on the detection of the natural fluorescence of microorganisms constituting the biofilm. Basically, the intrinsic fluorescence of the amino acid tryptophan is excited at a wavelength of $\lambda = 280$ nm and detected at $\lambda = 350$ nm utilizing a numerically optimized sensor head equipped with a UV–LED light source and optical fiber bundles for efficient fluorescence light collection. The sensor has been used in the Baltic Sea to monitor the growth of biofilm layers and could have other uses such as the mass measurement of biomass and cell activity using tryptophan and adenosine triphosphate fluorescence.

Optodes, sometimes referred to as optrodes, can also work using fluorescence spectroscopy principles. Here, indicator dyes (e.g., ruthenium or platinum complexes) are employed, and these are embedded or immobilized into sol–gel matrices of thin polymer layers. The presence of a test analyte in the light path modifies the properties of the indicator (e.g., emission of fluorescent light), and this forms the basis of operation these sensors. These devices are frequently used to measure oxygen (Prien 2007) but can also be used for pH and pCO_2. Recently, Clark et al. (2012) used an oxygen optode 4330F sensor (AADI, Norway) attached to an AUV to obtain a high-resolution 3D map of dissolved oxygen concentration in Hopavågen Bay, Norway. This powerful, 3D, mapping procedure offers much potential and could be used, for example, in estimating the quantity of dissolved oxygen per volume and has the potential to become a reliable test for the health of an underwater ecosystem (e.g., near fish farming activities).

Infrared devices can also be used, and this area was reviewed by Mizaikoff (2003). The application of these devices is mainly for the measurement of volatile chlorinated and aromatic hydrocarbons, and this relies on mid-infrared range optical systems. This wavelength region is particularly attractive for optical sensing, since molecule-specific information is provided by stimulation of the ground vibrational modes of organic substances. The use of Fourier transform methods enables simultaneous measurements of individual chemicals in multicomponent mixtures at concentrations in the $\mu g\ L^{-1}$ range. Interferences to the signal from changes in salinity and water turbidity also need to be taken into account. An *in situ* miniaturized modular Fourier transform-IR device with a fiber-optic sensor head was developed as part of the EU framework project SOFIE (Kraft and Mizaikoff 2000). The device can operate at depths of 300 m being deployed either on a tow frame or a remotely operated vehicle. The long-term stability and resistance to fouling of the device were good. The concentration of suspended particulate matter (turbidity) in a water body can be measured using the optical back scatter of infrared beams. An understanding of the concentration of suspended particulate matter is important when assessing the degree of penetration of sunlight as this can affect the growth of phytoplankton and this may vary hourly, daily, or seasonally.

Laser Raman spectroscopy is a type of vibrational spectroscopy based on Raman scattering (inelastic scattering) that is capable of nondestructive molecular identifications of solids, liquids, and gases. It can measure multiple species simultaneously and requires no reagents or consumables, making it ideal for *in situ* long-term deployments. Raman measurements are fast (2–10 s), and this makes them useful rapid sensing systems for applications such as profiling. *In situ* devices based on Raman spectroscopy have been developed. Brewer et al. (2004) were one of the first groups to develop a deep-ocean Raman *in situ* spectrometer (DORISS). The instrument uses a Nd:YAG green laser operating at 532 nm to provide the Raman excitation, with a holographic grating as a filter and a charged coupled device array to detect the weak Raman signals that are produced. The DORISS system is capable of being deployed from a remotely operated vehicle and can work to a depth of 3.6 km and at water temperatures of 2°C. *In situ* Raman spectra have been obtained from seawater at various depths and from various gases, liquids, and solid mineral samples. Another Raman-based device has been developed during the EU that funded SOFIE and MISPEC projects (Schmidt et al. 2004). *In situ* Raman sensors do suffer from a lack of sensitivity; however, this may in part be overcome by the use of surface-enhanced Raman scattering (SERS) techniques. Using SERS, Raman intensities can be enhanced by the use of chemical and electromagnetic mechanisms when molecules are adsorbed onto specially prepared metal surfaces such as electrodes or metal colloid particles. Proposed applications include the measurement of low concentrations of hydrocarbons such as dissolved methane (Boulart et al. 2010) and polycyclic aromatic hydrocarbons (Pfannkuche et al. 2012). Although both Raman spectroscopy and SERS show potential, these systems are still very much research instruments, and further work is needed to overcome issues such robustness, fluorescent interferences, and sensitivity issues.

Laser-induced breakdown spectroscopy is an emerging technology with potential *in situ* monitoring applications. This uses a laser pulse to create a microplasma in the sample; then, a spectrophotometer captures the transient light to identify and quantify the analytes. It is a relatively low-cost method and

can be easily adapted for use with automatic or robotic systems. Measurements can be taken rapidly (less than 1 s), and sensitivity (mg L^{-1} or better) is similar for most chemical elements. Michel et al. (2007) demonstrated, in laboratory, the potential of this approach for the detection of calcium, potassium, lithium, manganese, and sodium in seawater. Changes in pressures, temperature, and salinity had little effect on the signal. Preliminary results suggest that this technique could in the future be suitable for the *in situ* chemical analysis of the marine environment.

Membrane inlet mass spectrometers have been used for the *in situ* measurements of dissolved gases and volatile organic compounds at different ocean depths. Devices can be deployed on wide variety of platforms. As they use no reagents for their operation, the spectrometers can be deployed for extended periods. Using mass spectrometers underwater is still challenging since the devices operate under a high vacuum. Analytes must be transported from the pressurized aqueous environment into a vacuum system, and this can place severe demands on pumps, particularly for long-term deployments. It has also been necessary to give consideration to the power requirements of the equipment. Two designs (linear quadrupole or ion trap) of mass spectrometer are used with electron impact ionization (Short et al. 2001). Both have similar detection limits (about 1 mg L^{-1}); however, ion trap systems do have a higher mass limit (650 Da) compared with quadrupole detectors (100 Da). The most common sample introduction method is a high-pressure polydimethylsiloxane membrane, and this can be used to depths of 2 km. These membranes allow the selective permeation of gases and nonpolar, volatile organic compounds. The thickness of the membrane affects the response time and sensitivity of the instrument. Although thin membranes are often preferred, these are mechanically weak and not able to withstand harsh field conditions. Mass spectrometers can be used for the simultaneous detection of multiple species. Most underwater applications have been the *in situ* detection and quantification of dissolved gases (e.g., CO_2, O_2, methane) and small volatile organic compounds (e.g., dimethylsulfide, toluene) at different depths (Camilli and Hemond 2004; Short et al. 2006; Schlüter and Gentz 2008; Camilli and Duryea 2009). Much of this work is still at a preliminary stage. Larger molecular weight (i.e., above 200 Da) compounds are not detected as the permeability of the inlet membrane to such molecules is very low. By the use of global positioning technology, that is, time matched to the concurrent mass spectral data, it is possible to create high-resolution 3D maps of the spatial distribution of chemicals and locate pollutant plumes. Such systems offer potential for the future in monitoring the distribution of specific chemicals. Further developments in microfluidics and lab-on-a-chip technologies could hold much future promise for the development of small-scale gas and liquid chromatographic systems combined with various designs of mass spectrometer; as do the rapid developments taking place with ion mobility mass spectrometers. Future systems would need to have reduced space and power needs and allow for a reduction in consumption of mobile phases. This could allow for the direct analysis of higher molecular mass compounds such as the range of marine toxins (Zielinski et al. 2009).

Radionuclides in the marine environment have been measured using a gamma-radiation probe device, which uses a NaI(Tl) crystal as a scintillation detector with a fully integrated spectrum analyzer. Under field conditions, this *in situ* method delivered comparable results to those based on chemical analysis for mixtures of nuclides originating from accidents (Wedekind et al. 1999). The approach has been further developed into the KATERINA system to measure marine radiation and has been deployed on ROVs and fixed platforms with data output transmitted via satellite to a base station (Tsabaris et al. 2008). More recently, the device has been used off the Peloponnesus Island, Greece, to monitor over a 25-day period the temporal variation of radionuclides (e.g., ^{40}K, ^{214}Bi representing ^{222}Rn, and ^{208}Tl representing ^{220}Rn) in a submarine groundwater discharge (Tsabaris et al. 2012). This allowed for the investigation of the mixing processes between groundwater discharges with seawater. The system has potential to be used in other such radon tracer studies in coastal regions to further our knowledge of the dynamics of seawater mixing processes. Another system called the gamma energy marine spectrometer (GEMS) has been described by Sartini et al. (2011) for measuring the decay of ^{40}K and other natural (e.g., ^{232}T, ^{238}U) and anthropogenic (^{137}Cs) radionuclides. The sensor is very stable and has deployed in the Ionian Sea for 6 months at a depth of 3200 m and was able to provide continuous time-series monitoring data of radioactivity in the deep sea.

72.3.3 Electrochemical Techniques

Electrochemical-based instruments are among the most widely used devices for *in situ* chemical analysis (Denuault 2009; Moore et al. 2009; Kimmel et al. 2012) and include conductometric, potentiometric, and amperometric/voltammetric electrode systems (Taillefert et al. 2000) and can be used for both single and multiple analyte measurements. Conductometric electrodes are used to measure salinity and are incorporated into a variety of commercially available CTD instruments (Table 72.1). Examples of potentiometric devices include those to measure pH, sulfide (e.g., the Ag_2S electrode), and pCO_2. Examples of amperometric devices include those for measuring concentrations of O_2 and N_2O. Electrodes to detect (free) trace metal concentrations so far lack the sensitivity required for use in the marine environment. Furthermore, the analyses are usually affected by changes in salinity.

It is now accepted (Tercier-Waeber et al. 2008) that the development of rugged, submersible none or little perturbing probes, for automatic, *in situ* measurements (i.e., measurements performed inside the water and sediment/soil matrix), is an important research need. Voltammetry is suited to this purpose since it can be used in low-cost, automated, and miniaturized equipment with low-energy requirements. However, significant developments are required to improve conventional voltammetric devices before they can be deployed truly *in situ* rather than being limited to use as onboard analyzers. One commercially available system is the voltammetric *in situ* profiling (VIP) system. The VIP (Figure 72.5) has the capacity for monitoring concentrations of trace metals down to 500 m with subnanomolar sensitivity. This system consists of several units: an online oxygen removal module, a multiparameter probe (Ocean Seven 316, Idronaut-Milan), and a calibration deck unit. Difficulties in calibration and validation are limitations to the future use of *in situ* electrochemical devices. Unlike in the laboratory, in field use, it is difficult to keep the electrodes in pristine condition, and this can affect reproducibility. As the systems measure in real time, it is difficult to calibrate the instrument *in situ* without undertaking a large number of spot water samples for verification. New developments, such as environmentally

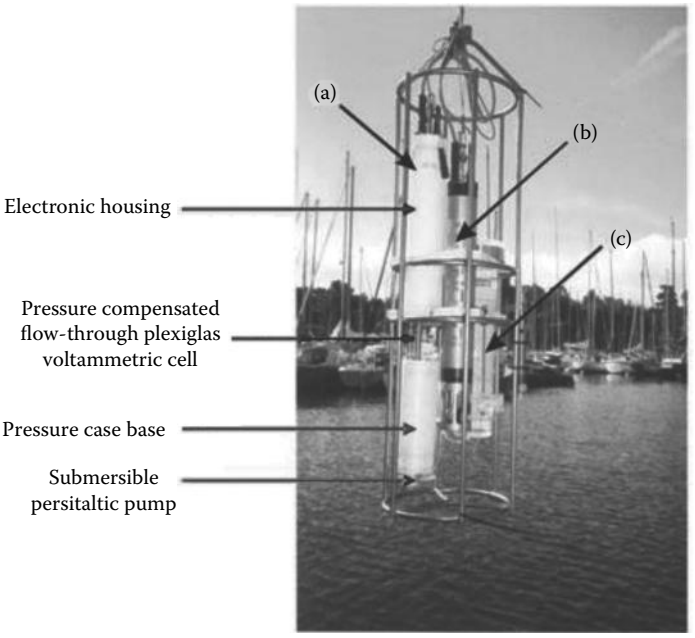

FIGURE 72.5 Standard version of the VIP system for *in situ* monitoring and profiling in freshwater and marine water columns: (a) voltammetric probe model 1, (b) multiparameter probe, and (c) online O_2 removal system. (From Tercier-Waeber and Taillefert, 2008: Reproduced by permission of The Royal Society of Chemistry, http://dx.doi.org/10.1039/B714439N.)

friendly disposable probes with microfabricated bismuth working electrodes for trace metal analysis (Zou et al. 2008), cobalt-based microelectrodes for phosphate (Lee et al. 2009), and screen-printed electrode sensors (Zaouak et al. 2010), are in the laboratory development phase; it will be then a challenge to adapt them for *in situ* operation. Gibbon-Walsh et al. (2011) used a vibrating, gold, microwire electrode (VGME) to detect low nanomolar levels of Mn and Zn in UK coastal waters. The VGME has advantages related to robustness, stability, and ease of use (no polishing, simple regeneration) facilitating on-site and potential *in situ* use. Using such approaches, it should be possible to simultaneously use arrays of sensors, and this will provide the necessary redundancy required for long-term deployments.

72.3.4 Biosensors

Biosensors are devices that integrate a biological recognition element with a transducer that converts changes associated with an interaction between the receptor and the target compound into an output signal that can be measured quantitatively. Several recent reviews (Farré et al. 2009; Roig et al. 2009; Kimmel et al. 2012) have provided useful definitions of biosensors and have differentiated them from biological systems (bioassays, biological early warning), where such an integral transduction mechanism is absent. Biosensors can be classified in a number of ways, usually on the basis of the type of recognition unit or the nature of the transducer. For instance, the biological component can be provided by DNA, enzymes, immunological systems, receptor proteins, and whole cells. The transduction component can be provided by acoustic, chemical, electrochemical (amperometric, conductometric, potentiometric) microbalance and optical (absorbance, bioluminescence, chemiluminescence, total internal reflection, surface plasmon resonance) and piezoelectric mechanisms (Kröger and Law 2005a). The advantages of biosensors, such as high specificity, sensitivity, in some cases biological relevance, and ability to work in a wide range of matrices, make them potentially very useful in environmental monitoring. The use of such devices that operate remotely to make repeated *in situ* measurements that could be transmitted to a laboratory is seen as the ideal way of meeting the legislative requirements for monitoring the quality of environmental waters. Many research, particularly in Europe, has been directed toward this target and continues to be so, for example, in European Union's Framework 7 Work Programme: The Ocean of Tomorrow 2013 call. However, so far there are few commercially available biosensors for use in the environment and even fewer that can be used *in situ* (Kröger and Law 2005b). There is currently a large gap between the research output and the commercial availability of appropriate instruments for environmental applications. In part, this is due to the potentially small market for such devices, the high costs of the development to manufacturing stages and of validation for *in situ* environmental use. This contrasts with the successful commercial development of instruments based on biosensors for use in medical applications (Kimmel et al. 2012).

An important environmental role for biosensors might be in the *in situ* measurement of general water quality (measured as levels of nutrients that can lead to eutrophication, BOD), sublethal effects (e.g., endocrine disruption), or general toxicity of the complex mixtures of toxicants that tend to be present in environmental waters (Rodriguez-Mozaz et al. 2005). Another area where biosensors might be favorably used is the detection of algal toxins that can cause damage to commercial seafood-rearing activities. Here, they could provide alarm systems that would justify the high development costs. The following gives some examples of where biosensors have been used successfully for environmental applications.

The biosensor RIver ANAlyzer (RIANA) and Automated Water Analyzer Computer Supported System (AWACSS) are two optically linked multichannel immunosensor devices. The former has been used in river water and in drinking water treatment plants for the detection of pesticides (Rodriguez-Mozaz et al. 2006). The latter has been used mainly in wastewater treatment plants and can measure up to 32 organic pollutants at low ng L^{-1} concentrations simultaneously, at a rate of 4 h^{-1} in real environmental samples (Tschmelak et al. 2005). One mature biosensor technology (Larsen et al. 2000) is based on the use of immobilized bacteria that convert NO_2^- or NO_3^- to N_2O. The bacteria and a reserve of an electron donor are separated from the sample by an ion-permeable membrane that

allows the substrates to diffuse into the sensor. The bacteria are separated from the electrochemical sensor for N_2O by a gas-permeable membrane. A commercial version of this sensor is available (www.unisense.dk) and can be modified by using different strains of denitrifying bacteria to measure either NO_2^- and NO_3^- or NO_2^-. This technology was originally developed for use in wastewater treatment plants but has been demonstrated to work in seawater. A fluorescence-based fiber-optic biosensor has been developed for determining *in situ* real-time concentrations of trace metals (copper and zinc) in seawater (Zeng et al. 2003; Zheng et al. 2004). The recognition unit is a protein molecule that is site-specifically labeled with a fluorophore that is attached to the distal end of an optical fiber. This binds free copper(II) with a high affinity and selectivity. The transducer reports the metal's concentration as a change in fluorescence intensity or lifetime, using a frequency domain approach. The sensor has a detection limit of 6 pg L^{-1} free copper(II) in seawater. However, these techniques have been mainly utilized in medical applications and are not available commercially. Spier et al. (2011) used a KinExA Inline Sensor (Sapidyne Instruments, United States), containing the monoclonal anti-PAH antibody, 7B2.3, that has specificity for 3–5-ringed PAHs. This device permitted near-real-time measurements in the field. A spatial study was conducted near a dredging site where contaminated sediments were being removed, and a temporal study was performed during a rainfall event. The method was able to determine aqueous PAH concentrations as low as 0.3 μg L^{-1}, within 10 min of sample acquisition, and to assess over 80 samples (not including standards and blanks) in less than 3 days. The field-based biosensor analyses gave a good correlation for the PAHs to conventional laboratory-based analytical methods. Here, the generation of high-resolution, near-real-time data guided management decisions in the field and determined proper sampling protocols for conventional analyses. There has been much concern of the presence of chemicals in the environment that can disrupt normal endocrine function, and work to develop biosensors for measuring endocrine disruptors (of sex and thyroid hormone systems) has been ongoing. Most work, however, is still in the laboratory stage. A biosensor based on a commercially available antibody was developed to detect sub-ng L^{-1} concentrations of testosterone in environmental water samples and was successfully incorporated in to the RIANA array of biosensors (Tschmelak et al. 2006).

With the exception of these few developments, most of the other systems are a long way from in field or *in situ* deployment for monitoring endocrine disruptors in environmental waters. Other recent developments have produced potentially useful materials such as molecularly imprinted polymers (MIPs) for use in biosensors. MIPs mimic the biological activity of antibodies and can be used as recognition units in sensors. They combine some of the desirable properties (specificity) of biological systems but are much more stable chemically, thermally, and mechanically (Rodriguez-Mozaz et al. 2005). MIPs have been incorporated in biomimetic sensors for a range of analytes including haloacetic acids in drinking water, monoamine naphthalenes in drinking water, explosives in natural waters, and soil and copper(II) ions in wastewater. These developments are exciting; however, the technology is still underdeveloped (Ávila et al. 2008), and it will be some time before these sensors become commercially available.

Currently, an array of laboratory-based bioassays is used to assess the overall toxicity of water samples. Biosensors offer the potential to replace the use of bioassays and to provide rapid, automated *in situ* monitoring of water quality. Several strategies have been used to develop biosensor systems that can provide rapid, sensitive measurements of the toxicological quality of environmental waters. One approach is to use an array of whole-cell sensors that respond to a range of toxic insults and signal damage to different cellular systems. One such system was developed by Lee et al. (2005) and comprised a set of 20 recombinant bioluminescent bacteria with different promoters fused with the bacterial *lux* genes. The bacteria were immobilized in a 384-well microplate and on chips, and luminescence was detected using a cooled charge-coupled device camera. The analysis time was 2 h. Different toxicants produced different patterns of response, depending on mode of action, among the strains of bacteria, and this has the potential for identifying the presence of particular types of pollutant in environmental samples. The use of biosensors for the measurement of general toxicity is a desirable goal and would enhance significantly the ability of regulators to monitor water quality in a way that would provide early warnings of problems

and timely information on the results of remediation actions. It would also allow a better regulation of waste discharges than is possible with infrequent spot water sampling and chemical analysis for a limited number of compounds of interest that provides no information on the interactions that can occur between toxicants. However, currently, there are no biosensor technologies available that could be fully applied *in situ* in the marine environment. Another priority area for research is the use of biosensors within the marine environment to detect harmful algae and their respective toxins. A DNA-based electrochemical sensor has been developed by Orozco and Medlin (2011), and this device shows some promise in being able to identify and quantify some toxic algal species in the laboratory-based experiments. Diercks et al. (2008) have also developed an *in situ* device for monitoring toxic algae. This is based on the use of multiprobe chip with an array of 16 gold electrodes and a semiautomated rRNA biosensor. The sandwich hybridization uses species-specific rRNA probes, and this allowed for the simultaneous detection of up to 14 target species of algae. Some devices are used for the screening seafood to detect phycotoxins at adequate sensitivities, but their limited availability, primarily as research tools, hinders their broader application as general environmental monitoring tools (Zielinski et al. 2009). Likewise in the future, biosensors could play an important role in the detection of other waterborne and fecal pathogens and play a key role on monitoring activities such as required by the European Union's Bathing Water Directive (2006/7/EC).

Scholin (2010) discussed the possibilities of developing *in situ* ecogenomic sensor devices that would detect, in real-time, molecular markers indicative of specific organisms, genes, or other biomarkers associated with an environmental context. For example, the instrument could sense in a time-series fashion molecular signatures that are already known, particularly defined sequences of DNA or RNA. The sampler would analyze intact cells and subcellular fractions. Typically, particles in a sample are concentrated and a series of reagents applied sequentially, followed by an extraction routine for further purification. The target molecules can then be detected on the basis of specific physical properties or revealed using a range of intermolecular reactions such antibody/antigen recognition, nucleic acid hybridization, and enzyme-mediated processes (Zehr et al. 2009). Signal transmission and quantification would be achieved by conventional optical, electrochemical, or spectrometric techniques. Researchers at Monterey Bay Aquarium Research Institute (MBARI) (http://www.mbari.org/ESP/default.htm) have developed the MBARI Environmental Sample Processor (ESP), which provides on-site (*in situ*) collection and analysis of water samples from the subsurface ocean. The instrument is an electromechanical/fluidic system designed to collect discrete water samples, concentrate microorganisms or particles, and automate application of molecular probes, which identify microorganisms and their gene products. The ESP also archives samples so that further analyses may be done after the instrument is recovered. The ESP has now been fully commercialized and is marketed as the Spyglass ESP (http://spyglassbio.com/content/products/autonomous-platforms); the system has been fully described by Paul et al. (2007) and Scholin (2010) and has been used on a number of field deployments (Greenfield et al. 2008; Ryan et al. 2011). Such *in situ* instruments offer much potential for the future (e.g., the ability of applying a number of molecular analytical techniques to a single sample); however, there are still a number of practical obstacles to overcome to fully link the upstream sample collection and processing requirements with the currently available molecular assays. Molecular analyses at present are also slow (typically 30 min or longer), and this limits response capability and can place an added drain on power requirements. Applications of such sensors in the future could be the early identification harmful algal bloom species by identifying and measuring specific biomarker toxins, for example, domoic acid and saxitoxin (Doucette et al. 2009; Scholin et al. 2009).

72.4 Conclusions and Future Developments

The importance of a healthy marine environment is widely recognized, and legislation is being extended to provide protection. The need for reliable and widespread monitoring data therefore becomes more urgent. The logistic problems associated with representative sampling over wide areas preclude the use

of strategies based on spot water sampling that were developed for monitoring freshwater. New strategies are needed, and although the task is daunting, some progress has been in developing methods that can collect information *in situ*. A number of sensors for substances such as nitrates and chlorophyll are available commercially from a number of companies, but progress has been slower for pollutants such as heavy metals, many organic compounds, and pathogenic agents. New compounds of interest will also evolve, such as the underwater detection of explosives and their signatures in relation to safety and security issues (Dock et al. 2010).

Many deployment devices (including Argo floats, AUVs, landers, and SmartBuoys) and associated communication systems are already available, but the range of routine measuring devices to use with them is relatively limited. Although outside of the scope of this chapter, significant progress is being made with remote sensing technology primarily through the use of satellites or in some cases airplanes, however, often these observations need to be validated from data ("ground truthing") obtained from *in situ* techniques. The main advantage of remote sensing methods is in spatial scale of measurements that can be achieved, and as such, there are clear benefits in the context of investigating concentrations of chlorophyll-a, climate change, or the extent of oil spill in the ocean, for example (Novoa et al. 2012). Furthermore, there is also some progress in attaching some simple design of sensors to marine fauna to track behavior and movement, and these data can be integrated with other information collected simultaneously by for instance satellites and linking this information to climatic changes. Such an approach also provides insights into physical conditions in the oceans at sites where access by conventional sampling platforms would prove difficult, for example, under Arctic or Antarctic sea ice. In addition, the use of electrochemical sensors that can be integrated into dry and wet suits worn by divers and recreational surfers/swimmers, thereby providing them with the ability to continuously assess their surroundings for environmental contaminants and security hazards, has recently been proposed (Malzahn et al. 2011).

Biofouling of optical and sensor surfaces remains to be solved and is often a neglected area of research by instrument manufacturers, as recognized in the recent EU FP7 call for the development of new antifouling materials. This is a particular challenge in nutrient-rich coastal waters where true operational lifetime can be only 1–2 weeks. Fouling can in some instances have a significant impact on the data obtained from *in situ* sensors, for example, some organisms can alter the local oxygen concentration near a sensing head, and some can exhibit natural fluorescence. The environmental situation in respect of biofouling is complex, and a number of different approaches have been suggested. These include mechanical scrapers or wipers, use of nontoxic (e.g., silicone greases) chemicals, the "uncontrolled" release of a biocide (e.g., leaching of tributyl tin and the use of copper coatings, meshes, and shutters), and "controlled" release methods based on localized seawater electrochlorination devices or automatic acid-dispensing systems (Delauney et al. 2010). Other solutions are being sought in the use of coatings and nanocoatings and those that peel away over a deployment period and biomimetic surfaces (e.g., peptide–peptoid conjugates and phosphorylcholine-based polymers) that were initially developed for medical applications. The use of natural occurring antifouling products from marine species has also been suggested.

Operational lifetimes of remotely deployed instruments are often limited by the available power supplies. Cabled observatories can provide the power to operate sensor networks for extended periods; however, the establishment of the infrastructure is expensive and therefore limited in scope. Many *in situ* sensors still rely on commercially available batteries. The use of renewable energy systems that can utilize naturally occurring chemicals and conditions in the water body is a potential option that holds some promise. These include the use of methane hydrate fuel cells, microbial fuel cells, sea-surface photovoltaic cells, and motion-to-electricity conversion techniques (Gong et al. 2011).

Recent developments in microfabrication, microfluidics, and integrated optics in many areas of analytical chemistry are being applied in the development of *in situ* monitoring devices. Lab-on-a-chip technologies have advantages of a small size and limited reagent and power requirements. The challenge is to ensure that these systems can attain the sensitivity needed for many marine applications where analytes are present at only trace concentrations. However, as the overall cost of the sensing system is

reduced, this would potentially enable the deployment of larger numbers of devices and thereby improve the spatial and temporal resolution and extent of offshore monitoring activities.

The proper calibration of sensors often still remains a critical issue. In addition, there is currently a lack of recognized verification and validation protocols and quality assurance and quality control procedures for many of the devices described previously. Their full validation in the field may in the future require, for example, the deployment of autosamplers alongside sensors so that reference samples over time could be collected. The future commercial development and wide acceptance of *in situ* technologies will depend on the availability of systems such as those available for laboratory-based analytical procedures. There is a need for innovations in the development of suitable reference materials and interlaboratory trials to fully validate any new sensor technologies. International collaborations and the development of specific scientific working parties and associated groups could help to address some of these accreditation, certification, and standardization issues (Waldmann et al. 2010). In addition, the need to continuously calibrate and recalibrate instruments over long-term deployments still remains an issue to be fully solved (Tan et al. 2010).

Most of the devices with the potential for use in the *in situ* monitoring of marine waters were developed for use in the laboratory where they could serve as less expensive, more rapid, and more sensitive replacements for conventional analytical methods. They could enable frequent screening of water quality to avoid the problems associated with infrequent regulatory sampling. The more expensive regulatory measurements could then be used only when required. However, much development and validation work is necessary to reach this goal. The long-term aim of using these technologies for *in situ* monitoring in the marine environment is even further away. Although many devices have been developed to proof of concept or prototype stage, the development work to convert these into robust, reliable, validated instruments that can be deployed in the marine environment for prolonged periods (weeks to months) has not been undertaken. This may be a consequence of the short-term nature of research funding and the failure to provide associated support for the development work necessary to take advantage of exciting research innovations. There have been many lost opportunities by failure of commercial manufacturers to capitalize on significant research developments.

There is little doubt, however, that in the future *in situ* sensors will play a significant role in ecological risk assessments, particularly those associated with larger spatial scales. If such activities are to be cost-effective, then they will require the continued application and development of sensors to cover (both spatially and temporally) an assessment of a wide range of stressors and must also include metadata storage and associated analytical capabilities. This will allow for improved data collection and permit more appropriate decision making on various marine hazards among the key environmental stake holders with the long-term aim of further protecting and restoring our natural habitats.

73.1 Introduction

In recent years, the tendency of people to share and record data via the Internet has grown increasingly. The same propensity has involved researchers to analyze distributed data. The explosion of information via blogs and social networks is an actuality that encourages lots of scientists and researchers to focus on this occurrence. New styles of life have appeared according to the advent of this phenomenon that affects business, commerce, government and politics, public discourse, health and medical, etc. This also made prominent changes on related technologies.

These decades, environmental information still remains one of the most interest areas for scientists because of its effect on people's real life. Environmental effects, changes, influences, and interactions in our life are important for the future. Consideration of these elements is valuable to have an applied definition of environmental sensing. However, understanding requires information that not only makes the complexities of studying the environment easier but also implies the limitations of existing related knowledge and uncertainties (Lein 2012).

The goal of this chapter is to have a general and practical definition of *mobile environmental sensing* that enables gathering and analyzing data to get environmental information. On the other hand, wireless sensor networks help to gather temperature, humidity, pressure, solar radiation, and so on from the environmental information. This chapter looks at the potency of *smartphones* that can be applied as sensors to remotely gather environmental data. Also, a new capacity of this technology is developing, in which persons or groups of people are involved in the data-gathering process. This characteristic called *participatory sensing* enables us to sense the environment's parameters using mobile phones. There are some sensors that are built into mobile phones that help to sense and interpret the condition of the environment.

Generally, using any ability such as sight, hearing, smell, taste, or touch from the outside of the body (Lein 2012) is an ordinary definition of the word *sensing*. In general, detecting or perceiving a

phenomenon by perceiving the human's external objects is identified as "sensing," and "remote sensing" technology is a simulated aptitude to detect and sense phenomena. Hussein (2006) defined it as follows:

> Collection of information about an object without coming into physical contact. Remote sensing is a technique to gather information. It is the quantitative analysis of digital information.

Also, Bureau for Africa's Office of Sustainable Development (2007) indicated that *remote sensing* is

> The science of obtaining and interpreting information from a distance, using sensors that are not in physical contact with the object being observed.

Remotely data gathering provides information that is not easily accessible. Time is also another important parameter that requires remote sensing systems to analyze data at the required intervals. Different systems are applied in different researches and projects to sense remotely. Unreachable information can become more attainable (but not completely) thanks to the aid of systems that make sensing the environments possible. The method or the way of sensing is different from its accuracy. On the other hand, more sensing means more information but not necessarily precise information. This leads to try to improve the process of sensing and also the accuracy.

For predicting, analyzing, and making decision on the environmental condition, *environmental remote sensing* can be defined. Since the environmental information itself and the process of data gathering are involved with uncertainty and complexity, remotely accessing this information is directed by different applied techniques to overcome subsequent problems. As an extension of these techniques, environmental remote sensing applies different approaches, methods, and technologies to obtain related information and also to reach the accuracy of gained data. Using mobile phones is a remote sensing approach to gather environmental information that allows the systems to remotely access data with one of the most popular and used devices (especially for small distances). For instance, Aram et al. (2012b) introduced a method by applying smartphone to acquire environmental information in small spaces. They showed that getting environmental information while moving can be easier by having warning.

73.2 Mobile Phone as a Sensor

The challenge of power consumption still remains from the first mobile phones, in the 1980s, which were not light, small, and smart. Mobile phones as a part of people's lives allow them to connect to each other via text and voice. More services such as the possibility of checking e-mail, playing games, and sending and receiving files were included in devices called personal digital assistants (PDAs). Smartphones appeared as a combination of primitive mobile phones and the PDAs' abilities and added more facilities (Zheng and Ni 2006). Table 73.1 shows the evolution of cell phones. This compares three different generations of cell phones. Size, shape, equipment, and power consumption have changed with

TABLE 73.1 Growth of Mobile Phones

Type	Analog	Digital	Smartphone
Weight	About 900 g	About 200 g	Less than 140 g
Processor	Simple tasks	Preliminary tasks	Advanced tasks such as multimedia, Internet communication, playback
Memory	Only for storing some setting and phone numbers	For storing more data in the range of megabytes	More than 32 MB with possibility to have extra memory
Bluetooth	—	A few of them	Yes
Battery	For talking short time and for standby time	For talking long time and for standby time	For talking in longer time and for standby time

each generation. There is technological evolution in different fields since the first generation of mobile phones. This fast growth was ongoing from the very low-end mobile phone category (Paananen 2011) to reach the smartphones that make it possible to perform a wide range of operations. Several attributes make these types of phones inseparable in daily life and also make them as one of most-used electronic devices (Firtman 2010):

- Multitasking operating systems
- Running a myriad of applications
- Having several features (such as Bluetooth)

Now, they are involved in various applications:

- Health and medical (Wei et al. 2005)
- Military
- Environmental
- Home and office (Kim and Paulos 2010)
- Commercial

In fact, this new generations' potential to compute, communicate, analyze, and monitor has many effects on the quality of life.

Now, the resultant combination is used in various areas such as business, health care, social networks, environmental monitoring, safety, and transport. These equipped devices enable different applications with the consideration of different domains according to their operating systems (Sugiharto 2010). This new mobile generation, especially smartphones and tablets, is being used to monitor quality of life parameters. They apply the following sensors:

- Accelerometers
- Compasses
- GPSs
- Gyroscope
- Microphones
- Cameras

These sensors are already embedded (Lane et al. 2010), but there are no sensors for air quality or the pollutants of the environment. These sensors are part of the mobile phones that can apply the internal application programming interfaces (APIs). Some of these embedded sensors are recognized by everybody such as the microphone, the camera, and the GPS module. There are also external sensors that are used besides the embedded sensors; two of them are also used as a prototype in this chapter. Generally, wireless sensor networks use sensors as preplanned sensors or equipped on carriers or vehicles, with immobile routing strategies; alternatively, nowadays, mobile devices that are working as data collectors, especially smartphones, can play a role as distributed movable sensors. Also, as smart devices, they can share information with groups or communities as an important parameter to aid for making decisions for governments, groups of people, and researchers in different communities (Staples 2011). Together, the computing, communication, and sensing, as potencies of the smartphones, make *participatory* or *opportunistic* operations possible (Das et al. 2010). For mobility, two types of sensors can be considered; the first type is *wearable sensors* that people can wear (Choudhury et al. 2008); the second is called *phone to web* (Mun et al. 2009), where it can also be called *phone sensors*. Some mobile devices such as PDAs and cell phones can connect to devices and transfer data via Bluetooth. In some projects, they apply storage such as memory cards to store data instead of transferring it online. On the other hand, they send the gathered data to other devices or a central station, either periodically or continuously. The second type applies mobiles to record information from the environment. Mobile phones can record required data and then send it in a short time to a certain station or upload them via the Internet to the web portal (Goldman et al. 2009). Users can gather the environmental information in different

situations such as walking, biking, driving, and running; also, the location and tagged (i.e., custom) data can be included. But it is not possible to apply camera, send text messages, or tag more information in these moving situations. Consequently, mobile phones and the web can communicate to aid to improve the quality of lifestyle and to help elders, their family, and doctors in the case of medical monitoring (Goldman et al. 2009).

There are different scenarios for monitoring the environment. These scenarios apply wireless sensor networks that can be followed by *personals*, *groups*, and *communities* (Lane et al. 2010) to have environmental information. Today, in doing so, the simplest way is to employ the mobile devices. Environmental sensors, such as temperature, humidity, solar radiation, and pressure, can monitor both outdoor and indoor sites. But usually the short distance data transferring is one of these types of networks' characteristics. The two important parameters that should be considered for designing any related networks' system are the low power and low cost. In general, four parameters have more effect on the sensor structures and consequently their platforms:

- Deployment (based on activities)
- Location (indoor or outdoor)
- The application
- Data

Sensing environmental information parameters such as temperature and humidity are useful parameters to control and monitor in different fields such as medical, social services, and agriculture. Mobile robot temperature sensing is a sample solution for temperature monitoring that is applied in airports and hospitals (Abdullah and Poh 2011). This robot can also apply to other applications such as heat temperature detection for firefighting. Also, there are wireless sensor networks' solutions with immobile distributed sensors (Kuchta et al. 2008; Rosi et al. 2010). Monitoring the environment of small places is possible via mobile phones instead of preplanned or robot sensor systems (Shan and Brown 2005).

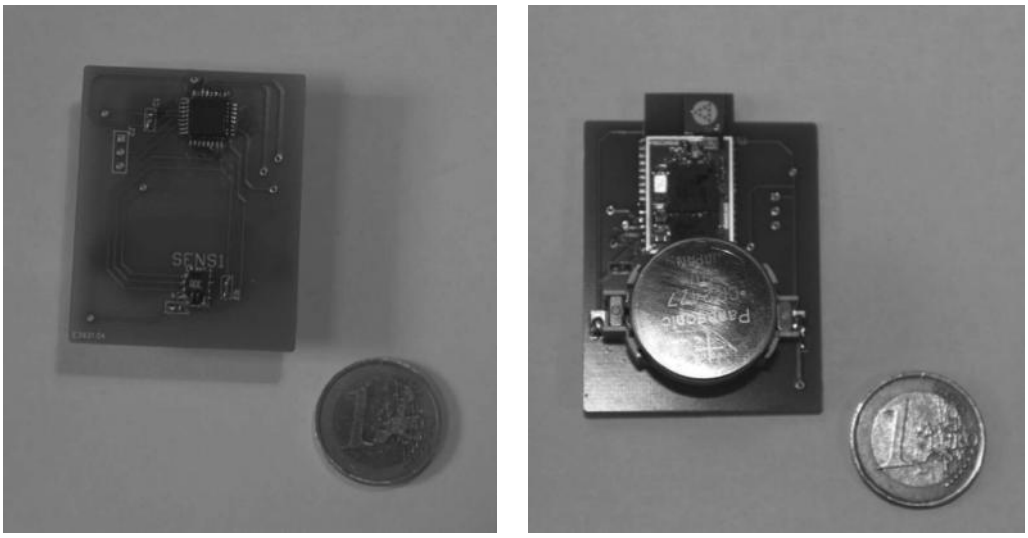
In this chapter, the possibility of applying smartphones for gathering data from other phones or sensors is presented. These days, temperature and humidity are two important parameters of monitoring climate condition to sense the changes of the environment in living or working places for the human. In doing so, distributed devices in different environments with high-resolution sensors and a wireless transmission apparatus for transferring data to smartphones can be a novel solution. Bluetooth (since it is embedded in almost all smartphones) is applied as a transmission tool that can work in the absence of a Wi-Fi connection. Smartphones easily communicate with other devices using the programmable tools that enable different kinds of applications. They can gather, analyze, and verify data. A prototype is proposed by Aram et al. (2012a) and improved by Aram et al. (2012b) by applying a Bluetooth-based sensor to sense *temperature* and *humidity* for the monitoring of environmental conditions using the android-based smartphone.

73.3 Prototype

73.3.1 Methods

73.3.1.1 First Version of the Bluetooth Sensor

The goal of the first version of the Bluetooth sensor was to demonstrate the feasibility of the architecture and to provide a device that is easy to interface to; this way showed how to have a simple data stream to develop the "client side" application more easily. The sensor is described by Aram et al. (2012a). It consists of a temperature and humidity sensor, a microcontroller, and a Bluetooth module. Figure 73.1 shows the first version of the sensor. The sensor used for this device is a Sensirion SHT11; it was chosen for its low-power consumption (about 80 μW) and its high accuracy (0.4°C for the temperature and 3% for the humidity, ranging from −40 °C to 125 °C and from 0% to 100%, respectively). It communicates with the microcontroller through a 2-wire serial interface. The microcontroller is a Silicon Labs C8051F314. It was chosen because its internal characteristics fit the requirements of the project; this microcontroller



(a) (b)

FIGURE 73.1 The electronic circuit related to the Bluetooth-based temperature and humidity acquisition system: (a) bottom view of the device including the temperature and humidity sensors and the microcontroller and (b) top view of the device including the battery holder and the Bluetooth module.

consumes about 1 mW at 1 MHz. As for the Bluetooth part, an integrated module was preferred to a custom circuit for two reasons: first of all, it is much simpler to use a module than to develop a Bluetooth interface and secondly because integrated solutions usually consume less power than discrete component solutions. An F2M03GLA Bluetooth module from Free2Move was chosen because of its simplicity and relatively low-power consumption (about 0.6 mW in sleep mode, with 200 mW peak consumption during transmission). Since the sensor has to be portable, it must be battery powered. A lithium battery (CR2247 from Motorola) was chosen because of its high capacity (1000 mAh).

This sensor was designed in order to be easy to interface to; consequently, the protocol that is implemented does not use low-power techniques to reduce consumption. The Bluetooth module is always on, giving the user the possibility to connect easily at any time. After opening a serial port, the user will start receiving an ASCII-encoded text string representing the measured temperature and humidity. Since no low-power techniques were adopted, this sensor consumes too much power, making it unsuitable for real measuring applications. The main issues to improve are

- Bluetooth module consumes too much power when turned on.
- Also the microcontroller can consume much less power.
- The protocol can be improved in order to transmit fewer bytes.

These were the guidelines that led to the development of the second version of the sensor.

73.3.1.2 Second Version of the Bluetooth Sensor

The first version consumed too much power. Consequently, the second version was designed to keep the power as low as possible. This is done in three ways: by changing the components, by changing the way they are handled, and by changing the protocol. As for the components, a new microcontroller was chosen. In doing so, a Texas Instruments MSP430F2132 was chosen because of its low-power features. Also, the sensor was changed by switching to a Sensirion SHT21. This sensor consumes even less power than the SHT11, and moreover, it has a common interface (I^2C) rather than a custom 2-wire connection. As a result, it is possible to use the integrated I^2C peripheral of the microcontroller so it can save some power. As for the Bluetooth module, the same feature is used as the first version, since it has the same power

consumption as the other modules available. As for the management of the devices, the microcontroller was given the possibility to turn off all other devices (the temperature sensor and the Bluetooth module). Additionally, since both the microcontroller and the sensor can exploit the battery until it decreases to about 2.3 V while the Bluetooth module requires at least 2.9 V, it was decided to use a dc–dc converter to provide 3 V from voltage sources between (slightly more than) 3 and 2.3 V. A charge pump converter from Maxim (MAX1759) was chosen because it could supply the current required by the module (75 mA at most) while requiring very few components (and no inductors). By using this converter, moreover, it was possible to switch off the module completely and also save the 0.6 mW of the power used for standby. As for the protocol, two issues were improved. First of all, transmitting ASCII messages is useful to develop since the information uses too many bytes. For instance, to transmit a number ranging from −40 to 120 (the temperature), in ASCII, it needs at least three characters (so three bytes), while sending it as a number uses only one byte. For this reason, pure numbers were used. The drawback is that it is easy to fine errors in ASCII strings (at the time of receiving nonprintable data, it is possible to recognize that the packet is corrupted), but with pure numbers, it is not possible. So a 1 byte CRC code is added at the end of every packet to enable the receiver to recognize bad packets. The second improvement of the protocol is to find periods when no listener is connected. In fact, it is useless to send data when no one listens for it. Therefore, instead of sending the information to one listener repeatedly, the sensor waits for its "clients" to send him requests. If there are no registered clients, the sensor doesn't even make a measurement or turn on the Bluetooth, which extends battery life. When a new client is registered, the sensor starts waking up at regular intervals to enable the client to make requests. If a client cannot be sensed, it will be removed from the list. These techniques extend the life of the battery. The intervals can be set directly by the user; since the power consumption is proportional to the measuring frequency, the user can select the best trade-off between high sampling rate and long battery life by modifying this parameter. The device is again powered by a 3 V lithium battery (CR2247) and is shown in Figure 73.2.

73.3.2 Smartphone Application for Sensing a Number of Sensors

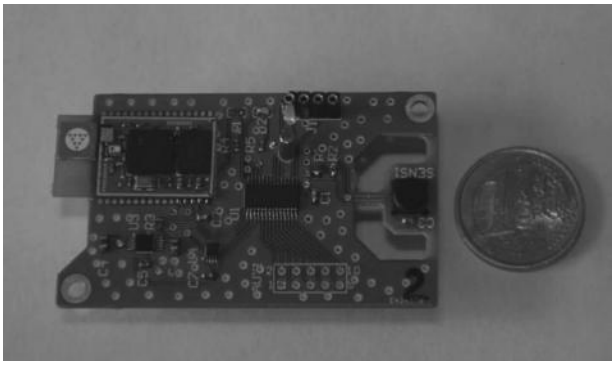
As a prototype, an application for sensing one sensor was developed by Aram et al. (2012b). It is called *aBluSen*. Figure 73.3 shows the data from a sensor. The application communicates, reads, and stores data from a paired Bluetooth-based sensor. This makes it possible to analyze data and also correct performance of the system. This application was developed to read data from several sensors at the same time. This new version makes it possible to communicate, read, and store data from distributed sensors within a short distance from the mobile phone.

The user can select the required sensors by himself or herself manually or automatically, or it is possible to organize system to communicate with all available sensors within a certain area automatically. The availability and connections of the sensors are checked continuously. The application can repeat the process for connecting, disconnecting, reading, and storing each sensor each minute. Figure 73.4 shows that it is possible to select several available sensors and run the system to work with selected ones.

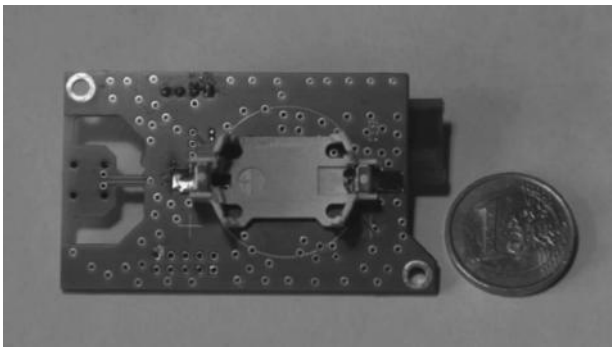
Unlike the first mobile phone application, the new version shows current and previous data of the current connected sensor and the last one (Figure 73.5). The system shows the temperature and humidity values of the previous connected sensor at the time the system tries to connect to the next sensor or reading the sensor. Thus, at the same time, there will be the values of last two read sensors on the screen.

Similar to the previous version of the application, the new one is also developed for the Android mobile phone with the updated version of the Android software development kit (SDK); Eclipse (together with its ADT Plugin) was chosen as the IDE. *aBluSen* has four main parts:

- Configuration
- Discovering
- Selecting sensors
- Display



(a)



(b)

FIGURE 73.2 The electronic circuit of the new Bluetooth-based temperature and humidity acquisition system. (a) Top view of the device including the temperature and humidity sensor, the microcontroller, and the Bluetooth module with the clear change in size. (b) Bottom view of the device including the battery holder.

Discovering and selecting parts both have a menu; Discovering is for scanning the available sensors, while Selecting makes it possible to select the desired Bluetooth-based sensors that gather the environmental information. *aBluSen* can distinguish between non-sensor Bluetooth-based devices and sensors. The application checks the name of the devices as a method of detecting sensors among all available Bluetooth devices. In the Configuration part, the user can set the number of sensors that can be simultaneously connected, sampling frequency, and also the way the system works (e.g., manually or automatically). As shown in Figure 73.5, the Display part shows the temperature and humidity values as environmental information related to the current and previous sensor, number of available and selected sensors, and sensor information. After the first communication, sensors are set as paired sensors. Immediately after doing the select procedure, the application tries to connect to the first sensor. Some communications and sensors may need two attempts for connecting to the sensor. There are two methods of connections:

- Standard method
- Reflection method

If the first method of connecting fails, the application tries to start the second method. The reflection method avoids the complete failure of connection with the standard method for connecting. After successful connection, the *aBluSen* starts reading data from the opened port. At the time of connecting to a sensor, the mobile phone keeps listening to the opened port to read input streams. In the Configuration part, the size of the buffer can change to permit handling the amount of data during the time of reading. The default value for the buffer size is 64. The read data from the sensors are not the data that are shown

FIGURE 73.3 The "Display" part of the aBluSen previous version shows the temperature and humidity values obtained from the Bluetooth-based acquisition system.

FIGURE 73.4 "Select Sensor" part of the new android application (aBluSen) for selecting several available sensors.

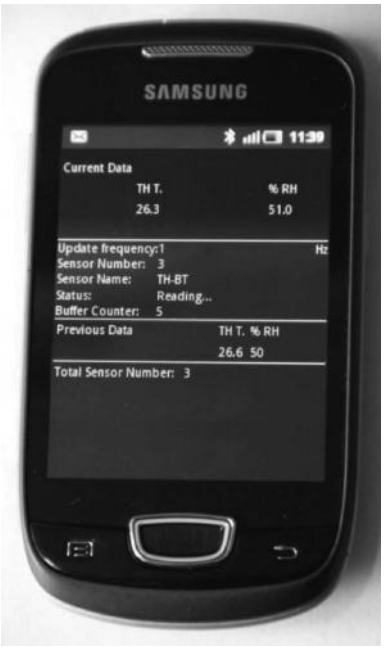


FIGURE 73.5 "Display" part of the new aBluSen application for the android's mobile phone that shows the current and last data of the temperature and humidity values of the two sensors at the same time.

in the Display. The data streams need to parse. The *tokenization* process breaks the streams of data to the desired values of temperature and humidity from the several lines of data that are reached from the connected sensor. A sample line of data is like

$$T = + ., +25.6{,}46$$

The temperature and the humidity are two values that are required to break from the lines of data. The temperature and humidity values are +25.6 and 46, respectively, in this sample. At the time of data reading, the data of the sensors are stored in a text file in the android-based mobile phone. Then the text file is used for analyzing. The interval for the process of reading from the connected sensor is 1 min as a default. In this experiment, the interval is the default. This frequency sample can be modified to communicate and read to/from the sensors via the Configuration part of the application. After each interval, the current communication of the sensor and the mobile phone disconnects, and immediately the application tries to connect the mobile phone to the other selected sensor via Bluetooth. Again, all the processes repeat for the connected sensor. Connecting, reading, storing, and disconnecting are all steps that are repeated continuously according to the configured interval.

73.4 Evaluation

Two experiments were carried out; the first to test the reliability of the sensors and the second to measure their power consumption. Results of the experiments are presented in this section. In order to test the reliability of this system, three temperature and humidity Bluetooth sensors were placed in a climate chamber (Angelantoni Challenge 250); this instrument is able to control environmental conditions such as temperature (from −40 °C to 180 °C) and humidity. The sensors were connected to the smartphone application in order to log the environmental data. They were set with a sampling frequency of one sample per minute. The climate chamber was set to follow a precise temperature profile. For the first 20 min, the temperature was kept constant at 25 °C; then the chamber was set to reach −20 °C with a temperature gradient

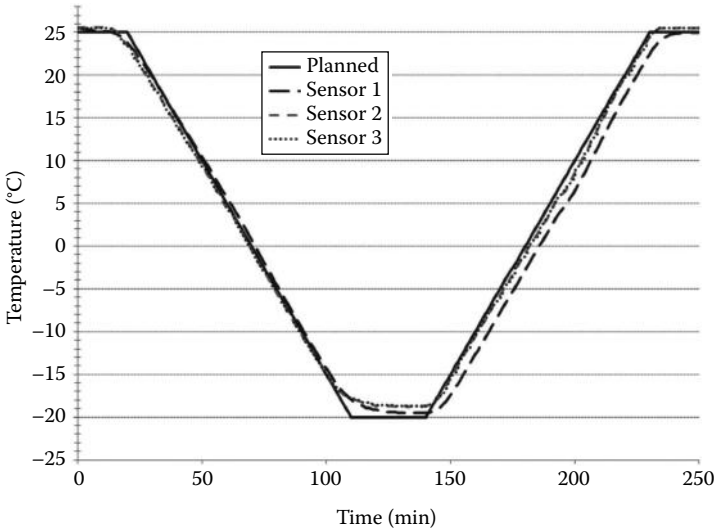

FIGURE 73.6 Temperature values that are obtained by the three Bluetooth-based temperature and humidity acquisition systems during the first experiment.

of −0.5 °C/min (90 min). This temperature was kept for 30 min. Then the chamber was set to reach 25 °C with a gradient of 0.5 °C/min (another 90 min). At the end of the experiment, this temperature was kept constant for 20 min. The overall experiment time was 250 min. The second experiment aimed at measuring the power consumption of the sensor and, consequently, the estimated battery lifetime. The sensor was powered by a power supply, with a constant voltage of 3 V, and the current was measured using a digital multimeter (Agilent 34401A), set in order to acquire current values with a sampling frequency of four samples per second. The second version of the sensor was tested, because it was the only one designed to save power. Figure 73.6 shows the results of the first experiment. The graph represents the temperature values collected by the sensors. The blue line follows the temperature profile imposed by the climate chamber.

As for the second experiment, current values collected by the multimeter are shown in Figure 73.7. The plot shows a 1 min measure; at $T = 0$, the sensor woke up and waited for the client to connect (first peak). At the connection (second peak), the sensor transmitted the values to the client; the operation lasted for about 5 s (due to the pairing required by Bluetooth) and then, since there were no other listeners, put itself into sleep mode for the remaining 50 s.

In low-power mode, the current absorbed by the device is about 1 μA, while during the 10 s of the "active phase," the average current is 27 mA. These values lead to some considerations. First of all, it is required

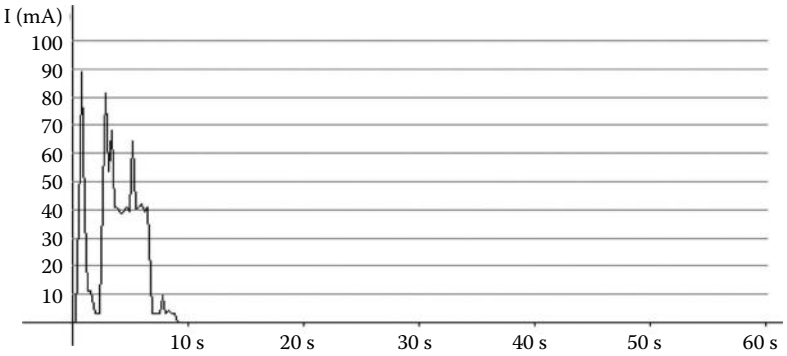

FIGURE 73.7 Current values for the Bluetooth-based temperature and humidity acquisition systems during the second experiment.

that the active phase lasts the shortest time possible. This is achieved by using "control messages," which means that the client sends to the sensor information such as "start measuring" or "disconnect from me." The second consideration is that the sleep time does not influence the current consumption. In fact, in a 1 min measurement, the sleep phase affects current consumption about 0.02%. Neglecting this term permits calculating the battery duration in terms of number of measurements (since the consumption is directly proportional to the frequency of measurement). Collected data, averaged over a 1 h period, indicate that the chosen battery (Motorola CR2477, 1000 mAh) should last for about 14,000 measurements; setting the system to acquire one data every 5 min, the battery should last for about 48 days.

This work studies a low-power wireless sensor network for acquiring temperature and humidity values from a number of sensors. Employing low-cost and low-power components, the Bluetooth as a transceiver (for transferring acquired environmental information) and a smartphone using an application for communicating, reading, and storing data automatically are the major issues of these two recent works.

A laboratory test using a climate chamber was applied to verify the performance of the system. The climate chamber changed the environmental conditions. The outcomes indicated that all involved elements together correctly reported the environmental condition in order to follow the climate chamber changes, and also, the smartphone's android-based application acquired and stored the data properly, which were transferred by the Bluetooth connections. In the first experiment, the smartphone application gathered the environmental data continuously with no absence of signal from any device. Also, the results from the second experiment indicated that the current consumption of the Bluetooth-based temperature and humidity acquisition system is 1 μA while waiting for a transmission, and it is 27 mA (as the average) during the time of transmitting to a smartphone. The results show that the device can transfer data to a smartphone for more than 4 months by using a time interval of 15 min between each two measures using the CR2247 battery. Therefore, the proposed wireless sensor network is working properly.

This prototype shows an approach that is useful for monitoring climatic conditions for small environments using smartphones. The environmental information of small places such as laboratories, home rooms, and medical spaces can be gathered by smartphones for analyzing and also alarming at the time the conditions change or go over fixed thresholds. Also, it is possible to have an application for detecting fire in small environments. Nowadays, the role of smartphones has changed by applying scientific research in projects using their sensors. Aram et al. (2012a,b) applied the smartphone to communicate with external sensors to gather and make possible analyzing obtained environmental data. They considered the power consumption because of the possibility of mobility for long working times that make the sensors—and consequently required information—available. Miniaturization of the proposed device can be considered for improvement of this work. It can be followed by using a smaller microcontroller with the radio part of the Bluetooth module, which needs only one external antenna. Also, reducing the power consumption of the device by considering the following issues can be focused for the future:

- Modifying the use of the Bluetooth protocol
- Having a Bluetooth module with a lower-power consumption (since most consumption of the power is because of the Bluetooth as a transceiver)
- Improving the operating system and software layer of the sensor and mobile phone

David M. Hamby
Oregon State University

74.1 Introduction

The advance of space exploration has been fraught with inherent risk throughout its history. Health effects from space radiation for off-world astronauts remain one such risk that has historically received little attention but in fact may be the most constraining factor for long-duration missions that depart from the relative safety of the Earth's magnetosphere. With interplanetary and lunar-based missions rapidly approaching on the horizon, it is now critically important to understand the impacts of the space radiation environment and to develop instrumentation capable of properly expressing that hazard. A summary is provided here for the status of those instruments and their recent developments and to briefly introduce the basis for space radiation hazards. Readers are encouraged to explore the cited literature for further details.

74.1.1 Space Radiation Environment

The space radiation environment is generally characterized by three contributing sources. Galactic cosmic rays (GCRs) represent the permanent baseline of radiation outside of low-Earth orbit (LEO) and the protective magnetosphere. The primary concern for GCR is the prevalence of high-Z (charge), high-energy particles (HZE) likely originating from distant ultra-energetic events such as supernova explosions. The flux profile of GCR peaks for particles with energies of around 1 GeV [1] and extends with decreasing probability to energies of up to 10^{20} eV [2]. HZE particles penetrate shielding and tissue while producing cascades of secondary particles that cause widely varied dose profiles throughout the spacecraft.

The sun periodically releases large masses of solar energetic particles (SEPs) in what are referred to as solar proton events (SPEs). Large solar storms are comparatively rare but can potentially deliver extreme doses sufficient to cause deterministic effects including radiation sickness. Events can often be forecast to some extent, but the high risks call for detectors that can rapidly alert crew to take shelter when needed.

Within LEO the main dose contributors are protons and electrons trapped in belts within the Earth's magnetosphere. Orbiting spacecraft typically maintain altitude below the most intense portion of the belt so that the main dose contribution occurs as it passes through a dip in the magnetic field known as the South Atlantic Anomaly (SAA) [1].

74.1.2 Space Dosimetry Units

Radiation dose is traditionally measured and quantified as average energy deposition within a given volume of known mass, deemed "absorbed dose" (D). Values of absorbed dose caused by photons have been studied and correlated to known health effects. Other radiations that cause dense regions of ionization are known to cause greater biological harm, or equivalent dose (H_T), for identical quantities of absorbed dose in a given tissue, T. In typical dosimetry applications, this difference in relative biological effectiveness (RBE) is corrected by simple radiation weighting factors (w_R) applied to the value of absorbed dose ($D_{T,R}$) for each radiation type, R. These are applied to the value of absorbed dose ($D_{T,R}$) averaged over an organ with w_R equal to 1 for photons and electrons, 2 for protons, 20 for heavy ions, etc., so that

$$H_{T,R} = w_R \cdot D_{T,R} \tag{74.1}$$

For mixed radiation fields, the total equivalent dose (H_T) is calculated by summing the various contributions:

$$H_T = \sum_R H_{T,R} = \sum_R w_R \cdot D_{T,R} \tag{74.2}$$

This can then be corrected with a set of tissue weighting factors (w_T) applied for each organ to determine the effective dose (E) that serves as a risk estimate for long-term effects [3]:

$$E = \sum_T w_T \cdot H_T \tag{74.3}$$

This method is not suited to space environments dominated by a varied flux of charged particles, where applying the basic radiation weighting factor of 20 for all HZE interactions would be overly conservative in most cases [3]. A method is instead recommended by NCRP 132 [4] for space dosimetry in LEO that employs the factor for radiation quality (Q) as a function of the linear energy transfer (LET) as provided by ICRP-60 [5]. Dose equivalent is traditionally expressed simply as

$$H = D \cdot Q(L) \tag{74.4}$$

where

(L) represents LET = dE/dx

$Q(L)$ is unity for (L) less than 10 keV/μm, which increases gradually to 30 for (L) up to 100 keV/μm and decreases thereafter due to the increased probability of cell death that does not contribute to cancer effects

The use of quality factor as a correction for absorbed dose results in point-location values of "dose equivalent" (H), rather than the "equivalent dose" as obtained by the weighting factor method. To take advantage of existing tissue weighting factors for data that include radiation quality, dose is determined as a tissue-averaged value as recommended by ICRU [6]:

$$H_T = \frac{1}{m} \int_m dm \int Q(L) \cdot \phi_T(L) \cdot L \, dL \tag{74.5}$$

where $\phi_T(L)$ represents the fluence of particles through organ T, in the differential increment of LET $(L + dL)$ [7,8]. Investigations continue for development of dosimetry methods in deep space [9] and research has shown significant evidence toward the importance of track structure and charge rather than simple LET to approximate RBE [7,10].

74.1.3 Challenges in Space Dosimetry

Radiation detectors can provide essential information regarding the environment experienced by astronauts, but such measurements serve to clarify only one aspect of a complex process. The stochastic nature of long-term radiation effects such as carcinogenesis has resulted in large uncertainties to risk estimates. This is true both for low-dose exposures where existing population cancer rates are already high and for astronaut exposures in mixed HZE fields with a small sample population and a number of other contributing factors [7]. Effects in deep tissue and organs are not easily measured, though biodosimetric methods can observe dose-dependent cytogenetic effects with methods that continue to improve rapidly [11,12].

Phantom experiments have been used to form relationships between shallow skin dose (the measurable quantity for dosimetry) and depth dose measured throughout a volume of water or tissue-equivalent resin. Several phantom experiments have been performed including the NASA [13] and MATROSHKA [14] human torso phantoms, as well as the early Mir [15] and later MATROSHKA-R [16] spherical phantoms. Computational transport models have also performed important roles in depth dose analysis for organs based upon measurable quantities [17,18] and are likely to become increasingly important as computing power and accessibility steadily improve. Ground-based studies for high-energy interactions and detector performance are also improving the scientific basis for space dosimetry [19–22]. Information gleaned from these studies can be used to extrapolate effective dose based upon flux profile data gathered by personnel dosimeters, area monitors, or in exploratory surveys.

Instrumentation for space dosimetry is then left with a series of challenges for development. The importance of particle discrimination and LET measurement is among the primary technological hurdles, generally requiring advanced processing techniques and extensive calibration studies in accelerator beams [22,23]. Beyond these performance requirements, limitations for weight, size, power consumption, reliability, and cost must be considered. Several instruments have been developed and expanded upon by a global variety of researchers. These include the operational devices from NASA for monitoring and dose records on the International Space Station (ISS) such as TLD/CR-39 (Figure 74.1),

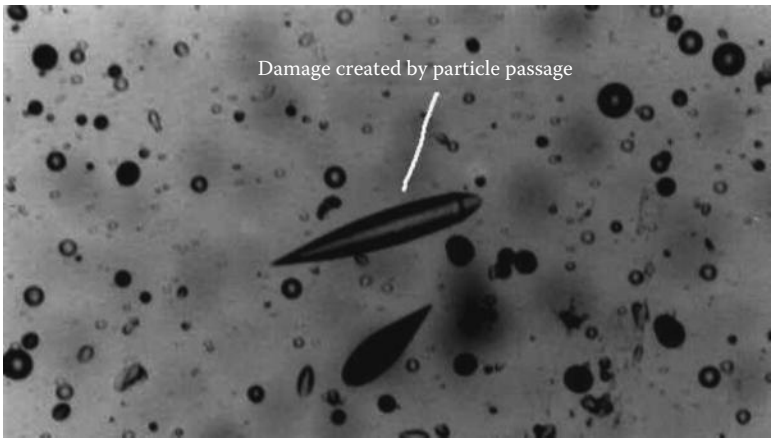

FIGURE 74.1 A CR-39 PNTD from the DOSMAP experiment reveals an etched particle track under microscope. (Courtesy of NASA/JPL-Caltech/SwRI. NASA Dosimetric Mapping (DOSMAP), *International Space Station—Research and Technology*, NASA, April 26, 2013, http://www.nasa.gov/mission_pages/station/research/experiments/1003.html, accessed August 8, 2013.)

tissue-equivalent proportional counter (TEPC), and CPDS (soon replaced by the radiation assessment detector [RAD]), in addition to the R-16, DB8, and Pille devices operated within the Russian module [23]. Beyond these existing operational instruments, a host of science-driven experiments have operated to improve the knowledge base of the space radiation environment while many others proceed in development to improve or replace the fleet of operational dosimeters.

74.2 Passive Dosimetry

Passive dosimeters accumulate a record of incident radiation that can later be processed to estimate the dose integrated over the time of exposure. They are typically small and economical and operate with no demands on the limited power onboard spacecraft. They have been an effective and practical choice for space dosimetry, particularly in measuring the widely varied radiation burden throughout spacecraft [24]. Passive dosimeters have also been central to phantom experiments conducted by a diverse group of researchers, and ground-based studies such as HAMLET continue to improve the understanding of results obtained therein [14,21,25,26].

74.2.1 Thermoluminescent Dosimeters

Thermoluminescent dosimeters (TLDs) have played a key role in space dosimetry throughout the history of manned spaceflight [27]. They are lightweight, affordable, and provide a time-integrated dose that translates easily to an administrative dose record. Space dosimetry introduces several problems not encountered in terrestrial TLD dosimetry due to the complex radiation field with significant high-LET contributions. TLDs respond poorly to high-LET radiation, as the dense ionization tracks tend to saturate electron/hole trapping centers and the deposited energy is then dissipated by competing mechanisms [28,29]. Efforts from many researchers have attempted to extend the function of TLDs by estimating LET and particle type through various methods and materials with limited success [28,30–32]. Their poor sensitivity to high-LET radiation limits TLDs to dose estimates from particles of less than 10 keV/μm [21,33].

TLD dosimeters are typically returned to Earth for laboratory processing, thus accumulating some dose throughout a mission and limiting its capability for long-term use. The notable exception is a portable readout TLD system known as "Pille" developed by the Hungarian KFKI Atomic Energy Research Institute. Pille dosimeters are constructed of $CaSO_4$:Dy crystal laminated to a resistive plate within a glass vacuum bulb. Ten such dosimeters can be worn or permanently stationed within a compact reader device that manages heating, light measurement, and dose records for each dosimeter. "Semipassive" systems such as the Pille offer a reasonable compromise for portability and power consumption for long-duration missions in which passive dosimeters must be read out in transit, though like other TLDs the Pille is not sensitive to high-LET particles [24,34,35].

74.2.2 Optically Stimulated Luminescent Dosimeters

Optically stimulated luminescent dosimeters (OSLDs) share the same fundamental mechanisms as TLDs for dose accumulation and readout but are instead stimulated by optical laser. Stimulation sensitivity to natural UV light adds to the risk of dose fading, so extra care must be taken to maintain total darkness for the crystal until readout is complete. OSLDs for space applications are constructed with Al_2O_3:C and have shown to be comparable to TLD in most cases [36,37]. Light stimulation methods require less power consumption than heating, provide greater flexibility for portable readout systems [38], and show improved capabilities for monitoring various effects such as light emission decay time. A possible advantage for OSL over TL is its capability to release a fraction of trapped electrons/holes by briefly pulsed stimulation to estimate dose without resetting (bleaching) the crystal. Dose record could therefore be monitored at periodic intervals while maintaining the dose record for long-term monitoring. A summary of OSLD with its history of development and applications in space is provided in reference [39].

74.2.3 Nuclear Track Detectors

Plastic nuclear track detectors (PNTDs) are the primary means of passive dosimetry for high-LET radiation. Among these, CR-39 (Figure 74.1) resin is the most widely used and studied. Researchers continue to investigate improvements in processing methods [40–44] and particle identification [45–48]. High-LET particles produce latent tracks as they traverse the resin, where ionization weakens molecular bonds. Following irradiation, the resin is etched in a caustic solution to dissolve the material. Latent tracks dissolve at a faster rate than the remaining plastic to form distinct conical pits that are clearly visible under microscope, either processed manually through observation or through automated scanning [44]. The profile of etched cones can be correlated with particle LET and charge, then coupled to the track density to determine fluence and dose [49].

74.2.4 Combined Passive Dosimeters

Estimating the equivalent dose received by individuals in mixed radiation fields generally requires a combination of dosimeters with varying response characteristics. CR-39 (Figure 74.1) is sensitive primarily to charged particles with LET between 5 and 1000 keV/μm and is typically coupled with TLD or OSLD sensitive to radiation below 10 keV/μm. This combined passive dosimetry method is widely used in space dosimetry and other mixed radiation fields to produce reliable measurements for dose of record [26,27,37,50,51].

74.2.5 Superheated Drop Emulsions

Superheated drop (bubble) detectors offer a novel approach to fast neutron detection in space. A fluid of polymer liquid droplets is encapsulated within a clear vial and sealed at a low-pressure (superheated) state. The polymer remains liquid at ambient temperature but readily vaporizes to form visible bubbles when ionized by recoil protons of fast neutron collisions [52,53]. A portable readout machine is used to measure the quantity of bubbles formed during irradiation, a value that is calibrated directly to dose equivalent. The device can then recompress the fluid to reset the dosimeter for a limited number of repeated irradiations. A single dosimeter has a limited capacity for bubble formation and requires resetting at regular intervals; thus, it behaves as a semipassive system requiring a powered device. Bubble detectors have been operated within the MATROSHKA-R spherical phantom for neutron depth dose measurements [25], as neutron-sensitive area dosimeters, and as a neutron spectrometer by exposing multiple detectors of varying threshold energies. Investigations on the ISS have pointed toward a greater sensitivity to fast neutrons than to charged particles [54,55].

74.3 Active Dosimetry

Active radiation detectors require power and are typically larger than passive measurement systems, but their ability to immediately resolve fluctuations in the radiation environment could be a lifesaving feature in the event of an unforeseen SPE. Recent progress in microelectronics has enabled the development of personal electronic dosimeters capable of LET measurement, though at this time no such devices are used as operational space dosimeters.

74.3.1 Tissue-Equivalent Proportional Counters

A variety of TEPC dosimeters have flown on missions including the International Space Station (ISS) and Mir Orbital Station beginning in 1994 [56]. The TEPC microdosimeter serves as the primary operational area radiation monitor on the ISS and is integrated into an alarm system to warn astronauts of radiation storms that may require refuge in the station's radiation shelter. The system has undergone

several design revisions over the past two decades, beginning as a cylindrical detector to simplify charge collection characteristics and recently changing to a two-detector spherical shell system. Propane is used as a fill gas at very low pressure to emulate the radiation effects inside of a micron-scale volume to approximate a single tissue cell.

In the case of the TEPC, lineal energy (y) is calculated for each event by dividing deposited energy over the mean chord length. Detector response calibrations are used to correlate the measured lineal energy with particle LET and, through previous research [57], determine the radiation quality (Q) or RBE for final calculation of dose equivalent (H). The occurrence of interactions in the detector wall and uncertainty in the use of mean chord length can result in deviations from true values of ionization density, especially when considering the nonuniform angular distribution of chords through cylindrical detectors [58,59].

The latest TEPC revision uses two independent spherical detection volumes that improve the uncertainty associated with mean chord length. Irregularities in the electric field caused by the varying anode/cathode distance within the chamber are mitigated in the new TEPC by constructing the spherical shell as a stack of several annular rings each with adjustable applied voltage [60].

74.3.2 Compact Diode Dosimeters

Semiconductors provide several advantages for use as compact active dosimeters. Solid diodes perform well in very small form factors and can operate with far lower voltage requirements than gas detectors. Power consumption is rather minimal by comparison, and battery-operated devices have a distinct advantage in noise isolation from the station power supply. Semiconductor materials are not tissue equivalent, however, and they require correction factors to apply Si-based measurements into tissue dose [61].

The Liulin-4 single-diode detector has been used extensively for detection in European space missions with remarkable reliability. Its measurements are generally limited to absorbed dose and dose rate in the absence of a known deposited track length, though it does attempt some estimate of dose equivalent by separating low-energy interactions from high-energy depositions assumed to originate from neutrons [62,63]. A separate single-diode instrument was flown recently onboard the Lunar Reconnaissance Orbiter as part of the CRaTER experiment to demonstrate miniaturization capabilities of a simple dosimeter [64].

Advances in microfabrication have led to the development of various instruments that facilitate LET measurements within silicon microdosimeters. Silicon-on-insulator (SOI) microdosimeters such as the MIDN are constructed as an array of microscopic sensitive volumes with thickness of 10 μm or less to permit reasonable estimates of lineal energy and LET [65–69].

An alternative approach involves monitoring energy deposition in a pixelated silicon wafer, essentially serving as an active nuclear track detector. The Timepix/Medipix device is one such pixelated detector approaching applications for space dosimetry based upon work from the CERN Medipix collaboration [70]. Dose equivalent is measured by calculating the primary particle's tangential track length and total energy deposition in all pixels [71–73]. Some measure of particle identification can be performed based upon track structure [74], and neutron dosimetry may be viable with proton recoil measurement under a polyethylene converter [75].

Other pixelated, or rather voxelated, devices based upon scintillator technology have been proposed that take advantage of the recent progress in CMOS technology. The advancement of solid-state photomultiplier (SSPM) technology has allowed for the replacement of large power-demanding photomultiplier tubes with small and efficient silicon sensors. SSPMs have been developed from the miniaturization of technology based upon the avalanche photodiode, where each photodiode micropixel operates in a Geiger mode that activates when struck by light photons. When coupled to a scintillating crystal, the quantity of radiation imparted can be measured as a function of the number of activated pixels. Improvements in microfabrication allow for a high density of pixels and therefore good dynamic range and high resolution for spectroscopy. A 3D voxel structure of small scintillators, each coupled to an independent SSPM, may provide a capable neutron-sensitive particle tracking dosimeter with minimal power requirements [76,77].

74.3.3 MOSFET Dosimeters

Metal oxide semiconductor field effect transistor (MOSFET) systems have become a very popular method of dosimetry for space applications. Standard MOSFETs are constructed by application of a silicon oxide layer upon a *p*- or *n*-doped silicon substrate between two electrical contacts, deemed the source and drain electrodes. In the case of a *p*-channel MOSFET (*p*MOSFET), the silicon substrate is doped with electron-donor (*n*-type) impurities, while nMOSFET systems utilize a *p*-type substrate. During irradiation, a positive bias voltage is applied to the gate electrode placed in the SiO_2 region, so that electron/hole pairs are separated after ionization. The electrons produced in the sensitive SiO_2 are drawn away by the positive gate bias, while holes migrate and trap within the Si/SiO_2 interface. During readout, an applied gate voltage is gradually increased while the source and drain electrodes are monitored for continuity. As the amount of ionization causes the number of trapped holes to increase, so too does the negative gate voltage required to induce a channel of conductivity in the silicon substrate [8].

MOSFET has been used extensively for dosimetry experiments and radiation monitoring in space, as they are generally very compact and require minimal power. In practice, they can operate similarly to the portable readout "semipassive" dosimeters such as the Pille TLD or bubble-detector systems, where the integrated dose is measured periodically such as in EVA dosimetry [78]. They are often operated as "semiactive" detectors, however, such as within the MATROSHKA-R phantom where the small detector region was placed at precise locations and wired to an automated measurement system for continuous cycling of readout and measurement [79]. Some performance features of MOSFET dosimeters include permanent dose storage, extremely small size, and adjustable sensitivity based upon applied gate voltage during irradiation. They show very good sensitivity to photons and charged particles across a wide range of energy and can be made sensitive to neutrons particularly with the addition of converter material. Various improvements are underway for space dosimetry applications, particularly for stability and for preventing source–drain leakage current after heavy irradiation [80].

74.3.4 Particle Telescopes

Systems of multiple detectors operated with coincident signal processing can reveal far more information about an incident particle than any individual detector. As mentioned previously, a single large-area semiconductor may accurately measure absorbed dose as a function of deposited energy but cannot reliably estimate LET due to the ambiguity of the particle trajectory and path length inside the sensitive volume.

Charged particle telescopes are capable of measuring LET for charged particles incident within a restricted solid angle as they pass through a series of detectors activated in coincidence. Isolating measurements to known trajectories allows for a reasonable estimate of the particle track length through each detector, where narrower fields of view serve to improve the uncertainty of this estimate. The charge collected within an individual detector is then divided over the thickness of the active region to calculate the particle's rate of energy loss, or dE/dx. Individual detectors within a telescope may still operate between coincidence events to independently accumulate measurements for absorbed dose or flux [81].

The early Voyager missions included cosmic ray telescope experiments with multiple stacked sets of silicon detectors that have operated reliably since their launch in 1977 [82,83]. Similar telescopes of large-area planar silicon detectors have been operated with various improvements, including the German DOSTEL 2D instrument flown in both Mir and ISS [27,84] to map the dose profile within the spacecraft. The Bulgarian Liulin instrument was expanded from previous work to build the Liulin-5 telescope within the MATROSHKA-R spherical phantom experiment [16,81,85], and the Liulin-Phobos telescope onboard the ill-fated Fobos-Grunt sample-return mission intended for Mars' moon in 2011. The CRaTER device currently onboard the Lunar Reconnaissance Orbiter uses a similar configuration as Liulin-5 but fills the volumes between detectors with tissue-equivalent plastic [86–88].

A telescope stack can further improve the accuracy of measured LET by including position-sensitive detectors (PSDs) to establish a more precise particle trajectory. Double-sided strip detectors (DSSDs) are commonly used for this purpose, in which perpendicular arrays of strip detectors create a detection grid for penetrating charged particles. DSSDs were used to construct the Japanese RRMD-III telescope spectrometer to measure real LET and dose equivalent [59,89,90].

The Italian SilEye devices use strip detector telescopes for particles traversing the eyes and brain to investigate the anomalous light flashes first noted by Apollo astronauts [91]. The SilEye3/Alteino device and the later ALTEA device were operated onboard the ISS as astronaut experiment facilities, then continued operation as area monitors under the Altcriss and ALTEA-DOSI projects. A set of six telescope units were mounted on a helmet that also contained an EEG cap for electrophysiological measurements. Astronauts operated the experiment by wearing the device and activating pushbutton sensors to indicate the observation of light-flash events [92]. The large telescope device is capable of identifying energetic particles with charges (Z) from 4 to 28 and energy greater than 25 MeV per nucleon [93,94].

Three DSSD detectors were also incorporated into NASA's charged particle directional spectrometer (CPDS) put into service on the ISS beginning in 2002 [95,96]. The intricate device housed three other silicon detectors for coincidence triggering, six lithium-drifted silicon (Si(Li)) detectors for spectroscopy and LET measurement below which sat a sapphire crystal with a small photomultiplier tube for Cherenkov detection. The instrument could perform spectroscopy and LET measurement in the Si(Li) detector stack across a wide field of view for particles that only activated the top two coincidence and DSSD detectors. Particles entering within a narrower field of view could penetrate all 12 silicon detectors and deposit into the Cherenkov detector allowing the CPDS to identify particles with charge of $Z < 12$. The CPDS was implemented in both the interior (IV-CPDS) and exterior (EV-CPDS) of the ISS as part of NASA's radiation monitoring program but was troubled by problems that resulted in the premature failure of one EV-CPDS as well as the IV-CPDS.

A similar spectrometer, MARIE, was included in the Mars Odyssey mission launched in 2001 [97–99]. The MARIE detector suffered from a few problems including excessive preamplifier gain that saturated with high-energy events, slow readout for pulse height that caused excessive system dead time, and a design flaw in the Cherenkov detector [83]. Regardless, the MARIE device successfully operated for over 2 years until a large SPE ended its operation in 2003 [7]. An advanced telescope design concept, the combined ion and neutron spectrometer (CINS), includes a charged particle stack based upon the MARIE design but features improved electronics [83]. It proposes to use two advanced neutron spectrometers, including a thick Si(Li) semiconductor fast neutron spectrometer as well as an Eljen boron-loaded scintillating spectrometer for mid-energy neutrons based upon the gamma ray and neutron spectrometer within the MESSENGER Mercury spacecraft [100].

The RAD (Figure 74.2), built by Southwest Research Institute, represents the latest implementation of telescope spectrometers. It is currently operating onboard the Mars Science Laboratory (MSL) Curiosity rover to measure the flux profile at the Mars surface in support of future human exploration and Martian life investigations. The RAD is also slated to replace the IV-CPDS as an operational area monitor inside the ISS by 2015. The MSL RAD houses three silicon diodes as a charged particle telescope, each segmented into several complex regions that provide position dependence sufficient to minimize path length uncertainty. Three scintillators housed beneath the diode stack measure energy deposition from charged particles arriving through the telescope and also perform spectroscopy for neutrons and photons arriving from all angles. The thallium-doped cesium iodide (CsI(Tl)) scintillator sits directly below the telescope and is shaped to match its field of view for charged particle collection. It also responds well to photons and, to some degree, neutrons from all directions. An organic plastic scintillator constructed of Bicron BC-432 m sits below the CsI(Tl) crystal, primarily intended for neutron detection by recoil proton production, but also sensitive in some degree to photons. A BC-432 m anticoincidence shield surrounds the inner scintillators to eliminate charged particle background, except for those traversing the telescope counted for spectroscopy or particle identification. Photodiodes, nearly identical to the diodes used in the telescope, are bonded to the scintillators for light measurement, thus requiring only a single power supply for the entire

system [101]. Neutron and gamma contributions are separated in the central scintillators by evaluating the unique response of each scintillator with a statistical maximum-likelihood inversion technique developed for that purpose [102]. Other independent neutron detectors are described in the following section.

74.3.5 Neutron Detector

Neutrons are notoriously difficult to detect efficiently, as their lack of charge prevents the occurrence of direct ionization to produce measurable electrical signals. Neutron detection must then rely upon the production of secondary recoil ions from scatter interactions, through photon emission after activating capture interactions or through the products of fission interaction. High-energy neutrons often produced as secondaries within spacecraft may proceed to scatter and maintain relatively high energy until entering a low-Z (especially hydrogenous) material where its kinetic energy can be transferred away as energetic recoil ions. Unfortunately, humans often serve as that hydrogenous material, and neutrons can therefore introduce a significant contribution to dose equivalent, approximated to be around 30% of total dose equivalent with significant uncertainty [7,103,104].

74.3.5.1 Bonner Sphere

Bonner sphere detectors provide a method for determining neutron energy spectra by surrounding a ^{3}He proportional counter with polyethylene spheres of varying thickness. ^{3}He proportional counters respond well to neutrons across a broad range of energy by way of the ^{3}He (n,p) ^{3}H reaction. Each moderating sphere yields a unique spectral response as energetic neutrons are moderated to varying degrees.

The Bonner Ball Neutron Detector (BBND) experiment measured the neutron energy spectrum onboard the ISS in 2001. Six ^{3}He proportional counters were installed within a large assembly, four of which included polyethylene spheres of varying thickness while two counters remained unmoderated. Gadolinium shields were mounted on one unmoderated detector as well as upon the smallest moderator serving as controls to reject the entry of prethermalized neutrons. An unfolding technique was then applied to the combined spectra to develop a single differential neutron energy spectrum [89].

74.3.5.2 Neutron Telescope

Several neutron telescope detectors have been developed within the Russian space program. The Board Telescope of Neutrons (BTN) system is mounted onboard the Russian segment of the ISS and is identical to the high-energy neutron detector (HEND) instrument operated on the Mars Odyssey orbiter. The detectors operate with three long-tube ^{3}He proportional counters oriented in each of the three axes sensitive to epithermal neutrons outside of the space station. Each counter is encased in polyethylene of varying thickness, where the directionality of the system provides information regarding the source of incident neutrons. A $C_{14}H_{12}$ stilbene scintillating crystal measures high-energy neutrons of 400 keV–10 MeV based upon a calibrated response for recoil protons, while a CsI:Tl^{3+} anticoincidence shield blocks/reduces background from charged particles [105].

A separate neutron telescope design, the Lunar Exploration Neutron Detector (LEND), is included on the Lunar Reconnaissance Orbiter to measure the neutron field around the moon and the flux of neutrons emitting from the lunar surface. LEND is constructed with eight ^{3}He proportional counters, four of which are located within parallel holes of a collimation module and covered with cadmium foil to restrict measurements to epithermal neutrons only. A fifth collimation tube houses a stilbene scintillator, again used for high-energy neutron measurements inside an anticoincidence shield. The collimation module is constructed of polyethylene and ^{10}B to moderate then capture any off-angle incident neutrons, restricting the collimated detectors' field of view to targeted locations on the lunar surface. The four remaining ^{3}He proportional counters are mounted outside of the collimator to measure the surrounding neutron flux, two of which are cadmium-wrapped to eliminate thermal neutron contribution [106].

74.4 Summary

Space dosimetry is a complex and developing science that will play a critical role in the forthcoming exploration of space. Astrophysics, health physics, materials science, electrical engineering, particle physics, and a host of other disciplines play vital roles in developing an understanding for the radiological risks of space travel. A broad array of instruments has been developed in this pursuit, either as operational monitors for crew dosimetry or as experiments to profile various aspects of the radiation environment. The importance of determining quality factor for incident radiation has added to the challenge of producing instruments capable of fulfilling the rigorous demands of spaceflight. Rapid developments in microelectronics and crossover from research in related fields have expedited the development of capable devices, but as with most aspects of radiation dosimetry, there is a pressing need for further research.

Capacitance Sensors for Nondestructive Moisture Determination in Agricultural Products and Biofuel Materials

Chari V. Kandala
United States Department of Agriculture

Naveen Puppala
New Mexico State University

75.1 Introduction

Previous research showed that the dielectric properties of hygroscopic materials can be used to estimate the MC present in these materials (Nelson, 1977; Klein, 1981). The variation in dielectric constant with MC for shelled yellow field corn (Figure 75.1) was found to be more pronounced between 1 and 5 MHz (Nelson, 1978). Thus, $(\varepsilon_{r1} - \varepsilon_{r2})$, the difference in the dielectric constants at 1 and 5 MHz or any other higher frequency, should be a good indicator of the moisture present in the material. The difference in capacitance of a parallel-plate system of plate area A and separation d at two frequencies can be written as

$$C_1 - C_2 = (\varepsilon_{r1} - \varepsilon_{r2}) \left(\frac{\varepsilon_0 A}{d} \right) \tag{75.1}$$

where

ε_{r1} and ε_{r2} are the dielectric constants of the material between the plates at the two frequencies
ε_0 is the permittivity of free space (8.854×10^{-12} F/m)

It was found earlier that though $(C_1 - C_2)$ was a good estimate of the MC, it was highly influenced by the sample size of the peanuts held between the plates (Kandala and Nelson, 1990). The volume of space that a sample of odd-shaped material, such as in-shell peanuts, occupies between two parallel plates

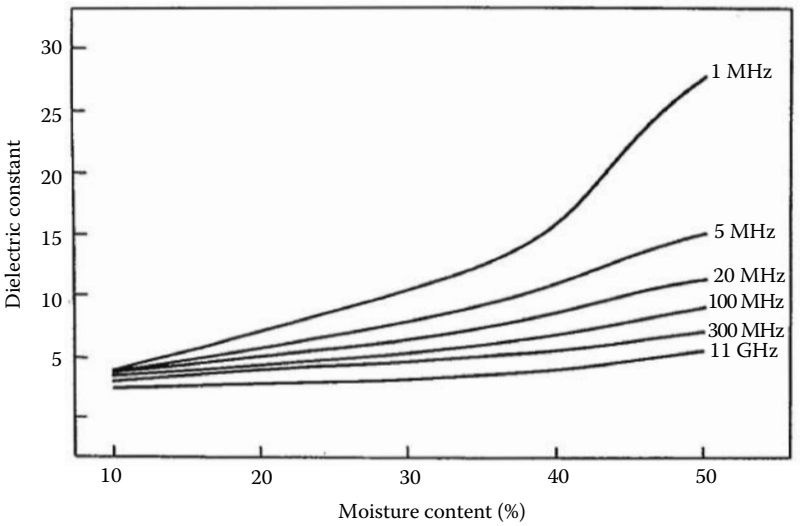

FIGURE 75.1 Moisture dependence of the dielectric constant of shelled yellow-dent field corn. (From Nelson, S.O., *J. Microwave Power*, 12(1), 67, 1977.)

varies each time they are placed between the plates. Air gaps between the peanut pods, and between the pods and the capacitor walls, occur differently. Variations in two other related electrical parameters, phase angle (θ) and dissipation factor (D), were also measured at these two frequencies. The capacitance and dissipation factor increased with moisture but were lower at higher frequencies. The phase angle decreased with moisture but was higher at the higher frequencies. Empirical equations were developed to estimate MC of corn, wheat, shelled peanut, and in-shell peanut samples from the differences in capacitance ($C_1 - C_2$), phase angle ($\theta_1 - \theta_2$), and dissipation factor ($D_1 - D_2$) at 1, 5, and/or 9 MHz without the need to weigh the samples (Kandala and Nelson, 2007). This minimized the errors due to the void space within the sample.

Dissipation factor is a measure of energy loss that results from subjecting a dielectric to an alternating current electric field. It is related to the Q factor of the peanut material and is a measure of the energy stored in the electric field relative to energy dissipated in any one period. The power dissipated depends on the equivalent resistance of the complex circuit, and thus the variation in the impedance values ($Z_1 - Z_2$) of the system at the two frequencies adequately represents the term ($D_1 - D_2$). Thus, from the values of ($C_1 - C_2$), ($\theta_1 - \theta_2$), and ($Z_1 - Z_2$) measured with a two parallel-plate system fitted inside a cylinder, the MC of the grain and nut samples could be estimated to an acceptable accuracy (Kandala et al., 2008). For a single parallel-plate system, the following semiempirical equation worked well:

$$\text{MC} = A_0 + A_1(C_1 - C_2) + A_2(\theta_1 - \theta_2) + A_3(Z_1 - Z_2) + A_4(C_1 - C_2)^2 + A_5(\theta_1 - \theta_2)^2 + A_6\,(Z_1 - Z_2)^2 \quad (75.2)$$

where

C_1, θ_1, Z_1 and C_2, θ_2, Z_2 are the capacitance, phase angle, and impedance at 1 and 5 MHz (in most of the cases), respectively

$A_0 \ldots A_5$ are calibration constants

The calibration constants were evaluated by making measurements on several samples of known MC values within the required moisture range, and applying a least squares computation. Statistical significance of the terms used in Equation 75.2 was verified by the t statistic, requiring that the probability of a greater absolute value of t under the null hypothesis had to be less than or equal to 0.05 for each variable. The numerical values of the constants were found to be different for different types of grain and nuts.

75.2 Moisture Meters

An impedance meter called the CI meter (Chari's impedance meter) designed and developed by the first author was used to measure the two parameters, impedance (Z) and phase angle (θ). Three frequencies 1, 5, and 9 MHz are generated by crystal oscillators as shown in the block diagram (Figure 75.2) drawn for 1 MHz. The electronic circuits for the three frequencies are similar except for slight variations in the values of certain capacitors and resistors. These signals are applied to the parallel-plate electrode system (z) alternately, by switching through a multiplexer. Initially, at 1.0 MHz, the current, flowing through this system with an impedance Z, is fed into an op amp. The same current flows through the range resistor R_r. The output voltage of the op amp and the original 1 MHz signal from the oscillator are rectified and measured as e_{m1} and e_{r1}, respectively. The current through Z is calculated as e_{m1}/R_r and the magnitude of the impedance of the parallel-plate system with the peanut kernel between them is obtained as

$$|Z_1| = R_r\left(\frac{e_{r1}}{e_{m1}}\right) \tag{75.3}$$

The phase angle at 1 MHz is determined by comparing the signal emerging out of the op amp with that of the original signal, using a phase detector. However, the phase detector can compare signals of the same amplitude only. To keep the amplitude of the output signal from the op amp constant and equal to the amplitude of the original signal, a comparator is used. The comparator would output a square wave, and a filter is used to convert it to a sine wave. The original signal from the oscillator is attenuated to the same amplitude as this signal and the two signals are fed into the phase detector. The phase detector compares the two signals and gives an output voltage e_{p1} proportional to the phase angle θ_1 between the two. The computer then switches the multiplexer to allow the 5 MHz signal to pass through the parallel-plate system. The signals are processed through a circuit similar to the 1 MHz circuit but with a range resistor of a different value. The impedance magnitude $|Z_2|$ and the phase angle θ_2 are determined at this frequency as was done for 1 MHz. Similar measurements were made with 9 MHz after switching to this frequency through the multiplexer and the values of impedance $|Z_3|$ and phase angle θ_3 are determined at this frequency. From the values of Z and θ, the real and imaginary parts of the impedance R and X at

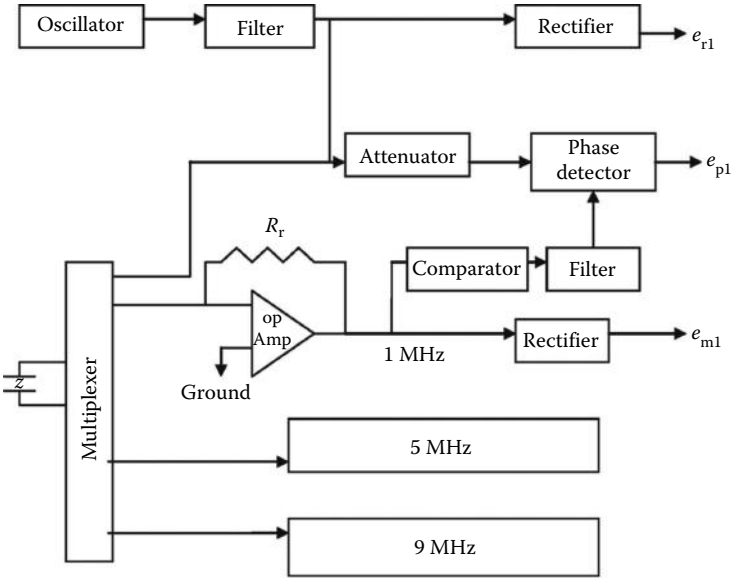

FIGURE 75.2 Block diagram of the CI meter electronic circuit to measure impedance and phase angle.

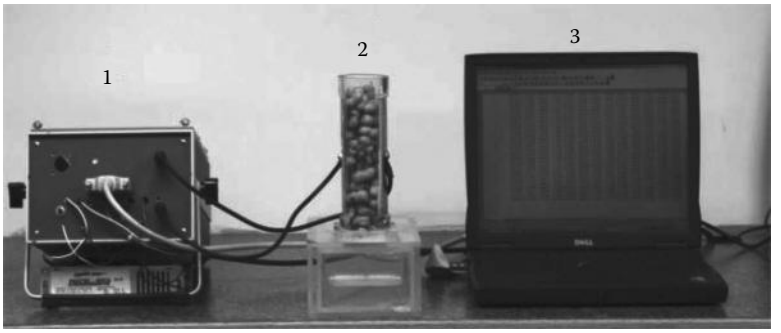

FIGURE 75.3 CI meter measuring system: (1) CI meter, (2) cylinder with electrodes filled with in-shell peanuts, and (3) computer.

each frequency are calculated as $R = |Z|\cos\theta$ and $X = |Z|\sin\theta$. The value of capacitance C of the parallel-plate system with the peanut sample between them is given as

$$C = -\frac{1}{2\pi fX} \tag{75.4}$$

The layout of the CI meter measuring system is shown in Figure 75.3. The power supply consists of two 12 V rechargeable lead–acid batteries from which the voltages, required to operate the circuits, were derived.

A laptop computer was used to register data from the system, compute the calibration constants, and calculate the moisture content.

A cylindrical acrylic tube, fitted with two sets of parallel-plate electrodes, serves as the test cell for moisture sensing. The test cell is 190 mm long, with an internal diameter of 50 mm and has a wall thickness of 7 mm. The electrode assembly for the test cell consists of two rectangular aluminum plates, 140 mm long and 50 mm wide. The electrodes are cemented to the inner walls of the test cell, as shown in Figure 75.1, about 25 mm from the ends. The distance of separation between the parallel plates for the test cell was 42 mm. The test cell would rest on top of a rectangular acrylic box and in a circular hole, centered about 35 mm from the front side of the box. This box is provided with an acrylic drawer that slides in and out of the box manually. The top of this drawer was covered 75 mm from the front end, with an acrylic plate. When the drawer is pushed all the way into the box, this plate covers the hole and prevents the sample placed in the cylinder from dropping into the drawer. Except for the electrodes, no metal parts were used in the assembly of the electrode system or the sample collecting system to prevent any interaction with the RF signal used in the measurements. With the drawer pushed all the way in, the cylinder was filled with the grain samples and the impedance measurements were taken. After the completion of the measurements, the drawer is pulled out slowly, allowing the sample to fall into the drawer. The drawer was emptied before another sample was placed in the cylinder for measurement. With the grain sample occupying the space between the electrodes, the analyzer measured the impedance and phase angle of this electrode system at 1, 5, and 9 MHz, and a computer controlled and collected the data from the analyzer. A Mettler* AE 163 electronic balance was also interfaced to this computer to record the wet and dry weights of the peanut pod samples to obtain their air-oven moisture values. Using these measurements in an empirical equation, the computer was programmed to calculate the moisture content of the sample.

75.3 Moisture Measurement of Agricultural Products

75.3.1 Moisture Measurements of In-Shell Peanuts

Peanuts of the Georgia Green cultivar, harvested in 2007, dried, cleaned, and stored at 4 °C at the National Peanut Research Laboratory, were used for these studies (Kandala and Sundaram, 2010). The initial moisture content* of these peanuts was about 7%. These peanuts were divided into 12 sublots and were placed in glass jars. Appropriate quantities of water were added to each jar, to raise the moisture levels in steps of about 2% moisture, to obtain a total of 11 moisture levels ranging between 8% and 24%. The jars were sealed and allowed to equilibrate at 4 °C for 1 week. The jars were periodically rotated during this period to aid uniform distribution of moisture. Thus, 12 moisture levels with nominal MC values of 8, 9, 11, 12, 13, 15, 16, 17, 18, 19, 20, and 23 were available for calibration and validation. The jars were removed from cold storage and the pods were allowed to reach room temperature in the jars before the measurements were made.

The peanut pod samples, after conditioning, were separated into two groups. The calibration group consisted of samples taken from the nominal MC levels of 8%, 11%, 13%, 16%, 18%, 19%, and 23% and the validation group was from nominal MC levels of 9%, 12%, 15%, 17%, and 20%. The MC values of the samples in each of these 12 moisture levels (called the sublots) were obtained by the standard air-oven method (ASAE Standards, 2003). Three samples, each weighing about 100 g, were taken from each sublot and placed in small aluminum containers and their wet weights were taken. The containers were placed in a hot-air oven at 130 °C for 4–6 h depending on their initial MC value. At the end of the heating period, the containers were removed and weighed again to determine the dry weight of the samples. Moisture content was determined for each sample as the percentage ratio of the weight loss to the original wet weight of the sample. The average of the three moisture values, for each sublot thus obtained, were labeled as the oven MC value of that sublot. Impedance measurements were made on 30 samples from each sublot. Peanut samples were transferred from the jars into the cylindrical electrode system, until the space between the two plates of the cylinder was completely filled. The cylinder accommodated about 100–150 g of peanut pods. The room temperature during the measurements varied from 21 °C to 23 °C. Peanut pods from one of the jars were transferred into the cylinder with the drawer sitting fully inside the box, until the space between the two plates of the cylinder was filled. In this position, measurements of impedance (Z) and phase angle (θ) were made at 1 and 5 MHz, using the CI meter. The sample was then collected in the drawer by gently pulling it out and tapping on the cylinder for the peanuts to drop down. The drawer was emptied and reset in the box. The procedure was repeated on all peanut samples (sublot) in the rest of the jars.

From the measured values of impedance and phase angle the capacitance value for each sample was obtained using Equation 75.4. From the capacitance value, measured values of impedance and phase angle, and the oven determined MC value of the samples in the calibration lots, the semiempirical equation developed by multilinear regression (MLR) model using statistical software (*The Unscrambler*) was

$$MC_{peanut} = -9.71 + 0.56(\theta_2 - \theta_1) - 3.71(C_2 - C_1) - 25.13(Z_2 - Z_1) \tag{75.5}$$

where

C_1, θ_1, and Z_1 are the capacitance, phase angle, and impedance values at 1 MHz
C_2, θ_2, and Z_2 are the capacitance, phase angle, and impedance values at 5 MHz

Using Equation 75.5, the MC of each pod sample in the seven calibration lots was calculated, averaged over the 30 samples in each MC level, and the results are shown in Table 75.1 along with the MC values determined by the air-oven method. The standard deviations and the difference between the oven

* Moisture contents are expressed in percent wet basis throughout this chapter.

TABLE 75.1 Comparison of Mean MC Values Determined by the Air-Oven and CI Meter Methods for Calibration Groups of Peanuts (Average of 30 Samples in Each Group)

R^2	RMSEC	SEC	Bias ($\times 10^{-6}$)
0.97	0.82	0.82	−2.59

and calculated MC values (difference) are also shown. The predictability shown in the last column of Tables 75.1 and 75.2 is defined as the percentage of samples for which moisture content was calculated within 1% of the air-oven MC values. An R^2 value of 0.97, a low value of SEC (shown in Table 75.2), relatively small differences in the calculated and the oven MC values, and acceptable standard deviation values suggest the suitability of Equation 75.5 for MC predictions. The standard error of calibration (SEC)* was 0.82 as shown in Table 75.2 which contains fitness measures for the calibration set. The mean calculated values agree very closely with the oven MC values.

The MC values of the pod samples in the five validation lots calculated by using Equation 75.5 are shown in Table 75.3. The calculated mean moisture values were compared with the air-oven values and the results are summarized in Table 75.3, along with standard deviations, difference, and predictability. The predictability was better than 95% for all the levels tested. The errors in individual samples in a moisture level could be due to nonhomogeneity of moisture distribution in the sample. The standard error of prediction (SEP)† was 0.70 as shown in Table 75.4. The bias value of −0.35, close to zero, indicates the closeness of the mean calculated values to the standard values confirming the fitness of the prediction Equation 75.3 (Moore, 2000).

Comparison of the MC values determined by the air-oven and CI meter methods, using the parallel-plate cylindrical sample holder, is shown in Table 75.3. Note that the average values predicted by the

* $$\text{SEC} = \left(\frac{1}{n-p-1} \sum_{i=1}^{n} e_i^2 \right)^{\frac{1}{2}}$$

where
n is the number of observations
p is the number of variables in the regression equation with which the calibration is performed
e_i is the difference between the observed and reference value for the ith observation

† $$\text{SEP} = \left(\frac{1}{n-1} \sum_{i=1}^{n} (e_i - \bar{e})^2 \right)^{\frac{1}{2}}$$

where
n is the number of observations
e_i is the difference in the moisture content predicted and that determined by the reference method for the ith sample
$\bar{e}$ is the mean of e_i for all of the samples

CI meter agreed well with the air-oven values. The time taken for one sample measurement was ~1 min as compared to several hours by the gravimetric methods. There is no need to shell, weigh, or measure the volume of the peanuts in this method.

75.3.2 Moisture Measurements of Corn

Yellow-dent field corn samples harvested in 2007 from Nebraska were used in this study (Kandala and Sundaram, 2010). The initial moisture content of the corn lot, as determined with an electronic moisture meter, was about 6%. This corn lot was divided into 12 sublots and was placed in glass jars. Similarly, as done for peanuts, appropriate quantities of water were added to each jar, to raise the moisture levels in steps of about 1% moisture, to obtain a total of 12 moisture levels ranging between 6% and 20%. Thus, 12 moisture levels with nominal MC values of 6, 7, 8, 9, 10, 11, 13, 15, 16, 17, 18, and 19 were available for calibration and validation.

From the CI meter measured values of impedance and phase angles, the capacitance value for each sample was obtained using Equation 75.4. Using the capacitance value, measured values of impedance and phase angle, at the frequencies 1 and 5 MHz, and the oven-determined MC value of the samples in the calibration lots, a MLR model was developed as shown below:

$$MC_{corn} = -8.395 + 1.17(C_2 - C_1) - 0.89(\theta_2 - \theta_1) + 15.90(Z_2 - Z_1) \tag{75.6}$$

where

C_1, θ_1, and Z_1 are the capacitance, phase angle, and impedance values at 1 MHz

C_2, θ_2, and Z_2 are the capacitance, phase angle, and impedance values at 5 MHz

Using the MLR Equation 75.6, MC values of the samples in both calibration and validation sets were determined. The fitness measures for the calibration set are shown in Table 75.5. The calibration set had an R^2 value of 0.98 and the SEC was 0.61.

TABLE 75.5 Fitness Measures for the Calibration Set of Corn

0.98	0.61	0.61	+0.19

TABLE 75.6 Comparison of Average MC of Corn Determined by the CI Meter and the Air-Oven Methods (Calibration Set)

Oven, % MC	CI Meter, % MC	Standard Deviation	Difference	Predictability, %
6.85	7.25	0.28	−0.40	100
8.90	8.68	0.16	0.22	100
11.00	11.01	0.003	−0.01	100
13.22	13.48	0.18	−0.26	97
15.67	15.18	0.35	0.49	100
17.86	17.91	0.04	−0.05	90
18.21	18.21	0.002	−0.002	97

The average MC values (of 30 samples) at each moisture level for the calibration set, as calculated by the MLR Equation 75.6 from the CI meter measurements, along with the corresponding air-oven moisture values, their standard deviations, and the difference between the two moisture values, are shown in Table 75.6.

The predictability shown in Tables 75.6 and 75.8 are the percentage of samples in each moisture group whose values are predicted within 1% of their air-oven values. For the validation set, the fitness measures are shown in Table 75.7. The validation set had an R^2 value of 0.96 and the SEP was 0.70. Here too, a low bias value of 0.15 indicates the closeness of the mean calculated values to the standard values confirming the fitness of the prediction (Equation 75.6).

The average MC values (30 samples) of each of the six moisture levels of the validation group (which are not used in the calibration) as predicted by Equation 75.6 from the CI meter measurements are shown in Table 75.8 along with their standard air-oven values. Also shown are the standard deviations, the difference between the two moisture values, and the predictabilities. The SEP is very close to the SEC value and both the calibration and the validation lots have a good R^2 value. The predictability for the validation sets are above 93% for any moisture level and averaged 98.6% over all the levels.

The overall predictability for peanuts (Table 75.3) was 96.6% while for corn it was 98.6% (Table 75.8). Variations in temperature and relative humidity, while measurements were made, may have caused some variations in the predicted values of the MC. The oil content and protein in the peanuts might have some influence on the predicted MC values. Including temperature as a variable in the prediction equations for both the crops could improve the predictability. In the case of peanuts, measuring the total oil content (TOC) of peanuts and including the TOC also, as a variable in their prediction equation, could further improve the MC predictions.

75.3.3 Moisture Measurements of Wheat

A total of six varieties of wheat, planted and harvested around the Texas panhandle and at the New Mexico State University Station near Clovis, were used in this study (Kandala et al., 2012). The wheat varieties are Tam111, Duster, Scoutt 66, Endurance, Jagger, and Hatcher (Brent, 2011), planted during October 2010 and harvested during July 2011. All the sample lots were stored at 4 °C and 40% relative humidity. The MC of the samples initially was about 9%. These lots were divided into 22 sublots and were placed in glass jars. Appropriate amounts of water were added to the samples to develop 22 moisture levels between 9% and 25%. Thus, from the available quantities, six MC levels of Tam111, five of Duster, four of Hatcher, five of Jagger, and one each of Scoutt 66 and Endurance were developed for calibration and validation. Moisture content of each subsample was determined by the standard air-oven method by drying triplicate samples of 10 g each for 19 h at 130 °C (ASAE Standards, 1994). Samples were weighed before and after drying and the MC of each sample was obtained as the percentage ratio of the weight loss to the original wet weight of the sample.

Impedance measurements were made with the CI meter on 30 samples from each sublot. From the measured values of C, θ, and Z on the calibration sublots with the CI meter, and using unscrambler procedures for regression analysis, the values obtained for the constants $A_0 \ldots A_6$ in Equation 75.2 were

$$A_0 = -27.235, \quad A_1 = 0.0032, \quad A_2 = 4.734, \quad A_3 = 20.476, \quad A_4 = -0.000088, \quad A_5 = -0.405, \quad A_6 = -2.694$$

These constants along with the values of impedance, phase angle, and capacitance (obtained from Equation 75.4) were used in Equation 75.2 to calculate the MC of each of the 30 samples from the calibration sublots. The calculated values were averaged over the 30 samples in each moisture group and were compared with their air-oven values, and are shown in Table 75.9 along with their standard deviations, differences, and predictability.

Shown in Table 75.10 are the fitness measures for the calibration lots. The SEC was 0.49% MC (with $p = 6$ and $n = 210$). The predictability was good at all the MC levels. The calculated values averaged over 30 samples from each moisture group agreed well with their air-oven values, and the predictability ranged from 97% to 100%. The standard deviation for 30 samples at any moisture level was under 0.5%. An R^2 value of 0.99, an SEC of 0.49, a low bias value, and a high rate of predictability suggest that this model is suitable for MC predictions. This was further verified from the fitness measures obtained for the validation sets.

TABLE 75.9 Calibration Sublots: Comparison of CI Meter and Air-Oven MC Measurements

	Moisture Content (%)				
		Predicted by CI Meter and Equation 75.2

[a] Mean of 30 samples in each moisture group.

[b] Predictability is the % of samples in each moisture group for which the predicted MC is within 1% of the air-oven value.

Shown in Table 75.11 are the MC values for 15 validation sets consisting of three varieties used in the calibration, and an additional variety, Hatcher, not used in the calibration. The moisture levels of the three varieties used in the validation are different from the levels used in the calibration. The MC values were predicted using the measured values of impedance and phase angle, and the calibration constants in Equation 75.2, averaged over 30 samples in each group, and compared with their air-oven values. Also shown are the standard deviations and the predictability of each moisture group. The predictability was 87% or better for any moisture level and averaged about 98% over the 15 validation levels.

Shown in Table 75.12 are the fitness measures for the validation group of samples. The validation set also came up with a good R^2 value of 0.98 and the SEP* was 0.60. The SEP value is close to the SEC value, and the R^2 value compares well with that of the calibration group. A low bias indicates the closeness of the mean calculated values to the air-oven values confirming that the prediction model is dependable.

* $$\text{SEP} = \left(\frac{1}{n-1} \sum_{i=1}^{n} (e_i - \bar{e})^2 \right)^{\frac{1}{2}}$$

where

n is the number of observations

e_i is the difference in the moisture content predicted and that determined by the reference method for the ith sample

$\bar{e}$ is the mean of e_i for all of the samples

R^2	RMSEP	SEP	Bias
0.98	0.62	0.60	−0.146

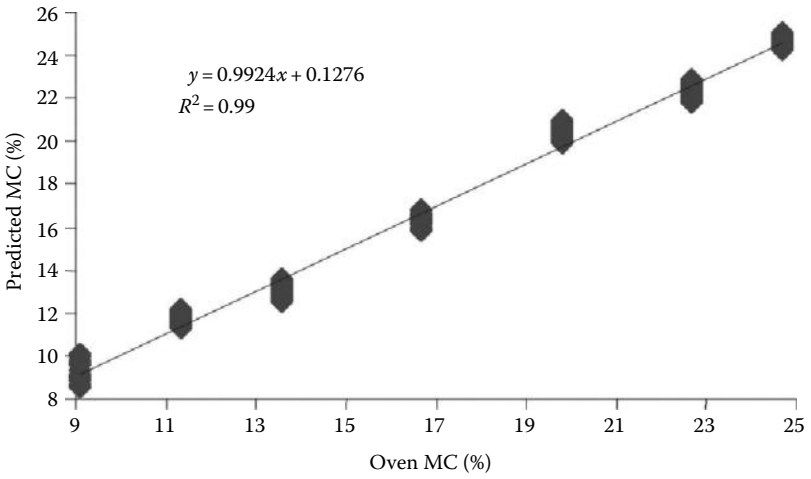

FIGURE 75.4 Comparison of oven and CI meter MC values for the wheat calibration lots.

The SEC value of 0.49 and the SEP value of 0.60 were better than the 0.88 for SEC and 0.91 for SEP obtained earlier with small wheat samples (Kandala et al., 1996). Shown in Figure 75.4 are the comparison of the predicted and the air-oven values of the seven calibration wheat lots. An R^2 value of 0.99 further indicates the fitness of the calibration equation. Similarly in Figure 75.5, the MC values of the validation samples of wheat are compared with their respective air-oven values and plotted. The predicted MC values compare well with their corresponding air-oven values with an R^2 value of 0.99. The CI meter predicted the MC values of different varieties quite well with a single calibration equation, developed with randomly picked MC levels from the different available varieties. Moreover, the measurement is rapid and nondestructive and there was no need to measure the volume or weight of the wheat samples.

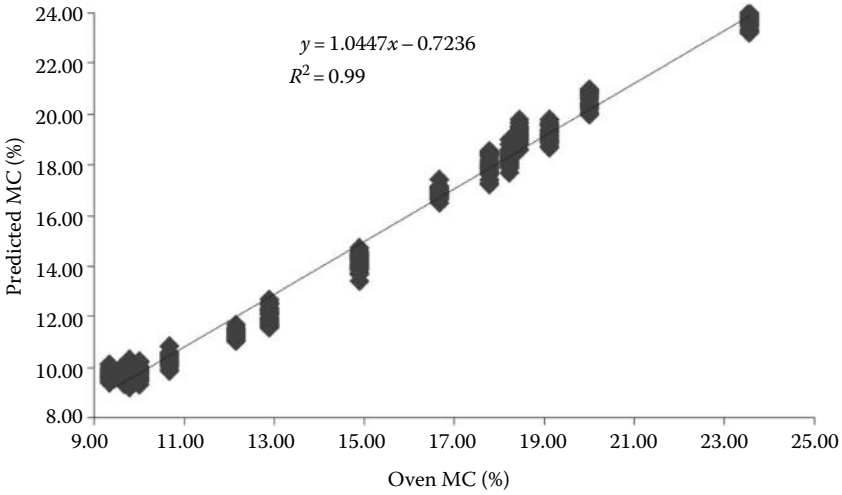

FIGURE 75.5 Comparison of oven and CI meter MC values for the wheat validation lots.

75.4 Moisture Measurement of Wood Chips and Powders

Measurement of MC of wood chips and related powders is important in the pulp and biofuel industries (Biermann, 1993; Nystrom and Dahlquist, 2004). Measurements of phase angle and impedance were made on pine and hard wood chips placing them between the parallel plates of the cylindrical sample holder, used above for grain and peanuts. With the phase angle and impedance values of the calibration samples, measured with the CI meter, and their known MC values, regression analysis was done and calibration equations were developed, separately, for pine and hard wood chips. Using these equations, MC of pine and hard wood samples in the moisture range between 5% and 50% was determined and compared with their air-oven values. The results are shown in Figures 75.6 and 75.7. For the seven moisture groups (30 samples in each group) of pine wood validation samples, the CI meter predicted the MC values close to their oven values with an R^2 value of 0.99 and an SEP of 1.37. Similarly, for seven moisture groups of hard wood samples used for validation the CI meter predicted the MC values close to the oven values with an R^2 of 0.99 and an SEP of 1.56.

Measurement of MC for biofuel materials in the form of powders was also done using the CI meter using a parallel-plate system. The plates were held horizontally with the lower plate held rigidly while the upper plate could slide up and down by about 20 mm. The sample powder was packed into a Petri dish about 20 mm diameter and 10 mm thick, and the lid was closed. The Petri dish was placed between the plates with both plates in contact with it, and measurements of phase angle and impedance were made with the CI meter. From these measured values of the calibration samples, and their MC values obtained by the standard air-oven method, regression equations were developed. Using the regression equations, MC predictions were made for the validation samples. Measurements were done for pine wood and switchgrass powders, in the MC range of 6%–25%, with the CI meter, and the results are shown in Figures 75.8 and 75.9.

The CI meter predicted well the MC of five moisture groups of pine wood powder, used for validation, with an R^2 value of 0.96 and an SEP of 1.45. Similarly, MC of five moisture groups of switchgrass powder predicted by the CI meter gave an R^2 value of 0.98 and an SEP value of 1.38, indicating that the CI meter is useful in rapidly and nondestructively predicting the MC of the biofuel materials either in the form of chips or in the powder form.

75.5 Conclusions

From the measurements of impedance and phase angle using a low-cost impedance meter and a capacitance sensor, the average moisture content of 150–200 g of in-shell peanuts, corn, and wheat samples could be determined. The weight or volume of the samples need not be measured. Ability to measure the MC of peanuts while they are in their shells would eliminate the need to shell them and clean them saving considerable time and labor. The MC of the corn samples tested was between 6% and 20% and the MC of the peanut samples was between 8% and 24% (most useful range for drying purposes in each case). The predicted MC values were within 1% of the air-oven values for over 98% of the samples tested for corn and 96% for in-shell peanuts. In the case of wheat, the moisture range of the samples used was between 9% and 25%. Calibration was done with five different wheat varieties, and validation was done on all these varieties and one additional variety. For 98% of the samples tested from the six varieties, the predicted MC values were within 1% of their air-oven values. This meter performed well for all the six varieties of wheat in predicting the MC with a single calibration equation. Using impedance measurements taken at two frequencies has helped in eliminating the errors due to air gaps that would occur randomly when the sample is filled between the plates. The CI meter would also be useful to rapidly and nondestructively determine the MC in materials used as biofuels such as pine and hard wood chips, and powders such as pine and switchgrass. This low-cost instrument would be useful for the grain, peanut, as well as pulp and biofuels industry for nondestructive and rapid measurement of moisture content using the principles of capacitance sensing.

Radio Location, Radio Navigation, and GPS Systems

Halit Eren
Curtin University

76.1 Introduction

Radio location is concerned with the use of radio waves for position sensing and locating objects. For this purpose, the radio signals can be used in an active or passive mode. In the passive mode, the characteristics of the radio signals received by a particular object situated in the field are used to determine the location. In the active case, the signals generated by an object yield the information about its location.

There are numerous radio location methods employed, being

- Backscattered properties waves, for example, radio-frequency identification (RFID), or radar
- Received signal strength (RSSI)
- Time of arrival (TOA)
- Differential TOA (DTOA) by receiving additional signals
- Angle of arrival (AOA)
- Phase differences and changes in frequencies, such as the Doppler shift
- Multilateration of multiple receivers that are receiving information from the same source
- Global Positioning Systems (GPS)
- Fingerprint and trilateration signals from the cellular telephony, such as TDMA, CSMA, and TSM
- Combinations of the earlier methods

Both active or passive radio location techniques are used in real-time locating systems (RTLS) for tracking and navigation purposes. There are many commercially available RTLS based on GPS, RFID, TOA, DTOA, and other techniques. Some of these will be explained in the rest of this chapter.

76.2 Radio Location Fundamentals

Radio location technology is used extensively in military applications, industrial and transportation systems, and general consumer applications. One of the most extensively employed technologies is radio navigation, which can be classified by its range, scope, error budget, and cost. The range classifications can be identified to be short, medium, and long range, within which exact limits are rather indefinite. The scope classifications can be either self-contained or externally supported, or active (transmitting) or passive (not transmitting) modes of operations.

Utilization of electromagnetic radio waves is the common denominator in all navigation systems discussed here. Particularly in the long-range applications, understanding of their behavior in the Earth's atmosphere is very important in the design, construction, and use of all kinds of navigation equipment—from the complex satellites and radar navigation and location systems to simple handheld devices that many consumers use in their cell phones. Therefore, fundamentals behind the electromagnetic wave propagation will be explained briefly.

When an FM radio wave is generated within the Earth's atmosphere, the wave travels outward. The waves may be absorbed or reflected from surfaces of materials they encounter. The absorption and scattering of electromagnetic waves take place for many reasons, one of which is caused by excitation of electrons within the molecules in the propagation media. The behavior of an electromagnetic wave is dependent on its frequency and corresponding wavelength. Figure 76.1 shows the frequency spectrum of electromagnetic waves. They are classified as *audible waves* at the lower end of the spectrum, *radio waves* from 5 kHz to 300 GHz, and *visible light* and various other types of rays at the upper end of the spectrum.

For practical purposes, the radio wave spectrum is broken into eight bands of frequencies; these are *very low frequency* (VFL) <30 kHz, *low frequency* (LF) 30–300 kHz, *medium frequency* (MF) 300 kHz–3 MHz, *high frequency* (HF) 3–30 MHz, *very high frequency* (VHF) 30–300 MHz, *ultrahigh frequency* (UHF) 300 MHz to 3 GHz, *super high frequency* (SHF) 3 to 30 GHz, and *extremely high frequency* (EHF) 30–300 GHz.

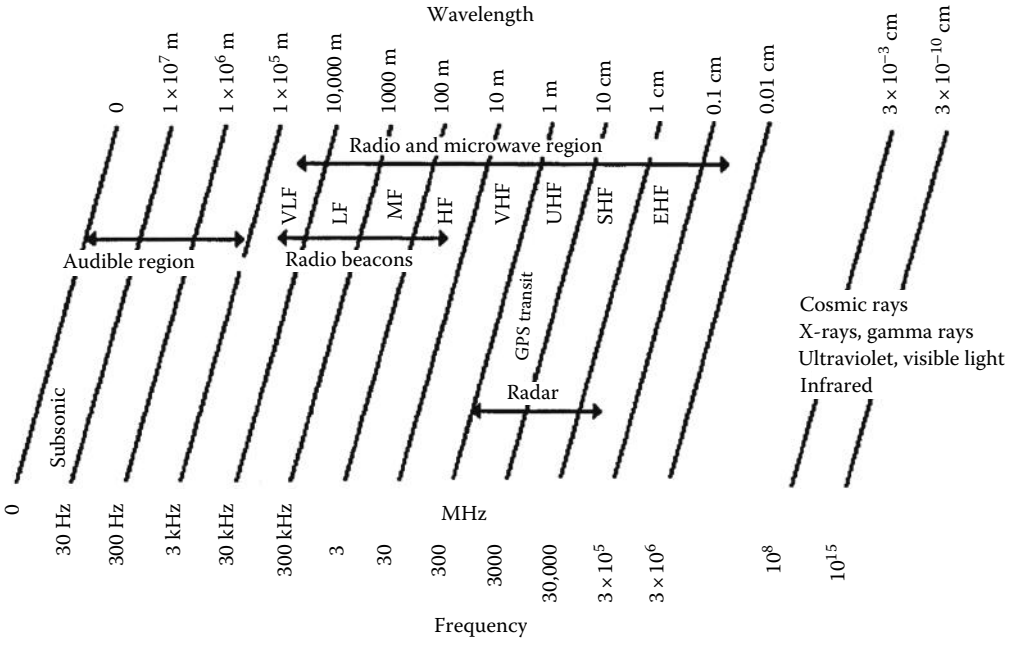

FIGURE 76.1 Electromagnetic wave frequency spectrum. Radio beacons operated in the VLF, LF, and MF ranges. GPS, Transit, and Glonass use UHF frequencies. Wavelengths <10 cm are not suitable for satellite systems, but they are used in radars.

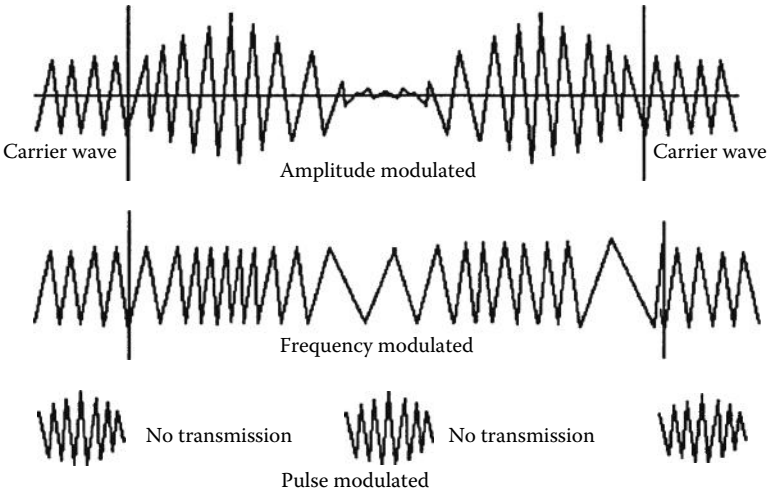

FIGURE 76.2 Amplitude, frequency, and pulse modulation of RF carrier waves. Amplitude modulation is suitable for broadcasting radio stations. Frequency modulation is used in commercial radio broadcasts. The pulse modulation is used in satellite systems, radars, and long-range navigation aids.

For easy identification, the frequencies above 1 GHz are further broken down by letter designators as L-band (1–2 GHz), S-band (2–4 GHz), C-band (4–8 GHz), X-band (8–12.5 GHz), and K-band (12.5–40 GHz). Since severe absorption of radar waves occurs near the resonant frequency of water vapor at 22.2 GHz, the K-band is subdivided into lower K-band (12.5–18 GHz) and upper K-band (26.5–40 GHz). Most navigation radars operate in the X- and S-bands, and many weapons fire control radars operate in the K-band range.

The radio waves are transmitted as continuous or modulated waves. A carrier wave (CW) is *modulated* to convey information in three basic forms: amplitude, frequency, and pulse modulation, as shown in Figure 76.2. The amplitude modulation (AM) modifies the amplitude of the CW with a modulating signal. In frequency modulation (FM), the frequency of the CW is altered in accordance with the frequency of the modulating wave. FM is used in commercial radio broadcasts and the sound portion of the television broadcast. Pulse modulation is different from AM and FM in that there is usually no impressed modulation wave employed. In this modulation, the continuous wave is broken up into very short bursts or "pulses," separated by periods of silence during which no wave is transmitted. This is used in satellite navigation systems, surface search radars, and long-range radio navigation aids.

When an electromagnetic wave encounters an obstruction, *diffraction* takes place marked by a weak reception of the signal within the "shadow" zone. Two waves acting on the same point will also result in *interference*. The degree of interference depends on the phase and frequency relationship. For example, two waves of the same frequency with a 180° phase difference will result in a null at that point. Also, under certain conditions, a portion of the electromagnetic energy in radio waves may reflect back toward the Earth's surface to form the *ionosphere*. The ionosphere is a layer of charged particles located about 90–400 km high from the Earth's surface; such reflected waves are called *sky waves*.

In the study of radio wave propagation, there are four *ionosphere layers* of importance, as shown in Figure 76.3. The D-layer is located about 60–90 km and is formed during daylight. The E-layer is about 110 km. It persists through the night with decreased intensity. The F_1-layer is between 175 and 200 km; it occurs only during daylight. The F_2-layer is between 250 and 400 km; its strength is greatest in the day but it combines with the F_1-layer later to form a weak F-layer after dark. The layers in the ionosphere are variable, with the pattern seeming to have diurnal, seasonal, and sunspot periods. The layers may be highly conductive or may entirely hinder transmissions, depending on the frequency of the wave, its angle of incidence, height, and intensity on various layers at the time of transmission. In general, frequencies in the MF and HF bands are most suitable for ionosphere reflections during both day and night.

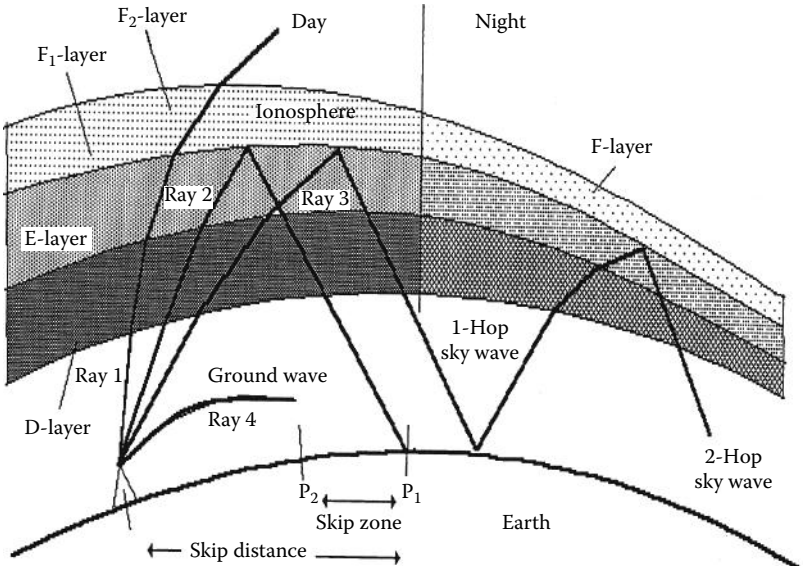

FIGURE 76.3 The four layers of the ionosphere and its effect on radio propagation. The four layers are produced by the ionization of molecules of particles in the atmosphere by ultraviolet rays of the sun. The effect of ionosphere on the radio waves is shown by reflections, also termed hops. The frequency of the electromagnetic wave is important in its behavior through the ionosphere.

Because of the higher resistance of the Earth's crust as compared to the atmosphere, the lower portions of radio waves parallel to the Earth's surface are slowed down, causing the waves to bend toward Earth. A wave of this type is termed a *ground wave*. The ground waves exist because they use the Earth's surface as a conductor. They occur at LF since LF causes more bending in conformity to Earth's shape. The ultimate range of such ground waves depends on the absorption effects. Sometimes, in the lower atmosphere, *surface ducting* occurs by multiple hopping, thus extending the range of a ground wave well beyond its normal limits. It is associated with higher radio and radar frequencies. This phenomenon is common in tropical latitudes. Behavior patterns of waves transmitted at various angles are illustrated in Figure 76.3.

76.2.1 Accuracy of Radio Location

There are a number of random effects that influence the accuracy of radio locations: atmospheric disturbances along the transmission path, errors in transmitters and receivers, clocks, inaccuracy in electronic circuitry, multipath, reflections, fading, etc. As a result, a series of positions determined at a given time and location usually results in a cluster of points near the true position. There are two measures commonly used to describe the accuracy: the first is the *circular error probable* (CEP)—a circle drawn on the true position whose circumference encompasses 50% of all indicated positions, and the second technique, more common, is the *root mean square* (rms), where

$$\text{rms} = \sqrt{\sum_{n=1}^{N} \frac{(E_n)^2}{N}} \tag{76.1}$$

where

E is the distance between actual and predicted positions
N is the number of predicted positions

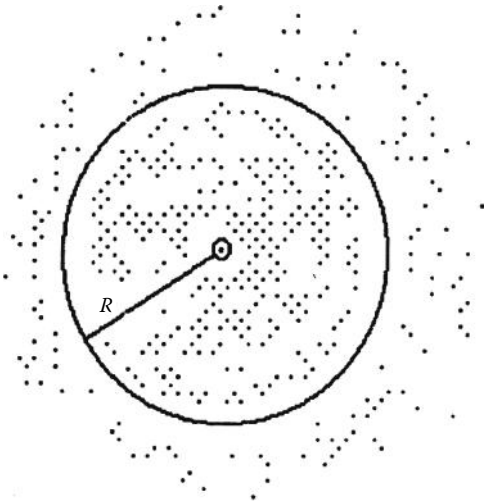

FIGURE 76.4 The rms radius circle that encompasses 68% of all measured positions. The variations in the measurements are due to a number of factors, including ionosphere conditions, precise location of satellites, and inefficiencies in electronic circuits (2 rms encompasses 95% of all indicated positions).

A circle, shown in Figure 76.4, with one rms value is expected to contain 68% of all the indicated positions. Another circle of radius equal to 2 rms should contain 95% of all the indicated positions, for isotropic scattering, or errors.

In electronic navigation systems, three types of accuracy are important: (1) *predictable* or *absolute accuracy*—the accuracy of a position with respect to the geographic coordinates of the Earth; (2) *repeatable accuracy*—the accuracy with which the user can return to a position whose coordinates have been determined at a previous time with the same navigation system; and (3) *relative accuracy*—the accuracy with which a user can measure position relative to that of another user of the same system at the same time.

76.3 Radio Navigation

In the 1930s, improved radio direction-finding techniques and better equipment led to the establishment of systems called *radio beacons*. These systems consisted of small radio transmitters located in fixed places to provide radio bearings that could be used in all weather conditions. Position findings by these beacons became known as *radio navigation*. Continued refinements in the state-of-the-art electronics technology and a better understanding of electromagnetic wave propagation led to the subsequent development of radar and longer-range radio navigation systems.

Essentially, radio beacons are single transmitters, transmitting a continuous wave at low power, usually modulated by audible Morse code characters for identification. The transmitted signal is received by an on-board receiver incorporating a radio direction finder (RDF) to be processed further.

Many radio navigation systems were developed and perfected by various countries over many decades since 1930s. Some well-known systems are Loran-C, Decca, Consol, Omega, GEE, Alpha, Lorenz-VOR, and a few others. However, most of these radio navigation systems are outdated and shut down as they are no longer commercially or militarily can be used in an economic way. Therefore, these systems will not be explained any further. However, some still find applications in a limited way such as the VOR. As the conventional radio location systems are replaced by the technologies such as the GPS or other satellite navigation systems, communication satellites, cell phones, and the like, more attention will be on these modern techniques.

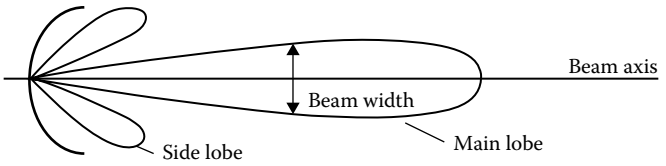

FIGURE 76.5 A surface search radar beam. High-frequency electromagnetic waves are formed by a parabolic antenna. The receiving antenna is rotated 360° to scan the entire surrounding area. The location of the target is determined by the reflected back signals and the orientation of the antenna.

76.3.1 Radar Navigation

The word is derived from *radio detection* and *ranging*. It works on the basic principle of reflection, which determines the time required for an RF pulse to travel from a reference source to a target and return as an echo. Most surface search and navigation radar high-frequency electromagnetic waves are formed by a parabolic antenna into a beam form, as shown in Figure 76.5. The receiving antenna is rotated to scan the entire surrounding area, and the bearings to the target are determined by the orientation of the antenna at the moment the echo returns. The standard radar is made up of five components: transmitter, modulator, antenna, receiver, and indicator. They operate on pulse modulation.

Radars are extremely important devices for air-control applications. Nowadays, airborne beacon radar systems are well developed in traffic alert and collision avoidance systems (TCAS). In this system, each plane constantly emits an interrogation signal, which is received by all nearby aircrafts that are equipped appropriately. The signal triggers a transponder in the target aircraft, which then transmits some information concerning three-dimensional (3D) location and identification.

There are a number of different radar-based radio navigation systems. These systems are primarily used in the avionics industry to provide information for pilots on the position of the aircraft based on the signals transmitted from the ground stations located worldwide. This information is used as the primary or the secondary navigation aid for course determination and correction, direction finding, and distance measuring.

An example of such radio location systems is the VHF Omni directional Range (VOR). In this system, a ground station transmits two signals; one is constant in all directions while the other varies the phase relative to the first. The receiver senses the phase difference between two signals, thus yielding the information on the relative position of the aircraft with respect to the ground station. The information is suitably displayed on the cockpit panel.

An application of radar is the *ground penetrating radar* (GPR) used for locating objects at soil subsurface, ice, and water. In GPR, microwave band pulses are generated and the reflected signals are processed to locate objects, materials, cracks, and structures. When the generated pulses encounter a buried object or a boundary, the reflected signals vary characteristics, which can be processed suitably to reveal information about the subsurface structures. Usually, image processing techniques are used for interpretation and display. The GPR finds applications in military, geologic explorations, soils and bedrocks formation studies, archeological discoveries, underground mining, oceanography, and ice structure determinations. The penetration of signals is dependent on power level and dielectric properties of the soil. It can penetrate soil up to 15–20 m.

76.3.2 Satellite Navigation Systems

The use of satellites is a highly developed technology utilized extensively throughout the world. In the past three decades, it has progressed from quasi-experimental in nature to one with routine provisions of new services for both military and civilian use. The satellite relay systems take advantage of the unique characteristics of *geostationary satellite orbits* (GSOs). The design of satellite systems is well understood, but the technology is still dynamic. The satellites are useful for long-distance communication services, for services across oceans or difficult terrain, and point-to-multipoint services such as television distribution.

Satellite navigation systems use electronic receivers to determine the location of an object within a few meters using time signals transmitted from the line-of-sight satellites. The receivers calculate the time as well as position (longitude, latitude, and altitude) of the object.

Today, there are two fully operational Global Navigation Satellite Systems (GNSS): GPS of United States and GLONASS of Russia. There are a number of projects run by different countries such as the Deidou and COMPAS of China, Galileo of European Union, Doris of France, QZSS of Japan, and IRNSS of India.

Frequency allocation for satellites is controlled by the International Telecommunication Union (ITU). In the United States, the Federal Communications Commission (FCC) makes the frequency allocations and assignments for nongovernment satellite usage. The FCC imposes a number of conditions regarding construction and maintenance of in-orbit satellites.

There are many satellite systems, known as ComSats, operated by different organizations and different countries mainly developed for communications and data transmissions. These include Iridium of Motorola, Globalstar of Loral Corporation, CS series of Japan, Turksat of Turkey, Aussat of Australia, Galaxy and Satcom of the United States, Anik of Canada, TDF of France, etc. Some of the communication satellite systems are suitable for navigation purposes. However, satellite systems specifically designed for navigation are limited in numbers as indicated earlier.

The first generation of the satellite system was the *Navy satellite system* (Navsat), which became operational in January 1964, following the successful launch of the first transit satellite into polar orbit.

The system was declared open for private and commercial use in 1967. Civil designation of the name of the system is *Transit Navigation Satellite System*, or simply *Transit*. Later, this system evolved to become the modern Navsat GPS system, which will be discussed in detail. Most of the operational principles discussed here are inherited by the GPS system.

The Transit system consists of operational satellites, plus several orbiting spares, a network of ground tracking stations, a computing center, an injection station, naval observatory time signals, and receiver–computer combinations. The transit satellites are in circular polar orbits about 1075 km above ground with periods of revolution of about 107 min. Because of the rotation of the Earth beneath the satellites, every position on Earth comes within range of each satellite at least twice a day, at 12 h intervals. As originally intended, if at least five satellites are operational at any given time, the average time between fix opportunities would vary from about 95 min near the equator to about 35 min or less above 70° North and South.

The Transit system is based on the Doppler shift of two frequencies, 150 and 400 MHz, transmitted simultaneously by each satellite moving its orbit at a tangential velocity of about 7.5 km/s. Two frequencies are used so that the effects of the ionosphere and atmospheric refraction on the incoming satellite transmission can be compensated for by the receivers. Each frequency is modulated by a repeating data signal lasting 2 min, conveying the current satellite time and its orbital parameters and other information. Within the receiver, a single Doppler signal is created by processing the two signals transmitted by the satellite. By plotting the frequency of this signal versus time, a characteristic curve of the type shown in Figure 76.6 is obtained. Since the frequency of the transmitted signal is compressed as the satellite approaches, according to what proportion of the velocity vector is seen by the user receiver, the curve begins at time T_1 at a frequency several cycles higher than the transmitted frequency.

Tracking stations record Doppler observations and memory readout received during each satellite pass to relay them to a computer center. Updated orbital position and time data communications are relayed to an "injection" station from the computer center for transmission to satellite in a burst once each 12 h. Enough data are supplied in this 15 s injection message to last for 16 h of consecutive 2 min broadcasts describing the current orbital positions of the satellite.

The system accuracy depends on the accuracy of the satellite orbit computation, the effect of ionosphere refraction, the precision of the receiver speed, and heading determination. Under optimal conditions, the system is capable of producing fixes with a maximum rms error of about 2–3 m for the stationary receivers anywhere on Earth. Errors can be reduced to give accuracy within 3 cm yielding an

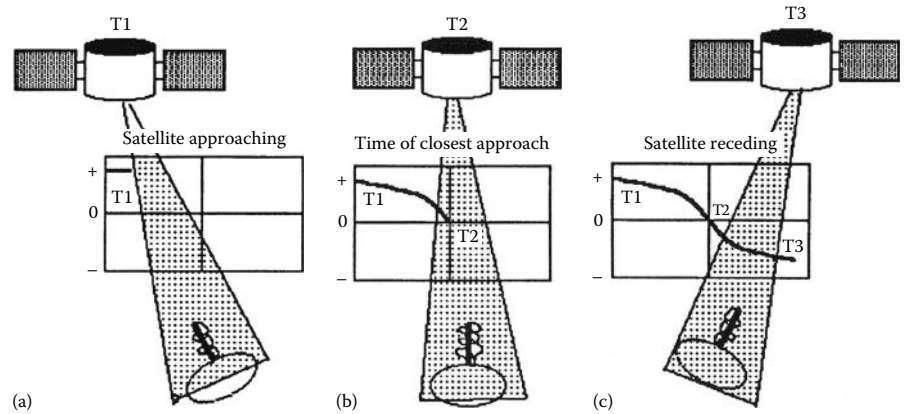

FIGURE 76.6 Transit satellite Doppler curve. (a) As the satellite approaches toward the receiver, the frequency of the received signal increases due to the Doppler shift. (b) At the time of closest approach, the transmitted and received frequencies are the same. (c) The frequencies received from a receding satellite result in lower values. This is also applicable in other position-sensing satellites such as GPS, Glonass, Starfix, etc.

absolute accuracy of 20–30 cm. Also, the time signal transmitted as a "beep" at the end of each 2 min transmission cycle coincides with even minutes of Coordinated Universal Time, which can be used as a chronometer check.

76.4 Global Satellite Navigation Systems

76.4.1 GPS

Global Satellite Navigation Systems are second-generation satellites evolved primarily from the Naval GPS. They provide a continuous 3D position-finding capability (i.e., latitude, longitude, and altitude), in contrast to the periodic two-dimensional information of the Transit system. Twenty-four operational satellites, as shown in Figure 76.7, constitute the system. Each satellite orbit is circular, about 2200 km high and inclined at angles of 55° with respect to the Earth's axis. Some of the older satellites are taken out of service to be replaced by their advanced counterparts.

The position determination using the GPS system is based on the ability of the receivers to accurately determine the distance to the GPS satellites above the user's horizon at the time of fix. If accurate distances of two such satellites and the heights are known, then the position can be determined. In order to do this, the receiver would need to know the exact time at which the signal was broadcast and the exact time that it was received. If the propagation speeds through the atmosphere are known, the resulting range can be calculated. The measured ranges are called *pseudoranges*. Nowadays, normally, information is received from at least four satellites, leading to accurate calculations of the fix. The time errors plus propagation speed errors result in range errors, common to all GPS receivers. Time is the fourth parameter evaluated by the receiver if at least four satellites can be received at a given time. If a fifth satellite is received, an error matrix can be evaluated additionally.

Each GPS satellite broadcasts simultaneously on two frequencies for the determination and elimination of ionosphere and other atmospheric effects. The Navstar frequencies are at 1575.42 and 1227.6 MHz, designated as L1 and L2 in the L-band of the UHF range. Both signals are modulated by 30 s navigation messages transmitted at 50 bits/s. The first 18 s of each 30 s frame contain *ephemeris* data for that particular satellite, which defines the position of the satellite as a function of time. The remaining 12 s is the *almanac* data, which define orbits and operational status of all satellites in the system. The GPS receivers store and use the ephemeris data to determine the pseudorange, and the almanac data to help determine

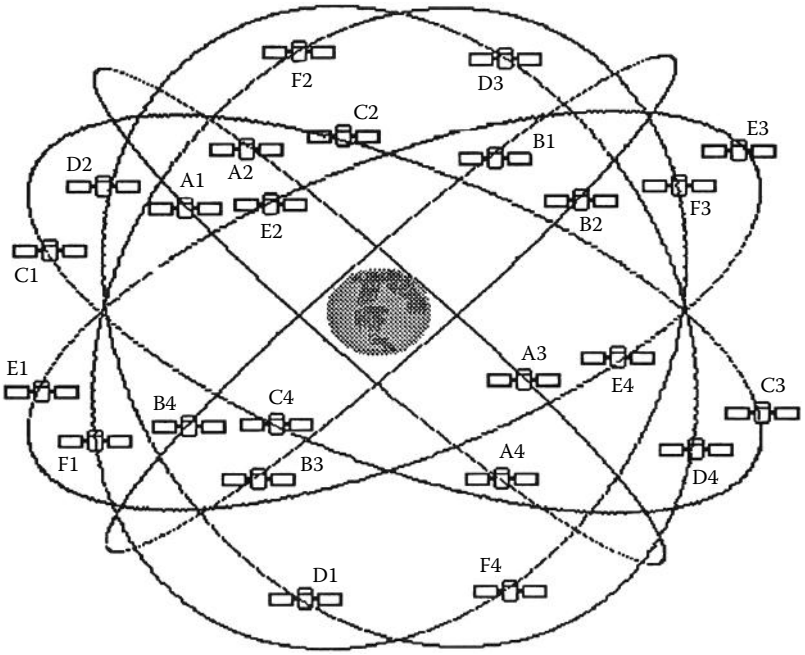

FIGURE 76.7 Operational GPS satellite coverage for navigation. Four satellites orbit in circular form. There are six such orbits inclined at angles of 60° from each other. In this arrangement, any point on Earth can see at least four satellites at any given time. This yields great accuracy in the position determination of the target, even only with C/A codes received.

the four best satellites to use for positional data at any given time. However, the "best four" philosophy has been overtaken slowly by an all-in-view philosophy.

The L1 and L2 satellite navigation signals are also modulated by two additional binary sequences called *CIA code* for acquisition of coarse navigation and the other *P-code* for precision ranging. The L1 signal is modulated both by the C/A and P-codes, and the L2 only by the P-code. The P-code, however, is not available for civilian users. The P-code is redesignated to be a Y-code, decipherable only by high-precision receivers having access to encrypted information in the satellite message. Civilian users have access to the so-called *Standard Positioning Services* (SPS), while U.S. and NATO military can use *Precise Positioning Service* (PPS) with better accuracy.

In enhancing SPS accuracy, differential techniques may be applied, as shown in Figure 76.8, to the encrypted GPS signals. Since the reference receiver is at a known location, it can calculate the correct ranges of pseudoranges at any time. The differences in the measured and calculated pseudoranges give the correction factors. Accuracy <1 m can be obtained in the stationary and moving measurements. Recently, differential receivers became commonly available, giving higher accuracy in subcentimeter ranges. They are getting cheaper day by day and finding applications in many areas such as airplanes, common transport vehicles, cars, geologic surveying, orienteering, farming, etc.

76.4.2 Glonass

There are a number of other satellite navigation systems similar to GPS of the United States, such as Russian *Glonass*. The Glonass consists of 31 satellites but 24 are in continuous use orbiting in circular form 1500 km above the ground. The accuracy of the system is about 10 m rms. Glonass satellites transmit details of their own position and a time reference. The carrier frequencies are in L-band, around 1250 MHz (L2) and 1600 MHz (L1). Only the L1 frequency carries the Civil C/A code.

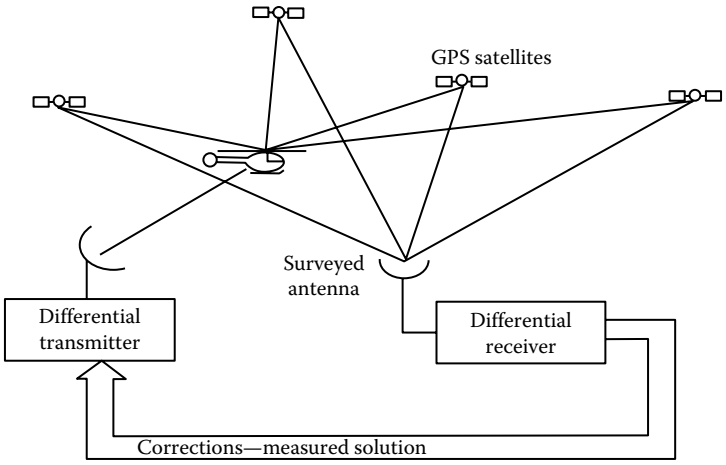

FIGURE 76.8 Differential GPS operation. Satellite and target positions are sensed by ground-fixed receivers or mobile receivers with exact known positions. Errors of the target position due to signals received from the satellites are corrected using the information from the fixed receivers. Using this method, very high accuracy within a few centimeter ranges can be obtained.

The radio-frequency carriers used by Glonass are channelized within bands 1240–1260 MHz and 1597–1617 MHz, the channel spacing being 0.4375 MHz at the lower frequencies and 0.5625 MHz at the higher frequencies. The number of channels is 24. The data message is formatted in frames of 3000 bits, with a duration of 30 s. The ephemeris data are transmitted as a set of position, velocity, and acceleration coordinates in a Cartesian Earth-centered, Earth-fixed (ECEF) coordinate system. The new ephemeris data are available every half hour, valid for the following quarter hour. The data are sent at a 50 baud rate and superimposed on a pseudorandom noise (PRN) code. The low-precision code has length 511 bits as compared to 1023 bits for Navstar. Glonass accuracy is as good as that for the GPS system. Glonass and GPS have different coordinate frames and different time frames that are being coordinated together.

76.4.3 Starfix

Another interesting satellite-based system—privately funded, developed, launched, and maintained—is the Starfix positioning system. This system is designed primarily for oil surveying. The system consists of a master site, which generates satellite ephemeris data, and four satellites in geosynchronous orbits. The system is said to have a precision of 2.5 m rms.

76.5 GPS Receivers and Their Uses

GPS receivers are devices constructed from electronic circuits, display units, and an antenna. They are supported by appropriate software. The devices are tuned to the frequencies transmitted by the satellites, and use a highly stable clock for timing purposes. Currently, there are three basic types of GPS receivers designed and built to address various user communities. These are called *slow sequencing*, *fast sequencing*, and *continuous tracking* receivers. The least complicated and lowest cost receiver for most applications is the slow sequencing type, wherein only one measurement channel is used to receive sequential L1 C/A code from each satellite every 1.2 s, with occasional interrupts to collect ephemeris and almanac data. Once the data are received, computation is carried out within 5 s, making this system suitable for stationary or near-stationary fixes.

Fast sequencing receivers have two channels: one for making continuous pseudorange measurements and the other for collection of the ephemeris and almanac data. This type is used in medium dynamic applications such as ground vehicles.

A number of companies produce highly sophisticated GPS receivers. EURONAV GPS receivers operate on two and five channels for military applications. They provide features such as precise time, interfacing with digital flight instruments, RS-422 interface, altimeter input, self-initialization, etc.

Software implementation satellite management functions, having different features, are offered by many manufacturers. In the case of DoD NAVSTAR GPS receivers, for example, three functional requirements are implemented: (1) database management of satellite almanac, ephemeris, and deterministic correction data; (2) computation of precise satellite position and velocity for use by navigation software; and (3) using satellite and receiver position data to periodically calculate the constellation of four satellites with optimum geometry for navigation. The DoD receivers are divided for three functions as Satellite Manager (SM), Satellite-Data-Base-Manager (SDBM) SV-Position Velocity Acceleration (SVPVA), and Select-Satellites (SS).

Differential navigation is also applied where one user set is navigating relative to another user set via a data link. In some cases, one user has been at a destination at some prior time and is navigating relative to coordinates measured at that point. The true values of this receiver's navigation fix are compared against the measured values, and the differences become the differential corrections. These corrections are transmitted to area user sets in real time, or they may be recorded for postmission use so that position fixes are free of GPS-related biases. The differential navigation and GPS systems find applications in en-route navigations for commercial and civil aviation, and military application.

GPS find wide applications in civilian uses. Some of these applications are

- Cellular telephony for position detections
- Time setting and clock synchronizations
- Emergency services and disaster relief
- Person, wildlife, animal tracking
- Vehicle detection, tracking and navigation systems
- Geotagging, cartographies, and map making
- Navigation of ships especially in shallow waters
- Aircraft position tracking
- Orienteering, tours, recreational activities, display of information about objects such as in museums
- Surveying, land management, tracking terrain changes, and terrain and property boundaries
- Tectonics, seismic geophysical explorations, landslides, and earthquakes
- Navigation, velocity determination, and orientation measurements
- Robotics, self-navigation, and autonomous mobile systems

All these applications are supported by software in a number of ways. For example, in some applications, the vector-based maps are used for route calculations and direction finding. In others, the GPS unit sends details of the locations based on time interval and distance traveled for tracking purposes.

Most commercial software run on Windows, Linux, Mac OS X, or Android platforms. There is much commercially available software to support GPS-based location determination and navigation, some of which are Destinator, Navigon, NDrive, ROUTE 66, Google Earth, Google Maps, Navit, VZ Navigator, and Tom Tom Mobile. There is also open source software such as Navit and Waze.

76.6 Transponders

Transponders are transducers that respond to incoming signals by generating appropriate reply messages. Recent developments in technology have made the configuration of transponders possible using elaborate and powerful on-board signal processing. This enhanced the capacity by improving

the link budgets, by adjusting the antenna patterns, and by making the satellite resources available on a demand basis—called the "switch board in the sky concept."

Increased interest in deep sea exploration has brought acoustic transponders to the forefront as an important navigation tool. They provide 3D position information for subsurface vehicles and devices.

Some transponders are based on radar signals that respond to radar illumination. Transponders are programmed to identify friend or foe or, in some cases, simply inform ground stations about the position of aircraft.

Transponders are used for emergency warning. The U.S. and Canadian satellites carry Sarsat transponders, and Russian satellites carry Cospas transponders. They are also used as warning devices in collision avoidance systems in aircraft and land vehicles.

76.7 RFID Radio Location Systems

RFID uses electromagnetic propagation to transmit information from a tag attached to an object. The tag contains nonvolatile memory to digitally store information that can be read from a distance. The system requires a transmitter and a receiver. The reader transmits an encoded signal to read the tag. The tag responds with its identification codes and with the information stored in it.

RFID tags can be active or passive or battery-assisted passive. An active tag contains an on-board battery to power the system. Passive tags use the radio energy transmitted by the reader as its energy source. A battery-assisted passive tag uses a small battery on-board to activate the system in the presence of a request from the reader. Tags may be read-only or may be read/write. In read-only tags, the information is factory set and cannot be changed. Read/write tags may be written by users.

Today's technology allows the production of small RFIDs. Hitachi produces RFID chips as small as 0.05 mm × 0.05 mm. These small-sized chips are capable of typically storing 38-digit numbers using 128 bit read-only memory (ROM). They can store information up to 2 kB of data.

RFID systems are used in

- Asset management
- Inventory systems
- Product tracking
- Transportation and logistics
- Passports
- Prevention of counterfeits such as chips in casinos
- Hospitals and healthcare
- Antitheft devices such as wallets, luggage, bags, keys, etc.
- Pharmaceutical industry
- Food industry and food safety
- Livestock or wildlife identification
- Libraries, books, CDs
- Telemetry
- Electronic toll collections
- Human or animal implantations
- Personal safety and alarm systems
- Tracking personal or commercial properties, etc.

A typical application of RFID is in healthcare. They are used in multiple ways, from keeping historical information about patients and collecting the status of vital life signs to equipment tracking in hospitals, clinics, and medical centers. For example, the locations of beds, wheelchairs, surgical and other medical equipment can be realized and tracked. Active RFID tags together with other sensors are used to detect any movement of equipment as well as any tampering and environmental conditions where they are kept.

Air Pollution Monitoring

Michael Bennett
Manchester Metropolitan University

77.1 Introduction

There is a huge range of atmospheric pollutants and for a given pollutant there may be several commercially available detection systems. In a document of this size, it is clearly not feasible to discuss in detail the theory of operation of every possible system. After some general remarks about air pollution monitoring, a broad introduction to the physics of molecular spectroscopy (the most widely used detection principle) will be presented. The detection of individual pollutants will then be discussed. Most of the practical examples given will refer to British experience, since this reflects the author's background. The principles involved, however, are universally applicable. The EPA's website (Table 77.3) provides an useful gateway to American legislation and practice.

Before spending money on a detection system, it is essential that the user understands the purpose of the measurement. This will affect both the choice of instruments and the location of monitoring sites. In general, active monitors with short response times will be more expensive than passive, slow response instruments. A survey intended to determine spatial variations of an ambient pollutant might therefore be best to employ very many cheap, slow response instruments. A classic example would be national surveys carried out in England and Wales in the early 1990s to measure indoor radon pollution [1]. The National Radiological Protection Board (NRPB—now part of the Health Protection Agency) supplied householders with two passive detectors, each consisting of a strip of plastic inside a protective

[a] Also Serinus series.

container. These are left in a living room and a bedroom for 3 months, at the end of which they are mailed back to the NRPB for analysis. (The number of α-particle trails in the plastic is counted.) The householder is then reassured (or not) as to the safety of the dwelling; the authorities, meanwhile, can build up a national map of Rn concentration in relation to geology, building type, etc. The essence of the system is that the individual detectors are so cheap—the Agency still (2012) provides a pair on request to individual householders at <£50—that the authorities can afford many thousands, such a number being necessary to provide realistic spatial coverage.

Identification of a particular source in the presence of background emissions, however, requires a sensor with a response time of minutes, or 1 h at most, supplemented by meteorological measurements. This need arises since at temperate latitudes the wind direction changes by order of 15° in 1 h and 90° in 24 h. Unless a source dominates local pollution, its impact is unlikely to be demonstrable through daily sampling.

Some applications may require response times of seconds or less. Odors are a very common cause of complaint. In this case the complainant perceives fluctuations in concentration over periods of a few seconds, while he may become inured to steady concentrations over periods of minutes [2]. It is also the case that many toxic gases (e.g., H_2S) are more dangerous in high doses over short periods than at a steady concentration over some hours [3]. Flammability, of course, also depends upon peak rather than mean concentrations.

Central to obtaining reliable information from such measurements is the protocol for the siting of instruments [4,5]. This naturally depends upon the objectives of the survey. The UK national survey for smoke and SO_2 [6], for example, was highly successful in demonstrating the effects on background pollutant concentrations of the 1956 Clean Air Act and (from the late 1960s) the availability of natural gas (cf. Figure 77.1). Sites were chosen so as not to be dominated by individual local sources, being typically in backyards or on the roofs of municipal buildings. By the early 1980s, however, urban air pollution had become increasingly dominated by road traffic emissions and the earlier network of sites no longer seemed appropriate [7,8]. Many roadside measurements have now also been made in addition to more general urban or rural surveys [9]. Note that a *typical* site is not necessarily a *representative* one [4]. The former is what we experience about our daily lives. The latter is chosen through a protocol so that measurements from one site may be compared with those from another. Depending upon the application, representative sites may be more or less typical.

A protocol is important not only for comparing one place with another but also for comparisons between different times. One should not be dismissive of the old technology of the national SO_2 survey: the conservatism of the design allows us to rely on the time series of concentrations over >60 years. Clearly, there are advantages in keeping up with the latest technology. But, if we are interested in long-term trends, we must be very sure of the relative responses of "improved" instruments and methods.

The deployment of fast response instruments around individual sources gives rise to somewhat different problems. Given the high cost of such instruments, we must be sure that statistically useful

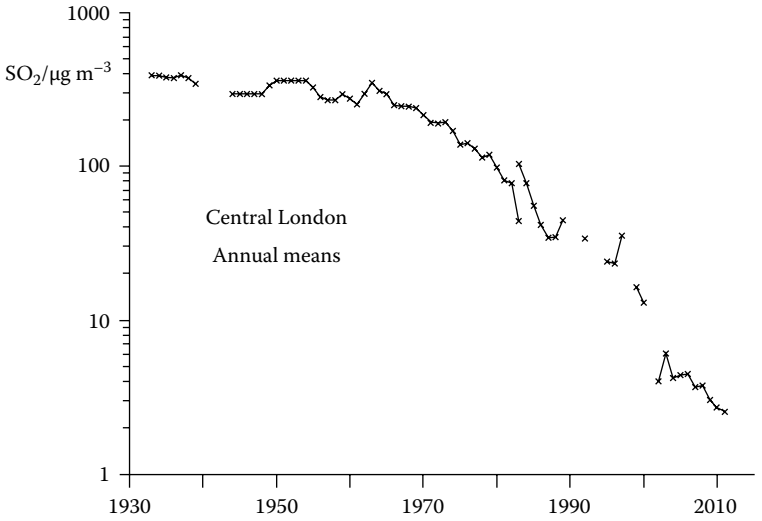

FIGURE 77.1 Annual average SO_2 concentrations in Central London, 1933–2011. Data for 1933–1983 are from a composite of sites in Lambeth and Westminster; for 1983–1999 from the Islington9 site. Data for 2002–2011 are from a modern instrument in Horseferry Road, Westminster.

measurements of environmental impact will be made over the course of the survey. Concentrations should ideally be measured simultaneously upwind and downwind of the source. For an elevated buoyant source, it is desirable to measure downwind concentrations over a range of distances: atmospheric dispersion models are not yet so foolproof that the calculated distance from the stack to the peak ground-level concentration may be relied upon. At a given point on the ground, pollution from such a source may typically be detectable during only a few percent of hours. Mobile laboratories are therefore commonly used to enhance the capture of data, but it is then essential that some statistical and climatological analysis be applied to extrapolate the measurements obtained to long-term means at fixed target points on the ground. The protocol and analysis should be planned before the instruments are purchased.

77.2 Spectroscopic Principles

The most common principle employed for the detection of contaminants in air involves the interaction of the trace species with light. The advantages are obvious: with careful choice of system, the interaction can be made specific to the chosen molecule, and the photon will then transport itself from the point of interaction to the detector. Reference [10] provides a general undergraduate-level introduction to molecular spectroscopy, while Ref. [11] describes specialized applications to atmospheric measurement.

The specificity of the interaction of light with a molecule arises from quantum theory. Light is absorbed or emitted as photons, of energy hc/λ, while individual atoms or molecules may only exist at discrete levels of energy or angular momentum. Light is thus only absorbed or emitted by gaseous species at discrete values of wave number, $1/\lambda$ (usually quoted in cm^{-1}). Generally, different molecular energy levels arise through three processes:

- *Rotational*: A molecule may spin with an angular momentum equal to a discrete value of $h/2\pi$. Transitions between angular momentum states are typically equivalent to photon energies of 1–100 cm^{-1}, i.e., microwave wavelengths.
- *Vibrational*: The atoms in a molecule may vibrate relative to one another. Transition energies between modes are typically of order 10^3 to 10^4 cm^{-1}, i.e., infrared (IR) wavelengths.
- *Electronic*: The electrons may occupy different orbitals within an atom. Transitions between these would typically take place at UV wavelengths.

Photons may initiate transitions between combinations of the above levels; observed molecular spectra thus tend to be extremely complicated, having structure over all scales of wave number. Atomic spectra, e.g., from a monatomic gas like Hg, are simpler, since there are no vibrational or rotational modes. Nevertheless, even for molecular spectra, "selection rules" permit only a restricted number of transitions to occur: a single photon can only effect a transition if the initial and final dipole moments of the molecule are different. (The direction of the change of dipole depends upon the polarization of the associated photon.) Conservation of angular momentum also requires that a molecule's spin may only change by one unit of $h/2\pi$ at a time.

Photon energies are broadened by temperature (which causes a Doppler shift in frequency) and by pressure (which shortens the lifetime of the excited state). In practice, of course, any practicable measurement system also has a finite resolution. Parts of the spectrum may thus contain so many possible transitions that it becomes impractical to distinguish individual lines. The specificity of molecule–photon interactions promised by quantum theory is thus seen to be somewhat limited in practice. Spectroscopic identification of a particular species relies upon the existence of resolvable structure in an accessible part of the spectrum where there is no serious interference from other common gases. In general, this search must be solved individually for each analyte, with no guarantee of the existence of a satisfactory solution.

77.3 Absorption Techniques

Detection of a specific molecule may be through either its absorption or emission of light at a particular wavelength. Consider monochromatic light of flux I passing through a gas of concentration χ. In so far as each interaction between a photon and a molecule is an independent event, then the rate of interaction is separately proportional to the number of photons and the number of gas molecules. Thus,

$$\frac{\partial I(x,\lambda)}{\partial x} = -\sigma(\lambda) I(x,\lambda)\, \chi(x) \tag{77.1}$$

where $\sigma(\lambda)$ is the absorption cross section. For constant gas concentration, this may be integrated as a function of path length, x, to give the Beer–Lambert law:

$$I(x,\lambda) = I(0,\lambda) e^{-\sigma(\lambda)\chi x} \tag{77.2}$$

The argument of the negative exponential is known as the optical density at this wavelength. The gas burden, χx, along the optical path is thus given by

$$\chi x = \frac{\ln(I(0,\lambda)/I(x,\lambda))}{\sigma(\lambda)} \tag{77.3}$$

and since $\sigma(\lambda)$ may be measured in the laboratory, we now have a measurement of the gas concentration.

The advantage of absorption techniques is that they require minimal disruption to the observed system. This is of benefit in ambient monitoring where, for example, a long-path measurement may be set up over many hundreds of meters without problems of safety or power. (This may be of particular value when monitoring, for example, at an airport.) Equally, in emissions monitoring it is advantageous to be able to measure gas concentrations in situ in the flue. Long-path techniques may also be applied in point samplers through the use of a multipass cell, e.g., a White cell [11]. The response time would then be limited by the volume of the cell in relation to the sample throughput.

Because of instrumental offsets and interference from other species, measurement of transmission at a single frequency is unlikely to give an accurate estimate of the gas concentration. More commonly, absorption is measured at several frequencies. Standard techniques are

- *Differential optical absorption spectroscopy* (*DOAS*): A broadband source is used in conjunction with a high-resolution spectroscope tuned around distinctive absorption features of the target gas. These days, the spectrum would typically be registered on a linear array of charge-coupled devices. The difference between online and off-line absorption (or between the absorption with and without the analyte gas being present) then gives the gas concentration. The measured absorption spectrum may then be fitted numerically to the target spectrum, allowing some correction for interferent species.

  A limitation with the method is that it is, as the name implies, *differential*. Molecular spectra are not usually so sharp that an absolute measurement can be made. Instead, one is usually looking for differences from a reference spectrum, obtained when it is believed that the analyte gas was at a very low concentration. This may be difficult to achieve in a real situation—and it may then be difficult to freeze the optical response of the system until the next reference can be obtained. In practice also, it is not a trivial task to fit the observed spectrum to that of the target gas. In the presence of noise and several interferent gases, the calculated concentration of the target gas will depend on which other gas spectra are included in the fit.
- *Fourier transform infrared* (*FTIR*): The output from the gas cell is put into an interferometer. The Fourier transform of the output signal as a function of phase lag is then the absorption spectrum. As with DOAS, fitting programs may be applied to estimate the mix of pollutants responsible for this spectrum. With an appropriate optical design, the full range of phase delays may be obtained simultaneously. There are two practical advantages to working in phase space rather than frequency space:
  - Rather than the image of a slit on the detector surface, we have the collimated focus of the whole aperture—in effect the real image of the radiation source. The photon throughput is thus much larger (Jacquinot advantage).
- All wavelengths are measured simultaneously and the device can thus obtain a spectrum more quickly for a given resolution (Fellgett advantage). With modern CCD arrays, this is less of an issue.
- Nondispersive infrared (NDIR). Optical filters are applied to limit the input spectrum to a window where interference effects from other gases are small. No further spectral separation ("dispersion") is then applied. Gross absorption by the target gas is measured and may be calibrated by switching gas cells into the light path. Clearly, this requires a careful choice of wavelength window. For CO detection, for example, a wavelength around 4.7 μm is frequently used, since this lies between the absorption bands of CO_2 and water vapor—both of which would also be present in high concentrations in combustion gases.
- *Tunable laser diode absorption spectroscopy* (*TLDAS*): This uses a very narrowband source (viz. a tunable diode laser) and a broadband receptor. The frequency of the source will typically be oscillated close to an absorption line of the target gas: the first harmonic of the signal is then proportional to the integrated concentration along the light path.

77.4 Emission Techniques

The converse of looking for the absorption of light of a given frequency by the target gas is to excite molecules of the gas and then examine the light emitted as they return to their ground state. The signal is passed through a narrowband filter and measured with a photomultiplier tube. There are several standard techniques:

- *Flame photometry*: A flame (typically of H_2) is burned in the sample gas. The heat breaks up and ionizes the target molecules which then relax to their ground state. Since we are now looking at fragments of the molecule rather than the molecule itself, the technique is not completely specific. Its advantage is that it tends to be very fast, being ultimately limited by the time scale for the ions to pass through the flame. A related technique, flame ionization detection (FID), though not strictly spectroscopic, is to measure the conductivity of the flame which arises from such ionization.

- *Chemiluminescence*: A reactive gas is added to the sample gas. Light from the excited products of the reaction is detected.
- *UV fluorescence*: The sample gas is excited with UV light and the subsequent fluorescence measured. A related technique, photoionization detection (PID), is to measure the ionization current arising from such UV irradiation. This then detects all species whose first ionization potential is less than the photon energy of the lamp. The technique is extremely fast [12].

77.5 Particulate Sampling

Sampling of particulate matter in air gives rise to a different set of considerations from the sampling of trace gases. Fundamentally, we are dealing with a much more diverse set of analytes. Clearly, one SO_2 molecule (say) is much the same as any other SO_2 molecule. The same cannot be said of an aerosol particle: particles may vary by mass, by morphology, or by chemical composition. All of these factors will determine their toxicity and how they will disperse in the environment.

At its simplest, we can classify aerosol particles by their sedimentation velocity. This is sensible because it gives an indication of how quickly they will be lost to deposition, and how easily they may be inhaled to the deep lung: since gravitational and centrifugal accelerations are equivalent, a massive particle cannot follow the tortuous streamlines from mouth to alveoli. In practice, it is conceptually more convenient to classify a particle by its equivalent "aerodynamic" diameter, this being the diameter that a spherical particle of unit density would need to have for it to have the same sedimentation velocity as the reference particle. Thus, aerodynamic and physical diameters will be similar for (say) a small droplet of ammonium nitric acid aerosol; for soot aggregate, however, the aerodynamic diameter will be much smaller than the envelope diameter. Particles of aerodynamic diameter <10 μm (PM_{10}) tend to travel with the air flow. Since, moreover, their Brownian diffusivity is very small, they exhibit very slow deposition [13]. At <2.5 μm ($PM_{2.5}$), such particles may be inhaled deeply into the lungs; as such, they are known as "respirable aerosol." Epidemiological studies [14] have demonstrated that urban aerosol in this size fraction induces significant mortality, even at modest concentrations.

Note that just because $PM_{2.5}$ has been shown to increase mortality in an urban environment does not mean that all fine aerosols are equally toxic. It is physiologically implausible, for example, that aerosols of soluble ions, e.g., sea salt or sulfate, should cause problems for public health at concentrations of 10 $\mu g/m^3$.

If we add an electron to each particle and then apply an electric field, the resultant electrostatic force takes the place of gravity, measuring the drift ("mobility") of the particle then provides a direct measure of the aerodynamic diameter, even of ultrafine particles. Summing up the rate of arrival of the electrons, i.e., the electric current, in a Faraday cup electrometer can then give us a number density of fine or ultrafine particulate (cf. Dekati or Grimm Aerosol Technik). Scanning the applied voltage and looking at the current as a function of arrival time gives us a number spectrum as a function of aerodynamic diameter ("differential mobility analyzer") down to diameters of a few nanometers.

Particles of diameters >10 μm exhibit significant inertial and gravitational effects. They may thus deposit through impaction as the air flows around small obstacles. For particles >50 μm, sedimentation becomes dominant. The sampling method must thus be tuned to the range of particle sizes which it is wished to monitor. For a general review, see the book by Vincent [15].

Spectroscopic methods are unlikely to be effective. The interaction of light with small particles (i.e., of diameter much less than the wavelength of the scattered radiation) is described by the Rayleigh scattering formula, while for larger spherical particles it is described by the more complicated Mie scattering analysis [16], with the maximum backscatter per unit aerosol mass occurring when the wavelength of the radiation is comparable to the circumference of the particles. For nonspherical particles, scattering can be modeled numerically. In any case, the response tends not to show very specific behavior as a function of particle composition.

77.6 Slow Ambient Monitoring

We will discuss first systems with sampling times of 1 day and upward. These would typically be used for background monitoring.

77.6.1 Diffusion Tubes

A diffusion tube is the classic inexpensive, slow response instrument which may be deployed in large numbers to quantify spatial variations of ambient pollutants. Typically, it consists of a sealed perspex tube with a removable cap and an active substrate at the closed end. It is deployed in the field with the open end downward and after the prescribed exposure time, typically 7 days, it is returned to the laboratory for analysis. The system was originally developed as a personal monitor of NO_2 exposure [17] but has since been widely used for ambient urban surveys (e.g., [18]).

Assuming that the substrate is a perfect trap for the target gas, the diffusive flux of gas into the tube is given by $DA\chi/L$, where D is the diffusivity of the target species, A the internal cross-sectional area of the tube, and L the length of the tube. So long as the diffusivity remains constant over the period of measurement, the total deposition to the substrate is therefore a measure of the mean concentration over the period of exposure. Theoretically, D should vary with temperature and there may also be some circulation within the tube arising from wind across its mouth. A typical commercially available model has $L = 71$ mm and an internal diameter of 12 mm, so such circulation is suppressed. Studies have shown acceptable correlation between samples from diffusion tubes and long-term means from adjacent point samplers [19].

The system employed for NO_2 is a substrate of triethanolamine deposited on a stainless steel mesh. The sample is dissolved in orthophosphoric acid and the nitrite detected colorimetrically using the Greiss/Saltzman technique at a cost of less than £10 per tube. More costly systems are also available (e.g., from Gradko) for SO_2, benzene, xylene, toluene, and a wide range of other gases.

77.6.2 Drechsel Bottles

The classic bubbler (a "Drechsel" bottle) consisted of a Pyrex® bottle containing a solution through which filtered sample gas was bubbled. For the detection of SO_2, a solution of hydrogen peroxide was used so that

$$H_2O_2 + SO_2 \rightarrow 2H^+ + SO_4^{2-}$$

In polluted areas, the H^+ ions were then detected by titration, it being assumed that all the acidity came from atmospheric SO_2. In cleaner, rural areas, this became insufficiently sensitive (NH_3 emissions from livestock could give apparently negative SO_2 concentrations!) and the sulfate ions were then measured using ion chromatography. Sampling times were typically 24 h for a sensitivity of a few ppb.

As implemented in the U.K. national surveys of smoke and SO_2, eight such bottles were mounted in a case with a separate pump and flow meter. At some preset time each day, the airflow was switched from one bottle to the next; at the end of the week, the operator then visited, replaced all the bottles, and returned the old ones to the laboratory for analysis. In this system, the air was first drawn through a separate filter for each day of measurement. This captured particulate in the range 5–25 μm diameter; the blackness of the stain was measured photometrically to provide a 24 h sample of "black smoke." The system is now obsolete, being replaced by UV fluorescence systems for SO_2 and an Aethalometer® for black carbon (see later).

The bubbler system was simple, inexpensive, and required minimal operator training. It was therefore possible to install many hundreds of such sites and to run them for a considerable period. In central London, for example, such systems were first installed in 1933. Figure 77.1 shows how urban SO_2

levels have dropped by two orders of magnitude over the subsequent 80 years. Concentrations in central London were still well in excess of 300 μg/m^3 in the early 1950s. (The reader may wonder how the author survived his early childhood.) With the arrival of natural gas for domestic heating in the late 1960s, concentrations had dropped to 40 μg/m^3 by the early 1980s. By that stage, smoke and SO_2 emissions from domestic coal burning were no longer a serious issue and the network was scaled down to around 250 active sites [9]. Concentrations continued to fall rapidly with power generation from natural gas being permitted from 1991, and ultralow sulfur fuel for motor vehicles being introduced over the following decade. They are now below 3 μg/m^3. Figure 77.1 also betrays how data capture fell off in the 1990s. Black smoke and SO_2 were no longer a priority of central government and the network was gradually wound up. The total number of sites sponsored by central government has remained at a similar level, however, but now split between various networks (urban background, rural background, black carbon, etc.) under the supervision of AEA technology and using modern technology. The Westminster site whose data are used in Figure 77.1 is one of the urban background sites. Other networks, sponsored by local authorities or commercial interests (e.g., airports), also operate. Reference [20] supplies helpful advice on the choice of modern instruments for such networks.

In practice, the real cost of any monitoring system is the manpower and the site. These are small if the system is sited in a municipal building and operated by existing staff. At a remote site, however, a secure cabin with power must be provided and a nonautomatic system must be visited weekly. The practical difficulties of identifying, securing, and maintaining a site should never be underestimated when designing a monitoring network.

77.6.3 Deposition Gauges [21]

Traditionally in the United Kingdom, measurements of atmospheric dust were made using the passive British Standard dust deposition gauge, while measurements of "smoke" were made using the active filter system described in the previous section. The standard dust deposition gauge consisted essentially of a bowl of diameter 300 mm and depth 225 mm mounted 1.2 m above the ground; the sample was washed into a bottle beneath the gauge, from where it was filtered, dried, and weighed. After having been in use for the better part of a century, the collection efficiency of the standard gauge was tested and found to be in fact rather poor. In very light winds, 50% of particulate at 100 μm and 80% at 200 μm might be captured, but these efficiencies fell off very rapidly with increasing wind speed. Such a gauge would thus give no more than an indication of nuisance from coarse aerosol—respirable aerosol could not be captured.

Later work showed that a gauge shaped like an upside-down Frisbee® has a far superior capture performance. With the addition of a foam substrate, collection efficiencies in excess of 80% in light winds, even for particle diameters as small as 50 μm, can be achieved and these efficiencies remain good at moderate wind speeds. Such gauges are now commercially available (www.hanby.co.uk).

77.6.4 Active Aerosol Sampling

Measurement of particulate matter of aerodynamic diameter <50 μm in air requires an active sampling system.

A conventional (e.g., Andersen) high-volume sampler for total suspended particulate (TSP) consists of a filter and a powerful blower. The system is mounted in a housing with a pitched roof, the air being drawn in under the eaves, i.e., at a height of about 1.1 m. Air sampling rates are in excess of 1 m^3/min. The filter may be changed and weighed, or otherwise analyzed, after 24 h.

Size discrimination can be introduced into such samplers by requiring the air to follow a tortuous path. Small particles then follow the streamlines while large particles are deposited. As a first stage, the high-volume sampler may have an inlet impaction chamber, which only allows the PM_{10} or $PM_{2.5}$ fraction to be subsequently captured in the filter.

In a more sophisticated system, the filter may be replaced with a cascade impactor. This consists of a stack of plates with successively smaller perforations. The holes are staggered so that air passing through one hole impacts on the following plate. As the perforation size diminishes, the air speed increases and the size of particle which can escape diminish. By covering each plate with a removable membrane, the particulate captured in each size fraction can be analyzed and, in principle, weighed. The classic Andersen systems are now available from Thermo-Scientific.

Low-flow systems (1 m^3/h) are also available which permit measurement of PM_{10} or $PM_{2.5}$. Inlet heads, certified by the EPA, are available for various cutoff diameters. Reference [22] quotes capture efficiencies for such devices as a function of particle size.

77.7 Fast Ambient Monitoring

The alternative to a mechanically based, slow response sampler which must be visited regularly is an automatic, fast response system, self-calibrating if possible, which is logged on site and may be interrogated remotely. Routine visits are then minimized, while visits can be made urgently if there is an alarm. We list later instruments currently available for various common gases. Most of these systems are designed to be bench or rack-mountable, weighing typically in the range 15–30 kg. Autocalibration versions are available for most of them. Most manufacturers also supply appropriate logging systems with user-friendly software. The lower detectable limit (LDL) is conventionally two times the standard deviation of the noise, while the response time is typically the rise time to 95% of final value; with some instruments, there may also be a significant lag time. Obviously, by averaging over a longer sampling period, the LDL can be reduced. The price of most gas monitors falls in the range of £5000–£10000 plus sales tax (U.K., August 2012), depending on model and manufacturer. Hydrocarbon monitors are slightly more; aerosol monitors are twice as expensive.

77.7.1 SO_2

For the last 20 years, most ambient monitors for SO_2 have used UV fluorescence; when irradiated, SO_2 molecules reemit light in the range 220–240 nm. The measured light intensity is then proportional to the SO_2 concentration. Currently available systems have response times of order 1–2 min and LDL of order 0.3–1 ppb. Most manufacturers also supply a converter which allows H_2S to be measured as a separate channel.

77.7.2 NO_x

Most ambient monitors for NO_x employ chemiluminescence. Ozone generated within the instrument is mixed with the sample air. NO in the sample then reacts very rapidly to form NO_2, with the emission of IR radiation (peaking at 1200 nm). This is a first-order reaction; IR emission is therefore proportional to the NO concentration. Total NO_x may be measured by first passing the sample air over a catalytic converter to reduce any NO_2 present to NO. By alternating this conversion, or through the use of a dual channel system, NO_2 concentrations may be found by difference. Inevitably, the measurement of NO_2 will be noisier than that of NO or NO_x separately. Currently available systems have response times of order 30–90 s and LDL of order 0.4–1 ppb. Most manufacturers also supply a converter which allows NH_3 to be measured as a separate channel.

77.7.3 O_3

Most ambient monitors for O_3 now use modulated UV absorption. O_3 has a broad absorption spectrum in the UV with a peak around 254 nm. Practical instruments alternate the gas in the absorption cell between sample air and a deozonized reference gas; from the Beer–Lambert law, the log ratio of the

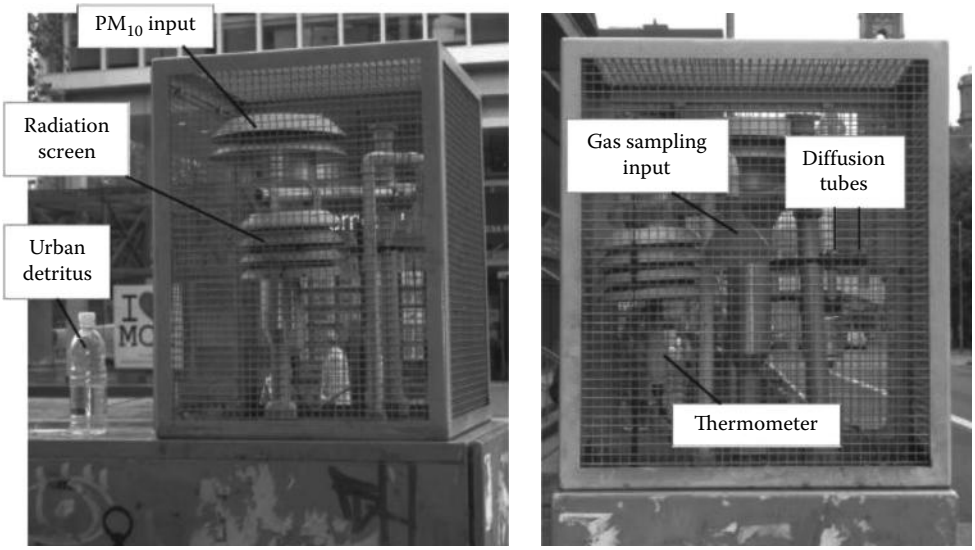

FIGURE 77.2 Sampling inputs for an air quality monitoring site in Central Manchester. The site monitors NO, NO_2 (chemiluminescence), and PM_{10} (β-absorption). The instruments are secured in the steel street-side box beneath: vandalism is a chronic problem at unmanned sites. This location is heavily trafficked, with the NO_2 concentrations being well in excess of the long-term limit of 40 μg/m^3 required under European law; peak diurnal concentrations of PM_{10} appear to be marginally within the limit.

signal must then be proportional to the O_3 concentration. Currently available systems have response times of order 20–50 s and LDL of order 0.4–1 ppb.

77.7.4 CO and CO_2

The standard method of measuring ambient CO or CO_2 is to use modulated IR absorption (NDIR); modulation of the signal allows detector offsets to be removed and may be achieved by alternating between sample and reference gas in the absorption chamber. A conventional way of doing this is through the deployment of a rotating wheel with gas cells containing N_2 and CO (or CO_2). Currently available systems have response times of order 20–60 s and LDL of order 40–100 ppb CO. An interesting variant of IR absorption is "photoacoustic detection," where the warming of the analyte is measured rather than the loss in IR flux. The irradiation is modulated—the varying heating of the sample gas is then registered as an oscillating pressure in the measurement chamber.

77.7.5 Hydrocarbons

The instruments available for the detection of ambient hydrocarbons tend to be somewhat more diverse than for the gases listed earlier. The most widely used technique is FID. A hydrogen flame is burned in the sample gas between two electrodes and the flame conductivity measured. This tends to be proportional to the concentration of ·CH ions in the flame, though the calibration varies between hydrocarbon species. Most commercial instruments allow CH_4 to be measured separately by first passing the sample gas across an oxidation catalyst. Nonmethane hydrocarbons (NMHC) are thereby removed from the sample; they may be estimated by difference from the total hydrocarbon (THC) channel. In principle, a FID is very fast, with some commercial instruments having response times as short as a few seconds. There is, however, a trade-off between sensitivity and response time, a sampling time of 1 min or more being required to give a LDL of 20 ppb.

TABLE 77.2 List of a Small Selection of Manufacturers of Cross-Duct Emission Systems and the Technique Employed

Supplier	Technique	Gases
Codel	NDIR	CO, CO_2, SO_2, NO, NO_2, HCl, H_2O, CH_4
Servomex	TDLAS	HCl, HF, NH_3, CO, CO_2, H_2S, HCN, CH_4
Sick AG	DOAS (UV)	SO_2, NO, NO_2, NH_3
	TDLAS	HF, HCl, NH_3
Teledyne Monitor Labs	Modulated UV	NO, SO_2
OPSIS	DOAS (UV or IR)	Many
	TDLAS	HF, HCl, NH_3, CO, CO_2

Note: The list is not intended to be exhaustive and no particular recommendation is implied.

Many of the manufacturers listed in Table 77.2 supply direct-throughput FIDs for ambient. Thermo-Scientific offers an instrument (55i) which combines a FID with a cycled gas chromatograph, thereby better guaranteeing separation between methane and NMHC, though at the cost of a longer cycle time. The Photovac range of instruments, now supplied by Inficon, includes a handheld FID (MicroFID), which is designed to be intrinsically safe and intended for, e.g., workplace monitoring or leak detection. As such it is extremely fast: <3 s to 90% response.

An alternative technique for hydrocarbons is PID. This is nonspecific, with the detector also responding to inorganic gases of low ionization potential (e.g., NH_3). It is, however, very fast (with response times from 0.2 s for an LDL of 10 ppb) and the instruments can be made to be economical, lightweight, and intrinsically safe. A typical application might be as a handheld leak detector in a chemical plant, or as a personal monitor of toxic solvents. Instruments are marketed by Photovac and RAE Systems.

77.8 Lightweight Chemical Sensors

Where weight and power consumption are critical issues, techniques based on surface chemistry may be used. Unisearch Associates markets a NO_x sensor ("Luminox") based on wet chemiluminesence: sample air is drawn over a wick containing a proprietary solution which reacts with the target gas. Light emitted in the reaction is monitored. The system is fast (response time $\leq$0.5 s), sensitive (LDL $\leq$0.1 ppb), and lightweight.

Small, lightweight sensors based on miniaturized fuel cells have also been developed [23] for the detection of NO, NO_2, CO, and other gases (cf. Alphasense in Table 77.3). These are prone to drift, but with suitable analysis this can be allowed for. The point is that such sensors are cheap enough to be distributed in large numbers around a site, permitting real-time spatial mapping of pollutant distribution.

77.8.1 Aerosols

Measuring atmospheric aerosol concentrations at ambient levels in real time is more demanding than measuring trace gases because the pollutant is concentrated into a relatively small number of tiny particles, inaccessible to spectroscopic examination. Optical methods are nevertheless useful. The most straightforward method is to look at the absorption of radiation across a test cell, preferably at several wavelengths. This is the principle of operation of the Aethalometer marketed by Magee Scientific and currently used in the United Kingdom black carbon monitoring network. The measured signal arises from the combined absorption from many particles within the test cell; some discrimination between elemental carbon and organic carbon compounds is provided by comparing the absorption at different wavelengths.

A more sophisticated technique is that of the optical particle counter (OPC, e.g., from Grimm or Turnkey Instruments). In this case, red or IR light from a laser diode is measured as it is scattered by individual particles as they pass through the system. The intensity and distribution of the scattered

light can be used to estimate the size of each individual particle. An OPC can thus provide both a particle size spectrum and an estimate of the total aerosol volume per unit volume of sampled air. The technique, however, has inherent limitations both for large and small particles. For particles smaller than the illuminating wavelength, the scattered intensity per unit mass is proportional to the particle volume. Particles smaller than ~0.1 μm are undetectable. Geometric scattering from large particles on the other hand gives a scattered intensity per unit mass inversely proportional to the particle diameter and thus also falls off with particle size. More seriously, the counting statistics can become very poor. An ambient aerosol concentration of 10 $\mu g/m^3$ made up of spheres of 10 μm in diameter and unit density corresponds to a number concentration of only ~20 particles/cm^3. For coarse particulate, the volume of input air actually passing through the optical field over the desired averaging time must thus be of order cm^3. This cuts both ways, of course: if the sampled volume is too large, then the detection system will not be able to keep up with the signals from the vast numbers of tiny particles.

It is also difficult to deliver coarse aerosol from the sample inlet to the detector. Sample lines should be short, straight, and preferably vertical.

Direct gravimetric methods are also employed, based either on β-absorption or on an oscillating filter. The sensitivity required for such a measurement may be appreciated if we consider a sampler drawing 3 L/min which is intended to measure aerosol concentrations over a sampling period of 6 min. A detection limit of 5 $\mu g/m^3$ then requires that the sample mass be measured to a precision of 90 ng.

In the β-absorption technique (e.g., Horiba, model APDA-371), the sample air is drawn through a filter tape which is exposed to β-radiation. As atmospheric aerosol is deposited on the filter, its transparency to the radiation gradually diminishes. Differentiating the transmitted signal with respect to time gives an aerosol concentration at close to real time. The tape is advanced every hour, in effect rezeroing the measurement and capturing a timed sample for subsequent analysis if so desired.

In the tapered element oscillating microbalance system (TEOM—Thermo-Scientific, model series 1400ab) system, the filter is balanced on a hollow tube through which the sample air is drawn. The tube is clamped at its base and induced to vibrate at a frequency which depends on the mass of the filter. Again, the differential of the filter mass with respect to time provides the aerosol concentration.

Whichever system is employed, care must be taken in the choice of inlet port so that the desired fraction of ambient particulate is sampled. Typically, a PM_{10} sampling head would be employed.

It is not always the mass of fine aerosol that is of regulatory or scientific interest. Often the number density is of more interest. As noted in an earlier section, ultrafine aerosol particles may be detected and counted electrostatically. An alternative technique is the condensation particle counter (CPC, e.g., from Grimm or TSI). In this device, the sampled air is passed through a warm chamber saturated with butanol or water and then into a cool chamber. The supersaturated vapor then condenses onto

the particles, which grow into droplets large enough to be detected optically. As with the electrostatic technique, this can count particles of aerodynamic diameter down to a few nm. If size discrimination is required, then the system can be used as the detector in a differential mobility analyzer.

Fine particles can also be differentiated by accelerating them through a critical orifice, i.e., in a supersonic jet, into a low pressure chamber. Smaller particles will then travel faster than larger ones. This is the principle underlying Aerodyne's aerosol mass spectrometer. Having separated the incoming fine aerosol into a spectrum of different sizes (40–1000 nm) using a aerodynamic lens and a chopper, the individual particles can then be volatilized and analyzed by one of a range of different detector modules. It is thus possible almost in real time to obtain both a size spectrum of ambient aerosol and a chemical profile of the particles in each size range.

77.9 Remote Monitoring

While point samples of air pollution can be very valuable, they are limited both in their position, which is normally near ground level, and in representing a single point rather than a broader spatial sample. A variety of optical techniques are available which permit more general measurement of pollution in the atmosphere.

77.9.1 Long-Path Measurements

With the use of a broadband source and a retroreflector, spectroscopic analysis of the returned light can provide spatially averaged measurements of a wide range of pollutants. OPSIS is the market leader.

For ambient monitoring, the OPSIS system applies DOAS to an absorption spectrum ranging between the UV and the near IR. Standard systems are available for monitoring three (NO_2, SO_2, O_3) or five (+ toluene, benzene) species. Modules may be added for a range of trace gases. The system may also be used for emissions monitoring. An absorption band in the IR may then be used and the calibration must be optimized to the optical density of the particular flue.

77.9.1.1 Overhead Burden

If we are interested in concentrations well away from the ground, a retroreflector may be impractical. In this case, spectral measurements of sunlight scattered from the sky may provide us with an estimate of the total overhead burden ("column") of a pollutant. "Cospecs" (analog correlation spectrometers) were available from the early 1970s for the measurement of SO_2 or NO_2 burden. These are most valuable in conjunction with mobile surveys of elevated emissions (power stations or volcanoes), since they allow the investigator to know when he is beneath the plume. With very careful calibration, and knowledge of the wind speed, they may also be used to estimate the pollutant flux. The instrument has no absolute zero level and so has difficulty distinguishing very broad plumes. While the Cospec is no longer manufactured, much more sophisticated digital systems are now deployed, for example, on satellite platforms to monitor regional SO_2 emissions [24].

The classic measurement of overhead pollutant burden is that of stratospheric O_3 using the Dobson spectrophotometer. This measures the difference in irradiance at two wavelengths 20 nm apart close to the peak of UV absorption by O_3: other things being equal, this difference is proportional to the overhead burden of O_3. The system was used to detect the ozone hole over Antarctica in 1984 [25]. The detection method had then remained unchanged since the original instruments of 60 years previously, though the optics had been refined and the valve electronics replaced with solid state. This continuity of method was important in giving confidence in the surprising observation of the ozone hole.

The Dobson instrument is now obsolete; an improved instrument, the Brewer spectrophotometer, which also measures column SO_2, is available from Kipp & Zonen.

77.9.2 Lidar

Light detection and ranging (lidar) is the optical equivalent of Radar [11,26]. A pulse of laser light is directed into the atmosphere. Backscattered light is collected by a telescope and directed to a photomultiplier tube. The strength of the return signal corresponding to a given range $R = ct/2$ is given by the lidar equation:

$$V(R) = \frac{CW}{R^2}\sigma_b\, n(R) \exp\left\{-2\int_0^R (\sigma(\lambda)\chi(r) - \sigma_e\, n(r))dr\right\} \tag{77.4}$$

where

C is a system constant
W is the pulse energy
$n(R)$ is the density of scatterers
σ_b and σ_e are the backscatter and extinction cross sections for scattering, respectively
$\sigma(\lambda)$ is the absorption cross section from a tracer gas of concentration χ

If the extinction is small, scanning the laser beam through an elevated plume allows a cross section of the scatterer density to be built up. The range resolution of this cross section depends on the frequency at which the signal is digitized: a 60 MHz digitizer gives a range resolution of 2.5 m. The time resolution of the measurement depends on the pulse repetition rate of the laser. At 30 Hz, a 2 s scan would normally give adequate lateral spatial resolution. *A priori* calibration for particulate density requires knowledge of σ_b, which in turn depends upon the particle size and refractive index. In practice, an independent gravimetric measurement must be made at some point in the scanned area.

Alternatively, shots may be alternated between two nearby wavelengths (λ_1 and λ_2) having very different values of $\sigma(\lambda)$. Neglecting variations in the other terms, the lidar equation may be rearranged to give

$$\chi(R) = \frac{1}{2(\sigma(\lambda_1) - \sigma(\lambda_2))}\frac{\partial}{\partial R}\ln\left\{\frac{V_2(R)}{V_1(R)}\right\} \tag{77.5}$$

Since the differential absorption $\sigma(\lambda_1) - \sigma(\lambda_2)$ may be measured in the laboratory, we now have a remote, range-resolved measurement of the tracer gas. This technique is known as differential absorption lidar (DIAL) [11] and has been applied to a wide range of atmospheric pollutants (SO_2, NO_2, O_3, CH_4, hydrocarbons, Hg, etc.). Its particular strength is in identifying and quantifying fugitive emissions, e.g., CH_4 from cattle or leaks in refinery plant [27]. Because of the greater subtlety of the measurement, it does not in general have the spatial or temporal resolution of a simple backscatter lidar. For a given DIAL system at a given range, the product of spatial, temporal, and concentration resolution is approximately fixed; optimal performance in one is at the cost of worse performance in the others. If the signal is rather weak, there is a temptation to average measurements over a period greater than the timescale for a significant change in the target gas concentration. Great care should be taken in this case since the nonlinearity of Equation 77.5 can then lead to very serious distortions [28].

DIAL services are available from (for example) National Physical Laboratory (NPL) or Spectrasyne in the United Kingdom.

77.10 Emissions Monitoring

Industrial plants are in general authorized to release effluent to the atmosphere on the condition that such emissions are monitored reliably enough to satisfy the regulator that authorized limits have not been exceeded. This has increasingly led to the installation of continuous emissions monitoring systems (CEMS) for prescribed substances, with measurements being automatically displayed and archived. Years ago, we used to hear stories of power stations turning off their electrostatic precipitators at night in order to save a little bit of power—this is no longer feasible.

Aside from satisfying regulatory conditions, such monitoring can also be of value to the operator in controlling his plant (e.g., optimizing the excess O_2 in a combustion plant). Note that any measured value of pollutant concentration must be converted to standard conditions of temperature, pressure, humidity, and excess O_2 before comparison with a regulatory standard.

To be credible, any such monitoring must be made to a defensible standard. In the United Kingdom, a measurement certification scheme (MCERTS) is run by the Environment Agency. Beyond merely regulating emissions, the Agency does its best to help industry to make reliable measurements and to work within the regulatory system successfully. Among other activities, it has published a series of technical guidance notes (up to M21 [29] at the time of writing). The system certifies the instruments to be used, the monitoring protocols, staff training, etc.

No respectable business wishes to pollute its environment. By training and advising industrial emitters, the Agency makes its own task easier. Similar arrangements are in place in other industrial countries. In the United States, certified methods are promulgated by the Emissions Monitoring Center of the EPA. In Germany, certification is the responsibility of the four Technical Inspection Associations (*Technischer Überwachungs-Verein*—TÜV), which in fact operate as technical consultancies worldwide and in contributing to the development of International Standards.

77.10.1 Isokinetic Sampling of Aerosol

The gold standard for the measurement of aerosol emissions is to take a sample of the effluent and weigh the particulate therein. This is done by introducing a sample line into the flue, pumping the gas through a filter, and measuring the mass gained per metered volume of flue gas. It is essential that the gas speed at the sample inlet is the same as the flow velocity in the flue: if it is too fast (or slow), large particulate will be under (or over) sampled. To ensure a representative sample, such measurements must be made at several diameters downstream of any bends or confluences in the flue. It is also necessary to take several samples (4 or 8) over the cross section of the flue. Even taking every precaution, the precision of the method may be as poor as 20% of the mean value. In practice, the nominal calibration against continuous monitors may be found to be *very much* worse than this from trial to trial.

Since each sample may take 30 min, this procedure clearly does not give a real-time measurement of particulate load. In poorly designed plants, there may also be severe practical difficulties in gaining access to the flue with heavy, powered sampling equipment at a sufficient height for the flow to be uniform. Nevertheless, this is the only direct gravimetric method of measuring particulate concentration in a flue. For this reason, regular (at least annual) such measurements would be required for the calibration of any continuous monitors.

77.10.2 Aerosol Sampling: *In Situ* Methods

In situ methods are particularly attractive for emissions measurements because the pollutant is measured directly without any possibility of loss or transformation in the path from flue to instrument.

The most obvious way of continuously measuring the dust load in a flue is to pass a beam of light across the flue and measure the obscuration. It may be assumed that the transmission obeys the Beer–Lambert law and that the optical density is proportional to the particulate load. Practical instruments,

of course, require a degree of sophistication to allow for instrumental offsets. It will not generally be possible to turn off the plant at regular intervals to check the instrument zero! Typically, the light source will be modulated and a modulated signal measured. Purge air is normally blown over transmitter and receptor windows (and the retroreflector if used) in order to keep the light path clear. The sensitivity of the system will nevertheless drift with time (and will change with the composition of particulate) so regular gravimetric calibration is essential.

Such cross-duct monitors are simple and robust, and they provide a measurement across the full width of the flue. They are limited to optical densities in the approximate range 0.01–2.5. Systems are available from Codel, Land Combustion, Grimm, United Sciences, and others.

For very narrow ducts, or for very low particle densities, a more sensitive technique must be chosen. As with ambient particulate monitoring, it is possible to use sideways scattering from a light beam. The transmission and reception optics are now set up so that there is no direct path between the two. Light scattered from particles in the flue may, however, be detected. This gives a true zero level in the absence of particulate, and a signal proportional to particle density. Care must be taken to ensure that the light path is representative of the particle distribution in the flue. By switching the light path, it may be possible to route it through a filter of known optical density, thereby permitting online calibration. Such systems are available from Erwin-Sick and from United Sciences.

An alternative technique is the triboelectric monitor. In this device, a metal rod is inserted across the flow. Particles striking the rod transfer static charge to it. The leakage current (or, better, the rms component thereof) is thus proportional to the particle flux along the duct. This method is fast, simple, and robust: it is little affected by the accumulation of dirt on the probe and is insensitive to the presence of steam (which would, of course, preclude optical measurements of particle density). In very wet flows, there are possible problems with leakage across the insulated base of the probe: these may be overcome with the use of purge air or extended insulation. It should be noted that, with this device, calibration is required not only for gravimetric particle density but also for the flow speed in the duct. If this speed varies significantly, the implicit particle density will be in error. Systems are available from PCME or Codel.

77.10.3 Gas Sampling: Spectroscopic Methods

The cross-beam technique can be applied to *in situ* sampling for pollutant gases. Practical devices are usually based on nondispersive absorption of IR or UV. DOAS may also be used. Sophisticated instrumental design is necessary to ensure

- Minimal interference from other species present in the effluent.
- Minimal interference from IR emissions from the hot flue gases. Typically, a modulated system would be used.
- Insensitivity to instrumental drifts (dirty windows, misaligned optics, aging of source, and detector). This may be achieved with dual light-path systems, where only one path is sensitive to the target gas. The differential signal then gives a robust measurement of concentration in the flue. This may be calibrated online by switching in cells containing a known concentration of the target gas.

Clearly, the operator will not wish to turn off his plant so that zero and span on the monitor can be measured directly. An alternative is to encase the beam path in a filtered chamber within the flue. The chamber can then be filled with clean or span air as necessary. This has the further advantage that dust can then be excluded from the beam.

77.10.4 Gas Sampling: Extractive Techniques

If flue gases are to be sampled by an extractive technique, great care must be taken in delivering the sample from the flue to the monitor. The simplest technique is in effect to take the probe sample chamber

outside the flue and deliver the flue gas to it using a heated, filtered, sample line. The same cross-duct technique can then be used as if the sample chamber were physically in the flue itself. In many systems, however, the same techniques are used for extractive emissions monitoring as are used for ambient gas monitoring; in many cases, even the same instruments might be used. Since process gases tend to be hotter, wetter, dustier, and more acidic than ambient air, there will often be a need to change the condition of the sample so that it is acceptable to the monitor. The aim of sampling technology is to deliver an acceptable sample to the instrument at a target gas concentration which bears a known relation to the gas concentration in the flue [30].

Generally, the sample may be conditioned by dilution, filtering, cooling, or drying. The techniques chosen will depend on the gas being measured and on the instrument being used. At its simplest, conditioning may amount to the sample gas being diluted with several hundred times its volume of clean air. Normal ambient monitors could then be used, but separate measurements would have to be made of O_2 and H_2O in order to express the measured concentration in standard form.

To avoid clogging of the sample line, it is usual to filter the sample as soon as practically possible. To avoid condensation, the normal practice is to keep the line heated. If, however, the instrument cannot tolerate flue gas temperatures, cooling will be necessary at some stage. If this is done without dilution, water will condense out and subsequent measurements will be on a dry gas basis. In itself, this is advantageous but any acid gases will remain with the water and be lost. Alternatively, the sample may be dried by passing it through a permeation drier. Such driers cannot tolerate acid gases. SO_2 (for example) must therefore be measured on a wet gas basis, with temperature and condensation being controlled by appropriate dilution.

Considerable skill is involved in designing and implementing continuous extractive emissions monitoring systems. Instruments are available for hydrocarbons and for the conventional range of stack gases from Codel, Horiba, Land Combustion, Teledyne Monitor Labs, Servomex, Sick AG, Signal-Ambitech, and Thermo-Scientific, among others.

Defining Terms

Aerosol: Particulate matter so finely divided in a gas that it remains in suspension.

Burden: The integrated concentration of an analyte along a defined path.

Column: The burden along a vertical path between the surface and the edge of the atmosphere.

Concentration: The mass or volume of an analyte in a unit sample volume. The volume may need to be defined in terms of temperature, pressure, humidity, etc.

Deposition: The transfer of material from the atmosphere to a surface.

Monitoring: A routine series of measurements made for control purposes.

Protocol: A written list of instructions for obtaining a reliable measurement.

Water Quality Measurement

Kathleen M. Leonard
The University of Alabama in Huntsville

78.1 Introduction

Maintaining and verifying water quality is important in many environmental applications. The most obvious is in drinking water applications, but industrial and municipal wastewater, natural surface/groundwater, industrial process waters, and closed-loop control systems all require a certain range or maximum concentration of species to operate properly. Therefore, the development of instrumentation for monitoring and detecting these contaminants is a highly competitive area. Of course, the chemical species of interest depend on the ultimate use of the water, but this section deals with some of the water quality sensors and instrumentation being currently used.

Table 78.1 provides a list of the most commonly monitored chemical species in the area of water quality. The third column categorizes the parameters in the general categories of drinking water, wastewater (municipal), industrial, storm water, and ambient water quality. The "ultimate reference" source for accepted methods of determining chemical concentrations in water is known as the *Standard Method for the Examination of Water and Wastewater* [1]. This book has been updated regularly since 1905 and contains the current techniques recommended by Water Environment Federation (WEF) and the U.S. Environmental Protection Agency (EPA).

The next section introduces the theory behind some of the major types of water quality sensors, including electrical, optical, and chemical separation. Since each technique has its own particular water quality applications, a brief discussion of advantages and disadvantages is included. This section is limited to commercially available instruments commonly used both inside and outside the laboratory, although emphasis is placed on field (i.e., portable) instruments. Future trends will be addressed in the conclusion section.

TABLE 78.1 Common Chemical Species Monitored in Water Quality

Chemical Parameter	Chemical Symbol	Primary Use
Ammonium	NH_4	DW, WW
Arsenic	As	DW
Barium	Ba	DW
Bicarbonate	HCO_3^-	DW, WW
Cadmium	Cd	DW, WW
Calcium	Ca^{2+}	DW
Carbonate	CO_3^{2-}	DW
Chlorinated hydrocarbons	Various herbicides and pesticides	DW, SW
Chloride	Cl^-	DW, SW
Fluoride	F^-	DW
Chromium	Cr	DW
Dissolved oxygen	O_2	WQ
Hydrogen (pH)	H^+	DW, WW, WQ
Iron	Fe	DW
Lead	Pb	DW
Magnesium	Mg^{2+}	DW
Mercury	Hg	DW
Nitrate	NO_3^-	DW, WW, SW
Nitrogen	N	DW, WW
Petrochemicals	Various	
Phosphates	PO_4^{3-}	WW, SW, WQ
Potassium	K^+	WW
Selenium	Se	DW
Silver	Ag	DW
Sodium	Na^+	DW
Sulfate	SO_4^{2-}	DW, WW
Gross measures		
Alkalinity	As $CaCO_3$	DW
Biochemical oxygen demand	BOD	WW, WQ
Conductivity		
Chemical oxygen demand	COD	WW, WQ
Hardness	As $CaCO_3$	DW
Particle counts		WW, WQ
pH	H^+	DW, WW, WQ
Total organic carbon	TOC	SW, WW, WQ
Other parameters		
Color		
Dissolved solids	In ppm	SW, DW
Turbidity	In NTU	DW, WQ
Microbiological contaminants	Counts/100 mL	DW, WW, WQ
Radiological contaminants	In curies	DW

Note: DW, drinking water; WW, waste water; SW, storm water; WQ, water quality.

78.2 Theory

78.2.1 Electrical Methods of Analysis

There are various electric mechanisms employed for determining water quality concentrations. For example, in the area of electrochemical sensors, there are potentiometric, amperometric, and conductometric devices [2]. The pH sensor for determining hydrogen ion concentration is probably the most widely used instrument in this category.

78.2.1.1 Potentiometric Sensors

This type of sensor is based on the relationship of the electrochemical cell and the chemical activity of a sample, based on the general form of the Nernst equation:

$$E_{\text{cell}} = E^0 - \left(\frac{RT}{nF}\right)\ln\left\{\frac{(\text{red})}{(\text{ox})}\right\} \tag{78.1}$$

for the general reaction: ox + ne^- ↔ red. ox and red indicate the oxidized and reduced species [3]. The term RT/F has a value of 0.059. E^0 is the standard cell potential and E_{cell} is the adjusted cell potential. In short, the activities of the oxidized and reduced species determine the potential of the electrode. If the relationship of the reacting species is known, it is used to measure concentration of that species in another solution. In most electrochemical instruments, it is important to maintain a reference electrode whose potential remains constant for all cell conditions or one that can be easily calibrated for other species. These sensors are commonly known as ion-selective electrodes (ISE) in environmental applications (also known as ion-sensitive field-effect transistors or ISFET). They are all based on the activity level of a specific ion within a solution. The key to the ISE is the use of an ion-specific membrane with channel size proportional to the concentration of the ion. It is necessary to maintain a reference potential to ensure that the "ion concentration will be directly related to the substrate potential" [4]. Specific electrodes can be based on a gas electrode, metal electrode, oxidation–reduction electrode, membrane electrode, glass, liquid membrane, crystalline membrane, or electrode with metal contacting a slightly soluble salt [5]. Examples of this type of sensor and instrumentation for gross measurements include pH sensors, dissolved oxygen (DO), hardness, and dissolved solids.

Commercially available ISE include sensors for ammonia, chlorides, cyanide, iodide, fluoride, nitrates, potassium, and sodium. The instruments labeled as multiparameter water quality monitors, such as that available from Solomat, are usually composed of 1 m with separate probes for each measurement parameter. However, some of these multiparameter monitors have been upgraded with a multichannel probe that contains the separate probes within a single housing.

A membrane probe in popular usage is the DO probe based on the principle of polarography. It consists of a gas-permeable membrane over a silver anode and a platinum cathode within a cavity full of electrolyte (usually KCl). Figure 78.1 shows the placement of the anode and electrode in a typical polarographic membrane probe. Since the oxygen will be reduced at the cathode, a current is induced. The amount of oxygen can then be correlated to the current when a potential is applied to the anode and cathode.

The pH instrument is one of the most commonly used potentiometric sensors in water quality applications. It is based on a glass electrode that develops a potential related to hydrogen ion activity of the solution. Since this probe was initially developed in the early part of the 1900s, there are numerous probes and meters on the market. Small, battery-operated, handheld units are excellent choices for fieldwork. However, for more precise applications, advanced (i.e., expensive) laboratory-grade instruments are also available. Most pH probes require standardization and may have other upkeep requirements after prolonged usage.

78.2.1.2 Amperometric Sensors

The amperometric classification of electrical sensors is based on the measurement of current through a working electrode. An empirical relationship can be used to enhance the performance of these electrodes.

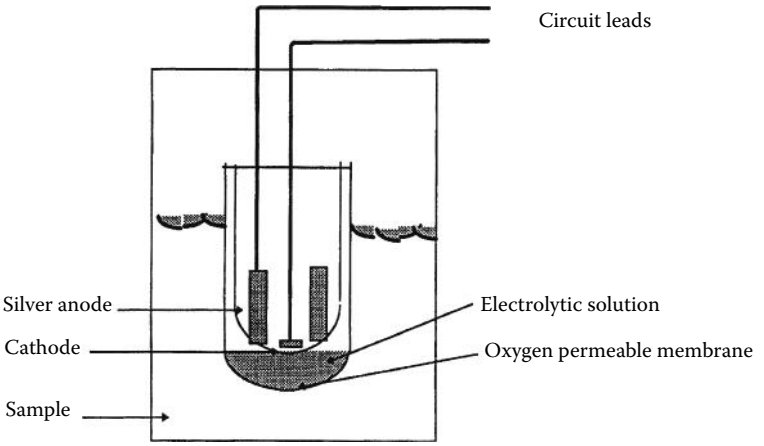

FIGURE 78.1 Simplified diagram of dissolved oxygen sensor based on polarography. The oxygen-permeable membrane surrounds the anode and cathode to deter other chemical species from entering the electrolytic solution.

An example of such a probe is an electrode for chlorine, consisting of a silver anode and platinum cathode within an electrolyte reservoir. A chemically specific membrane allows only the ions of interest within the probe cavity near the cathode. Reduction occurs at the cathode and then the silver anode reacts with the electrolyte and, through oxidation, positively charged ions produce a current.

78.2.1.3 Conductometric Sensors

The conductometric sensors are based on measurements of concentration of a sample due to modulation in conductivity. For example, conductivity is usually measured with a direct reading of electrical conductivity in water, which is then correlated with the number of ions present. The probe usually consists of two voltage electrodes (+ and –) and two current electrodes (also + and –) supported by some type of housing. The newer instruments have a temperature compensation option and data storage. Most will also provide a reading of total dissolved solids. Conductometric sensors are also available for resistivity, salinity, and temperature measurements.

The most commonly available DO sensors are galvanic electrodes with replaceable membranes. The current is proportional to the DO concentration under steady-state conditions [1]. One of the drawbacks of this type of probe has been the need for periodic calibration, either in air or in a saturated medium. Some of the newer products are self-calibrating, thus eliminating this error source. There are many companies that sell these products and the prices range from modest ($300) to high, depending on extras. If the application will be messy (e.g., wastewater), the added expense for the deluxe model, such as a self-cleaning probe, may be realized very quickly. A company that has been producing DO instruments for many years is YSI. It has a "deluxe" model with microprocessor control and RS232 interface for continuous reading.

78.2.2 Optical Sensors

This category involves any type of measurement system that relies on an optical property to measure a chemical concentration, including reflection, colorimetry, fluorescence, or absorption of light. The general equation relating wavelength of light (λ) to the energy of a photon (E) is given by the Planck's equation:

$$E = \frac{hc}{\lambda} \tag{78.2}$$

where

h is Planck's constant (6.626×10^{-34} J s)

c is the velocity of light (3.0×10^{8} m/s)

Some of these mechanisms are included in the category of "gross optical measurements." This category includes any method that uses reflection/refraction of light beams, colorimetry, or absorption of light. For example, in order to determine the efficiency of a water treatment system due to deteriorating filter capacity or to optimize coagulant dosages, a particle counting method is used. This type of measurement can give not only quantity, but also size ranges. This method is helpful in guarding against the intrusion of cryptosporidium cysts and guardia in a drinking water facility.

78.2.2.1 Nephelometry

In this method, light is directed to the sample and the light reflected at right angles to the beam is measured (Tyndall effect). This type of analysis is the accepted method for quantifying turbidity (cloudiness) since the intensity of light scattered by a water sample can be compared to the scattering of a standard (usually Formazin polymer) under similar conditions. The units measured are known as nephelometric turbidity units (NTUs), which are approximately comparable to the older "candle" units. A turbidimeter consists of a light source and a photoelectric sensor that measures the light scattered at 90° from the source.

78.2.2.2 Absorbance Methods

Certain chemical species exhibit natural light absorbance patterns over a range of wavelengths. These include nitrates/nitrites, heavy metals, unsaturated organics, and aromatics. This approach is valid even in multicontaminant solutions, since no two substances have exactly the same absorbance pattern. Several commercially available instruments take this technology to water quality applications with online capabilities. For example, in the water/wastewater area, there are flow-through monitors that measure a broad range of wavelengths of ultraviolet light simultaneously. This pattern is checked against a "signature" for the contaminant of interest and both the presence and concentration are verified.

Some contaminants do not have a natural absorbance, so a "conditioning" step is required in order to use this method. This usually involves the addition of a secondary chemical, or indicator, that will absorb in the presence of the contaminant. This is commonly known as induced light absorbance. Ammonia, phosphates, and chlorine absorbance probes are available with this conditioning step.

There are several advantages to using absorbance, including low maintenance, especially when compared to ISEs, high reliability, and automatic compensation for turbidity (which can cause havoc in other systems). One of the major drawbacks of the available models is the need to buy a separate unit for each contaminant, at a comparatively higher cost than ISE.

78.2.2.3 Colorimetry

This simple method works by correlating the color of a solution with the concentration of a specific chemical. The theory is that light absorption (A), which is the amount of light intensity (I/I_0) absorbed, is related to concentration based on Beer's law [5]:

$$A = \log\left(\frac{I}{I_0}\right) = k^n C \tag{78.3}$$

where

k^n is the constant for a particular solution
C is the concentration of the solution

Beer's law is valid for most water quality ranges of concentration, but it can be verified using dilutions of a specific contaminant. The first and still simplest colorimetric methods involve the use of color comparator tubes (or Nessler tubes) for comparing a range of standards to water samples. However, this method is susceptible to large discrepancies due to human error in selecting variations of tints of a color. An instrument that improves upon the accuracy of colorimetry is a

photoelectric colorimeter. A light source is directed through a filter (making it monochromatic), then passed through the sample cell and on to the photoelectric detector. The obvious advantage over the comparator is the elimination of the human factor for identifying variations in color. Another adaptation is the spectrophotometer, which employs a diffraction grating to select the wavelength for a wide variety of uses. It is a very versatile instrument since both the incoming and outgoing wavelengths are selectable. Newer models incorporate computer chips for automatic programming and data storage.

Colorimetric tests include single analyte meters for chlorine and DO, and direct readout multianalyte photometers for many parameters. For example, the DPD colorimetric method is commonly used to measure total chlorine concentrations in water and wastewater. However, it must be used with caution, since turbidity, other organic contaminants, monochloromine, etc. will cause interference.

78.2.2.4 Fluorimetry

This method utilizes the fluorescence, either natural or induced, of a compound. Fluorescent chemicals absorb radiation of a specific wavelength and emit at another. Fluorescent tracers are commonly used in water quality studies to determine direction of flow for both surface and groundwater systems. Fluorescent tracers include Rhodamine B, Fluorescein, and Pontacyl Pink B. The detection instrument is known as a fluorimeter, which range from moderate cost for a stationery (single chemical) wavelength model (<$4000) to high cost for a unit with variable wavelength and detection capabilities.

78.2.2.5 Remote Fiber-Optic Spectroscopy

In the area of in situ chemical analysis, remote fiber spectroscopy (RFS) shows much promise for a variety of monitoring applications. RFS is a fiber-optic application of existing spectroscopic techniques that can be applied to the monitoring of chemical species in remote locations. In this method, light of an appropriate frequency is launched into a single optical fiber or fiber bundle. The light is guided to the region of interest through the fiber by the mechanism of total internal reflection. An optical sensor (optrode) designed for a specific chemical or chemical group is positioned at either the distal end of the fiber or a length along the fiber. The altered signal is returned through the same fiber to the spectrometer for signal decoupling and analysis. The major advantages to fiber-optic chemical sensors (FOCS) include their small diameter, in situ nature, resistance to harsh environments, and imperviousness to electric interference. These properties make FOCS ideal for many environmental applications.

The distinguishing feature of most RFS systems is the type of sensor employed. There are basically two approaches to the sensor, either intrinsic or extrinsic. The intrinsic method utilizes the fiber itself as the active element, for example, using change in index of refractions from the fiber to the media as the parameter being measured. The extrinsic method uses the fiber optic only as light pipe, and usually involves incorporating a chemical onto the fiber as the active element. Most of the related literature for FOCS deals with design and advantages of various types of optrodes that exploit either absorbance, surface enhanced Raman scattering, or fluorescence. Although FOCS have been mentioned in literature for the past decade, there has been little success in developing a multicontaminant sensor for practical applications.

The direct fluorescence approach (measuring the natural fluorescence of the media) is an attractive technique for applications where aromatic chemicals are to be monitored. However, since many chemicals that act as contaminants are nonfluorophores, a fluorescent intermediate can be incorporated in the FOCS. Ideally, the intermediate should be sensitive to either a group of chemicals or a specific compound, and exhibit a spectral response that could be exploited to identify the compound.

As mentioned previously, the standard pH instrumentation is based on a glass pH electrode; however, optical methods have obvious advantages in corrosive conditions and fluctuating temperatures [6]. Optical-based pH sensors are generally based on the changes in the absorbance or fluorescence of an

indicator dye that has been immobilized on a fiber optic. Recently, pH sensors based on the immobilization of fluorescein dye in a sol–gel matrix have been developed. Sol–gel chemistry is a method of producing a porous glass matrix at a low temperature using a hydrolysis of an alkoxide (usually TEO). An example of such a probe is a pH probe based on fluorescein dye in a sol–gel matrix [7].

Optical sensors for O_2 and DO, which are based on fluorescence or phosphorescence quenching, have the advantage of size, nonconsumption of oxygen, and resistance to interference due to flow rates or sample stirring over traditional DO electrodes. The major limitations are finding an indicator dye with a strong sensitivity to oxygen quenching. There are many such studies being performed; however, most are still in the research stage. For example, polycyclic aromatic hydrocarbons such as pyrene and long-wave absorbing dyes have been investigated due to their ability to be quenched by oxygen [6]. A fiber optics–based sensor that is on the market detects VOCs, such as carbon tetrachloride, TCE, and BTX in water systems (FiberChem). A similar application is a fluorescence-based system for measuring petroleum products in the groundwater.

78.2.3 Other Sensors

78.2.3.1 Infrared Spectrophotometry

Most organic chemical compounds exhibit absorption in the infrared. This attribute can be used to determine atomic groupings based on quantum mechanics [5]. An example is a unit that measures total organic content (TOC) using UV-promoted persulfate oxidation and nondispersive infrared detection. This methodology allows for online TOC monitoring. Correlations can be made to convert values of TOC to biochemical oxygen demand (BOD) and chemical oxygen demand (COD) for particular samples. Drawbacks to this method include pretreatment to remove inorganic carbon and the high cost of instrumentation.

78.2.3.2 Respirometry

The standard method to calculate BOD_5 is to measure oxygen consumption (based on DO concentration) over a 5 day period. However, there are other respirometers based on extremely small differences in DO or CO_2 concentrations using external gas sensors. This method is great for respirometry rates of animals, biodegradable contaminants, and sediment oxygen demand studies.

78.2.4 Chemical Separation Techniques

Separation techniques are based on the phase partitioning of molecules within a mixture. Gas chromatography refers to a mobile phase of a vapor, while liquid chromatography refers, of course, to a liquid mobile phase. There are several commonly used types such as gas–liquid chromatography, high-performance liquid chromatography (HPLC), and ion chromatographs. An excellent reference book for these methods is *Chemistry for Environmental Engineering* [5]. The advantages of these instruments are the ability to detect components in complex mixtures and high sensitivity. Chromatography instruments have long been considered standard in environmental laboratories, but the size of the instruments has been a drawback for field applications. However, size constraints are being challenged with the availability of equipment with size reductions of over 90%.

78.2.4.1 Mass Spectrometry

In environmental applications, these are normally used in conjunction with gas chromatography and are referred to as GC/MS. The attraction of these instruments is the ability to detect a variety of compounds and also determine the mass fragmentation patterns of a complex organic structure [1]. The MS essentially ionizes the substances with an electron beam. The ions are then accelerated through a series of lenses according to their mass-to-charge ratios. The charged fragments are detected by a electron

multiplier, which results in a mass spectra for the particular compound. In addition to the old-fashioned laboratory-scale GC/MS, there are portable units now commercially available that can be taken into the field for on-site environmental characterizations. These are very useful for ambient air toxics analysis, process diagnostics, and "real-time" groundwater plume movement. However, a newer technique of capillary electrophoresis (CE) has been gaining in popularity over capillary GC since it requires less solvent and can be extremely sensitive.

78.2.4.2 Atomic Absorption Spectrometry

Since metals have their own characteristic absorption wavelengths, they are usually measured by the atomic absorption method where a light beam is directed into a sample being aspirated onto a flame. The resulting light is then sent to a monochromator with a detector that measures the amount of light absorbed by the flame. This method exhibits high sensitivity and is applicable to all of the commonly found metals in water. The drawback of this type of instrument is that it is not portable and is more of a laboratory method.

78.3 Instrumentation and Applications

Table 78.2 lists some of the instruments that are commercially available for specific water applications. This is not an exhaustive list of all types and manufacturers, but is indicative of the chemical parameters and types of instruments that are useful for field use. For example, the chemical separations category is very sparse in the table; although there are numerous laboratory instruments, very few are useful in the field.

Many of the manufacturers provide helpful technical information on theory and applications for their products. For example, Hach Company has many excellent publications for a variety of water/wastewater applications. They sell and develop instruments that vary from inexpensive kits (e.g., for colorimetry) to spectrophotometers with computer compatibility. Additionally, due to the broad range of diversity in the water quality area, there are many small companies that produce instruments for specific applications. Table 78.3 provides contact information for each of the companies listed in Table 78.2. Another excellent source of information is the annual listing of industrial manufacturers by WEF.

78.3.1 Data Evaluation

In the past, the better instruments may have had a self-storing data system, usually in the form of paper graph or a retrievable magnetic tape. Although this allowed for continuous sampling, it was not without problems. The ease of obtaining data, in situ data gathering, and digital data acquisition are all attributes that are attractive in environmental applications. New technology has made these wishes a reality. For example, radio telemetry is a wireless technology to link remote sensors to dedicated computers or Supervisory Control and Data Acquisition (SCADA) systems. This capability allows for truly automated data acquisition and real-time uplinks. Other systems can be hardwired to computers (usually via RS 232 boards) or through modems to a remote acquisition site.

78.4 Trends in Water Quality Measurements

Analytical Chemistry publishes a biennial review dealing with recent literature in the area of water analysis [8]. These review articles, while not in-depth on a single topic, are quite extensive in topic matter and really illuminate trends in environmental sensing. For example, in a recent review, the area of in situ analysis contains a significant amount of coverage. Since many water quality applications would benefit from in situ, real-time data, it will be an area of research and development growth for the next 5 years.

TABLE 78.2 Instruments for Remote Water Quality Analysis

Product Name	Water Quality Parameters	Company
Biological analyzers: Portable		
Potatlite	Extreme Portable kit WE 1000	RB Instruments
Ion-selective electrodes: single parameter and combination types		
AdvantEDGE	Dissolved Oxygen Electrode Sensor	HF Scientific, Inc.
HQ30d	Portable Dissolved Oxygen Meter Package	Hach
D63/5440D	pH/ISE Meter	Thermo Scientific Orion
SCAMP	DO, temperature	Precision Measurement Engineering
9110/9120	Dissolved oxygen	Royce Instrument Corporation
Professional Plus with ISE probes D	Ammonia, conductivity	YSI
Nephelometers: Turbidity		
1110-TUX	Temperature, pH, Conductivity, Dissolved oxygen, Turbidity, Selective ions, Redox and water flow	Solomat
Model 2100Q	Turbidity	Hach Inc.
Conductivity sensors		
DataSonde 4A	Multiprobe Conductivity, TDS, salinity, resistivity	Rickly Hydrological Co
2100Q	Turbidity	Hach Inc.
Smart Sensor	Conductivity, pressure	Greenspan Technology Pty Ltd.
YSI 5000 series	DO	YSI Inc.
Optical		
AdvantEDGE sensor	DO	HF Scientific, Inc.
AccUView	UV transmission	HF Scientific, Inc.
711	Turbidity and suspended solids	Royce Instrument Corporation
PC3400	Online particle counter	Chemtrac, Inc.
pH probes: with data storage and computer compatibility		
Orion VERSA STAR Meter multiparameter	Thermo scientific	
Respirometry		
OXITOP IS RESPIROMETER SYSTEMS	Global Water	
Micro-Oxymax	Oxygen, CO_2, NH_3, CO	Columbus Instruments International Corp.
Spectrometer: in-line types only		
DR 5000™	UV-Vis	ALToptronic
	Spectrophotometer	Hach Inc.
FPA 1000 Series	Chlorine, oils in water, H_2S	Tytronics
Tytronics Sentinel	NH_3, Fl, Cy, NO_3, Na	Galvanic Applied Sciences, Inc.
UV absorbance instruments		
ChemScan	Nitrate, ammonia, iron, turbidity	Applied Spectrometry
Multiparameter systems		
AQUALAB	Phosphate, ammonia, nitrate, pH, conductivity	Greenspan Technology
Chemscan 6101	Over 30 parameters	ASA Analytics
HI 9828	Multiparameter Meter	Hanna Instruments
DataSonde	4 Temperature, conductance, TDS, resistivity	Hydrolab
YSI 4 series	Over 10 parameters	YSI Inc.

Defining Terms

A light absorption
c velocity of light (3.0×10^8 m/s)
C concentration of the solution
E energy of a photon
E_{cell} cell potential adjusted

E^0 standard cell potential
F Faraday's constant (96,500°C/equivalent)
I light intensity
I_0 initial light intensity
k'' constant for a particular solution
h Planck's constant (6.626×10^{-34} J s)
n number of moles
ox oxidized species
R ideal gas law constant (8.31 J/mol/K)
red reduced species
T absolute temperature
λ wavelength of light

Satellite Imaging and Sensing

Robert F. Cromp
National Aeronautics and Space Administration

79.1 What Can Be Seen from Satellite Imagery?

Satellite imaging and sensing is the process by which the electromagnetic energy reflected or emitted from the Earth (or any other planetary) surface is captured by a sensor located on a spaceborne platform. The Sun as well as all terrestrial objects can be sources of energy. Visible light, radio waves, heat, ultraviolet, and x-rays are all examples of electromagnetic energy. Since electromagnetic energy travels in a sinusoidal fashion, it follows the principles of wave theory, and electromagnetic waves are categorized by their wavelength within the electromagnetic spectrum. Although it is continuous, different portions of the electromagnetic spectrum are usually identified and referred to as (from shorter to longer wavelengths) cosmic rays, γ rays, x-rays, ultraviolet, visible (0.4 μm, 0.7 μm), near-infrared (near-IR), mid-infrared (mid-IR), thermal infrared (thermal-IR, above 3 μm), microwave (1 mm, 1 m), and television/radio wavelengths (above 1 m). Figure 79.1 shows the electromagnetic spectrum and these subdivisions.

79.2 General Sensor Principles

Sensors are often categorized as "passive" or "active." All energy observed by "passive" satellite sensors originates either from the Sun or from planetary surface features, while "active" sensors, such as radar systems, utilize their own source of energy to capture or image specific targets.

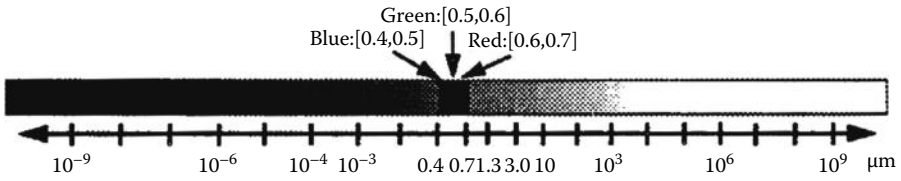

FIGURE 79.1 Electromagnetic spectrum.

79.2.1 Passive and Active Sensors

All objects give off radiation at all wavelengths, but the emitted energy varies with the wavelength and with the temperature of the object. A "blackbody" is an ideal object that absorbs and reemits all incident energy, without reflecting any. If one assumes that the Sun and the Earth behave like blackbodies, then according to the Stefan–Boltzmann law, their total radiant exitance is proportional to the fourth power of their temperature. The maximum of this exitance, called dominant wavelength, can be computed by Wien's displacement law (see Refs. [1–4] for more details on these two laws). These dominant wavelengths are 9.7 μm for the Earth (in the IR portion of the spectrum) and 0.5 μm for the Sun (in the green visible portion of the spectrum). It implies that the energy emitted by the Earth is best observed by sensors that operate in the thermal-IR and microwave portions of the electromagnetic spectrum, while Sun energy that has been reflected by the Earth predominates in the visible, near-IR, and mid-IR portions of the spectrum. Most passive satellite sensing systems operate in the visible, IR, or microwave portions of the spectrum. Since electromagnetic energy follows the rules of particle theory, it can be shown that the longer the wavelength, the lower the energy content of the radiation. Thus, if a given sensing system is trying to capture long wavelength energy (such as microwave), it must view large areas of the Earth to obtain detectable signals. This obviously is easier to achieve at very high altitudes, thus the utility of spaceborne remote sensing systems.

The most common active satellite sensor is radar (acronym for "radio detection and ranging"), which operates in the microwave portion of the electromagnetic spectrum. The radar system transmits pulses of microwave energy in given directions, and then records the reflected signal received by its antenna. Radar systems were initially employed by the military as a reconnaissance system because their main advantage was to operate day or night and in almost any weather condition. They are very important in satellite remote sensing because microwave radiations are hardly affected by atmospheric "screens" such as light rain, clouds, and smoke. The time it takes for the radar signal to return to the satellite is also measured by instruments such as altimeters which are very useful in determining surface height measurements.

79.2.2 Polar Orbiting and Geostationary Earth Sensing Satellites

Satellite remote sensing systems are also characterized by the different Earth orbiting trajectories of a given spacecraft. These two modes are usually referred as "polar orbiting" and "geostationary" (or "geosynchronous") satellites. A polar orbit passes near the Earth's North and South poles. Landsat, SPOT, and NOAA are near-polar satellites; their orbits are almost polar, passing above the two poles and crossing the equator at a small angle from normal (e.g., 8.2° for Landsat-4 and -5). If the orbital period of a polar orbiting satellite keeps pace with the Sun's westward progression compared to the Earth rotation, these satellites are also called "sun synchronous." This implies that a sun-synchronous satellite always crosses the equator at the same local sun time. This time is usually very carefully chosen, depending on the application of the sensing system and the type of features that will be observed with such a system. It is often a trade-off between several Earth science disciplines such as atmospheric and land science. Atmospheric scientists prefer observations later in the morning to allow for cloud formation, whereas the researchers performing land studies prefer earlier morning observations to minimize cloud cover.

A geostationary satellite has the same angular velocity as the Earth so its relative position is fixed with respect to the Earth. Examples of geostationary satellites are the "Geostationary Operational Environmental Satellite" (GOES) series of satellites that orbit at a constant relative position above the equator.

79.2.3 Sensor Characteristics

79.2.3.1 Spectral Response Patterns

The design of new satellite instruments is based on the principle that targets of interest can be identified based on their spectral characteristics. For example, different Earth surface features, such as vegetation or water, present very distinctive reflectance or emittance curves that are a function of the energy wavelength. These curves are often called the "spectral signatures" of the objects being observed. Although these curves are very representative of each feature and can help identify them, they do not correspond to unique and absolute responses. Because of different reasons, such as atmospheric interactions, temporal or location variations, the response curves of a given object observed under different conditions might vary. For this reason, these curves are often called "spectral response patterns" instead of "spectral signatures." Figure 79.2 shows an example of such reflectance patterns for several features: fir tree, clear lake water, barley, and granite.

79.2.3.2 Atmospheric Interactions

Earth satellite sensors are designed to take into consideration the fact that all observed radiation must pass at least once through the atmosphere; therefore, the energy interactions of the atmosphere must be considered during the design phase. The distance through which the radiation passes through the atmosphere is called "path length." The effect of the atmosphere depends on the extent of the path length and on the magnitude of the energy signal. The two main atmospheric effects are known as "scattering" and "absorption."

Scattering is the unpredictable redirection of radiation by particles suspended in the atmosphere. The type and the amount of scattering mainly depend on the size of the particles but also on the wavelength of the radiation and the atmospheric path length. If these particles are smaller than the radiation wavelength, this effect is known as "Rayleigh scatter." This scattering especially affects the shorter visible

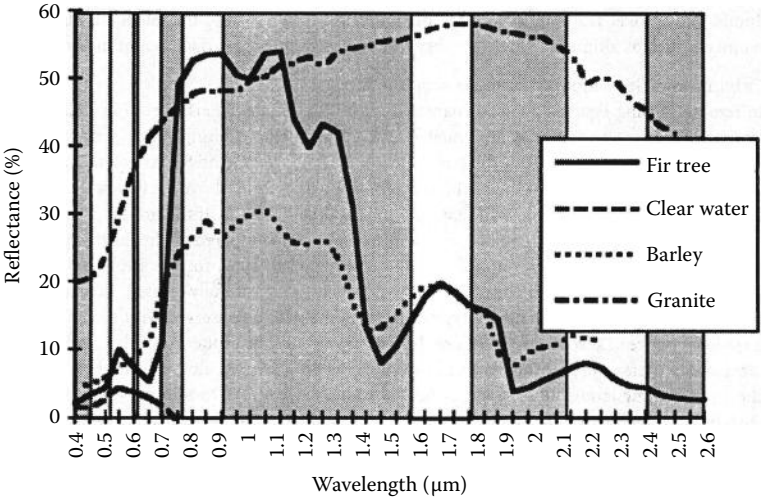

FIGURE 79.2 Examples of spectral response patterns for four different types of features: fir tree, clear water, barley (example of crop), and granite (example of rock). White areas show the portions of the spectrum corresponding to the 7 channels of Landsat-Thematic Mapper (TM-4&5).

wavelengths of the sunlight (i.e., blue visible wavelength) and it explains why the sky appears blue to the human eye. In the evening, when the path length is longer, the effect of the Rayleigh scatter is only visible on the longer red wavelengths of the sunlight and the sky appears red or orange. If the particles are about the size of the radiation wavelength, the scatter is known as "Mie scatter"; this scattering effect is often due to water vapor and dust. When the atmospheric particles are larger than the radiation wavelengths, a "nonselective scatter" occurs; all visible wavelengths radiations are scattered equally and this type of scattering explains why clouds appear white.

Atmospheric absorption occurs in specific wavelengths at which gases such as water vapor, carbon dioxide, and ozone absorb the energy of solar radiations instead of transmitting it. "Atmospheric windows" are defined as the intervals of the electromagnetic spectrum outside these wavelengths, and Earth remote sensors usually concentrate their observations within the atmospheric windows. As an example, white areas of Figure 79.2 show the portions of the spectrum (i.e., the "channels" or "bands") from visible to mid-IR used by the Landsat-Thematic Mapper (TM).

79.2.3.3 Spectral, Radiometric, Spatial, and Temporal Resolutions

Although the spectral response patterns are not absolute, they play an important role in the design of new sensors. When a new sensor is being designed, the type of features to observe and the accuracy with which they will be mapped define which wavelengths are of interest, the widths of the wavelength intervals to be used, what is the accuracy to be achieved in these bandwidths, and what is the "smallest" or "faintest" feature that might be detected by the sensor. Following the examples of Figure 79.2, the best wavelength interval to distinguish between vegetation and granite will be the (1.55 μm, 1.75 μm) wavelength interval. The earlier sensor requirements correspond to the "resolutions" of the sensor by which it is usually identified—spectral, radiometric, spatial, and temporal resolutions. The term "resolution" is usually employed to define the smallest unit of measurement or granularity that can be recorded in the observed data. The spectral resolution of a sensor is defined by the bandwidths utilized in the electromagnetic spectrum. The radiometric resolution defines the number of "bits" that are used to record a given energy corresponding to a given wavelength. The spatial resolution corresponds to the area covered on the Earth's surface to compute one measurement (or one picture element, "pixel") of the sensor. The temporal resolution (or frequency of observation), defined by the orbit of the satellite and the scanning of the sensor, describes how often a given Earth location is covered by the sensor.

79.2.3.4 Signal-to-Noise Ratio

Sensors are also characterized by their signal-to-noise ratio (SNR) (i.e., the noise level relative to the strength of the signal). In this case, the "noise" usually refers to variations of intensity that are detected by the sensor and that are not caused by actual variations in feature brightness. If the noise level is very high compared to the signal level, the data will not provide an accurate representation of the observed features. At a given wavelength λ, SNR is a function of the detector quality, the spatial resolution of the sensor, as well as its spectral resolution (see Ref. [1] for a detailed formula). To maintain or improve the SNR and therefore improve the radiometric resolution of the sensor, a trade-off must be made between spatial and spectral resolutions; in particular, improving spatial resolution will decrease the spectral resolution. Of course, other factors such as atmospheric interactions will also affect the SNR.

79.2.3.5 Multispectral and Hyperspectral Sensors

The remote sensing industry is experiencing a rapid increase in the number of spectral bands of each sensor. The first Landsat sensors (Landsat-1 and -2) were designed with four bands in the visible and near-IR portions of the spectrum. Landsat-4 and -5 were refined with seven bands from visible to thermal-IR. Then, Landsat-6 and -7 were planned with an additional panchromatic band, which is highly sensitive over the visible part of the spectrum. In general, most Earth remote sensors are *multispectral*; that is, they utilize several bands to capture the energy emitted or reflected from Earth features. The addition of panchromatic imagery, which usually has a much better spatial resolution than multispectral

imagery in the visible part of the spectrum, provides higher quality detail information. Multispectral and panchromatic data, usually acquired simultaneously, are coregistered and can be easily merged to obtain high spatial and spectral resolution. Coregistered multispectral–panchromatic imagery is available from sensors such as the Indian satellite sensor, IRS-1, and the French sensor, SPOT.

Ideally, if a sensor had an infinite number of spectral channels (or bands), each observed area on the ground (or pixel) could be represented by a continuous spectrum and then identified from a database of known spectral response patterns. Adding more bands and making each of them narrower is the first step toward this ideal sensor. But, as previously explained in the previous section, due to technology limitations, it was very difficult until recently to increase the number of bands without decreasing the SNR. Due to recent advances in solid-state detector technology, it is now possible to increase significantly the number of bands without decreasing the SNR, thus seeing the rise of new types of sensors, called *hyperspectral*. Although the boundary between multispectral and hyperspectral sensors is sometimes defined as low as 10 bands, hyperspectral imaging usually refers to the simultaneous detection in hundreds to thousands of spectral channels. The aim of hyperspectral sensors is to provide unique identification (or "spectral fingerprints") capabilities for resolvable spectral objects. Potential applications include agricultural yield monitoring, urban planning, land use mapping, mining and mineral deposits, disaster relief/assessment, tactical military operations, and forest fire protection management. The NASA Airborne Visible InfraRed Imaging Spectrometer (AVIRIS) simultaneously collects spectral information from visible to IR ranges (from 0.4 to 2.5 μm) in 224 contiguous spectral bands. Each band has an approximate bandwidth of 10 nm (or 0.01 μm), with a spatial resolution of about 20 m. The instrument flies aboard a NASA ER-2 airplane at ~20 km above sea level. The science objectives of the AVIRIS project are mainly directed toward understanding processes related to the global environment and climate change.

79.2.3.6 Super Resolution

When data are collected from a satellite sensor, each sample of information represents an area on the ground that might correspond to several features with different spectral responses and the final information represents a "mixture" of several disparate information. When a sensor does periodic imaging over the same area, the direction of observation slightly changes, and even when successive data are correctly registered (i.e., in a perfect correspondence), two respective samples might represent two slightly different areas on the ground. Super resolution is an area of research that aims at combining such information from different directions but taken under similar lighting conditions in the goal of improving spatial and spectral resolutions. As an example, some recent work [5] utilizes a Bayesian method for generating subpixel resolution composites from multiple images with different alignments. Software products have also been proposed by some commercial systems, such as ERDAS-Imagine and ENVI, to help in the unmixing of spectral bands (see Ref. [6] for more detail).

79.2.4 Direct Readout Data

Examples of different spectral and spatial resolutions are given in Figure 79.3 with a summary of current Earth remote sensing systems that operate from visible to thermal-IR wavelengths. Figure 79.3 provides information about their bandwidths and their spatial resolutions. The table also indicates if the data from these sensors can be acquired by direct readout. Sensors can transmit data in two modes. The first mode, called "direct readout," transmits data as soon as it "sees" them, and any receiving station within that satellite footprint can receive these data. In the second mode, the sensor records whatever it sees for playback at a later time, and specialized receiving stations (or "ground stations") are required to receive these data since they are transmitted at higher rates than direct readout. The data received by these ground stations can cover a larger extent. Historically, the cost of acquiring and processing Earth remotely sensed data has limited satellite data collection to a small number of expensive ground stations around the world, operated by the owners of the satellites. Direct readout

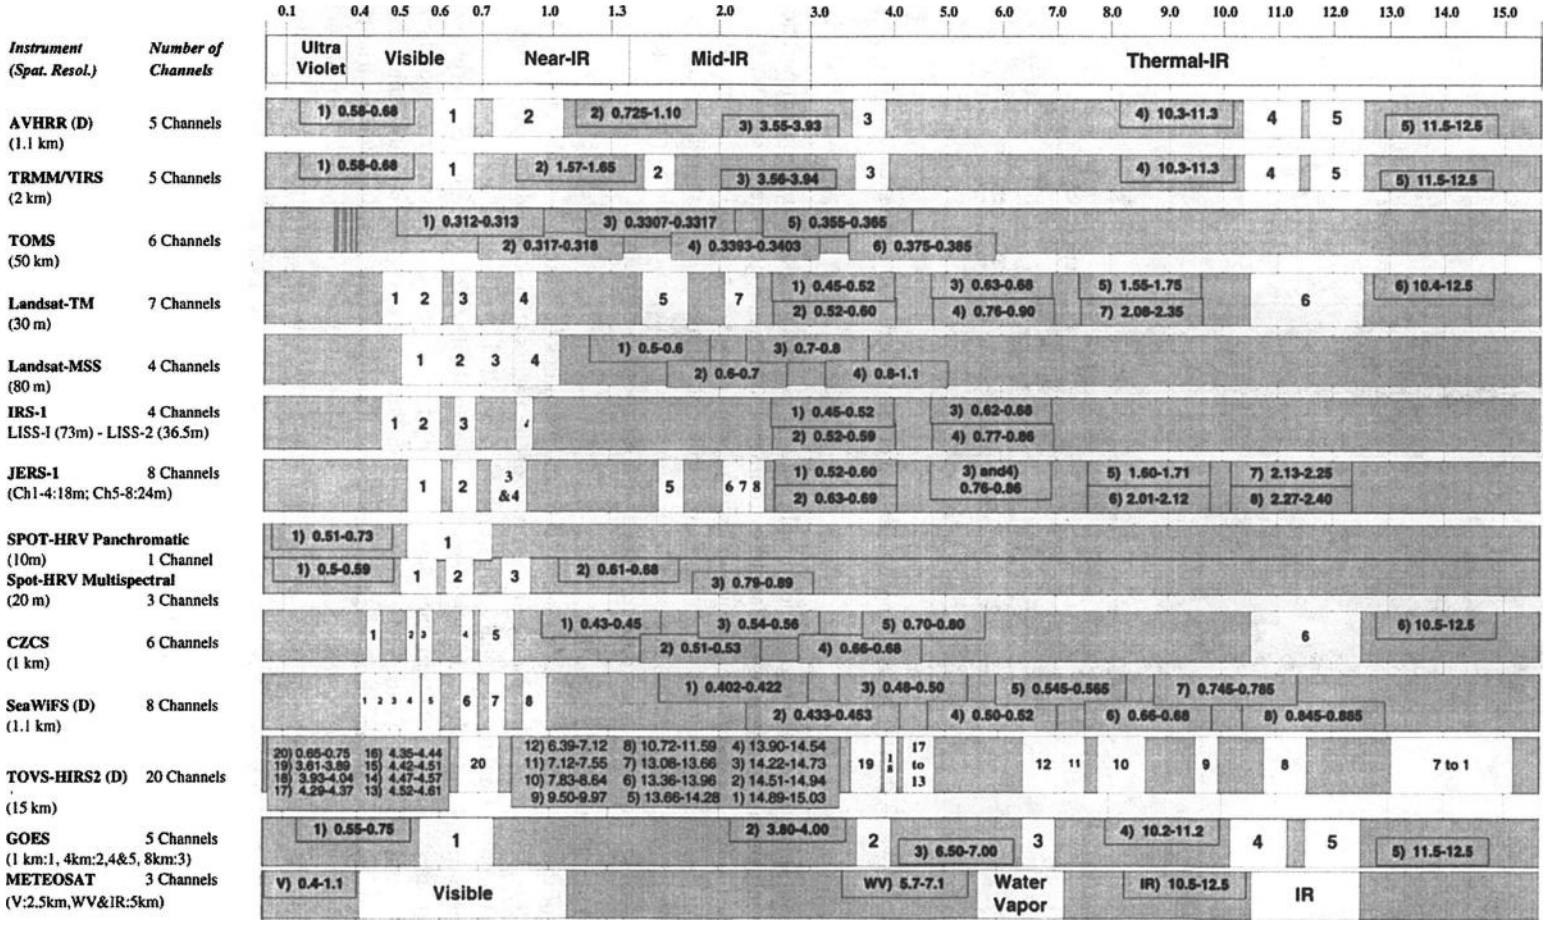

FIGURE 79.3 Summary of the main current earth science satellite data operating from UV to thermal-IR "D": Direct Broadcast.

sensors were mostly confined to meteorological applications that required timely data such as weather forecasting, severe weather identification and tracking, and disaster prediction and assessment. But this situation is changing; due to new technology, costs have been greatly reduced and direct readout data that were initially expensive and beyond the reach of the nontraditional user are now generating a growing interest. A small industry has evolved to design, install, and upgrade ground stations around the world that acquire direct readout data.

79.2.5 Typical Attributes Measured from Space

This section does not intend to be an exhaustive up-to-date description of all Earth and space applications of satellite imaging and sensing, but rather it presents a few representative applications and their associated satellite sensors. The References section as well as the World Wide Web (WWW) offer more extensive references to other applications and sensors.

79.2.5.1 Earth Science Applications

Over the past few decades, a number of international global change research programs have been initiated whose goals are to understand the relation between human activities and the global Earth systems processes and trends. Mission To Planet Earth (MTPE [7]) is a multiagency program, whose goal is to achieve this kind of understanding, especially through improved satellite observations. As part of NASA's Mission to Planet Earth program, the Earth Observing System (EOS [8]) will launch, over the next 2 decades, several platforms of sensors aimed at ecology, oceanography, geology, snow, ice, hydrology, cloud, and atmospheric studies. Each platform will carry one or several instruments, thus globally covering a wide range of spectral, spatial, and temporal resolutions. Europe and Japan have similar programs, such as the ADvanced Earth Observation Satellite (ADEOS [9]), developed by the Japanese space agency, NASDA, in collaboration with France and the United States. ADEOS, launched in 1996, flew for 9 months before it failed, and included remote sensing instruments for observing the Earth's atmosphere, land surfaces, and oceans. Other examples of such programs are the ERS and ENVISAT satellites from European Space Agency (ESA) and the Indian satellites, IRS. ERS-1 and -2 were launched in 1991 and 1995, respectively, and ENVISAT was launched in 1999. All these satellites carry on the same platform with different instruments making simultaneous observations. The first satellite in the IRS series was launched in 1988, and in 9 years, India has designed and launched six remote sensing satellites. For more information on the IRS series, see Ref. [10].

In all the earlier programs, studies concentrate on global processes occurring in the atmosphere (especially lower parts of the atmosphere), on the Earth surface (terrestrial studies), and in the oceans (hydrospheric studies). Results of all these studies will contribute to international programs such as the World Climate Research Programme, the International Geosphere–Biosphere Programme, and the International Human Dimensions of Global Environmental Change Programme.

Several of these instruments show application promise for regional and local community interests, in helping farmers to monitor and control their agricultural productivity (weather, disease control), in early warning and in rescue efforts in case of severe storms (e.g., hurricanes), and in predicting the spread of diseases based on vegetation data combined with socioeconomic data.

79.2.5.2 Examples of Atmospheric Studies

One of the key issues in climate research is to understand global atmospheric changes and how human activity affects the composition and chemistry of the Earth's atmosphere. To create accurate models, a large number of multiyear global studies must be conducted.

The atmosphere is divided into several layers. From the Earth's surface up to interplanetary space, which starts at about 1000 km, these layers are called troposphere, stratosphere, mesosphere, thermosphere, and exosphere. Figure 79.4 shows a simplified diagram of the different atmospheric layers. Each of these layers is characterized by differences in chemical composition that produce variations in temperature. The two

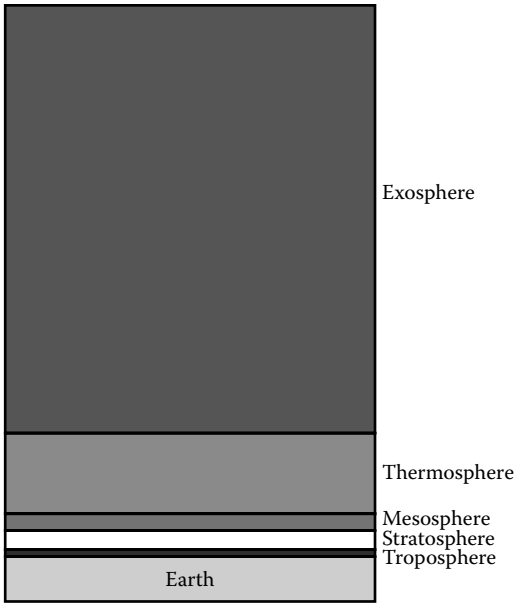

FIGURE 79.4 Simplified diagram of the different layers of the atmosphere.

lower layers, troposphere (up to 10 km) and stratosphere (10–50 km above the Earth), are particularly important since 99% of the water vapor in the atmosphere is included in the troposphere, and 90% of the ozone of the atmosphere is included in the stratosphere. All weather phenomena occur within the troposphere, with some turbulence sometimes extending to the lower stratosphere. The concentration of ozone, which should stay mainly concentrated in the stratosphere, is being studied in both the troposphere and stratosphere.

Ozone is a relatively unstable molecule made up of three oxygen atoms. Depending on the altitude where it is found, ozone is referred to as "good" or "bad" ozone. The largest concentration of ozone is located in the stratosphere, at an altitude between 20 and 30 km, and plays a major role in the evolution and the protection of life on Earth. Since it absorbs most of the harmful ultraviolet radiation from the Sun, stratospheric ozone protects life on Earth. When found closer to the Earth's surface, ozone may be harmful to lung tissue and plants. Recent studies have shown that the proportions of ozone in the air are increasing compared to decreasing amounts of protective ozone. However, studies still need to determine if these changes are due to human activity or if they are part of regular natural cycles.

The mission of the total ozone mapping spectrometer (TOMS) is to provide global measurements of total column ozone as well as of sulfur dioxide on a daily basis. The TOMS instrument measures the reflectivity of the atmosphere in six near-UV wavelengths (see Figure 79.3) and provides differential UV absorption and surface reflectivity data. From these measurements, total ozone is computed by searching precomputed albedo tables, which depend on solar zenith angle, view angle, latitude, surface reflectance, and surface pressure; a lower amount of radiation measured by TOMS corresponds to higher concentrations of ozone. Maps of volcanic eruptions are a by-product of TOMS sulfur dioxide measurements. The first TOMS instrument was flown on Nimbus 7 in 1978; successive ones were launched on a Russian Meteor spacecraft in 1991, on an Earth Probe satellite in 1994, and on the Japanese ADEOS satellite in 1996. See Refs. [11–16] for more information on TOMS and ozone measurements.

The TOMS measurements are also being compared to the ozone measurements provided by the National Oceanic and Atmospheric Administration (NOAA) series of the Television Infrared Observing Satellite (TIROS) Operational Vertical Sounder (TOVS) data. The TOVS sounding unit consists of three

instruments, including the High-Resolution Infrared Sounder-2 (HIRS-2) whose channels are shown in Figure 79.3. TOVS-type instruments have been flying since 1978. These instruments provide information about the structure of the atmosphere, vertical temperature and moisture profiles, as well as cloud amounts and heights. Through analysis of this data, the TOVS Pathfinder data set is created and contains 74 layers of measurements on attributes such as temperature, water vapor, ozone level, precipitation, cloud coverage, etc. taken at various atmospheric pressure levels (e.g., 1000 mb, 850 mb). A full global coverage of TOVS data is produced twice daily, and a 16 year global data set for climate studies is being gathered [17].

Another satellite that obtains atmospheric data is the Upper Atmosphere Research Satellite (UARS). UARS was launched in 1991 and performs a comprehensive study of the stratosphere and furnishes important new data on the mesosphere and the thermosphere. UARS operates 585 km above the Earth in a near circular orbit inclined 57° to the equator. This orbit permits UARS sensors to provide global coverage of the stratosphere and mesosphere and measurements are made approximately every 36 days. The 10 UARS chemistry and dynamics sensors are making measurements of temperature, pressure, wind velocity, and gas species concentrations. All these simultaneous measurements will help define the role of the upper atmosphere in our climate and its variability.

The Tropical Rainfall Measuring Mission (TRMM [18]) is a joint project between the United States and Japan. The goal of this project is to measure precipitation at tropical latitudes and to provide accurate mapping of tropical rainfall. The mission consists of three instruments: precipitation radar, a multichannel microwave radiometer, and a visible–IR scanner. The data provided by TRMM will be very important to verify and develop climate models.

The French space agency, CNES, has also developed the POLDER (POLarization and Directionality of the Earth's Reflectances) instrument, which flew on ADEOS. This is the first French/Japanese cooperative project in the area of Earth observation. A second, identical instrument is to be flown on ADEOS-2, successor to ADEOS, in 1999. POLDER is a wide field-of-view imaging radiometer that will provide global, systematic measurements of spectral, directional, and polarized characteristics of the solar radiation reflected by the Earth/atmosphere system, as well as aerosols, land and sea surfaces, and water vapor measurements.

NOAA's Advanced Very High Resolution Radiometer (AVHRR [19]) is very useful to study biomass burning in the tropics, and the interactions of smoke particles with clouds. More generally, information from the five AVHRR channels (see Figure 79.3) is integrated into clouds and climate models.

Weather images are an everyday occurrence televised all over the world. Several weather satellites are operated by several countries. In the United States, NASA and NOAA are operating the GOES series of geostationary satellites, which provide global weather data every 30 min since 1974, positioned at 36,000 km above the Earth. GOES image and sounder data are also used for climate studies. In Europe, the Meteosat weather satellites are developed and launched by ESA, and financed and owned by Eumetsat, an international organization of 17 European weather services. Meteosat-1 was launched in 1977, followed by five others in 1981, 1989, 1991, and 1993. Three of them are currently in service, each equipped with an imaging radiometer. Figure 79.3 shows the spectral ranges of operations of these two series of geostationary satellites. Several channels in the visible, water vapor, and thermal-IR spectral bands provide important information about cloud coverage, storm formation and evolution, as well as Earth radiation.

79.3 Examples of Terrestrial Studies

79.3.1 Land-Cover Applications

There are two basic types of data considered most important for global change research [20]; the data for documenting and monitoring global change, and the data for discovering the dynamical interplay among the various elements that define our environment. Previous studies show that global studies of land transformations require extrapolation among several scales (spatial, radiometric, and temporal).

This extrapolation is especially important to control the minimum detectable change, whether spatial, spectral, or temporal. This accuracy in change detection, which is based on the properties of the sensing systems [21], can be especially essential in distinguishing between nature- and human-induced changes.

Getting accurate quantitative information about the distribution and the areal extent of the Earth's vegetation formations is a basic requirement in understanding the dynamics of the major ecosystems. Among all land transformations most critical to study for global change research, the assessment of tropical forests is one of the most important [22–25]. The tropical forest biome forms 7% of the Earth land surface, and its extensive loss could have a major impact on the future of the Earth (habitat fragmentation, species extinction, soil degradation, global climatic modifications, etc.). Previous studies have shown that in the last 2 decades, 50% of the areal extent of tropical forests might have been lost to deforestation [23]. At present, there is a wide range of estimates of the areal extent of tropical forests and of their rates of deforestation. Therefore, there is a great need to produce accurate and up-to-date measurements concerning the Tropical Forest worldwide. A range of different sensors must be utilized for such applications.

Other examples of land-cover applications include agriculture and crop forecasting, water urban planning, rangeland monitoring, mineral and oil exploration, cartography, flood monitoring, disease control, real estate tax monitoring, detection of illegal crops, etc. In many of these applications, the combination of remote sensing data and Geographic Information Systems (GISs; see Refs. [26,27]) shows great promise in helping the decision-making process.

Most instruments utilized to observe land features are on-board low Earth orbit satellites and are multispectral sensors with two or three bands in the visible part of the spectrum and at least one band in the IR [6].
