Cambridge Handbook of Psychology, Health and Medicine

Second edition

Wholly revised, reworked and extended, this new edition of the much acclaimed *Cambridge Handbook of Psychology, Health and Medicine* offers a fully up-to-date, comprehensive, accessible, one-stop resource for health care professionals, clinical psychologists, mental health professionals and broadcasters specializing in health-related matters. There are two new editors: Susan Ayers from the University of Sussex and Kenneth Wallston from Vanderbilt University Medical Center.

The highly prestigious editorial team and their international, interdisciplinary cast of authors have reconceptualized this new edition. The old Part I has been dropped and its most useful elements revised and incorporated into relevant parts of the new book. Among the many new topics added throughout are: diet and health, ethnicity and health, clinical interviewing, mood assessment, communicating risk, medical interviewing, diagnostic procedures, organ donation, IVF, MMR, HRT, sleep disorders, skin disorders, depression and anxiety disorders.

No one interested in healthcare issues, promotion and care should be without this book.

Susan Ayers is Senior Lecturer in Health Psychology at the University of Sussex.

Andrew Baum is Professor of Psychiatry and Psychology at the University of Pittsburgh School of Medicine, and Deputy Director for Cancer Control and Supportive Sciences at the University of Pittsburgh Cancer Institute.

Chris McManus is Professor of Psychology and Medical Education at University College London.

Stanton Newman is Professor of Health Psychology at the Centre for Behavioural and Social Sciences in Medicine, University College London.

Kenneth Wallston is Professor of Psychology in Nursing at the Vanderbilt University Medical Center, Nashville.

John Weinman is Professor of Psychology as applied to Medicine, Health Psychology Section, Institute of Psychiatry, King's College London, London.

Robert West is Professor of Health Psychology, Department of Epidemiology and Public Health, University College London.

From reviews of the first edition:

'The new Cambridge Handbook is simply indispensable. . . . The book will find a wide market. No clinical psychologist is going to want to be without it. Perhaps more important, many doctors will continue to dip into it from time to time, since one of the book's virtues is to be written in a generally jargon free manner, accessible to all health professionals. Journalists from the better papers will use it frequently, since it gives a quick synopsis of the current state of play on a vast range of topics which are rarely absent from the health pages. Finally, journal editors will find it a valuable address book when they need referees for the ever increasing flow of research papers in this fascinating field'. Simon Wessely, *Psychological Medicine*

'This book is a rich mine of information for the general practitioner. . . . The day I received it a student came to ask me for advice about essays. Putting the "encyclopaedic handbook" to its first test, we looked up a few keywords. There was a chapter on each one. Bite-size morsels of information, easily digestible, comprehensive. I shall certainly keep this book within easy reach for future reference'. Caroline Selai, *Journal of the Royal Society of Medicine*

'Easy to read; a practical book'. *Journal of Pediatric Endocrinology and Metabolism*

Contents

<i>List of contributors</i>	page xi	Diet and health	75
<i>Preface</i>	xxi	Jane Ogden	
Part I Psychology, health and illness			
<hr/>			
Section I Psychological aspects of health and illness			
Adolescent lifestyle	5	Disability	80
Leif Edvard Aarø		Timothy Elliott and Laura Dreer	
Age and physical functioning	10	Emotional expression and health	84
Gail Williamson and David Shaffer		Richard Slatcher and James Pennebaker	
Age and cognitive functioning	15	Expectations and health	87
David Shaffer and Gail Williamson		James Maddux	
Ageing and health	20	Gender issues and women's health	92
Elaine Leventhal		Jane Ussher	
Architecture and health	23	The health belief model	97
Angela Liegey Dougall, Stacie Spencer and Andrew Baum		Charles Abraham and Paschal Sheeran	
Attributions and health	26	Health-related behaviours: common factors	102
Yael Benyamini, Howard Leventhal and Elaine Leventhal		Timothy Carmody	
Childhood influences on health	33	Hospitalization in adults	109
Julie Turner-Cobb		Rachael Powell and Marie Johnston	
Children's perceptions of illness and death	38	Hospitalization in children	113
Richard Boles and Michael Roberts		Thomas Whelan	
Coping with bereavement	41	Hostility and Type A behaviour in coronary artery disease	119
Margaret Stroebe, Henk Schut and Wolfgang Stroebe		Willem Kop and David Krantz	
Coping with chronic illness	46	Lay beliefs about health and illness	124
Keith Petrie and Lisa Reynolds		Howard Leventhal, Yael Benyamini and Cristina Shafer	
Coping with chronic pain	50	Life events and health	128
Naomi Lester, Francis Keefe, Meredith Rumble and Jeffrey Labban		Tirril Harris	
Coping with death and dying	55	Men's health	132
Colin Murray Parkes		Christina Lee and Glynn Owens	
Coping with stressful medical procedures	59	Noise: effects on health	137
Yael Benyamini		Staffan Hygge	
Cultural and ethnic factors in health	64	Pain: a multidimensional perspective	141
John Berry and David Sam		Dennis Turk and Tasha Burwinkle	
Delay in seeking help	70	Perceived control	148
Suzanne Scott		Kenneth Wallston	
		Personality and health	151
		Stephanie Stone and Robert McCrae	
		Physical activity and health	155
		Neville Owen, Kym Spathonis and Eva Leslie	
		Placebos	161
		Irving Kirsch	

Psychoneuroimmunology Elizabeth Bachen, Sheldon Cohen and Anna Marsland	167	Health status assessment Ann Bowling	266
Psychosomatics Christopher Bass	173	Illness cognition assessment Ad Kaptein and Elizabeth Broadbent	268
Quality of life Lena Ring	178	IQ testing Robert Sternberg	273
Religion and health Karen Hye-cheon Kim and Harold Koenig	182	Assessment of mood Michele Tugade, Tamlin Conner and Lisa Feldman Barrett	278
Risk perception and health behaviour Baruch Fischhoff	187	Neuropsychological assessment Jane Powell	287
Self-efficacy in health functioning Albert Bandura	191	Neuropsychological assessment of attention and executive functioning	290
Sexual risk behaviour Lorraine Sherr	194	Melissa Lamar and Amir Raz	
Sleep and health Jason Ellis	198	Neuropsychological assessment of learning and memory	294
Social support and health Thomas Wills and Michael Ainette	202	Nancy Chiaravalloti, Amanda O'Brien and John DeLuca	
Socioeconomic status and health Lion Shahab	207	Pain assessment	300
Stigma Robert West and Ainsley Hardy	213	Sandra Waters, Kim Dixon, Lisa Caitlin Perri and Francis Keefe	
Stress and health Susan Ayers and Andrew Steptoe	215	Patient satisfaction assessment Susan Eisen	304
Symptom perception Elizabeth Broadbent and Keith Petrie	219	Psychoneuroimmunology assessments Andrew Baum and Angela Liegey Dougall	309
Theory of planned behaviour Stephen Sutton	223	Qualitative assessment Felicity Bishop and Lucy Yardley	314
Transtheoretical model of behaviour change Stephen Sutton	228	Quality of life assessment Ann Bowling	319
Unemployment and health Stanislav Kasl and Beth Jones	232	Social support assessment Brian Lakey and Jay Cohen	321
		Stress assessment Andrew Baum and Angela Liegey Dougall	326
Section II Psychological assessment		Section III Psychological intervention	
Brain imaging and function Erin Bigler	239	Behaviour therapy Gerald Davison	333
Communication assessment Linda Worrall	242	Biofeedback Robert Gatchel, Carl Noe and Raymond Gaeta	335
Coping assessment Ellen Skinner	245	Cognitive behaviour therapy Andrew Eagle and Michael Worrell	340
Diagnostic interviews and clinical practice Richard Rogers and Peggilee Wupperman	251	Community-based interventions Deborah Polk, Christie King and Kenneth Heller	344
Disability assessment Raymond Fitzpatrick	256	Counselling Robert Bor and John Allen	348
Health cognition assessment Brian McMillan and Mark Conner	260	Group therapy Peter Hájek	352

Health promotion Gerjo Kok	355	Medical decision-making Clare Harries and Peter Ayton	454
Hypnosis Michael Heap	359	Medical interviewing Jonathan Silverman	459
Motivational interviewing Janet Treasure and Esther Maissi	363	Patient-centred healthcare Peter Bower and Nicki Mead	468
Neuropsychological rehabilitation Barbara Wilson	367	Patient safety and iatrogenesis Maria Woloshynowych and Charles Vincent	472
Pain management Stephen Morley	370	Patient satisfaction Raymond Fitzpatrick	477
Physical activity interventions Michael Ussher	375	Psychological support for healthcare professionals Valerie Sutherland	482
Psychodynamic psychotherapy Jo-anne Carlyle	379	Reassurance Patricia Loft, Geraldine Meechan and Keith Petrie	487
Psychosocial care of the elderly Jennifer Morse and Charles Reynolds, III	383	Screening in healthcare: general issues Anne Miles	490
Relaxation training Michael Bruch	389	Shiftwork and health Katharine Parkes	496
Self-management interventions Kathleen Mulligan and Stanton Newman	393	Stress in health professionals Chris McManus	500
Social support interventions Benjamin Gottlieb	397	Surgery Claus Vögele	505
Stress management Dianna Kenny	403	Teaching communication skills Angela Hall and Jane Kidd	510
Worksite interventions Paul Estabrooks and Russell Glasgow	407	Written communication Lorraine Noble	517
Section IV Healthcare practice		Part II Medical topics	
Adherence to treatment Rob Horne	417	Abortion Pauline Slade	525
Attitudes of health professionals Hannah McGee	421	Accidents and unintentional injuries Robert Frank and Andrea Lee	527
Breaking bad news Katherine Joekes	423	Acne Stephen Kellett	530
Burnout in health professionals Christina Maslach	427	Alcohol abuse Michael Sayette	534
Communicating risk David French and Theresa Marteau	431	Allergies to drugs Mary Gregerson	537
Healthcare professional–patient communication John Weinman	435	Allergies to food Mary Gregerson	540
Healthcare work environments Rudolf Moos, Jeanne Schaefer and Bernice Moos	439	Allergies: general Mary Gregerson	543
Informed consent Robin Fiore	444	Amnesia Barbara Wilson and Narinder Kapur	546
Interprofessional education in essence Hugh Barr	449	Amputation and phantom limb pain Ronald Melzack and Joel Katz	548

Anaesthesia and psychology Keith Millar	551	Chromosomal abnormalities Jeremy Turk	625
Antenatal care Kirstie McKenzie-McHarg and Rachel Rowe	554	Chronic fatigue syndrome Ruth Cairns and Trudie Chalder	629
Aphasia recovery, treatment and psychosocial adjustment Chris Code	556	Chronic obstructive pulmonary disease (COPD): chronic bronchitis and emphysema Ad Kaptein and Klaus Rabe	631
Asthma Ad Kaptein and Klaus Rabe	559	Cleft lip and palate Brent Collett and Matthew Speltz	634
Back pain Amanda C. de C. Williams	563	Cold, common Anna Marsland, Sheldon Cohen and Elizabeth Bachen	637
Blindness and visual disability Linda Pring	565	Complementary medicine Felicity Bishop and George Lewith	639
Blood donation Sarah Afuwape	567	Contraception Beth Alder	641
Breastfeeding Antony Manstead	570	Coronary heart disease: impact Paul Bennett	644
Burn injuries: psychological and social aspects Claire Phillips	572	Coronary heart disease: cardiac psychology Robert Allan, Stephen Scheidt and Christopher Smith	648
Cancer: breast Alice Simon and Kathryn Robb	577	Coronary heart disease: heart failure Kathleen Mulligan and Stanton Newman	654
Cancers of the digestive tract Sharon Manne	581	Coronary heart disease: rehabilitation Robert Lewin	656
Cancer: general Barbara Andersen and Laura Simonelli	584	Coronary heart disease: surgery Jan Stygall and Stanton Newman	659
Cancer: gynaecologic Kristen Carpenter and Barbara Andersen	591	Cystic fibrosis Claire Glasscoe	662
Cancer: head and neck Gerry Humphris	595	Acquired hearing loss Laurence McKenna and David Scott	665
Cancer: Hodgkin's and non-Hodgkin's lymphoma Jennifer Devlen	598	Dementias Jenny Rusted	667
Cancer: leukaemia Janelle Wagner and Ronald Brown	601	Diabetes mellitus Alison Woodcock and Clare Bradley	670
Cancer: lung Angela Liegey Dougall	605	Domestic violence, intimate partner violence and wife battering Irene Frieze and Maureen McHugh	674
Cancer: prostate Stephen Lepore and Katherine Roberts	607	Drug dependency: benzodiazepines Heather Ashton	675
Cancer: skin Ron Borland and Suzanne Dobbinson	610	Drug dependence: opiates and stimulants Michael Gossop	679
Carotid artery disease and treatment Jan Stygall and Stanton Newman	613	Drugs: beta-blockers Sari Holmes and David Krantz	683
Chemotherapy Ingela Thuné-Boyle	616	Drugs: psychotropic medication Andrew Scholey, Andy Parrott and David Kennedy	685
Child abuse and neglect Kevin Browne and Catherine Hamilton-Giachritsis	619		

Dyslexia Christine Temple	688	Hysterectomy Susan Ayers	749
Eating disorders Eric Stice and Heather Shaw	690	Immunization Roger Booth	751
Eczema David J. de L. Horne and Elizabeth Coombes	693	Incontinence Siobhan Hart	754
Endocrine disorders Eric Storch and Gary Geffken	696	Infertility Annette Stanton and Julia Woodward	756
Enuresis Martin Herbert	700	Inflammatory bowel disease Paul Bennett	759
Epilepsy Graham Scambler	702	Intensive care unit Christina Jones and Richard Griffiths	760
Epstein–Barr virus infection Rona Moss-Morris and Meagan Spence	705	Intimate examinations Penelope Cream	763
Facial disfigurement and dysmorphology Nichola Rumsey	708	Irritable bowel syndrome Paul Bennett	765
Fetal wellbeing: monitoring and assessment Peter Hepper, James Dornan and Dan McKenna	711	Lymphoedema Anne Williams	768
Gastric and duodenal ulcers Paul Bennett	714	Malaria Julie Carter	771
Growth retardation Michael Preece	716	Mastalgia (breast pain) Antonio Millet and Frederick Dirbas	774
Haemophilia Ivana Marková	718	Meningitis Julie Carter	776
Head injury Erin Bigler	720	Menopause and postmenopause Myra Hunter	779
Headache and migraine Bjørn Ellertsen	724	MMR vaccine Emily Buckley	781
Herpes John Green	727	Motor neurone disease Laura Goldstein	784
HIV/AIDS Michael Antoni and Adam Carrico	729	Multiple sclerosis Rona Moss-Morris, Kirsten van Kessel and Emma Witt	786
Hormone replacement therapy Christine Stephens	732	Myasthenia gravis Ruth Epstein	789
Hospital acquired infection Jan Stygall and Stanton Newman	736	Neurofibromatosis Rosalie Ferner	790
Huntington's disease Maurice Bloch	738	Non-cardiac chest pain Christopher Bass	793
Hyperactivity Bjørn Ellertsen and Ine Baug Johnsen	740	Obesity Jennifer Thomas and Kelly Brownell	797
Hypertension Katherine Joekes and Sandra Boersma	742	Oral care and hygiene Gerry Humphris	801
Hyperthyroidism Nicoletta Sonino and Giovanni Fava	745	Osteoarthritis Isidro Villanueva and Alex Zautra	803
Hyperventilation David Nias	747	Osteoporosis Myra Hunter	807

Parkinson's disease Marjan Jahanshahi	809	Sickle cell disease James Elander	877
Pelvic pain Robert Edwards and Jennifer Haythornthwaite	811	Skin disorders Ulrich Stangier	880
Post-traumatic stress disorder Donna Posluszny, Stacie Spencer and Andrew Baum	814	Sleep apnoea Jane Harrington	883
Postnatal depression Sandra Elliott	820	Sleep disorders Jason Ellis	887
Pregnancy and childbirth Lyn Quine and Liz Steadman	823	Spina bifida Ineke Pit-ten Cate and Jim Stevenson	889
Premature babies Heather Mohay	827	Spinal cord injury Paul Kennedy	892
Premenstrual syndrome Jane Ussher	830	Sterilization and vasectomy Robert Edelman	895
Psoriasis Catherine O'Leary	833	Stroke John Pimm	897
Radiotherapy Sara Faithfull	836	Stuttering Peggy Dalton and Frances Cook	901
Rape and sexual assault Irene Frieze and Maureen McHugh	839	Suicide David Lester	904
Reconstructive and cosmetic surgery Nichola Rumsey	841	Tinnitus Gerhard Andersson	906
Renal failure, dialysis and transplantation Keith Petrie	844	Tobacco use Robert West and Ainsley Hardy	908
Repetitive strain injury Gerard van Galen	846	Toxins: environmental Gerhard Winneke	912
Rheumatoid arthritis Kathleen Mulligan and Stanton Newman	850	Transplantation Konstadina Griva and Stanton Newman	915
Road traffic accidents: human factors Frank McKenna	852	Urinary tract symptoms Martin Cartwright and Mark Emberton	919
Screening: antenatal Elizabeth Dormandy	854	Vertigo and dizziness Lucy Yardley	921
Screening: cancer Kevin McCaul and Amber Koblitz	857	Vision disorders Beth Grunfeld	924
Screening: cardiac Alethea Cooper	861	Voice disorders Ruth Epstein	926
Screening: genetic Shoshana Shiloh	864	Volatile substance abuse Michael Gossop	927
Self-examination: breasts, testicles Glynn Owens	870	Vomiting and nausea David J. de L. Horne and Elizabeth Coombes	929
Sexual dysfunction Patricia Morokoff	872	<i>Index</i>	933
Sexually transmitted infections Barbara Hedge	875

Preface

Health psychology is an established field, with an impact on many aspects of medical training, practice and research. Although there are some very good textbooks and handbooks of health psychology available, these are directed primarily at psychologists working in health-related areas. There has been a need for a comprehensive reference text suitable for medical practitioners who wish to be appraised of ways in which psychology can help them in their work. Such a book should also provide a unique resource for undergraduate and postgraduate medical education.

This book is intended as a comprehensive handbook for medical practitioners and health professionals, and for psychologists who work with health professionals. It will also be of interest to undergraduates undertaking psychology, medicine and other health-related courses, and to postgraduate students on MSc and PhD courses.

The book is in two parts.

Part I: Psychology, health and illness is in four sections and reviews the main theories and findings in psychology as applied to medicine, covering (i) psychological aspects of health and illness, (ii) psychological assessment, (iii) psychological intervention and (iv) psychological factors associated with the practice of healthcare.

Part II: Medical topics examines psychological theories and findings relevant to particular medical conditions, investigations, treatments and prophylaxes.

It will be apparent that the decision to place some chapters in Part II rather than Part I is a matter of judgement. In general, the decision was made on whether the topic appeared to cut across a range of illnesses or treatments. However, if the reader cannot find a topic in Part II, he or she is quite likely to find material relevant to it in Part I.

This is primarily a reference text and therefore it is expected that readers will seek out particular chapters for particular purposes. For this reason the chapters within each section are arranged alphabetically and the titles phrased in encyclopaedic language.

Inevitably there is some overlap between chapters dealing with related topics because each chapter is self-contained and we have tried to keep to a minimum the need for movement back and forth between entries.

Clinical practitioners will probably wish to use the book by looking up entries in Part II that are of interest, gaining further background information or clarification of concepts from Part I. Teachers will probably focus mostly on chapters in Part I as basic reading for courses on psychology as applied to medicine, using material from Part II as supplementary reading to show how basic principles can be applied.

Although we have attempted to make the book as comprehensive as possible, it would be unrealistic to imagine that a single text could encompass the whole field adequately. It must also be the case that there are topics that have not been addressed at all. However, we have tried to make the coverage as broad as possible, and keep such gaps to a minimum. For added depth of coverage, the extensive reference lists should be an invaluable resource.

This second edition has been a long time in gestation and the editors are deeply indebted to the contributors for their efforts in producing what we believe are some very fine chapters and for their patience. We believe that the effort has been worthwhile and that the result has been worth waiting for. We hope that the contributors and the readers will agree.

Finally, special thanks are due to Dr Katherine Joeke for her editorial assistance.

Part I

Psychology, health and illness

Section I

Psychological aspects of health and illness

Adolescent lifestyle

Leif Edvard Aarø

University of Bergen

Definitions

Leading organizations in the field of disease prevention and health promotion, such as the World Health Organization (Headquarters in Geneva, Switzerland) and the Centers for Disease Control (Atlanta, USA), have since the early 1980s used healthy lifestyles as a label for a cluster of behaviours known to reduce the risk of injury, morbidity and mortality and increase the chances of good health and well-being. Health-related behaviours (health-enhancing or health-compromising) include eating habits, physical exercise, smoking, alcohol use, use of illegal addictive substances, sexual practices, risk-taking in traffic, work etc., use of safety devices (for instance wearing safety helmets when biking), sleeping habits, oral hygiene and personal hygiene. Examples of health-related behaviours which are relevant only to specific ethnic groups are exposure to the sun in order to obtain a more tanned skin among Caucasians, or use of skin-whitening creams among ethnic groups with dark skin colours.

The concept of lifestyle is also used in other contexts. In the field of marketing, analysis of consumer lifestyles means examining the way people live (their activities, interests, values and opinions) in order to better tailor marketing efforts to specific target groups.

According to Elliott (1993):

... a lifestyle has been defined as a distinctive mode of living that is defined by a set of expressive, patterned behaviors of individuals occurring with some consistency over a period of time.

It should be evident from this definition that the lifestyle construct is not meant to capture the totality of a person's behaviour. There are three aspects that make lifestyles more specific: their consistency or relative stability over time, their interrelatedness (being patterned), and the meaning they convey to others as well as oneself (expressiveness). Health-related lifestyles refer to behaviours that have been shown by epidemiological and other health research to predict disease or health. A related term, 'risk-taking behaviour', refers to behaviour patterns which are volitional and which increase risk of disease or injury (Irvin, 1990).

The lifestyle concept is less accepted as a term in developing countries. In Lalonde's classic report on 'The health of Canadians' (Lalonde, 1974) the definition of lifestyle that was suggested implied that lifestyles are the result of choices made by individuals. The lifestyle of an individual is seen as the result of an aggregate of decisions made by the person him- or herself, decisions over which the person has considerable control. Environmental and social factors have, however, been shown to exert a powerful influence on health behaviours, even in affluent societies, and factors over which

the individual person has limited or no control are obviously of even higher importance in developing countries (Eaton *et al.*, 2004).

When defining 'adolescence', several criteria are relevant, for instance secondary sex characteristics, cognitive abilities, social criteria or simply age. According to Adams *et al.* (1994), adolescence covers the age-groups 11–20, and distinction is made between early adolescence (11–14), middle adolescence (15–17) and late adolescence (18–20). There is no global consensus regarding the definition of adolescence. The World Health Organization defines adolescence as the period from 10 to 19 years of age.

Defining adolescence as a period covering such a wide age-range may seem particularly relevant for affluent societies of the West. During recent decades, however, it has become clear that a transitional stage between childhood and adulthood is evident in most societies of the world. This expanded, more-distinct transitional period includes longer schooling, earlier puberty, later marriage, removal from full-time labour, and greater separation from the world of adults (Larson & Wilson, 2004). During this period of life, through a complex interplay between biological, physiological, psychological, social, societal and cultural factors, lifestyles are shaped.

Health behaviour change during adolescence

During adolescence a number of health-compromising behaviours emerge. When entering adolescence, children are normally spontaneously physically active, and there is hardly any use of tobacco, alcohol or other addictive substances. When leaving adolescence, a substantial proportion of adolescents are physically inactive, have started smoking, and some have started using illegal addictive substances. The sexual debut usually takes place during adolescence, and being sexually active without adequate protection against unwanted pregnancies and sexually transmitted diseases, including HIV/AIDS, represents a serious threat to health and wellbeing.

According to a report from the World Health Organization international study on Health Behaviour in School-Aged Children (HBSC), the proportion of smokers increases during early adolescence (Currie *et al.*, 2004). At age 11 the average proportion of smokers (smoking daily or weekly) across all samples (35 countries) is 2%, at age 13 it is 8%, and at age 15 it is 24%. The differences between boys and girls for all countries combined (mainly European countries plus Canada and the United States) were negligible. Corresponding figures for weekly alcohol consumption are 5, 12 and 29%. More boys than girls used alcohol weekly at age 15 (34 and 24% respectively).

Prochaska *et al.* (2001) have developed a screening instrument which defines 'moderate-to-vigorous physical activity' (MVPA). Their definition was applied to data from the HBSC study. The proportion of young people meeting the MVPA guidelines on physical activity was (across all samples) 38% at age 11 and 29% at age 15; in other words there is a marked decrease with age that most likely continues across the remaining years of adolescence as well as into early adulthood (Stephens *et al.*, 1984). Food habits were also covered by the HBSC survey. The proportion of adolescents who eat fruit daily decreases from 38% among 11 year olds to 29% among the 15 year olds (Currie *et al.*, 2004).

Thuen *et al.* (1992) have shown that use of safety equipment (seat belts, bicycle helmets, reflectors, life jackets) drops dramatically during early adolescence, and the proportion involved in behaviour associated with elevated risks of accidents and injuries increases.

It must be kept in mind, however, that a majority of young people never become regular smokers, heavy drinkers or drug addicts, and a substantial proportion of young adults remain physically active and continue eating healthy food throughout and after the adolescent years. During adolescence the basis for a lifelong health-enhancing lifestyle may be established.

The effects of health-compromising behaviours during adolescence can be short-term as well as long-term. Drink driving increases the risk of dramatic and fatal accidents, and represents a major short-term threat to young people's health and lives. Daily smoking may lead to coronary heart disease and lung cancer, but these effects usually become visible only after many years of exposure. The importance of promoting healthy lifestyles among adolescents therefore to some extent depends on the stability of such behaviours. The higher the stability, the more important it is to promote healthy lifestyles at a young age.

Jessor *et al.* (1991) have studied the stability of problem behaviours from adolescence to adulthood, and conclude that there is considerable stability and continuity. They claim that 'the adolescent is parent of the young adult'.

Although few research projects have focused on the stability and change of physical activity from childhood to adolescence, there is one study which concludes that the level of physical activity in childhood and adolescence to some extent predicts the level of physical activity later in life (Anderssen *et al.*, 1996). Other studies of longitudinal tracking of behaviours (physical activity, food preference and smoking behaviour), have provided convincing evidence that behaviours established during early adolescence do predict behaviours measured during late adolescence and beyond (Klepp, 1993; Kelder *et al.*, 1994; Telama *et al.*, 1997). Substantial tracking has also been found for body mass index over an 18 years' age span (from 15 to 33 years) (Kvaavik *et al.*, 2003).

The promotion of healthy lifestyles among young people is obviously important, not only because of its short-term impact on health and wellbeing, but also because of its consequences for health-related behaviours later in life.

Clusters of health behaviours

A number of studies have examined to what extent health behaviours are intercorrelated, and to what extent these correlations reflect underlying clusters or dimensions. Analyses from the

international study on Health Behaviour in School-Aged Children indicated two such underlying dimensions: (a) addictive and risk-taking behaviours and (b) health-enhancing behaviours (Nutbeam *et al.*, 1991; Aarø *et al.*, 1995). The correlation between the two factors was negative and estimates varied from approximately -0.40 to -0.50 . Within these two 'second order factors', sub-clusters of health-related behaviours could also be identified. Røysamb *et al.* (1997) identified factors at three levels, a multidimensional level with a number of specific factors, a few-dimensional level with three broad factors, and finally a general factor encompassing the three broad factors. The three broad factors were 'High action', 'Addiction' and 'Protection'.

The addictive dimension corresponds well with Richard Jessor's 'problem behaviours' (Jessor & Jessor, 1977; Jessor, 1984). He claims that a number of health-related behaviours reflect a 'syndrome', or an underlying tendency to behave defiantly and unconventionally. He includes such behaviours as use of alcohol, marijuana and tobacco, and he maintains that these are associated with a higher likelihood of involvement in other types of risk behaviour, such as precocious sexual activity, aggression and delinquency. Jessor maintains that for these behaviours the pattern of associations with a number of personality and social environmental correlates is essentially the same.

Health-enhancing behaviours, which in some studies form a second factor, include physical activity, consumption of healthy food, oral hygiene, use of safety devices (seat belts, reflectors, etc.) and use of vitamins. The diffusion of innovation processes, which have been described by Everett Rogers, may serve as a framework for explaining why such behaviours are intercorrelated (Rogers, 2003). If we assume that health-education and health-promotion activities reach and influence health behaviours in certain individuals and certain groups to a larger extent than in other individuals and other groups, correlations among a range of health-enhancing behaviours tend to emerge.

Intercorrelations and clusters of intercorrelations among health-behaviour variables imply that they do not exist as independent and unique domains. Their interrelatedness indicates the usefulness of the notion of 'lifestyles'. It may be argued that such intercorrelations indicate similarities in the processes underlying different health behaviours. Furthermore, intercorrelations between health behaviours imply overlap in target groups across behavioural risk factors, and support the notion of a more integrated and holistic approach to health promotion among adolescents (Nutbeam *et al.*, 1991).

Predictors and correlates of health behaviours

A number of conceptual models and theories are relevant in order to identify factors and processes that influence health-related behaviours. The mainstream of health behaviour research is dominated by social cognition models (Rutter & Quine, 2002; Conner & Norman, 2005). A group of experts at a meeting organized by the National Institute of Health (NIH) came to the conclusion that the most important predictors were intentions, skills, environmental constraints, anticipated outcomes (or attitudes), social norms, self efficacy, self-standards and emotions (Fishbein *et al.*, 2001). They did not reach consensus regarding any specific theoretical or conceptual model by which these factors could be arranged into a single causal

system. Among the most influential theories are Social Cognitive Theory (Bandura, 1986) and the Theory of Planned Behaviour (Ajzen, 1988). Ajzen assumes that a specific behaviour is determined to a large extent by intentions to perform the behaviour, and that such intentions are influenced by personal attitudes to the behaviour, subjective norms and perceived behavioural control. Rather than simply assuming that such factors as attitudes and perceived behavioural control are predictors, while behaviours are outcomes, we must suppose that there is an ongoing and continuous process of reciprocal determinism (Bandura, 1986). Bandura sees behaviours as shaped by an ongoing process of interrelationships with personal and environmental factors. Key concepts in Bandura's analyses of health behaviours are goals (proximal and distal), outcome expectations and self-efficacy (Bandura, 1998; 2005).

Although the major determinants of health-related lifestyles among adolescents are social, some personality characteristics have been shown to be consistently associated with 'problem behaviours'. Jessor claims that in the personality system, the main characteristics of proneness to problem behaviour include placing a lower value on academic achievement and lower expectations of academic achievement (Jessor, 1984). The sensation-seeking personality trait (Zuckermann, 1979) has been shown to correlate with such problem behaviours as smoking, alcohol consumption, number of lifetime sex partners and experience of casual sex (Kraft & Rise, 1994).

The cross-cultural relevance of theories and conceptual models for prediction of health behaviours developed in western countries has repeatedly been questioned (Campbell, 2003). Jessor *et al.* (2003), in a study of predictors of problem behaviours among adolescents in the United States and China, came to the conclusion that although the levels of problem behaviours may be different, the same set of predictors (protective factors and risk factors) seem to be relevant in these two widely different societies and cultures. The relevance of social cognition models in an African context is currently being examined in a large-scale multi-site study of sexual and reproductive behaviours (Aarø *et al.*, 2006).

Structural and demographic factors

Health-compromising lifestyles are to a large extent a product of the modern world. Physical inactivity is fostered by modern means of transport and by passive exposure to TV channels, DVD movies, internet use and PC games. Widespread use of addictive substances may reflect a weakening of social norms and the deterioration of social networks. Broken families and family problems may lead to reduced parental control over food habits, sleeping habits and use of addictive substances.

Changes in health behaviours do not take place at the same speed and simultaneously in all groups. In the industrialized countries the use of tobacco first became widespread among men and among high-status groups. Presently, high-status groups have reduced their use of tobacco substantially. Low-status groups are falling behind, and in many countries the prevalence of regular smokers in low-status segments of the population is 3–4 times higher than among those belonging to high-status segments (Ferrence, 1996). Similar processes can be observed for other health behaviours. Belonging to high-status groups means that you are also more

likely to be physically active, to eat healthy food and to wear seat belts, just to mention some examples.

Since health behaviours of adolescents are closely related to those of their parents, similar socioeconomic inequalities may exist for adolescents as well. Adolescents are in a process of transition from having their socioeconomic status defined by their parents' education, income and jobs towards having their socioeconomic status defined by their own position in the societal structure. Several studies have reported rather moderate or weak associations between parents' level of education and offspring's health behaviours (Friestad & Klepp, 2006). Problems with obtaining valid and reliable measurements of parents' level of education may have contributed to reducing the strength of associations. Adolescents' relationship to school and education has sometimes been used as an indicator of their socioeconomic position. Friestad & Klepp (2006) found consistent associations between educational aspirations and composite measures of health behaviour (low aspirations predicting high scores on health-compromising behaviours and low scores on health-enhancing behaviours). Nutbeam *et al.* (1988; 1993) found strong associations between school alienation and use of addictive substances (tobacco and alcohol). This indicates that a socioeconomic gradient in lifestyles also exists for adolescents. Researchers have concluded that health-related behaviours to some extent carry over from one generation to the next, and that a process of social reproduction of socioeconomic inequalities in lifestyles can be demonstrated (Wold, 1989; Ketterlinus *et al.*, 1994). Other researchers have found empirical support for adolescent lifestyles being predictive of future socioeconomic status (Koivusilta *et al.*, 1999).

Health behaviours are also influenced by such factors as advertising, legislation (including bans on advertising), price and availability of products. Increasing the price of tobacco products leads to a decrease in consumption, and this decrease is higher among adolescents than among adults. Among adults the price elasticity is probably close to -0.5 . A price elasticity of -0.5 means that increasing the price by 10% leads to a 5% reduction in consumption. The price elasticity is particularly high among young people. In one study it was shown to be -1.40 among 12–17 year olds (Warner, 1986).

The effects of tobacco advertising and the effects of banning such advertising on smoking habits of adolescents have been debated. The tobacco industry has aggressively defended their right to market legal products, while health authorities, health professionals and non-governmental organizations have argued that bans on all kinds of tobacco advertising are necessary in order to reduce smoking among adolescents. An increasing body of research gives both theoretical and empirical evidence for a causal relationship between advertising and use of tobacco, and it is likely that 'the dynamic tobacco market represented by children and adolescents' is the main target of tobacco sales promotion (Rimpelä *et al.*, 1993). Braverman & Aarø (2004), in a study among adolescents, found that even low levels of exposure to tobacco marketing was associated with stronger expectations of future smoking, after controlling for present smoking habits and important social predictors of smoking. Longitudinal studies have consistently shown that exposure to tobacco advertising is associated with increased risk that adolescents will start to smoke (Lovato *et al.*, 2003). It is reasonable to assume that effectively enforced bans on advertising contribute to reducing smoking among adolescents. In order to make the healthy

choices the easiest ones, the prices of healthy products should be kept low, the prices of unhealthy products should be high, and for young people in particular, the availability of unhealthy products like alcohol and cigarettes should be limited as much as possible.

Health-behaviour interventions

Health-behaviour interventions targeting adolescents take place in the mass media, schools and communities. Examples of programmes that have not proven effective are numerous. There are also, however, examples of well-designed and research-based interventions that have had substantial effects. Kirby & Coyle (1997) reviewed 35 evaluations of school-based sexual education programmes, and found that a few programmes had contributed to delaying the onset of intercourse, reduced the frequency of intercourse, reduced number of sexual partners, or increased the use of condoms or other contraceptives. For the majority of the programmes, however, no statistical effects on risk-taking behaviours were observed. Thomas (2002) reviewed 76 randomized controlled trials of school-based interventions to prevent smoking. Among interventions based on the social influence approach, which has been regarded as the most effective approach to smoking prevention among adolescents, half of the studies showed statistically significant effects of the interventions. Jøsendal *et al.* (2005) found that a three-year programme based on the social-influence model reduced the prevalence of smoking by about 30%. Positive results have also been found for school-based interventions to reduce drug use (Faggiano *et al.*, 2005).

There is less strong evidence for positive effects of mass-media and community-based interventions (Sowden & Arblaster, 1998; Sowden *et al.*, 2003). This does not necessarily mean that such interventions are ineffective. Planning and conducting studies with strong research designs and demonstrating significant effects of interventions is much easier in schools than in most other settings. In addition, programmes which have no visible immediate effects on behaviour, may contribute to raising awareness, and changing

beliefs, attitudes and social norms, and they may lead to increased support for restrictive and societal measures. Such indicators of change may, in the long term, trigger processes that are just as important for behaviour change in populations as programmes that succeed in bringing about immediate effects on behaviour.

Adolescents in developing countries

Among 1.2 billion adolescents worldwide, about 85% live in developing countries, and this proportion is increasing. Also, in the developing world, health-compromising lifestyles are gradually becoming a threat to health, and in developing countries such behaviours become more prevalent during adolescence. Research has shown that increasing production and consumption of alcohol is taking place in both rural and urban areas in Africa (Maula *et al.*, 1988). Parallel with the reduction in tobacco smoking in Western Europe and North America, effective marketing contributes to increasing the prevalence of smoking in developing countries and in Eastern Europe (World Bank, 1999).

Eide & Acuda (1996) in a study from Zimbabwe showed that cultural influences from industrialized countries are accompanied by introduction of forms of alcohol use which are less well regulated by rituals and social norms than the use of traditional beverages. Young people with a 'western' cultural orientation have alcohol preferences which are different from those with a more traditional cultural orientation, and their consumption is higher. Similar cultural influences may operate on a variety of health behaviours, and the introduction of a 'modern' lifestyle may lead to a gradual increase in diseases which used to be typical of western countries. This adds health burdens and economic burdens to nations which are already confronted with infectious diseases (including the AIDS pandemic) and overwhelming health problems caused by poverty, poor housing, malnutrition, inadequate sanitation and lack of clean water.

Age and physical functioning

Gail M. Williamson and David R. Shaffer

University of Georgia

Over the life span, the human body increasingly functions less efficiently. Skin wrinkles and sags; hair thins and turns grey; muscle mass and strength are more difficult to maintain; joints deteriorate; aerobic capacity and cardiac output decrease; the immune system becomes less responsive; visual and auditory acuity decline – and this is just a partial list. Faced with these changes, it is not surprising that many people dread growing old because they believe ageing portends losses in functional capacities and the enjoyable aspects of life. This chapter highlights the demographic realities of an ageing population, debunks some of the myths about age and physical functioning and summarizes research on the factors that promote successful ageing.

There is no doubt that the population of many western countries is ‘greying’¹. Average life expectancy in the US in 1900 was 47 years; today, it is closer to 76 years. Over two-thirds of people now live to at least age 65 (a three-fold increase from 1900). Furthermore, the fastest growing segment of the population is in the category over age 85 – 4% in 1900 to more than 10% today (e.g. US Department of Health and Human Services [DHHS], 1992; Volz, 2000). The first wave of the 76 million baby boomers born in the USA between 1946 and 1964 will approach traditional retirement age in 2010 (Binstock, 1999); in less than 30 years, there will be twice as many people 65 years of age and older, comprising 20% or more of the total population (e.g. Hobbs, 1996). By 2050, the number of centenarians (those over age 100) in the USA may be as high as 4.2 million (Volz, 2000).

The common view of old people is that they are physically disabled (e.g. Center for the Advancement of Health [CAH], 1998; Palmore, 1990; Rowe & Kahn, 1998), but an important truth is that most adults over age 65 are remarkably healthy and active. Rates of disability, even among the very old (i.e. those over age 95), are steadily declining. Only 5.2% of older adults in the USA live in nursing homes and similar facilities, a decrease of 1.1% since 1982 (CAH, 1998). In 1994, 73% of adults 78–84 years of age reported no disabling conditions and among the ‘oldest old’ (i.e. those over age 85), fully 40% had no functional disabilities (Manton *et al.*, 1995). Changing health status and attitudes have led to age 65 no longer being considered ‘old’ (Kiyak & Hooyman, 1999).

Along with increasingly widespread public knowledge and acceptance of the behavioural aspects of chronic illness, advances in medical technology forecast less age-related functional decline for current and future generations (DHHS, 1992). Through medical

and psychological research, we know that the human body is remarkably forgiving (CAH, 1998) and that it is never too late to begin a healthful lifestyle. For example, regardless of duration of smoking and magnitude of tobacco consumption, after five years of abstinence, ex-smokers have about the same risk for heart disease as those who never smoked. The same is true for a variety of other risk factors, including obesity and a sedentary lifestyle. Thus, people, both young and old, bear some responsibility for their health status; the ‘use it or lose it’ adage about sexual functioning applies to other aspects of physical functioning as well. However, in addition to the inevitable physical decrements that accompany ageing, numerous psychosocial factors influence wellbeing in old age.

Physical, mental and social wellbeing are intertwined, and ageing successfully depends, to a large extent, on effective coping in all of these domains. In terms of the association between physical and mental health, physical illness and depression are closely, perhaps inextricably, linked, and the direction of causality remains a subject of considerable debate (see Williamson *et al.*, 2000a). With their age-related decrements in physical functioning, one might assume, as Rowe & Kahn (1998, p. 106) alleged, that ‘depression is ... terribly prevalent in older people’, but evidence is overwhelmingly to the contrary. In fact, clinically diagnosable depression is less prevalent in older than younger adults (e.g. Rybash *et al.*, 1995; Schulz & Ewen, 1993). Rather, elders often cope more effectively with stressful life events than do younger adults (McCrae, 1989). The prevailing explanation is that, over the life course, experiences and successes in coping with a variety of stressors build adaptive attitudes and beliefs that generalize to coping with new stressors (see Williamson & Dooley, 2001). Being able to find satisfying replacements for activities that have been given up may be as beneficial as not having to give up activities at all (Benyamini & Lomranz, 2004). Individuals who are able to continue engaging in valued activities cope well with life changes, avoid becoming depressed, and are physically healthier. They are also those who have high levels of social and personal resources.

One of the strongest and most consistent findings in health psychology research is that social support has powerful effects on both psychological and physical wellbeing (e.g. Cohen & McKay, 1983; Cohen & Wills, 1985) (see ‘Social Support and Health’). It is true that social network losses occur over the life span through death, relocation and retirement, but even among very old people, new relationships are formed to replace lost ones (Rowe & Kahn, 1998).

¹ Most of the data reported in this chapter are based on trends in the population of the United States. All industrialized countries are facing similar situations, however, and emerging nations may soon be dealing with even more extreme increases in the proportions of older adults in their populations (e.g. Hendricks, Hatch & Cutler, 1999). We have chosen to focus on US-based data, but the conditions in other countries are either highly analogous to, or even more critical than, indicated in this chapter.

Using data from the MacArthur Foundation Study of Ageing in America indicating that social networks remain remarkably stable in size throughout the life span, with the number of close relationships among non-institutionalized older adults equaling those of younger people, Rowe & Kahn (1998, pp. 159–60) concluded that ‘... the common view of old age as a prolonged period of demanding support from an ever-diminishing number of overworked providers is *wrong*’ [emphasis added].

Today’s ageing adults also have other social advantages. Many are utilizing technology and cyberspace to stay in touch with family members and friends via email. Baby boomers are more likely than their younger counterparts to access internet information and support from a wide spectrum of people who share their needs and concerns (Kiyak & Hooyman, 1999). Another important way to maintain social contact after retirement is through activities outside the home. When given the opportunity, large numbers of seniors are eager to do voluntary work or take on low-paid part-time jobs (e.g. working in fast-food restaurants and bagging groceries). Moreover, relative to previous cohorts, current and future generations will be more advantaged in the employment domain as they age. Not only are attitudes about older employees becoming more favorable, but also, because of post-baby boom declines in birth rates, the number of employable adults will decrease relative to the number of new jobs (DHHS, 1992; Kiyak & Hooyman, 1999). Consequently, older workers will become more valued and sought after, and those who do not feel ready to retire will be less likely to be compelled to do so. The standard retirement age is rising, based on observations that, in terms of health and life expectancy, age 70 today is roughly the equivalent of age 65 in the 1930s when Social Security was established in the USA (e.g. Chen, 1994). Although most individuals who have adequate (or better) financial resources will retire at the usual time or follow the trend toward early retirement (e.g. Quinn & Burkhauser, 1990), physically healthy elders will be able to choose whether or not they will continue to work.

The point here is that the sense of personal control is critical. People who feel in control, who can make choices about the important aspects of their lives, are both physically and psychologically healthier than are those who perceive that they lack personal control (e.g. Peterson *et al.*, 1988; Taylor, 1983; Taylor & Brown, 1988). Older adults are not unique in this respect. Regardless of age, people are motivated to exercise personal control (e.g. Schulz & Heckhausen, 1996). Although fully resolving the problems that go along with getting older (e.g. declines in health status) may not be possible, those who adapt well will shift their focus from actively trying to change the situation to managing stress-related emotional reactions by, for example, accepting the situation and continuing to function as normally as possible, thus maintaining a sense of personal control. Today’s trend toward less stigmatization of older adults offers seniors more choices, as do other societal changes. For example, economic prosperity has created financial security for many current and future older Americans, enabling them to exercise control over how they spend their retirement years.

Closely tied to the benefits of maintaining a sense of control is a substantial literature on the importance of being able to continue valued activities. Continuity in social roles and personal identities appears to be a critical factor in ageing successfully (e.g. Atchley, 1989; Benyamini & Lomranz, 2004; Calderon, 2001; Ogilvie, 1987;

Zimmer *et al.*, 1995). In response to earlier research (e.g. Parmelee *et al.*, 1991; Williamson & Schulz, 1992), Williamson and colleagues devised the Activity Restriction Model of Depressed Affect (ARMDA), defining activity restriction as the inability to continue normal activities (self-care, care of others, doing household chores, going shopping, visiting friends, working on hobbies, sports and recreation, going to work and maintaining friendships). The ARMDA proposes that activity restriction mediates the association between stress and mental health. In other words, major life stressors (e.g. age-related health problems) lead to poorer mental health outcomes because they disrupt normal activities. An extensive programme of research supports this model (Walters & Williamson, 1999; Williamson, 2000; Williamson & Dooley, 2001; Williamson & Schulz, 1992, 1995; Williamson *et al.*, 1994; Williamson & Shaffer, 2000; Williamson *et al.*, 1998; Williamson *et al.*, 2000b; also see Benyamini & Lomranz, 2004; Zeiss *et al.*, 1996).

As a comprehensive conceptualization of the physical illness–mental health association, the ARMDA posits that losses in physical functioning are not the only contributors to activity restriction. Rather, individual differences are important factors as well. For example, older adults tolerate similar levels of pain better than younger adults do (Cassileth *et al.*, 1984; Foley, 1985; Williamson & Schulz, 1992), a phenomenon most commonly attributed to the increased exposure to pain and disabling conditions that older people encounter. Indeed, less experience with pain and comprising health conditions is a better predictor of more activity restriction than is chronological age (Walters & Williamson, 1999; Williamson & Schulz, 1995; Williamson *et al.*, 1998). Thus, old age does not necessarily foster activity restriction and depression.

As noted previously, another important individual difference is social support. People with stronger social support networks cope better with all types of stressful life events (e.g. Mutran *et al.*, 1995; Oxman & Hull, 1997), and routine activities are facilitated by supportive others (e.g. Williamson *et al.*, 1994). For example, disabled elders will attend church and visit friends more often if other people help with walking, transportation and words of encouragement. However, social support, to a large extent, depends on personality variables (e.g. Williamson & Dooley, 2001). Those with more supportive social ties, less activity restriction and lower levels of depressed affect also have more socially desirable, proactive personality characteristics (e.g. Abend & Williamson, 2002; Williamson, 1998, 2000).

Dispositionally, some people cope in maladaptive ways across all situations throughout their lives. In contrast, there are those who consistently face the situation, rationally evaluate possible solutions, seek help and information as appropriate and, if all else fails, accept that the problem has occurred, deal with their emotional reactions (often with help from others) and make every effort to resume life as usual (e.g. Williamson, 2002). Indeed, research indicates that numerous personality traits influence adjustment to major life stressors, including the declines in physical functioning associated with advancing age. To give just a few examples, people low in dispositional optimism do not cope effectively or adjust well to stress (e.g. Abend & Williamson, 2002; Carver *et al.*, 1993) and are more vulnerable to activity restriction (Williamson, 2002). High levels of neuroticism are related to a maladaptive coping style (e.g. McCrae & Costa, 1986) that may include foregoing

pleasurable activities. When faced with disrupting life events, individuals who are less agentically oriented and do not have a strong sense of mastery will have more difficulty finding ways to avoid restricting their rewarding activities (e.g. Femia *et al.*, 1997; Herzog *et al.*, 1998). In addition, those who are low in the dispositional predilection to hope for positive outcomes are less likely to conceptualize ways to continue (or replace) valued activities or to persist in their efforts to do so, particularly when pathways to achieving these goals are blocked (e.g. Snyder, 1998). Although research in this area is in its infancy, personality factors should not be ignored, particularly when the goal is to identify those who are at risk for restricting their activities, adapting poorly to declines in physical functioning and in need of early intervention.

Clinical implications

In the ARMDA, coping with stress is posited to be a complex, multi-faceted process that is influenced by numerous factors (see also 'Coping'). With increasing age, decline in physical functioning may mean that coping successfully requires replacing previously adaptive strategies with ones better suited to the individual's own physical limitations. Therefore, worthwhile interventions could focus on helping elders shift from problem-focused to emotion-focused coping mechanisms (e.g. Costa & McCrae, 1993; Schulz & Heckhausen, 1996), but there may be better options.

Specifically, by acknowledging that depressed affect is a function of restricted activities, interventions can be designed to reduce both activity restriction and depression. Efforts to increase activity might take three (and, probably, several more) forms. First, by taking into account both personality and social factors, practitioners should be able to target the individuals most at risk for activity restriction and depression. Second, they should carefully consider the multiple reasons that activities have become restricted and design their interventions accordingly. Third, because finding satisfactory replacements for lost activities promotes wellbeing (Benyamini & Lomranz, 2004; Searle *et al.*, 1995), programmes should be targeted toward identifying manageable activities and available resources that engage ageing adults in pastimes which meet their specific interests and needs.

Social support, like personality traits and experience with illness, interacts with physical functioning to influence normal activities. With more supportive social support networks, activity restriction can be reduced (Williamson *et al.*, 1994). Maintaining usual activities, in turn, reduces the possibility of negative emotional responses and further decrements in health and functioning. Thus, identifying community-residing older adults with deficits in social support is a good starting point for intervention (see 'Social Support Intervention'). Before intervening, however, we need to specify which aspects of social support are absent or most distressing and target treatment accordingly (Oxman & Hull, 1997). Some older people may be depressed simply because they do not have enough social interaction. Others may have concrete needs for assistance that are not being met (e.g. getting out of bed or grocery shopping). Still others may be exposed to exploitative or abusive behaviour (Cohen & McKay, 1983; Suls, 1982; Williamson *et al.*, 2000b; Wortman, 1984).

Conclusion and directions for future research

No solution is in sight for the fact that, with age, physiological systems slow down (e.g. Birren & Birren, 1990; Whitbourne, 2005), but the best option appears to be remaining active for as long as possible. Traditional attitudes and the projected increase in elderly people have led scholars, commentators and policy-makers to conclude that society is about to be overwhelmed by people who are disabled and require constant care. With fewer children per capita than previous generations, a major concern is that as the baby boomers age, there will be fewer adult children available to provide care, creating a demand for formal care that may severely (if not, impossibly) tax societal resources. As with any major demographic shift, there are problems to be addressed. Substantial numbers of older adults will be disabled, socially isolated and depressed, but the same is true for other age groups as well.

On the other hand, research indicates that, more than ever before, ageing adults are and will be physically, psychologically and socially healthy. Older adults are remarkably skilled in making gradual lifestyle changes to accommodate diminishing physical abilities (e.g. Williamson & Dooley, 2001). Simply directing them towards the numerous resources available to elders (e.g. senior centre activities) can help some, but others may need psychological intervention to help them make adjustments that maximize their ability to remain engaged with life. From accumulating evidence, it is now clear that people consistently become depressed in the wake of physical illness and disability largely because these circumstances disrupt their ability to go about life as usual (see Williamson, 1998, 2002, for reviews). Lack of experience, less social support and personality variables all contribute to the ability to cope with major life changes (e.g. Walters & Williamson, 1999; Williamson, 1998, 2002; Williamson & Schulz, 1992, 1995; Williamson *et al.*, 1998).

In their acclaimed book, *Successful ageing*, Rowe and Kahn (1998) proposed that there are three components of successful ageing: (1) avoiding disease; (2) engagement with life; and (3) maintaining high cognitive and physical function. These factors are closely aligned with and, perhaps, subsumed in the ARMDA. First, avoiding disease is largely a function of routine activities. Physical exercise and temperance in detrimental behaviours (e.g. smoking, drinking alcohol, eating a high fat diet) are, under ideal circumstances, routine activities that promote better physical health, less disability and greater longevity (e.g. Cohen *et al.*, 1993; McGinnis & Foege, 1993). Second, 'engagement with life' (Rowe & Kahn, 1998) is virtually synonymous with continuing valued activities. People who feel engaged with life are those who are involved in personally meaningful activities, but what qualifies as 'meaningful' will vary according to each person's history. In the ARMDA, it is postulated that continuing to be involved in personally relevant activities (whether intellectual, physical, or social) is what matters most.

Finally, Rowe and Kahn (1998) advocated maintaining high levels of physical (and cognitive, see 'Age and Cognitive Functioning') functioning as the third key to ageing successfully. When confronted with age-related declines in physical functioning, the telling factor may well be the extent to which a semblance of normal activities can continue or be replaced in a satisfactory fashion (e.g. Benyamini and Lomranz, 2004). What does this mean when, for example, disability precludes playing several sets of tennis every day? If this activity was driven by love of the sport, then the ageing tennis addict can still

participate by watching matches or, even better, by coaching others in the finer aspects of playing the game.

The ARMDA, like other stress and coping models (e.g. Lazarus & Folkman, 1984), implies that the causal path is unidirectional – e.g. that age-related declines in physical functioning cause activity restriction which, in turn, causes negative affect. Without doubt, this is an inadequate representation. Consider pain and depression as an example. Depression can result from the inability to deal with chronic pain. Conversely, substantial research suggests that depression fosters higher levels of reported pain (e.g. Lefebvre, 1981; Mathew *et al.*, 1981; Parmelee *et al.*, 1991). As clinicians have long known, being depressed causes people to forego many of their previous activities. In fact, one of the better behavioural treatments for depression is to motivate patients to become more socially and physically active (e.g. Herzog *et al.*, 1998). In a reciprocal fashion, for both physiological and psychological reasons, inactivity also increases level of experienced pain (e.g. Williamson & Dooley, 2001).

Controlled experimental studies will help clarify previous results by showing that strategies designed to increase activity level will, in fact, improve wellbeing. In addition, identifying differences between people who will tolerate discomfort in order to continue engaging

in meaningful activities and those who will not voluntarily make such efforts under similar levels of discomfort will bring us closer to successful intervention programmes.

Contrary to common belief, growing old in the twenty-first century is not likely to be an onerous experience for many people. Those who age well feel in control of at least some of the important aspects of their lives and maintain (often with the help of others) the activities they value most. The association between decrements in physical functioning and adjustment is multifaceted and complex. In addition, because they vary as widely as their younger counterparts, lumping older adults into a homogenous group is inappropriate.

At this point, we know relatively little about what really happens when people are faced with the decrements in physical functioning that accompany growing old. Consequently, there are no easy answers about the best ways to intervene. Nevertheless, the ARMDA provides a foundation for intervention and further research. If people can continue to engage in at least some of their valued activities, they should be physically and psychologically healthier and depend less on others for assistance. Indeed, ageing well appears to revolve around maintaining participation in valued, meaningful activities despite losses in physical functioning.

University of Georgia

Ageing and cognitive functioning: an overview

Attitudes about ageing reflect many negative stereotypes about the intellectual prowess of our senior citizens (Center for the Advancement of Health, 1998). Are older people as cognitively deficient as is commonly assumed? Are they significantly less capable than middle-aged or younger adults of profiting from classroom instruction, solving everyday problems such as remembering to turn off the oven after removing a roast, or learning to operate such new technologies as computers, DVD players, or ATM machines?

Study of the abilities to learn, remember, and solve problems has a long history in psychology and is arguably the most thoroughly investigated aspect of adult development and ageing (Siegelman & Rider, 2003). One reason for this emphasis is that cognitive functioning in adulthood has so many important implications for the quality of ordinary people's lives. Furthermore, cognitive functioning can play a major role in how people feel about themselves as they age. Middle-aged adults occasionally claim that they have experienced a 'senior moment' after forgetting someone's name, their own telephone number, or a step in a well practiced procedure such as recording a programme on their VCR. Although such comments may be offered in a humorous light, they also may reflect a deep-seated concern that many middle-aged and older adults have about losing their memories (Whitbourne, 2005) (see 'Dementias').

Indeed, older adults have reasons for suspecting that their cognitive powers are declining. With age, there is a slowing of the rate at which we process information, a lessening of the amount of information that we can keep in mind to solve problems, and even a reduction in ability to inhibit distractions and focus on the most pertinent information for problem-solving, changes that many have attributed to an ageing nervous system (Gaeta *et al.*, 2001; Persad *et al.*, 2002; Salthouse, 1996). However, other researchers favour a contextualist approach to ageing and cognitive functioning. They are not convinced that there is a universal biological decline in basic learning, memory and problem-solving capabilities, noting instead that older people's cognitive performances depend very heavily on such individual characteristics as the person's goals, motivations, abilities, and health, characteristics of the task at hand and characteristics of the broader context in which the task is performed (Siegelman & Rider, 2003). In a word, older adults can compensate for many of their shortcomings, learn new things and learn them well (e.g. Schaie, 1996; Volz, 2000). Moreover, whether older adults believe that they can learn, remember and solve problems is crucial to their success in doing so (Artistico *et al.*, 2003; Cavanaugh, 1996). In practical terms, the contextualists believe that ageing adults bear some responsibilities for preventing (or

slowing) cognitive decline by emphasizing their strengths and expertise and continuing to engage in cognitively challenging activities (Williamson, 2002).

Research on cognitive ageing

Age and intelligence

When people think about intelligence, they have an idea that it represents a person's ability to think and solve problems. Psychological definitions of intelligence come close to this simple idea of intelligence-as-mental-ability. Spearman (1927) conceptualized intelligence as a general factor (*g*) that influences performance on all mental tests. By contrast, Thurstone (1938) argued that intelligence is comprised of seven 'primary mental abilities' (PMAs): verbal meaning, word fluency, number, spatial relations, general reasoning, perceptual speed, memory) that were said to be separate, distinct and cover all possible aspects of intelligence. More recently, Cattell (1963, 1971) claimed that the PMAs can be clustered into two basic sets of abilities. 'Fluid intelligence' refers to the ability to solve abstract problems that are free of cultural influences (e.g. word fluency, reasoning, spatial relations). By contrast, '*crystallized intelligence*' refers to the ability to solve problems that depend on knowledge acquired as a result of schooling or other life experiences (e.g. numerical reasoning, verbal meaning, tests of general knowledge).

Age-related changes in intellectual functioning were the focus of Schaie's (1983, 1996) Seattle Longitudinal Study. In 1956, participants aged 20–72 were tested to assess five PMAs and retested seven years later on the same abilities. In 1963, 1970, 1977 and 1984, new samples of 20–70-year-olds were given the same tests and retested periodically. This sequential study made it possible to determine how the performance of particular individuals changed over time (longitudinal comparisons) and to compare the performance of people of a particular age (e.g. 70 in 1956) with different cohorts of people who were the same age (70) in 1963, 1970, 1977 and 1984, thus providing ample information about different cohorts, as well as longitudinal data on some participants for as long as 28 years.

Several important findings emerged from this study. First, cohort effects implied that when an individual was born influences intellectual performances as much as does chronological age. Specifically, younger cohorts outperformed older cohorts on most tests. The only exception was numerical ability, on which older cohorts performed better than younger cohorts. Judging from these findings, young and middle-aged adults today can look forward to better intellectual functioning in old age than their grandparents.

Second, longitudinal data revealed that age-related patterns of performance vary for different abilities. Fluid intelligence declined earlier and more steeply than crystallized intelligence. Nevertheless, scores on fluid intelligence remained fairly stable until the late 60s, showing no meaningful decline until the late 70s and 80s. Indeed, a recent longitudinal study of relatively healthy 78–100-year-olds confirmed these patterns, revealing that the ‘crystallized’ ability of general knowledge did not show a meaningful decline until the 90s (Singer *et al.*, 2003). So adults may lose *some* of their ‘fluid’ abilities to grapple with novel problems by age 60–70 but will generally retain, well into old age, the crystallized abilities that support solving most practical problems.

One final message of the longitudinal studies: declines in intellectual abilities are not universal. Only 30–40% of the 81-year-olds in Schaie’s (1994) study had experienced a significant decline in intellectual ability in the past seven years and declines among healthy participants, particularly in crystallized abilities, often are not pronounced until the mid-80s (Singer *et al.*, 2003). Furthermore, although few 81-year-olds in the Seattle study maintained all five mental abilities, almost all maintained at least one ability over time, and about half maintained four of the five abilities (Schaie, 1989). Clearly, individual variations in intellectual functioning among older adults are large, and anyone stereotyping elders as intellectually deficient is likely to be wrong most of the time.

Age and information processing

Information processing researchers regard human cognitive functioning as comparable to that of computers. ‘Data’ are entered into the brain through various sensory channels where they either disappear or are processed further. Should we attend to input, it passes into working memory (WM), a limited capacity store that holds information temporarily until we can operate on it. WM is where all conscious mental computations are thought to occur. For information in WM to be remembered for any length of time, it must be moved to long term memory (LTM), a relatively permanent store of information that represents what most people think of as memory. Finally, information in LTM must be retrieved to WM before it truly can be ‘remembered’ or used for some other purpose, such as problem-solving.

Age and processing speed

According to Salthouse’s (1996) General Slowing Hypothesis, age-related declines in cognitive function are largely related to a general decrease in the speed of information processing within an ageing nervous system. Processing speed is assessed by reaction time tasks in which participants attend to and respond appropriately to information as quickly as possible. One example is the Digit Symbol Substitution Test (DSST), consisting of a reference table with a code illustrating how particular digits are paired with particular hieroglyphic symbols. Below are rows of boxes with a digit in the top section and an empty space in the bottom section of each box. One’s score is the number of appropriate hieroglyphics inserted into the empty boxes in 90 seconds. The greater the number of correct symbol substitutions, the higher one’s processing speed.

A recent review of 141 DSST studies that included more than 7000 adults aged 18–79 revealed a clear association between age and processing speed: 60–70-year-olds attained much lower scores on the DSST than did 18–30-year-olds (Hoyer *et al.*, 2004). These findings are consistent with a large body of data from studies employing other reaction time tasks indicating that processing speed peaks in early adulthood and then declines slowly over the adult years (Frieske & Park, 1999; Kail & Salthouse, 1994). Age-related sensory limitations (e.g. visual deficits), a gradual slowing of neural transmissions, or both, may underlie this decline in processing speed. If older adults have a sluggish ‘computer’ they may simply not be able to keep up with the processing demands of complex intellectual tasks to the point that they eventually evidence declines on tests of primary mental abilities.

Age and working memory

Another possible contributor to age-related declines in cognitive functioning is that WM capacity declines with age. Capacity of WM is assessed with memory-span tasks, measures of the number of unrelated and rapidly presented stimuli (e.g. digits) that one can recall when prompted to do so. WM capacity generally increases until middle age and slowly declines thereafter (Park *et al.*, 2002; Swanson, 1999). Moreover, adult WM capacity predicts performance on a wide variety of cognitive tasks (Engle *et al.*, 1999; Whitbourne, 2005). Older adults, it seems, require more limited WM space to carry out such basic processes as recognizing and storing stimuli, thus leaving less space for other purposes, such as reasoning or executing other cognitive operations. Indeed, differences between older and younger adults are most apparent on cognitive challenges that tax WM by requiring effortful thought or strategizing, and older adults struggle when they must devote a great deal of effort to carry out several activities at once. For example, trying to memorize a list of words (a mentally effortful activity requiring strategies such as rehearsal) while walking is much more difficult for older adults than for middle-aged or younger adults (Li *et al.*, 2001; Lindenberger *et al.*, 2000).

Age-related declines in WM functioning may be related to reduced processing speed. The older adult (who processes more slowly) may simply run out of time while performing WM tasks and be unable to complete the computations necessary to solve problems or attend to and store new input relevant to the task at hand (Salthouse, 1996).

An alternative explanation for the increasing inefficiency of WM in older adults stems from Hasher and Zack’s Inhibitory Deficit Hypothesis (Hasher *et al.*, 1999). According to this view, efficient use of WM requires an individual to inhibit task-irrelevant information by preventing it from entering WM or by removing from WM information that is no longer of use. Consistent with this model, older adults are more likely than middle-aged or younger ones to activate irrelevant information and are less efficient at suppressing such information once it enters WM (Bowles & Salthouse, 2003; Hedden & Park, 2001; Malstrom & LaVoie, 2002). Thus, ‘mental clutter’ may overwhelm WM, resulting in a decline in WM capacity with age and interfering with retrieval of task-relevant material from LTM necessary for efficient problem solving. Cognitive neuroscientists have identified deficits in prefrontal cortical regions of the brain

that suggest a biological basis for the inhibitory deficiencies of older adults (Braver *et al.*, 2001; Simensky & Abeles, 2002).

Age, learning and long-term memory

Older adults learn new material more slowly and sometimes do not learn it as well as young and middle-aged adults do, and they may not remember what they have learned so well (Howard *et al.*, 2004; Whitbourne, 2005). However, noticeable declines in learning and memory rarely occur until the late 60s, and the memory of 'young-old' adults (60–70 years) is more similar to that of 18–34-year-olds than to that of 71–82-year-olds (Cregger & Rogers, 1998). Moreover, not all older people experience noticeable learning and memory difficulties, and not all kinds of cognitive tasks cause older people difficulty.

Consider a sample of the weaknesses and, by implication, strengths of older adults. First, owing largely to the slowing of cognitive processing and reduction of WM capacity, older adults may need to go through new material more times than younger adults to learn it equally well – or need more time to respond when memory is tested. Thus, they show larger learning and memory deficits on *timed* as compared with *untimed* tasks (Sigelman & Rider, 2003).

Second, older adults fare especially poorly compared with younger ones when material to be learned and remembered is abstract or unfamiliar and cannot be tied to their existing knowledge. By contrast, older adults often equal or exceed the performance of younger adults when practical challenges are more familiar to them than to their younger counterparts (Artistico *et al.*, 2003; Barrett & Wright, 1981). As we have noted, such crystallized abilities as vocabulary and general knowledge continue to build well into old age (Schaie, 1996; Verhaeghen, 2003) and are slow to decline (Singer *et al.*, 2003). So, for many everyday learning, memory, or problem-solving challenges, older adults, by virtue of their greater knowledge base, have expertise that may compensate for their slower processing and less efficient WM and permit them to equal or exceed the performance of younger counterparts. By contrast, these same information-processing limitations place them at a strong disadvantage, relative to younger adults, on abstract, unfamiliar, or seemingly meaningless cognitive tasks.

Similarly, older adults are likely to be at a disadvantage when challenges require unpracticed skills that they rarely use as opposed to skills that are well-practiced and automatized (i.e. applied without conscious mental effort). Thus, it is much easier for older adults to remember whether a sentence makes sense in the context of what they have just read (an automatized skill for readers) than to judge whether a specific sentence has appeared in a story (requiring effort and skills seldom used outside of school; Reder *et al.*, 1986).

One interesting idea about ageing and memory is the Environmental Support Hypothesis (ESH): age differences in memory are most apparent when tasks provide little context or support and demand high levels of effortful processing (Craik, 1994; Naveh-Benjamin *et al.*, 2002). For example, older adults do much worse than younger adults on tests of free recall of previously presented material but no worse (or only slightly worse) on tests of recognition memory, which simply require the participant to say whether or not an item has been presented before. According to ESH, these findings support the notion that recognition tasks

provide more contextual support and require less effortful processing than recall tasks (Whitbourne, 2005).

Older adults are also more likely to be disadvantaged on tests of explicit memory, which require effortful cognitive processing to encode, store, and retrieve information (e.g. lists of words) than implicit memory, or recall of information acquired unintentionally and retrieved automatically. Even an 85-year-old might demonstrate excellent implicit memory about how to drive a car or tie his or her shoe (implicit procedural memory), but he/she may have a very difficult time, compared with a young adult, consciously learning and remembering the list of steps one must perform to successfully complete either operation (Mitchell & Bruss, 2003; Whitbourne, 2005).

Prospective memory (PM) is particularly relevant to older adults when it comes to health regimens. PM requires one to retrieve from LTM an intention to perform an action (e.g. taking prescribed medication at noon). Because PM requires effortful processing to form intentions and later retrieve and implement them, we might expect older adults to perform worse than younger ones on such challenges. This is precisely what one recent review of the literature found for all laboratory-based measures of PM. The caveat, however, was that older adults outperformed younger adults on simple, everyday PM challenges (Henry *et al.*, 2004). Older adults may be less challenged by meaningful real-world PM tasks if they develop strategies to compensate for the effort required to retrieve an intention by creating their own 'environmental supports' (e.g. a post-it note to go to the dentist at 2:00 p.m.).

Overall, these findings suggest that older adults seem to have more difficulty with tasks that are cognitively demanding – those that require speed, grappling with unfamiliar material, unexercised skills, and effortful strategizing to learn and remember – rather than implicit and automatic processes. Nonetheless, older adults often can compensate for their processing deficiencies by relying heavily on their crystallized knowledge (expertise) and other ploys (e.g. external memory aids) to cope quite successfully with most everyday cognitive challenges.

Explaining age-rated changes in cognition

Throughout, we have mentioned such factors as a gradual slowing of information processing, a lessening of WM capacity, and a growing inability to inhibit attending to irrelevant information, as well as (yet poorly understood) neurological and sensory correlates of these events, as likely contributors to age-related declines in intellectual skills and learning/memory performance. Yet, recall that there are tremendous individual differences in the cognitive functioning of older adults, and these variations provide some clues about factors influencing the rate at which cognitive functioning declines with age.

Health and cognitive functioning

Poor health is one of the best predictors of cognitive decline among older adults. Aside from the various forms of dementia that have a devastating impact on intellect and information processing, people with cardiovascular diseases or other chronic illnesses show steeper declines in mental abilities than their healthier peers. Indeed, one longitudinal study found that 78-year-olds with hypertension had more white matter abnormalities in the brain than disease-free age

mates and that these abnormalities were associated with lower levels of functioning, even after controlling for levels of intellect participants displayed earlier in life (Deary *et al.*, 2003). Diseases often contribute to a rapid decline in intellectual and information-processing capabilities in the years immediately preceding death (Johansson *et al.*, 2004), a phenomenon often labeled 'terminal drop'. Maybe there is something to the saying 'Sound body, sound mind.' (See also 'Ageing and health').

Lifestyles and cognitive functioning

Cognitive declines among the oldest-old (those 85 and older) often are more closely related to biological than to environmental factors (Singer *et al.*, 2003). However, twin studies reveal that environmental factors are more important than genes and genetically influenced characteristics for predicting age-related cognitive declines of 70–84-year-olds (Johansson *et al.*, 2004; McGue & Christensen, 2002). What environmental factors might be implicated?

Schaie's Seattle study revealed that elders showing the largest intellectual declines were widows living unstimulating lifestyles, residing alone, engaging in few activities and remaining seemingly disengaged from life. By contrast, elders who maintained (or improved) their capabilities tended to have above average socioeconomic status and mentally active lifestyles. Similar relations between the intellectual complexity of elders' environments and maintenance of intellectual performance have been demonstrated in Chinese samples (Schaie *et al.*, 2001) and in a variety of other contexts (Whitbourne, 2005) (see 'Socioeconomic status and health').

Clearly, these findings are consistent with the 'use it or lose it' rule that is widely touted to people hoping to maintain their muscular or sexual prowess. Simply stated, we are likely to maintain our intellectual faculties longer if we exercise them. Even reading books, working crossword puzzles, or learning to operate new technologies can help build new skills or maintain old ones (Rogers *et al.*, 1996). Apparently, the nervous system remains plastic (changeable) over the life span, enabling elderly individuals to benefit from intellectual stimulation, maintain the skills most relevant to their everyday activities and compensate for the loss of unpracticed abilities (Schaie, 1966, 1983). By contrast, even eminent college professors are at risk of declining intellectual performance if their retirement activities are far less stimulating than their working lives (Christensen *et al.*, 1997).

Self-efficacy and cognitive functioning

Finally, older people may fare worse than younger adults on many cognitive challenges, particularly abstract laboratory tasks, because they feel less self-efficacious about their abilities. Yet, on tasks for which elders feel more efficacious, they work as hard as, or harder than, younger adults and post higher levels of performance (Artistico *et al.*, 2003).

The implication? Older adults who feel mentally efficacious are less likely to display meaningful learning, memory and intellectual deficiencies later in life (Cavanaugh, 1996). However, it is not necessarily adaptive for seniors to ignore signs of mental decline and assume that they can do anything; motivation to maintain cognitive skills may be critical. Schaie (1983, 1996), for example, reported that elders who were most concerned about and who overestimated their cognitive

declines were the ones most likely to continue to engage in cognitively challenging activities that fostered maintaining their intellectual prowess over time (see 'Self-efficacy and health behaviour').

Conclusions and implications for intervention

Clearly, most older adults are not the mental incompetents that stereotypes about ageing suggest. With age, there are some undeniable losses in cognitive processes such as fluid intelligence, speed of processing, and WM capacity/efficiency. However, many healthy older adults, particularly those who feel mentally self-efficacious and who continue to engage in intellectually challenging activities learn to rely on their crystallized intellect and find ways to automatize cognitive processes to master everyday problems, thereby maintaining their cognitive prowess until very late in their lives.

The continuing plasticity of the ageing nervous system has prompted cognitive ageing researchers to design a variety of interventions to slow (or even reverse) declines in cognitive functioning. Early studies from the 1970s and 1980s revealed that, given practice and training in cognitive strategies, older adults could improve performance on such fluid intellectual abilities as spatial and inductive reasoning (e.g. Plemons *et al.*, 1978; Willis *et al.*, 1981; see also Saczynski *et al.*, 2002). Moreover, Schaie and Willis (1986; Schaie 1996) reported that about 40% of their 64–95-year-olds who had evidenced cognitive decline, through training, restored their performance levels of 14 years earlier, before decline set in, and these gains were still evident seven years later. Other investigators have shown clear training effects among older adults for such cognitive activities as memory and timed (speeded) tasks (Whitbourne, 2005).

Knowing why older adults struggle with particular challenges is the key to designing effective interventions. Liu and Park (2004), for example, reasoned that medical regimens presenting complex PM problems (e.g. remembering to monitor blood glucose four times daily) could be made easier for their 60–81-year-old participants if their intentions could be activated and implemented automatically rather than through effortful cognitive processes. In this study, some participants formulated a specific plan that tied monitoring to particular activities that would automatically activate the intention (e.g. monitor just before lunch, at mid-afternoon before walking the dog, just before dinner, just after the evening news). Others simply verbally rehearsed the intention to monitor at noon, 1:30 p.m., 6:00 p.m. and 7:30 p.m. A third group spent an equal amount of time deliberating the pros and cons of monitoring. Results revealed that participants whose intentions had been automatically linked to daily activities were twice as likely to follow the regimen as were those in the other two groups who had to expend substantial mental effort to form, retrieve and implement their intentions to monitor.

The larger messages? You can teach old dogs new tricks – and retrain them old tricks – in very little time. These interventions cannot restore cognitive function in elderly people with dementia or in old-old adults who have experienced significant neurological ageing. But they do attest to the plasticity of an otherwise healthy nervous system well into late life and the ability to maintain or improve cognitive functioning by reviving unused skills or finding ways to automatize the processes older adults can use to master everyday challenges.

Ageing and health

Elaine A. Leventhal

UMDNJ-Robert Wood Johnson Medical School

Although there have been many theories advanced to account for ageing with none gaining wide acceptance, some generalizations are agreed upon by most investigators. The life span is represented by growth and development and then decline or senescence (normal ageing) over time. These are not static stages but represent the continuously changing processes of the life cycle. Senescence results from declines in actual numbers of active metabolic cells and cellular functions because of the accumulation of environmental exposures and behaviours coupled with genetic vulnerabilities over time (Jazwinski, 1996; Kirkwood, 1996).

However, individuals also have an innate and unique genetic or biological plasticity that is coupled with adaptive or coping strategies for the management of ageing-related somatic changes. Thus ageing also produces increasing heterogeneity between individuals as they age. Coupled with this heterogeneity and particular health behaviours can be seen differential rates of decline and change among cells, tissues and organ systems, so that individuals will age at different rates with some biologically ‘old’ at 45, while others can be vigorous and ‘young’ at 75.

General ageing

Generally, with senescence, there is a quantitative loss of tissue mass as well as functional decline. An example of functional changes can be seen in the timing of circadian rhythms that affect temperature control, sleep patterns and the secretion of hormones such as cortisol, as well as growth hormone, the gonadotropins,

thyrotrophin and melatonin. The significance of these latter changes is not yet well understood, yet it is interesting to speculate about them in the light of the reports from the MacArthur studies on successful ageing which showed that individuals with higher nocturnal secretion of cortisol and catecholamines, and higher systolic blood pressures were more likely to show greater declines in cognitive and physical function during the follow-up period of three years (Rowe & Kahn, 1998).

Of the organ systems, the normal kidney, lung and the skin age much more rapidly than the heart and liver in both sexes, while the musculoskeletal system and the gonads decline at different ages in males and females (Finch & Schneider, 1985; Kenney, 1989). There is an 80% decrease in overall muscle mass and an average of 35% increase as well as a significant redistribution of body fat. Fat deposition accumulates around and within the viscera while there is a loss of fat on the surface. Thus older people lose ‘insulation’ and are more sensitive to extremes of ambient temperature than are younger people.

Cardiovascular system

The age-related decline in the cardiovascular system may be critical for decreased tolerance for exercise and loss of conditioning, and the major factor contributing to feelings of agedness and overall decline in energy reserve. However, there is much more than heart and blood vessel deterioration in the loss of energy reserve. There is a gender-specific dependency as well, on the muscles and skeleton

and the lungs. Changes occur in the heart chambers, and the blood vessels and valves. With time, the heart muscle thickens, the ventricular cavities become smaller and the amount of blood pumped per contraction decreases. Heart rate also slows with time as cells in the sinus node decline by up to 90%. The decrease in rate may be related to 'down regulation' or decreased responsiveness of adrenergic receptors on heart muscle even though synthesis and clearance of epinephrine does not change. Thus, the maximum heart rate in response to increased activity and responses to stress demands diminishes (Lakatta, 1987; Marin, 1995).

Blood vessels narrow and become more rigid contributing to the slow elevation in blood pressure with ageing in the absence of cardiovascular disease. Women appear to enjoy a slower rate of progression of cardiac disease before the menopause with a lower incidence of coronary artery disease in pre-menopausal women. (Anderson *et al.*, 1995). However, cardiovascular disease becomes the major killer of older post-menopausal women, can present with atypical symptoms and can be more lethal than in men often with delay in seeking care because of stereotypic or lay perceptions of what heart disease and acute attacks should feel like (see 'Symptom Perception' and 'Delay in Seeking Help').

Respiratory system

There is an even more rapid rate of functional decline in all parts of the respiratory system. This includes lung tissue as well as the chest cavity, with its muscles and the ribs and vertebral column. There is less work capacity as all the types of muscles age in bronchi, the diaphragm and chest wall. There are clear gender differences in thoracic cage ageing. This may result from bone and muscle mass losses that are greater in females and cause diminished exercise capacity as well as a greater vulnerability of and a greater possibility for immobilization. Within the lung itself, the alveolar or air sac septae are the exchange sites for the gases, oxygen and carbon dioxide. Old lungs have scattered areas of scarring and damage to the septae that interfere with gaseous exchange. These manifestations of 'senile' emphysema may limit the amount of exercise and energy that can be expended even more than functional changes in the cardiovascular system described previously (Rossi *et al.*, 1996).

Moreover, it is difficult to determine how much of the respiratory functional decline that is observed is age-related and how much is environmentally and behaviourally induced since most individuals are exposed to some degree of air pollution and cigarettes or other inhaled substances abuse exaggerates the ageing changes. Smoking produces scarring or fibrosis, increased secretions and an increased rate of chronic infection. The cough is less vigorous and clearance of foreign particles is slower and bronchitis and emphysema result.

Musculo-skeletal system

Skeletal ageing probably generates most of the common symptoms responsible for limitations of recreational activities and functions of daily living as well as restrictions in job related activities; the joint and muscle aches and stiffness attributed to 'getting old'.

Bones thin at a rate of 0.8–1.0%/yr over the lifespan for both men and women, but there is acceleration in the rate for females around the menopause, of between 8–10%/yr. Thus post-menopausal

women are more vulnerable than males of the same age to pathologically thin bones or to osteoporosis which can cause fractures of the vertebral spine. While both men and women are at risk for fractures of the long bones, women are fracture prone 10 years earlier than men of the same cohort. (Kenny, 2000; Raiz, 1997). Smoking changes these fracture risk odds for men and women because cigarette smoking is also toxic for bone growth cells and is a major cause of osteoporosis in both male and female smokers.

Liver

The liver has remarkable regenerative capacity but undergoes modest decreases in weight and size. Hepatic blood flow shows a 1.5% fall/yr so that there will be a 50% reduction in flow over the lifespan. All ingested drugs as well as metabolites absorbed from the small intestine and stomach, pass through the liver; some are unchanged while most undergo metabolic detoxification by microsomal enzymes into water-soluble substances for renal excretion. With decreases in liver mass, losses in this critical enzymatic function (primarily Cytochrome P-450) are seen and, along with a decrease in blood flow, there is a decrease in the rate of Phase I biotransformation, particularly in men. These functional changes result in a prolongation in the half-life of many of the metabolites and drugs that are inactivated by the liver. Conjugation or Phase II remains largely unchanged.

Kidney

All kidney functions deteriorate with age because of a steady loss of nephrons over time. Thus there are declines in filtration, active tubular secretion and re-absorption and passive tubular diffusion. This decline in renal function has serious implications for drug prescribing patterns (Kenney, 1989; Finch & Schneider, 1985) since the kidneys serve as the major excretion site for metabolites and drugs after transformation through the liver and renal insufficiency or functional loss prolongs the body's exposure to drugs and toxic substances as well as digestive by-products.

Immune system

With increasing age, the total number of immune cells changes minimally, but the functional, or qualitative changes in immunity with age are much more notable than the quantitative ones.

Investigators in the field of physiological psychology have described complex and direct links between the central nervous system and the immune system. The neurohumorally mediated effects of stress on the immune system have also been well demonstrated in carefully controlled experiments with rodents and primates (Borysenko & Borysenko, 1982; Rosenberg *et al.*, 1982). Studies in humans have demonstrated similar effects, though it is impossible to achieve the same degree of control as in the animal studies. Health surveys have reported clusters of illness (from the common cold to cancer) occurring around the time of major life changes (Minter & Patterson-Kimball, 1978). Other studies have found strong correlations between loneliness and decreased proliferative responses of lymphocytes to mitogens, decreased natural killer cell activity and impaired DNA splicing and repair in

lymphocytes (Glaser *et al.*, 1985). Healthy adults over the age of 60 years with a strong social support system (i.e. a close confidant/e) have significantly greater total lymphocyte counts, and stronger stimulus-induced responses than those without such a relationship (Thomas *et al.*, 1991). Persons experiencing the stress of care giving for a spouse with dementia have poorer antibody responses to influenza vaccination than matched control subjects, and their lymphocytes make less interleukin 1 β and interleukin 2 when stimulated with virus in vitro (Kiecolt-Glaser *et al.*, 1996). These caregivers also display delayed wound healing after punch biopsy of the skin compared to non-care giving, age-matched controls (Kiecolt-Glaser *et al.*, 1995). The mechanisms that underlie such associations, and the modulating effects of age, are not fully understood but are clearly important for maintaining full independent function (see also 'Psychoneuroimmunology', 'Stress and Health' and 'Social Support and Health').

The nervous system

Given the complexity of the nervous system, it is to be expected that there will be significant variability in the functional changes that mirror anatomic changes of ageing. In general, these descriptions are based on cross-sectional studies and are thus open to criticism, but it appears that functions that change very minimally from ages 25 to 75 include: vocabulary, information accrual and comprehension and digit forward pass. There are subtle changes in hand two point discrimination, and minimal touch sensation loss in the fingers and toes. A greater than 20% decline is seen in 'dexterity areas' including hand- and foot-tapping and tandem stepping. Greater decrements are seen in the ability to rise from a chair; however, these tasks must reflect muscle as well as nervous system function and may be confounded by joint disease. Arthritic changes in the hands will produce difficulty in 'dexterous' activities such as cutting with a knife, zipping and buttoning. Thus, studies of function using ADL types of behaviour may significantly confound ageing with chronic illness.

Recent research has shown that there is much less neuronal loss than had previously been assumed, although brain weight declines significantly with age and blood flow is decreased by about 20% in the absence of vascular disease. In addition, decrements are seen in cerebral autoregulation. Cells disappear randomly throughout the cortex, but in other brain areas, there is clustered loss, i.e. the disproportionately greater loss of cells in the cerebellum, the locus ceruleus and the substantia nigra. The hypothalamus, pons and medulla have modest age-related losses (Anglade *et al.*, 1997). These may be responsible for the altered sleep patterns characteristic of the elderly, and disturbances of gait and balance. The alterations in sleep patterns are a source of much concern for up to 50%

of persons aged 60 and older with 12% of an epidemiological sample of persons over 65 reporting significant and chronic insomnia. Ageing individuals believe they sleep poorly and insist they are up all night long. Indeed they are frequently aroused, but the total amount of sleep that occurs during the night is essentially unchanged (see 'Sleep and Health'). Careful inquiries reveal that such persons are usually refreshed and rarely sleepy when they awake, even though their sleep patterns have changed. Up to half of community-dwelling elderly persons use either over-the-counter or prescription sleeping medications. Most studies suggest a greater prevalence of subjective sleep abnormalities and greater use of hypnotics by older women, and those that have been studied have been shown to have sleep aberrations on monitoring. On the other hand, older women appear to have better preservation of slow wave sleep than older men. (Fukuda, 1999). The problem that confronts the clinician becomes the seeking of sleeping or hypnotic potions. The excessive prescribing of hypnotic medications is common for older patients. Hypnotic drugs cannot increase locus ceruleus cell number or reverse age related sleep cycle changes but can increase vulnerability to confusion and delirium as well as addiction. Thus it may be inappropriate to prescribe hypnotics, except under times of extreme stress or during hospitalization or sickness. Non-pharmacologic interventions to facilitate good 'sleep hygiene' need to be utilized to treat a maladaptive response to normal ageing.

Myelin decreases primarily in the white matter of the cortex. (Saunders *et al.*, 1999; Mielke *et al.*, 1998; Sjobeck *et al.*, 1999). Apoptosis or programmed cell death may be responsible for brain neuron loss. (Sastry *et al.*, 1997). Although there is cellular dropout, new synapses continue to form throughout the life span. (Aamodt & Constantine-Paton, 1999). The number of spinal cord motor neurons remains essentially unchanged until the seventh decade, after which losses occur in the anterior horn cells (Cruz-Sanchez *et al.*, 1998). Vibratory and tactile thresholds decrease and the thermal threshold in the fingers goes up thereby decreasing sensory sensitivities.

In summary, there are significant organ and cell-specific biological changes that occur at different rates within and between ageing individuals. The ability to respond to stress becomes compromised, yet in the absence of significant chronic disease, functional independence can be maintained well into the ninth decade. Specific aspects of senescence are particularly relevant for the health psychologist who must appreciate the limited reserve of the older patients, the fragility of the immune response and the increased vulnerability to medications of all types and, in particular, to psychoactive drugs and yet appreciate the remarkable resiliency of the elderly 'survivor'.

Architecture and health

Angela Liegey Dougall¹, Stacie Spencer¹ and Andrew Baum²

¹University of Pittsburgh

²University of Pittsburgh Medical Center

Overview

Architecture can be considered in many ways, as art or aesthetic stimuli, as an expression of societal pride or aspiration, and as a way of structuring interior and exterior spaces to facilitate their use by human occupants. This latter function of architectural design has strong but modifiable effects on social behaviour and users' mood and productivity and, to some extent, design features also affect health and wellbeing. Too often, however, these important sources of influence are ignored or not recognized, despite repeated demonstrations of these effects. While much remains to be done, research has identified several architectural features that appear to be associated with mood and health. Design characteristics or the way space is structured, presence or absence of windows and illumination all appear to affect people. For some features, the relationship to health is indirect (e.g. small, crowded work spaces may result in stress that may in turn affect health) while for other features the relationship to health is more direct (e.g. eye strain from poor lighting, illness from exposure to fumes).

The structural design or arrangement of space imposes restrictions on behaviour. Doorways determine our access to a room and room dimensions restrict the kinds of behaviours that can take place inside a room. As a result, one of the most important goals when designing a building is to match the built environment with the needs of the individuals for whom the environment is designed. However, even under the best conditions, primary uses of a building may change and interior changes must be made to meet the current purposes. Flexibility may therefore supersede many desirable design characteristics, which may have negative effects on use. Regardless of circumstances, among its effects, the interior design of space has an impact on the perception of density and crowding, can impose excess interaction or isolation and has been associated with arousal and stress (see Baum & Paulus, 1987).

Three inter-related variables are important considerations in the design of space because of the potential for indirect influences on mood and health. These variables are the perception of density, privacy and control. Density is the ratio of the number of individuals within a space to the actual size of that space and is thus an

expression of physical properties of the setting (Baum & Koman, 1976; Stokols, 1972). Density can increase when the absolute amounts of available space decrease, and such changes in spatial density reflect the negative effects of decreasing space. For example, as density increases, people may have to work harder to maintain privacy (Altman, 1975). As the number of people increases, regardless of how much space is available, social overload and stress are also likely (see 'Stress and Health'). This focus on social density reflects the subjective experience of frequent or unwanted interaction and is often not easy to change (Baum & Valins, 1979). The high social density environment may threaten the control an individual tries to maintain over privacy and regulation of social interactions. If density increases because the amount of available space decreases, stress associated with exposure to high social density environments where there is little privacy or control over social interaction can lead to negative health outcomes (Paulus *et al.*, 1978).

A series of studies carried out in the 1970s investigated the impact of architecturally determined differences in social density on behaviour in college dormitories. Long-corridor-type dormitories in which a large number of individuals were required to share a hallway, bathroom and lounge also required residents to interact with many individuals, often with people they disliked and/or did not know very well. Further, many interactions occurred at inconvenient times (Baum & Valins, 1977).

In comparison, suite-type dormitories structurally determined smaller groups and reduced the number of required interactions when using shared spaces usually three to five suite-mates (Baum & Valins). Residents of corridor dorms reported that they felt more crowded than did suite residents, despite living on halls with comparable densities and total numbers of residents. Associated with this, corridor residents exhibited lower thresholds for crowding and avoided social interaction outside the dormitory environment, reported lower feelings of control in shared spaces, were less likely to know how hallmates felt about them and were less willing to share information about themselves with other people living on the floor (Baum & Valins, 1977; Baum *et al.*, 1975). In comparison with suite residents, long-corridor residents were more competitive and reactive, and appeared to be more motivated to regulate social contacts in the first few weeks of dormitory residence. However, in as few as seven weeks, behaviour changed and residents became more withdrawn and exhibited symptoms of helplessness (Baum *et al.*, 1978). The effects of crowding were strong enough to generalize to non-dormitory settings (Baum & Valins, 1977). One of the basic conclusions of these studies of dormitories was that design and layout of interior residential space affects crowding stress and health under conditions of high physical density (Evans *et al.*, 2002). Research has continued to report evidence of mediation of social behaviour by architectural design. For example, Evans *et al.* (1996) studied mitigating effects of interior design on residential density using a measure called architectural depth (AD). They defined AD as the number of spaces one must pass through to get from one room in a residence to another, reflecting variety, complexity and privacy afforded by a residential environment. High AD (presumably high complexity, privacy and so on) was associated with less social withdrawal and buffering of residential crowding (Evans *et al.* 1996). Independently, residential density was associated with mental health and task performance, with higher density linked to poorer mental health and less task persistence (Evans *et al.*, 2001).

Similarly, a study of 2017 households in Thailand found that household crowding was associated with wellbeing (Fuller *et al.*, 1996). Objective crowding (measures of physical density) was inversely linked with wellbeing but perceived crowding showed stronger negative relationships, suggesting that factors which increase perceived stress also increase the negative impact of residential crowding.

High social density and loss of control have also been associated with self-report, behavioural and biochemical indices of stress. In studies of prison inmates, death rates and rates of psychiatric commitments were higher in years when prison population was higher (Paulus *et al.*, 1975). Paulus *et al.* (1975) also found that inmates living under high social density conditions had higher blood pressure. In another study of prison inmates, perceived crowding was associated with urinary catecholamine levels (Schaeffer *et al.*, 1988). Residents of low density cells (private cells) reported less crowding and exhibited lower urinary catecholamine levels than did residents of high density cells (open dormitories). Residents of high density cells that had been modified to reduce social density (cubicles within a dormitory) exhibited catecholamine levels comparable to the private-cell inmates. However, these inmates had the highest number of health complaints (Schaeffer *et al.*, 1988).

These studies suggest that design of residential space has far-ranging effects on residents and should be considered when designing new buildings. In the case of pre-existing buildings, modifications can be made to reduce the stress of crowding. Studies have shown that partitioning space can accommodate increases in spatial density without increasing effective social density (Desor, 1972). These changes should be aimed at increasing the perception of control over regulation of social experiences and supporting local control of shared spaces. Cubicles within dormitory-style prison housing increased regulatory control and were associated with catecholamine levels similar to that of private-cell inmates (Schaeffer *et al.*, 1988). Similarly, an architectural intervention, in which a long-corridor dormitory hall was bisected, resulted in greater confidence in residents' control over social interactions in the dormitory, less residential and non-residential social withdrawal, and less crowding stress compared with the non-bisected long-corridor residents (Baum & Davis, 1980).

These findings have implications for the design of other spaces in which large numbers of individuals must share areas and/or work together. For example, in work environments it is often too costly to provide private offices for every employee. Simply filling a large room with desks would not be a good alternative because of the resulting noise as well as inefficiency and decreased regulatory control over social interaction (see 'Noise: Effects on Health'). Such a design would be likely to decrease productivity, increase stress levels and increase the likelihood of negative health outcomes. Use of modular cubicles or other methods of breaking space up would provide the structure for increasing control over local spaces and productivity and prevent increases in distress associated with crowding.

Other architectural features also have important influences on behavioural health. Windows and illumination appear to be particularly important factors. As with the interior design of space, each of these features has an impact on perceptions and behaviours that may affect health. Windows are so important to individuals that the assignment to an office with a window is tied directly to office hierarchies. Big promotions often include a move to an office with a window. The importance of windowed offices is also

demonstrated by findings indicating that people in windowless offices report less job satisfaction, less interest in their jobs and are less positive about the physical work conditions (e.g. appearance, light, temperature) (Finnegan & Solomon, 1981). People in windowless offices also use more visual materials (typically of nature scenes) than do occupants of windowed spaces to decorate their environments (Heerwagen & Orians, 1986). While there is little argument about whether windows are a desired feature, they are expensive, energy inefficient and are limited to exterior walls. In large office buildings, some windowless offices are inevitable. The reductions or changes in the views people have, the positive ambience of the setting, and other effects of having or not having windows appear to affect mood and health in dramatic ways.

For example, research suggests that windows are important in recovery from surgery and in intensive care units. Ulrich (1983, 1984) argues that natural views are associated with positive emotional states which may play a role in the reduction of stressful thoughts and recovery from surgery. In a study of patients recovering from a cholecystectomy procedure, Ulrich compared post-cholecystectomy patients who had a window view of trees with patients who had a window view of a brick wall. In comparison with the wall-view patients, patients with a natural view had fewer post-surgical complications, took fewer moderate and high doses and more weak doses of pain medication, were described by nurses as demonstrating fewer negative characteristics (e.g. being upset and crying, needing much encouragement), and stayed in the hospital for less time post-surgery. In a different study, Keep, James and Inman (1980) found that intensive care patients in windowless units had less accurate memories of the length of their stays and were not as well orientated during their hospitalization as intensive care patients in windowed units. Comparisons of 137 staff and 100 inpatients' responses to variable windows and views in hospital settings suggested that patients were more negatively affected by poorly windowed rooms than were staff (Verderber & Reuman, 1987). Discharged hospital patients identify several sources of satisfaction with hospital environments including interior design, privacy and ambient environmental features such as lighting and view (Harris *et al.*, 2002). Others have proposed a different, overlapping set of elements of satisfaction in hospital settings, with

factors such as attractiveness, privacy, safety, comforts and conveniences emerging as important in affording therapeutic effects of clinical spaces (Grosenick & Hatmaker, 1999).

Windows are also related to illumination; they provide natural lighting and the extent and nature of illumination are important features of design on many different levels. The kind of illumination (incandescent, fluorescent), the brightness of illumination and the spectral range of the illumination, are all important characteristics of light and govern their effects on mood and behaviour. The cool white fluorescent lights used in public places are economical, energy efficient and maintenance free, but these lights produce only partial spectrum light waves and lack the spectrum of natural sunlight (Sperry, 1984). In comparison with exposure to full spectrum lights, exposure to cool white fluorescent lights for as little as four hours has been associated with increased lethargy, visual fatigue and decreased visual acuity (Maas *et al.*, 1974). This is important in settings such as libraries and offices, where the majority of work is visual (Sperry, 1984). Over days and weeks, the cumulative effects of repeated exposure to cool white fluorescent lighting may result in job stress, chronic fatigue and poor vision. The use of lighting which includes the full spectrum may be preferable.

Architectural features such as the design of space, the presence of windows, and illumination affect social behaviour, mood and productivity, and appear to be associated with health (Devlin & Arneill, 2003). While these features are important to consider during the design of space, they are sometimes easy to modify in existing space. Partitions can be used to decrease social density while allowing increases in special density. Window views can be designed to include natural scenes and where a window looks onto another building or in offices in which a window does not exist, murals can be used to simulate natural scenes. Interior lighting can be chosen to maximize the full spectrum of available light. Research and intervention in the design or redesign of space with these features in mind will provide further evidence of the impact of the design of interior spaces and will provide new insights in to the complex but important interactions of behavioural, biological and environmental variables in determining health and wellbeing.

Attributions and health

People are often motivated to determine the causes of events: the more unexpected and disruptive the event, the more likely is the individual to ask, 'Why did this happen?' (Weiner, 1985). As the symptoms and diagnoses of illness are often unexpected and disruptive and may have threatening implications, we can expect health threats to stimulate preoccupation with questions of cause. As social psychologists suggested decades ago (Heider, 1958), causal, i.e. attributional, thinking can clarify the meaning of an event and define its long term implications. In this brief chapter we will address the following questions about the attributional facet of commonsense psychology: 1) do illnesses (symptoms and diagnoses) stimulate causal thinking, i.e. attributions, and when are these attributions most likely to be made? 2) how are attributions for health threats formed? 3) what kinds of attributions do people make? 4) what are the behavioural consequences of these attributions for the management of and adjustment to illness? 5) do attributions have long-term effects on health?

Unfortunately, a straightforward review of results for each of these questions would be difficult to complete as there is considerable disagreement among published findings. Existing reviews of the

literature in this area have also resulted in conflicting conclusions regarding questions such as the relationship of attributions to adjustment. Hall *et al.* (2003) reviewed 65 studies and found little evidence of a relationship between attributions and outcomes. Roesch and Weiner (2001) reviewed 27 studies and found evidence of an indirect relationship of attribution with adjustment, mediated through ways of coping. We have therefore decided to begin by addressing a prior question: 'Where do attributions fit within the context of common-sense reasoning and adjustment to anticipated and current health threats?' The answer to this question assumes that the meaning of an attribution, and hence its consequences, will differ as a function of the context, i.e. disease model, in which it is made. Thus, we hope to provide a framework that will transform inconsistencies into an orderly set of moderated effects and illuminate areas in need of further research.

A model for understanding attributions

If attributions are important for clarifying meaning (Jones, 1990), it is critical to define the structure and content of the behavioural

system within which attributions are made. Our 'common-sense model of self-regulation in response to health threats' (Leventhal *et al.*, 1980; Leventhal *et al.*, 1992; Leventhal *et al.*, this volume), provides one such framework (see 'Lay Beliefs about Health and Illness'). The constituents of the behavioural system as defined by this and similar models are the representation of an illness/threat, a set of procedures for threat/illness management, and criteria for evaluating outcomes. Thus, the implication or meaning of an attribution will vary depending upon the question it addresses, i.e. is it an attribution about a symptom, e.g. is the symptom a manifestation of a particular disease or of some non-disease process?; is it an attribution about the cause of a disease, e.g. a virus, genetic factor, psychological factor, etc.?; is it an attribution about the coping procedures for disease management, e.g. why is it plausible that this procedure will be effective, who is responsible for performing the procedure, self or doctor?; or is it an attribution about the outcome of a treatment procedure, e.g. did the symptom/disease go away because of the treatment or fade on its own?

Different diseases have different models, differentiated by biology and culture. For example, the concrete experience and abstract meaning of illness representations will differ for hypertension, breast cancer and the common cold; hypertension is believed to be accompanied by heart pounding, warm face and headaches though it is actually asymptomatic (Meyer *et al.*, 1985); breast cancer can produce discolouration of the breast and palpable lumps, and the common cold is accompanied by a stuffy nose, headaches, sneezing and coughing. These models are further differentiated according to one's cultural background.

Abstract, cultural concepts of methods for controlling these diseases and their likely success also differ. For example, surgery is appropriate for cancer but not for the cold, and cultural expectations for the success of control (cure) are clearly poorer for breast cancer than for hypertension or the common cold. Finally, the facet of the representation that is salient at a given point in time, e.g. its symptoms or consequences, will reflect the history of the specific disease episode, e.g. is the episode at its beginning with only vague manifestations, or has it progressed to diagnosis, treatment, or recovery and rehabilitation? (Alonzo, 1980; Safer *et al.*, 1979). Additionally, it will reflect the personal and vicarious illness experiences of the individual in the past (Benyamini *et al.*, 2003). The motivation for question asking, the type of question asked, the answers to this question, i.e. the attribution that is made and its consequences, will vary as a function of these factors. With this understood, we can proceed to address our questions.

Attributions in response to illness threats: are they made?

Our self-regulation model suggests that questions are more likely to be asked and causal attributions formed at some points within a disease episode than at others, e.g. when trying to identify the nature of a symptom rather than when considering the consequences of a diagnosis or treatment, and for some rather than for all diseases, e.g. a life-threatening cancer in contrast to an innocuous cold.

Investigators have typically used direct questions, requesting either closed-ended or open-ended answers, to determine the type of attributions being made, rather than using open-ended approaches to find out whether they are being made at all. Thus, the typical approach assumes that people will attempt to probe the cause of their illness once it is diagnosed and the meaning of symptoms clarified (Rodin, 1978). Indeed, Taylor, Lichtman and Wood (1984) interviewed women who have been diagnosed with breast cancer and found that 95% of them were able to provide a causal attribution for their cancer. Similarly, only one of 29 subjects paralyzed as a result of serious accidents did not come up with a hypothesis respecting its cause (Bulman & Wortman, 1977). In their review of the literature, Turnquist *et al.* (1988) reported that 69 to 95% of individuals make causal attributions for their illness, and that the frequency of causal reporting is usually higher the more severe the diagnosis (e.g. cancer) and the longer the time since diagnosis. Although patients do not always report explicit causes for their illness, they view cause as one of the most important pieces of information from their physician at diagnosis (Greenberg *et al.*, 1984).

These findings clearly indicate that people generate hypotheses about the causes of their illness, but they do not address whether they do so without being prompted. Two studies that asked chronically ill patients (with arthritis, diabetes, hypertension or soon after a myocardial infarction) if they have ever thought why this had happened to them, found that roughly half of the sample had said that they had not (Lowery *et al.*, 1987; Lowery *et al.*, 1992). Another study reported that, when asked, almost all patients provided causes for arthritis-related symptoms and for ambiguous symptoms, but only patients with a past history of cancer were preoccupied with the cause: a much larger number of those who called the doctor did so in order to verify the cause (Benyamini *et al.*, 2003). Taken together, these findings question the validity of the assumption that causal search is universally initiated under the conditions of unexpectedness, uncertainty and threat that are posed by illness, at least for diseases and risks other than cancer. For cancer, attributions may serve a function in promoting the belief that recurrence can be prevented; but for arthritis, hypertension or diabetes, recurrence is not the issue, and for a myocardial infarction, soon after the event, it is recovery and not recurrence that troubles people. When taking into account the low utility in holding attributions for these diseases it is not surprising that studies have found lower preoccupation with causes in these cases.

Studies have also examined the strength and perceived importance of causal attributions for disease, and found that patients with severe conditions and patients perceiving the outcome of their illness to be a failure seem to hold their attributions with less conviction (Turnquist *et al.*, 1988). This also seems to have an adaptive value: as health status changes, people change their illness model to include causes that show more promise in terms of current and future management of the illness threat. Being highly committed to any specific cause sets a higher value on such changes. In sum, it is likely that the occurrence and strength of attributional processes depend on their contribution to one's coping with the health threat at question. A mere understanding of the types of attributions made provides little insight into these processes. As researchers and practitioners, it is more useful to first understand how these attributions are made.

Attributions in response to illness threats: how are they made?

Efforts have been made to identify the rules guiding the attributional process. Examples from studies of social cognition include factors such as the actor–observer bias, i.e. actors identify environmental factors as the causes for their actions while observers attribute these actions to the personal characteristics of the actor (Jones & Davis, 1965), and self-serving biases such as attributing failure to environmental factors and success to characteristics of the self (Fiske & Taylor, 1991). A recent study of causal attributions for myocardial infarction (MI) in patient and non-patient samples provided evidence that does not favor the actor-observer hypothesis (French *et al.*, 2004). The data suggested that method effects account for differences in attributions, with the important distinction being that between attributions in general and attributions regarding a specific person's MI (self or other). Attributions of causes of the disease in general are important in order to explain public opinions or 'stereotypes' of the disease and they may impact upon policy decisions and attitudes (and stigma) towards certain patient populations. For example, causal attributions were related to the perception of greater consequences of diabetes when judging this disease in general, but not when judging it as personally relevant (Shiloh *et al.*, 2002). However, when the focus is on patients' coping with a disease, attributions to a specific person's disease are important in order to understand how people adjust and how close ones, such as spouses, provide support to the patient (Benyamini *et al.*, 2007).

As is the case with determining if people make attributions spontaneously, the method of questioning is a source of difficulty for identifying mental rules. A wide variety of methods has been used to assess attributions in prior studies, and each may create its own biases. For example, closed-ended methods included Q-sort of possible causes, attribution of percentage of blame to different factors, ratings of importance of different internal and external causes, and more. Open-ended questions also varied, especially in their focus on 'what caused your illness?', on 'why me?' or even more specifically on 'why me, instead of someone else?' By focusing on the specifics of the disease, the first approach may generate information on rules that are disease-specific, while the second may elicit thoughts and comparisons that generate rules relevant to one's life situation and disease development. When asked about the causes of their MI, patients may be answering the questions 'Why did it happen now? What triggered it?' while researchers typically ask about the patients' perceptions of the causes of the underlying disease (French *et al.*, 2005). Even the 'Why me?' question is multi-layered, as Steensma (2003) suggested, ranging from a search for a more mechanistic explanation of the condition to unanswerable questions of injustice.

Initially, patients use heuristics to identify causes, which serve as 'working cognitions' that can be later modified according to the progress of the disease and the patient's knowledge about it. These include rules such as the symmetry rule, which is the need to find labels for symptoms and symptoms for labels (Leventhal *et al.*, 1992); the stress–illness rule, or the tendency to attribute symptoms to stress in the presence of stressors (Cameron *et al.*, 1995); and the age–illness rule, which is the tendency to attribute slow-developing, not too severe symptoms, to age (Leventhal *et al.*, 1992) (see 'Aging and health behaviour'). The latter two rules

result in attributions to non-disease sources, a tendency that is particularly noticeable in the early stages of illness episodes when symptoms are ambiguous. Thus, when the symptoms of a disease are mild and slow to develop, they can be interpreted as 'normal' or as unavoidable signs of ageing rather than as signs of disease (Kart, 1981; Prohaska *et al.*, 1987). In a similar vein, ambiguous symptoms, the onset of which is associated with recent life stresses, e.g. examinations, family quarrels, etc. are likely to be attributed to stress rather than illness (Baumann *et al.*, 1989; Cameron, *et al.*, 1995). Both interpretations lead to delays in seeking professional care.

As patients become more knowledgeable over time regarding the causes of their disease, their answers may increasingly come to reflect medical and cultural views based on what they have heard from their physician and other sources rather than reflecting their own thoughts and mental operations. For example, 'Western' Israeli women with breast cancer mentioned a variety of physiological causes, reflecting a more rational–scientific attitude while more 'traditional' religious women either did not know or perceived the cause to be personal–emotional (Baider & Sarell, 1983), similar to the differences found between Western and Asian Canadian students (Armstrong & Swartzman, 1999).

There are some indications that patients who have little medical knowledge follow very simple causal rules in addressing attributional issues, such as 'causes should be temporally and spatially close to effects' (Taylor, 1982), and 'causes should resemble effects' (Salmon *et al.*, 1996). These rules are especially in error for chronic diseases such as cancer which have lengthy developmental histories. Most studies have paid little attention to variations in the content of attributions associated with differences in socioeconomic status (Pill & Stott, 1982) and ethnic group membership. For example, minority respondents are more likely to view serious chronic illnesses as unpreventable and uncontrollable, because of the fatalistic themes sometimes present in their culture (Landrine & Klonoff, 1994; Pérez-Stable *et al.*, 1992). Thus, the questions asked about illness and the rules of inference observed in subjects from various social backgrounds will reflect orientations general to the culture rather than rules specific to the person.

Attributions: types and consequences

Attributions of symptoms

Do women later diagnosed with cancer ask questions about the source of their symptoms early in the disease process? In a retrospective study of women diagnosed with cancer, participants were clearly motivated to find explanations for uncertain physiological signs and symptoms, and the strength of this motivation was related to the salience and the perceived personal consequences of these bodily reactions (Cacioppo *et al.*, 1986). As symptoms do not advertise their underlying, disease cause, people are far from accurate in self-diagnoses. In addition, their evaluations of the perceived symptoms tend to be hedonically biased: many subjects in the Cacioppo *et al.* (1986) study found it much easier to accept a non-threatening explanation for unexpected symptoms and stopped searching for further explanations.

A disease attribution is no assurance, however, of appropriate action. Studies find mis-attribution due to both the inherent ambiguity of symptoms, e.g. cardiovascular symptoms can be confused with symptoms of gastro-intestinal disorders, and to fear-motivated defensiveness. While defensiveness seems more likely to occur for life-threatening diseases, its frequency varies with the type of disease. For example, data suggest that defensive avoidance is more likely for many cancers than for heart attacks: while both sets may be susceptible to 'safe' alternative interpretations, the symptoms of cancer are usually slower to develop, less disruptive of daily function, and, therefore, easier to misinterpret (Cacioppo *et al.*, 1986). Attributions to the 'wrong' disease generate wrong meanings and inappropriate procedures for self-management. An interesting example of both misinterpretation and changing interpretation was reported by Matthews *et al.* (1983) in their study of delay in care-seeking following the onset of coronary symptoms by type A and type B males; the type A delayed longer than did type B individuals while symptoms were vague during the early phase of an attack, but were quicker to seek care once it became clear that they were having a MI (see also 'Symptom perception' and 'Delay in seeking help').

Attributions of disease cause

Researchers have tried to categorize attributions using either bottom-up or top-down approaches. The top-down ones arose from general attribution theories and led to the classification of causes according to several core dimensions, such as locus of causality (internal/external), controllability and stability (Roesch & Weiner, 2001). Bottom-up approaches strived to uncover the structure of attributions derived from empirical data. These approaches typically resulted in categories such as environmental, behavioural and hidden causes (Senior *et al.*, 2000; Shiloh *et al.*, 2002). These attributions often differ between patients and providers, with patients sometimes offering a more varied array of causes and providers a narrower biomedical one (Bar-On & Cristal, 1987), or the opposite, for example, as with low back pain patients who strive to establish a biomechanical explanation as a response to the clinicians' uncertainty of the cause, which leads to implications of a psychological explanation of the illness (May *et al.*, 2000). The problem with both approaches is that they are attempts to simplify a complex phenomenon. Trying to uncover the dimensions that underlie the empirically derived structures also shows that while a central feature such as the controllability of the cause explains some of the variance in these attributions, it is far from being a sufficient explanation since more features are likely to be involved (Shiloh *et al.*, 2002). There is also evidence that people perceive multiple causes of disease (Arefjord *et al.*, 2002), which makes sense in the light of the accuracy of such a perception for many chronic diseases. Since attributions are not formed in a void but within the person's struggle to reconstruct a narrative which incorporates the illness into their lives and enables them to cope with it (Williams, 1984), one should not be surprised that a focus on specific attributions or a few generalized dimensions is insufficient to understand why attributions are formed and what are their effects.

Attributions of responsibility

Many studies have examined the extent to which people attribute disease to themselves. It is important to distinguish attributions of causes of the event from attributions of success or failure in controlling it and to recognize that internal attributions in contrast to external ones, can lead to quite different outcomes depending upon the model of the underlying condition. For example, diabetic children who held themselves responsible for symptomatic episodes when their diabetes was out of control were in better metabolic control than children attributing such episodes to external factors: self-control was superior to external control (Brown *et al.*, 1991). By contrast, poorer adherence to diets was found among those moderately overweight women who attributed adherence failures to internal factors (Ogden & Wardle, 1990). The seeming contradiction in outcome reflects fundamental differences in the models of the underlying conditions. Whereas the cause of diabetes in children is perceived as external, it is a disease that one must act to control, the cultural view of obesity is that it is caused by the actor's failure of control (a perception that is contrary to medical findings, Garner & Wooley, 1991). Thus, holding the self responsible for failure episodes, an internal attribution, by diabetic children, implies temporary deficits in self-regulation rather than chronic deficiencies in self control, the inference for failure episodes among the overweight (see also 'Perceived control').

Another example showing that differences in models of treatment and disease can alter the meaning of an internal attribution was provided by the Hypertension Prevention Trial (Jeffery *et al.*, 1990). They found that participants assigned to weight-loss groups were significantly more likely to blame themselves for adherence failures than participants assigned to a non-weight-loss intervention, e.g. a reduced sodium group, though there was no relationship between these attributions and health outcomes. Thus, even though it is presumed to be more difficult to adhere to diets for reducing sodium and increasing potassium than to diet for reductions in caloric intake, failure in the latter may lead to self-blame. This is because dieting to reduce caloric intake can be perceived as a weight loss issue that requires self-efficacy skills which have been shown to be deficient by the very presence of the hypertensive disorder.

Attributions and adjustment to illness

Two hypotheses have been tested respecting the relationship of attributions to adjustment. The first is that adjustment is better when attributions are made than when they are not made, and the second is that adjustment is better if specific types of attributions are made, e.g. to the self rather than to others or to controllable rather than to uncontrollable causes. Data on the first are inconsistent, several studies showing more depression, anxiety and feelings of helplessness among patients failing to make causal attributions for their conditions (Affleck *et al.*, 1987; Lowery *et al.*, 1983, 1985; DuCette & Keane, 1984), others showing lower levels of anxiety in the presence of denial and the absence of causal search (Lowery *et al.*, 1992). These inconsistencies appear to be resolvable if, as suggested in our discussion of the commonsense framework, we postulate that different aspects of a disease problem may be salient at different points in time. Thus, three days after a MI (Lowery *et al.*,

1992) and soon after the occurrence of an accident (van den Bout *et al.*, 1988), the absence of causal search is related to lower levels of anxiety, while later in time the presence of causal attributions is related to lower levels of anxiety (Affleck *et al.*, 1987; Lowery *et al.*, 1983; Lowery & Jacobsen, 1985). As Suls and Fletcher (1985) suggested, engaging in causal search soon after an event may be maladaptive, though causal search at later time points plays a positive role by providing the meanings needed to motivate risk reduction and avoidance of recurrence.

Data on the second question, i.e. the relationship of specific types of attributions to adjustment, is also inconsistent (Hall *et al.*, 2003). Several studies pointed to relationships between attributions and health behaviour change (e.g. changing your diet if you believe your illness was caused by poor diet, etc.; De Valle & Norman, 1992) or healthcare utilization (Herschbach *et al.*, 1999) and turning to complementary and alternative medicine (Maskarinec *et al.*, 2001). Thus, attributions could lead to behaviour change but whether or not this is adaptive depends on the accuracy of these attributions.

Regarding the benefits or harm in self and other attributions, Turnquist *et al.* (1988) concluded in their review that attributions to 'others' tend to relate to poorer outcomes (as did Tennen & Affleck, 1990, in another review) and attributions to 'self' fail to relate clearly to either a beneficial or a detrimental outcome (see also Michela & Wood, 1986). The inconsistent findings for internal attributions could be due to at least two sets of factors. First, the distinction between internal and external cause has been coded in different ways by different investigators, and the meaning of an internal attribution could be different depending upon whether it is an attribution for the initial cause of illness or an attribution of responsibility for managing oneself in relation to treatment or rehabilitation. If an internal attribution is for self-management, it will be equivalent to the perception of internal control, which is usually coupled with events that are controllable, in contrast to external control, which is usually attributed to events that are uncontrollable. Several findings are consistent with this reasoning: e.g. Taylor *et al.* (1984) found that attributions of cancer patients for the disease were mostly unrelated to adjustment, while beliefs in control of treatment and rehabilitation by self and medical experts were both independently associated with better adjustment; DuCette and Keane (1984) found that patients were better adjusted if they had attributed their post-thoracic surgical performance to their own effort or to care from the staff; and, Gilutz *et al.* (1991) found that thoughts of self 'limits and strengths' were positively associated with rehabilitation 6 months post MI, while thoughts about 'fate and luck' were predictive of poor rehabilitation. It seems, therefore, that attributing the onset of an illness to an uncontrollable event, as opposed to personal responsibility due to bad habits, and attributing responsibility for treatment and rehabilitation to controllable, mostly internal though sometimes external factors, is the combination that results in the least emotional distress and the most optimistic view of the future health status. In other words, taking responsibility and asserting control over future recurrence while avoiding blame could be adaptive and people seem to do so whenever possible (French *et al.*, 2005; Tishelman, 1997).

Second, many of the studies of illness attributions were cross-sectional or at best retrospective. Thus, a note of caution is in order as

reports of negative correlations of emotional distress with factors such as preoccupation with 'why me?', the absence of causal attributions, and/or the presence of a specific type of attribution, may only reflect distress in the face of deteriorating health (Macleod, 1999). Among women with newly diagnosed breast cancer, behavioural self-blame was correlated with concurrent distress whereas characterological self-blame predicted increased distress over time (Glinder & Compas, 1999). As health deteriorates, individuals may shift from internal attributions to attributions that are external and unstable, reflecting the realities of loss of control over the disease process. Lowery and Jacobsen (1985) have suggested that this shift, along with reduced conviction about any specific causal factor, was characteristic of chronically ill patients whose disease was no longer under control, with actual loss of control generating causal beliefs that are least emotionally upsetting, i.e. to factors implying that the failure to control the disease was unavoidable. Indeed, Lowery *et al.* (1992) suggested that patients may oscillate between preoccupation with and ignoring of causes, focusing on causes as they attempt to come to terms with illness and retreating to denial when anxiety levels are too high, and both the focus of attention and the rate of fluctuation may vary as a function of where they are in the disease and coping process. Given the capricious nature of chronic, life-threatening diseases, the most effective way of minimizing distress produced by lack of confirmation of expectations may be to consider alternative explanations and not commit strongly to any of them. This may explain why attributions show low consistency over time (Arefjord *et al.*, 2002) and why patients who perceive themselves as recovering rapidly attribute their recovery to more stable and personally controllable factors than patients who perceive themselves as recovering slowly (Brewer *et al.*, 2000).

Finally, it is essential to recognize that attributions and adjustment are likely to vary with different illnesses. Accident victims are faced with an irreversible disaster resulting from a one-time mistake; cancer patients are dealing with long treatments accompanied by fear of recurrence; the prognosis for breast cancer is far more optimistic than that for lung cancer; MI survivors experienced a serious trauma with a brief recovery period and lingering fear of recurrence; daily, lifetime coping is the concern for arthritis and diabetics, recurrence is not. If attributions affect adjustment via their impact on control, it is clear that attributions and control will have different meanings in each of these contexts, as perceived control can be helpful only when it can contribute to positive outcomes. When the disease prognosis is extremely unfavourable, e.g. for lung cancer, an internal attribution can induce control but control will have no effect on adjustment (Berckman & Austin, 1993).

Attributional styles and long-term effects on health

Individual differences in the types of attributions people form may be a function of more stable, dispositional tendencies, namely, attributional styles. Research has focused mainly on the pessimistic attributional style, or the tendency to perceive negative events as caused by internal, stable and global factors. This attributional style is considered to be characteristic of learned helplessness (Abramson, Seligman & Teasdale, 1978) and has been found to be related to depression (see Sweeney *et al.*, 1986 and Robins,

1988, for reviews; but see also Cochran & Hammen, 1985 for an alternative view) and to be a risk factor for illness, as Peterson *et al.* (1988) have found in a 35-year longitudinal study. A possible mediator for this effect may be the effect of pessimistic explanatory style on immune functions: this style has been found to be related to lowered immunocompetence, controlling for health status, depressive mood and other possible mediators (Kamen-Siegel, *et al.*, 1991).

Another dispositional difference which may be related to health outcomes was reported by Strube (1985), who found more internal, stable and global attributions for positive than for negative outcomes for all respondents, but this self-serving bias was more characteristic of Type A personalities than Type Bs. In general, Type As are more likely to form causal attributions, especially under high-stress conditions (Keinan & Tal, 2005) (see 'Hostility, Type A behaviour and coronary heart disease').

Conclusion

Attributions are important for the person forming them and for investigators of health and illness behaviours if they help us to predict and to understand the determinants of these behaviours and their consequences for treating and adjusting to disease.

Research arising from a social-psychological view of attributions does not necessarily capture the critical dimensions required for understanding attributions in the domain of health and illness. In the attribution literature, internal attributions have often been linked with control, and therefore were usually expected to be associated with more favorable outcomes, whereas external attributions have been linked with depression, illness and overall poorer adjustment. The majority of studies of attributional processes, however, are cross-sectional and involve a short time frame. Reviews of this area attempted to reach overall conclusions, which are difficult to formulate without taking into account the specific context that each disease creates, the subjective model of that disease, and the needs of the person in each stage of the disease. The formation of attributions is a dynamic process, which happens over time, and in which people negotiate certain explanations for their illnesses in ways that play a positive role in their self-perception and ability to cope. Studies in this domain can reveal the multiple meanings that can be assigned to attributions and their varied consequences. Thus, we should view the study of attributions in the health area as an opportunity for developing a more comprehensive and deeper view of the determinants of human behaviour rather than viewing it as a narrow area of applied research.

Childhood influences on health

Julie M. Turner-Cobb

University of Bath

Overview

Early social experience appears to be one of the most important psychological factors influencing health outcome in children. Social experience in childhood includes interactions with care givers (e.g. parents and childcare providers) and with peers (e.g. friends made at childcare or school). Of particular note in the classical psychology literature is the significance of parental attachment, especially that of the maternal bond. When applied directly to health, research initially focused on the psychopathological or mental health implications of maternal attachment or parental abuse. Indeed such developmental work has yielded a number of important findings. More recent research applying the influence on physical health of stressful experiences during childhood, has revealed some potential physiological indicators involved in this relationship, primarily that of the hormone cortisol. This chapter deals with the themes and debates surrounding this emerging literature, applying the social experiences in childhood to the health arena throughout childhood and across the lifespan. It is acknowledged that whilst there may be more broader issues influencing health during childhood, the stress response focus given here outlines a possible psychophysiological mediating mechanism through which such factors might influence health.

The relevance of cortisol to health

The basic premise behind the research discussed here is that early life experiences and individual differences can activate the

stress response systems of the body to influence health outcomes across the lifespan. These two response systems, which work in conjunction with one another, are those of the hypothalamic-pituitary-adrenal (HPA) axis and the sympathetic-adrenomedullary system (SAM) (for more detail see ‘Psychoneuroimmunology’). Measurement of cortisol, the end product of the HPA axis stress response system, is now considered a reliable indicator of increased physiological stress arousal (Kirschbaum & Hellhammer, 1989) (for more detail see ‘Psychoneuroimmunology assessments’). Cortisol is important to health as it is linked to suppression of some parts of the immune response and an overall dysregulation of immune function (Kirschbaum & Hellhammer, 1989, 1994). Under normal conditions, cortisol reveals a circadian rhythm with a diurnal decline from awakening to evening levels (Smyth *et al.*, 1997) from approximately three months of age (Gunnar, 1992).

Allostasis and allostatic load

The theory of allostasis and associated allostatic load offer an explanatory link between psychosocial stress responses and health outcome across the lifespan. Allostatic load is the collective somatic burden or accumulated lifetime stress associated with repeated stress responses (Sterling & Eyer, 1988; McEwen, 1998). This theory has generated interest particularly in relation to adult research, for example Seeman *et al.* (2002) demonstrate the importance of positive social experiences in lowering allostatic load in various ages within the adult population. Yet there exists a

comparative lack of direct developmental investigation of childhood experience, particularly noticeable given the focus of allostatic load on accumulated lifetime stress and hence its relevance to early life. Both noise and crowding are potential sources of allostatic load and both have been linked to raised cortisol levels in children (Johnston-Brookes *et al.*, 1998; Haines *et al.*, 2001).

Activation of the stress response system of the HPA axis in early childhood has been associated with a range of psychological factors and physiological alterations during childhood and adolescence. For example, family environments characterized by aggression and conflict (termed 'risky' families) have been associated with negative mental and physical outcomes (Repetti *et al.*, 2002). One of the earliest areas of interest within the field of developmental psychology is that of maternal attachment and critical periods or 'windows' of time have been the focus of recent work linking maternal attachment with neuroimmunological consequences in animals and children (for a recent review see Coe & Lubach, 2003). Under experimental conditions, maternal separation in healthy nine-month-old children has been found to elicit HPA axis activation, as demonstrated by raised salivary cortisol levels in the presence of an unfamiliar sitter who responded only when the infant fussed or cried. (Gunnar *et al.*, 1992). The importance of a positive social environment for neuroendocrine adjustment is demonstrated by the fact that this physiological effect was diminished to almost that of the no separation condition when the sitter offered a nurturing and stimulating environment, demonstrating. Furthermore, higher diurnal cortisol in adult men who experienced parental loss at an average age of 12 years demonstrates the long term neuroendocrine effects of early experience (Nicolson, 2004).

Cortisol and psychopathology in response to maltreatment and maternal attachment

Neuroendocrine alteration in response to severe maltreatment and subsequent psychopathological development, a number of different patterns of alteration in cortisol levels and diurnal regulation have been observed. Variation in morning cortisol in children is reported by Cichetti & Rogosch (2001); depending on type and severity of maltreatment, the most severely maltreated children showed significant elevations in morning cortisol levels. Some clinical research in children with PTSD symptoms, following trauma such as separation and loss, reports HPA axis alteration as evidenced by a raised cortisol profile (termed 'hypercortisolism') particularly in girls (Carrion *et al.*, 2002). Yet in other experimental studies, sexual abuse in children has been significantly related to lower cortisol levels compared to controls (King *et al.*, 2001). A similar pattern of lower cortisol levels and a flatter diurnal cortisol rhythm is seen in children rescued from orphanage maltreatment (Gunnar *et al.*, 2001). Indeed, as Gunnar and Vazquez (2001) point out, the concept of hypocortisolism suppression of the HPA axis response resulting in low cortisol levels, may be manifested during childhood itself rather than being a delayed effect in adulthood, as initially believed. Differences in the direction of cortisol appear to reflect the type of maltreatment and timing of assessments following the experience. For example, what may initially show itself as high cortisol may subsequently, or following a repeated episode of abuse, reveal a low cortisol response e.g. as evidenced in Resnick *et al.*'s (1995) study of repeated rape.

Intergenerational stress transmission

As already alluded to above, the notion of intergenerational stress transmission pervades this literature. This notion was examined directly by Yehuda and colleagues (2001), in an investigation of adult children of Holocaust survivors with post traumatic stress disorder (PTSD). They report a lower mean 24-hour urinary cortisol level in those who experienced childhood emotional abuse, compared with controls (Yehuda *et al.*, 2001). Later studies have also reported subsequently altered cortisol levels in adult survivors of child sexual abuse (Newport *et al.*, 2004) and similar observations have been made in animal models of maltreatment (Mar Sanchez, 2001). Relating to this notion of intergenerational transmission, a literature is also developing which links heritability of cortisol, both genetic and social. From the genetic perspective, twin studies estimate the heritability of cortisol responses at 60% (Bartels *et al.*, 2003). With regard to social influences, evidence clearly links cortisol with socioeconomic status e.g. morning cortisol levels in children with low SES status are significantly higher and this appears to be linked to mothers' level of depressive symptoms (Lupien *et al.*, 2000).

Stress and cortisol in healthy children

As described above, the influence of social experience during childhood was originally examined in relation to specific groups of children deprived of normal social contact or suffering maltreatment in one form or another. Both naturalistic and experimental studies have explored adaptive physiological responses to stressful social experiences in such children. An area that has more recently emerged is the examination HPA axis activation in healthy children as a window for exploring the origins and adaptation and accumulated life stress.

That early experiences may contribute to a child's allostatic load and be linked to poorer health outcome in healthy children is revealed in a study by Bugental *et al.* (2003). This study examined HPA axis reactivity to physical punishment by their mothers in a group of toddlers from low SES families. They found that children whose mothers disciplined by use of frequent spanking/slapping, exhibited greater cortisol reactivity to the stress of experimental separation. Also, mothers who employed various forms of emotional unavailability, regardless of intention, had higher baseline cortisol levels.

Research focusing on the role of social interaction beyond the family, to encompass social relationships of peers and group interaction in naturalistic daycare settings has also yielded some notable findings. In keeping with increasing exposure of preschool age children to various forms of childcare outside the home brought about by changes in maternal occupational patterns, more recent research has examined the nature of the childcare experience and differential outcomes of varying levels of care quality. Both naturalistic and experimental research have studied the interplay between social experience and temperament within this context. Evidence is accumulating which reveals that negative emotional temperaments and poorer quality of preschool care are associated with altered physical stress responses (Dettling *et al.*, 2000; Gunnar & Donzella, 2002; Crockenberg, 2003).

Cortisol disruption in the social context of preschool (under fives)

With regard to neuroendocrine disruption, a dysregulation of the diurnal pattern of cortisol which is reflected in the rate of decline from morning to evening levels and is particularly evidenced by an elevation in afternoon cortisol levels, has been reported in children attending full day preschool. In those children whose social skills are less well developed, alterations to this evening pattern are particularly prevalent (Dettling *et al.*, 1999; Watamura *et al.*, 2003). Assessing cortisol reactivity in response to starting preschool, Gunnar *et al.* (1997) note that it is the neuroendocrine adaptability that is important rather than simply the level of the response. These ideas as applied to healthy children in this context fit well with the person–environment interactional model of stress put forward by Lazarus and Folkman (1984) now well accepted in the adult stress literature. In understanding childhood influences on health this neuroendocrine ‘window’ provides an opportunity to examine these person–environment responses. Although Gunnar *et al.* (1997) report that more outgoing, socially competent children exhibited high cortisol response to the initial start of preschool, when followed up one term later, these children exhibit a low reactivity. Similarly, the importance of infant–mother attachment on cortisol levels during adaptation to daycare has been recently demonstrated (Ahnert *et al.*, 2004). These studies all point to the importance of adaptability rather than initial reactivity for health outcome.

In the light of this, evidence for direct pathways between temperament and cortisol reactivity has not always been clear. Recent evidence from Gunnar *et al.* (2003) points to the existence of an indirect pathway involving aggression and peer rejection. Further explanation of this is provided by Zimmerman and Stansbury (2004) in their experimental study using a stranger-approach scenario in three-year old children. They report cortisol rise in both shy and bold children with the level of the response predicted by degree of shyness. In the majority of the children the response was attenuated after termination of the stressor (Zimmermann & Stansbury, 2004). Providing further support for the idea of context-specific HPA axis activation during childhood experiences (Watamura *et al.*, 2003), the authors argue that it is the repeated triggering of the stress response rather than neuroendocrine activation itself which may be problematic for shy children, as they may perceive threat to a greater number of everyday events.

From the parental perspective, issues surrounding home-life-balance are also important to consider in relation to childhood influences on health, particularly as neuroendocrine sensitization effects following exposure to maternal stress during the first year of life have been reported in four-and-a-half-year olds (e.g. Adam & Gunnar, 2001; Essex *et al.*, 2002). As yet unpublished findings from our own laboratory have found that mother’s occupational factors (e.g. maternal satisfaction with work, level of emotional exhaustion) interact with daycare experience to influence cortisol levels in preschool children. Furthermore, we have found these factors to take on even greater significance once the child has made the transition to school.

The implications of this developing field of research are enormous, with applications extending to include the effect of social experience on learning and on health outcomes. Social and physiological adaptation is required in order to cope with transitional life experiences, whether these are due to early maternal separation

in the form of childcare, starting school, or the experience of competition and the need to achieve, brought about through the assessments and examinations now demanded throughout childhood and adolescence in the UK. Indeed, it has been argued that neuroendocrine patterns seen in infants in response to maternal separation may be mirrored in older children for different age-related stressors such as academic examinations (Gunnar *et al.*, 1992).

Physiological responsivity in school transition (rising fives onwards)

On this basis, school transition can be classified as a dynamic process. Whether or not the child has experienced preschool, it is likely to be experienced as novel and socially stressful, leading to an increase in HPA axis reactivity and potentially to immune suppression (Boyce *et al.*, 1995). Life transitions provide a naturalistic research opportunity to investigate adaptability to stress and the link to health outcomes. Work by Gunnar and colleagues (e.g. Gunnar *et al.*, 1997; Gunnar & Donzella, 2002; Gunnar *et al.*, 2003) supports the notion that school transition stress is generated predominantly by the need for social engagement and social competence within the new environment. In an assessment of physiological responsivity to socio-emotional adjustment in children entering kindergarten in the USA, Smider *et al.* (2002) report that higher cortisol levels at age four-and-a-half years predicted poorer behavioural adjustment to kindergarten at age six. Similarly, in four-year old preschool children, classroom observations have also linked social isolation with cortisol levels depending on the meaning of the isolation behaviour for the child (Sanchez-Martin *et al.*, 2001). Children retreating into social isolation due to anxiety and inadequate social interaction skills revealed higher cortisol levels compared with children showing social isolation as a result of avoidance of the stressful social behaviour who revealed lower cortisol responses (Sanchez-Martin *et al.*, 2001). When considering the influence of stress in children, this link between cortisol and the meaning of the social interaction has also been demonstrated in a longitudinal study of diurnal cortisol response during the first five days of a new school year (Bruce *et al.*, 2002). In a group of six- to seven-year-old children, compared with weekend days, a greater rate of change in cortisol was observed on school days and in particular for those children who scored high on surgency (extroversion); this greater rate of change was still apparent on day five of school (Bruce *et al.*, 2002). Whilst some inconsistencies in the direction of the temperament–cortisol relationships exist between this study and previous research (Davis *et al.*, 1999), both studies found that more surgent children showed greater cortisol responses to transition on the fifth day of the first week (Bruce *et al.*, 2002). Further evidence of the importance of individual differences in cortisol regulation is provided by experimental work examining self-competence in seven-year-olds (Schmidt *et al.*, 1999). In this respect, self-competence in novel/social situations is argued as reflecting the ability to regulate emotion and to elicit less fear of approach, the process itself increasing levels of self-competency (Schmidt *et al.*, 1999). Furthermore, parental expectations of the school transition experience have also been linked to morning cortisol levels (Quas *et al.*, 2002).

A further stream of research is emerging in respect of stress responses during school transition: namely the effect on learning. Firstly, chronic high levels of cortisol secretion have been linked to

hippocampal damage in the brain (Sapolsky *et al.*, 1986) and associated reduction in cognitive functioning e.g. in memory and spatial impairments (McEwen, 1997). These effects however, are in response to chronic stress exposure but when acute stress under experimental conditions is considered, the effects on healthy individuals become less clear. For example, experimental studies examining hormonal responses to stress at both ends of the life spectrum, in the elderly and in young adults, have shown a modulatory rather than a 'unidirectional' effect of stress hormones on learning and memory (Lupien *et al.*, 2002). In young adults (mean age 23.1 years), morning cortisol levels have been reduced by the addition of the pharmacological agent metyrapone, leading to delayed memory impairments, yet when hydrocortisone was administered during the diurnal trough in cortisol, positive effects for word recognition tasks were observed (Lupien *et al.*, 2002). In a recent experimental laboratory-induced stress study of children aged approximately four- to seven-years old (mean age five years and three months), differential effects for cortisol and autonomic reactivity at two-week follow-up, with cortisol reactivity linked to poorer memory and autonomic reactivity conferred risk only when a non-supportive interviewer was employed (Quas *et al.*, 2004). Learning and memory outcomes need further consideration in respect of the psychophysiological effects of life transitions.

Assessment of acute physical health outcome

The study of psychosocial factors influencing the onset and duration of an upper respiratory infection (URI), or an episode of the common cold has linked higher levels of stress with increased susceptibility to infection in adults and in children. This has been reported under both experimental conditions (for example, Cohen *et al.*, 1991, 1995) and naturalistic conditions (for example, Graham, 1986; Turner Cobb & Steptoe, 1996, 1998; Cohen *et al.*, 2002). Implicated in these findings are a number of psychosocial resources, such as coping responses, social support and health-related behaviours which act as moderators and mediators of stress on health (for more detail see 'Common cold'). In this chapter it is sufficient to say that measurement of the onset and duration of the common cold is a simple and non-intrusive way to assess the immune impact of stressful events (Boyce *et al.*, 1995). As already noted, there is comparatively little research to date that has incorporated acute physical health outcomes as measures of ability to deal with naturalistic psychophysiological challenge in children. One study which stands out in this regard evaluated susceptibility to the common cold for the duration of the first 13 years of life (Ball *et al.*, 2002). Interestingly, the

authors report that those children who attended the largest scale day care centres, were found to be protected from the common cold at ages 6, 8 and 11 years although a higher infection rate was seen earlier in life at the age of two years (Ball *et al.*, 2002). This study however, did not specifically examine school transition and it failed to examine temperament directly, or in association with, mediating hormonal responses to the social situations encountered.

As the majority of the preschool and school transition research to date has been carried out in the United States, it is important to point out that some important differences in educational practice exist between the two countries which could influence interpretation of research. Cultural differences may provide insight into the psychophysiological stress process, the effects of which may be highlighted by variations in age of entry or style of education. Yet there is a lack of research directly assessing school and indeed life transition influences on health. These transitions have been explored in depth by educationalists and developmental psychologists resulting in numerous child welfare intervention programmes, yet the psychobiological adaptation has itself largely been ignored. At the transition to senior school stage, a particular challenge to and opportunity for psychoneuroimmunological research is provided, given physiological challenges naturally occurring at this time, in relation to cortisol and dehydroepiandrosterone (DHEA) (Goodyer *et al.*, 2001; Tornhage, 2002; Netherton *et al.*, 2004).

In summary

As detailed above, childhood influences on health are bound up with the psychophysiological activation of the HPA axis during development and subsequent functioning in respect of health across the lifespan. Research in the developmental health arena may further our understanding of crucial psychosocial factors and relevant developmental junctures for providing intervention. The studies cited attest to the fact that it is not just extreme cases of maltreatment that give rise to changes in HPA axis patterning but that such individual differences are also observed in healthy populations of children under both experimental and naturalistic conditions. These alterations may serve as early subtle indicators of, and contribute to, physical health outcomes in adulthood. In order to further understand these influences and their importance in both short- and long-term health, further longitudinal studies are called for which include measures not only of physical health outcome but also of learning and memory as indicators of potential health effects.

Children's perceptions of illness and death

Richard E. Boles and Michael C. Roberts

University of Kansas

Psychologists have long attempted to gain an understanding of how children view the world and its components. A particular interest within paediatric psychology has been children's perceptions of such environmental components as medical events; personnel, and procedures; diseases; and death (Roberts, 2000). In order to effectively change the environment in ways to create more positive perceptions, it becomes paramount to know, in fact, how children perceive chronic illness and death. Psychologists have investigated what have been variously called children's knowledge, attitudes, attributions, understanding, conceptions and perceptions of health-related events, issues and concepts. Similarly, clinicians have sought to understand children's perceptions of diseases such as asthma or cystic fibrosis in order to design interventions and explanations for those with such conditions. Additionally, perceptions of siblings and peers about children with chronic illness and disease have been examined in order to enhance their acceptance and development of social relationships. Finally, clinical investigators have assessed children's views of medication and the causes of disease in order to influence adherence to treatment regimens. The following selective review highlights children's perceptions regarding chronic illness and death, explicating theoretical and conceptual considerations, peer and sibling relationships, medication issues and clinical implications.

Theories of children's perceptions and attitudes

Several theoretical frameworks have been developed or modified within which to conceptualize children's perceptions and understanding of chronic illness and death. The Health Belief Model (HBM) has been widely used to conceptualize adults' motivations to adopt health-enhancing behaviours (Rosenstock, 1974). In general, research has been supportive of the HBM with adults (see 'The Health Belief Model'). However, noticeably less research has investigated the applicability of HBM with children (e.g. DePaola *et al.*, 1997). A somewhat similar theoretical model, Protection Motivation Theory (PMT), has been advanced as a more comprehensive and adaptable model. PMT postulates that preventive health behaviour results from the cognitive mediational processes of threat appraisal and coping appraisal. As with HBM, PMT relies on cognitive perceptions and has been supported by considerable research with adults; although PMT concepts have been extended to children (e.g. Knapp, 1991), support for the extension remains limited. Thus, with both HBM and PMT frameworks, the downward extension of adult-oriented theories to children has not been sufficient, just as it has not been for other aspects of health and clinical psychology.

Models that have incorporated a more developmental approach have been advanced with regard to children's perceptions of

phenomena in paediatrics. For example, many of these formulations have relied upon Piaget's concepts in which increasingly sophisticated cognitive development leads directly to positive changes in children's health conceptions, beyond the predictive ability of simply looking at child age (e.g. Berry *et al.*, 1993). Often, research studies have not been organized by a particular theoretical framework. These studies have been guided more by pragmatic considerations or questions of 'what are children's beliefs and perceptions?' and 'what influences children's conceptions?'. These have been valuable for explicating children's beliefs and as heuristics for developing theories and interventions to help children and families. The following sections summarize the research studies into children's conceptions of various paediatric phenomena.

Children's conceptions of illness and death

Early work into children's conceptualizations and perceptions of illness and death was conducted with healthy children. For example, Nagy (1951) determined that preschool children (3–5 years) were relatively unsophisticated in their causal explanations of illness. Slightly older children explained illness as a result of infections (6–7 years) and exposure to germs (8–10 years), while children ages 11–12 years understood multiple causes of illness. Potter and Roberts (1984), in an application of Piagetian constructs, determined that preoperational children (ages 2–7 years) perceived themselves as more vulnerable to contagion.

Investigations into healthy children's disease conceptions have examined perceptions of AIDS in terms of contagion, vulnerability, attitudes toward persons with AIDS, etc. Children and adolescents, for example, have limited understanding of AIDS and possess a variety of conceptions of the disease not commensurate with professional knowledge (but probably not unlike what adults know and believe). Walsh and Bibace (1991) found that children's conceptions of AIDS followed developmental progressions related to cognitive development and are similar to their understanding of other illnesses. The importance of developmental factors has been revealed when considering children's AIDS knowledge. For instance, older children with more AIDS knowledge show more mature illness conceptualizations when compared with children who have less knowledge (De Loye *et al.*, 1993). Zimet, *et al.* (1991) determined that knowing somebody with AIDS lowered adolescents' social anxiety about interacting with a person with AIDS, but had no effect on perceptions of personal vulnerability.

Researchers have also studied relatively abstract concepts such as the development of concepts about death and personal mortality. Nagy (1948; as cited in Willis, 2002) proposed that children understand death as occurring in a progression across 3 stages. Stage 1 is a simplistic belief by children ages 3 to 5 years old that death is nothing more than individuals not being present at that time. In Stage 2, children (ages 5 to 9 years old) may think that death is completely avoidable. Finally, during Stage 3, children (ages 9 and 10 years old) begin to recognize that death is permanent, unavoidable and omnipresent.

When considering a child's ability to conceptualize death, cognitive development is considered a key influential characteristic (Koocher & MacDonald, 1992). For example, infants and nonverbal toddlers are thought not to make inferences of causality between

disease and treatment process. As toddlers become older they may often attribute negative events and outcomes to events far from reality and show evidence of magical thinking. However, as children begin grade school, they begin to understand that death is permanent, irreversible and not simply a form of sleep (Koocher & MacDonald, 1992). Similarly, Reilly *et al.* (1983) found belief in personal mortality beginning in children at about the age of six years. Death is a fairly abstract concept, but apparently death-related experiences facilitate acquisition and increased understanding of death concepts. Similarly, experiences with chronic illness also appear to facilitate children's understanding of the aetiology of illness, although more definitive investigations are needed to determine which features of experience create facilitating effects.

Children's perceptions of peers with illness or disorders

The paediatric psychology research previously noted considered children's perceptions of health and illness in general. Even when specific to a disease such as AIDS or cancer, the interest has been relatively focused on their conceptions in the abstract. A large body of literature has developed into how children view, interact with and hold attitudes about those individuals who may have an illness or disorder. Knowledge of children's understanding about conditions of disability can assist all parties during integration of children with chronic diseases into the classroom. Furthermore, professionals have realized the importance of children's understanding of illness in order to facilitate communication about illnesses and improve interactions among children (see 'Breaking bad news').

Several studies have found that children hold more negative attitudes about peers who are different, namely, who are mentally retarded, visually, hearing or speech impaired and physically impaired. Across perceived conditions, younger children and girls tend to hold more prosocial behaviours and empathy than do older children and boys (e.g. Gray & Rodrigue, 2001). When considering peer acceptance of disabled or non-disabled children, healthy children often indicate a preference for non-disabled peers. In contrast, hypothetical peers diagnosed with cancer were rated by children as equal in social image and acceptance when compared to healthy hypothetical peers, suggesting a diagnosis of cancer is not necessarily socially undesirable.

Peer perceptions have a potentially large impact during peer interactions. For instance, an increasingly higher number of children who are HIV-positive will be attending school, where many peers (and teachers) may worry about such close proximity or have a stigmatizing view of individuals with AIDS. When assessing the factors that affected the acceptance of hypothetical peers with AIDS, there is more support for increased peer acceptance when informing children about how HIV is *not* transmitted (e.g. the myth of drinking from a water fountain) compared with providing information about the modes of transmission (Maieron *et al.*, 1996). These findings may be the result of children's higher frequency of myth behaviours as opposed to behaviours that are likely to lead to HIV transmission, such as sex or drug sharing.

Cole *et al.* (1996) also used vignettes of hypothetical ill peers to elicit children's views about disease perceptions. Interestingly, they found that the type of disease and the impact on physical interactive

activity did not have a significant effect on peer acceptance; however, older children reported greater acceptance of chronically ill children. In general, regardless of methodology, perceptions about peers with physical, medical, or psychological disorders tend to be more negative than those about peers without disorders and show age or developmental relationships.

Children's perceptions of medication for chronic illness

In studying perceptions of specific phenomena in paediatrics, the importance of knowing children's knowledge and attitudes about medication and treatment regimens has been demonstrated in several reports (see 'Hospitalization in Children'). Practitioners have asserted that attitudes and beliefs about treatment and its components influence the acceptance, the adherence and the outcome of health care interventions.

For example, DePaola, *et al.* (1997) examined the perceptions of children and their mothers regarding the most common prescribed medical treatment for asthma: at-home medication use. Providing modest support for the application of the Health Belief Model to children, this study revealed that when children disliked a medication, so did the parent. Additionally, when children perceived benefits to the medication, parents did also. Overall, these perceptions were shown to be related to the severity of the children's asthma and mother and child perceptions were significantly correlated. While these findings support similar previous correlational research, it is important to note that the directionality of influence is unknown; it is more likely that a bidirectionality of influence exists between child and parent perceptions of medical phenomena. Furthermore, McNeal *et al.* (2000) found similar perception complexities in the perceptions of mothers and their children diagnosed with attention deficit/hyperactive disorder (ADHD) regarding medication treatments. Attitudes about treatment such as these influence communication, information seeking and adherence. Thus, studies support the view that parents do have an important relationship with and influence on their children's health beliefs and behaviours.

Clinical implications

Recognizing that children and adults generally perceive people with physical and behaviour disorders as less acceptable than those without disorders, health care and educational professionals have attempted a variety of interventions to influence the perceptions and improve acceptance and understanding. These interventions are often envisioned to have positive effects for the child with a disorder (e.g. illness, physical handicap, or behavioural problems) in understanding their own situation and improving regimen compliance, lessening anxiety and enhancing adjustment. Children with chronic health disorders generally report having more adjustment problems when compared with various control groups. However, only a minority of children with chronic illness appear maladjusted, supporting the finding that there is an increased vulnerability for maladjustment but is not the most likely outcome (Eiser, 1990). Although research on the perceptions of chronic illness and the effects on adjustment has grown substantially in recent years,

much more conceptually driven research is still needed (see Wallander & Varni, 1998).

Currently, little empirical evidence exists regarding interventions designed to facilitate children's understanding and adjustment to death. In general, guidelines suggest that parents and service providers use a developmentally based approach to provide an appropriate healthy model of emotional behaviour, minimizing euphemistic speech, being concrete and engaging in activities which promote self-expression, such as art, music, or writing pretend letters to those who died (e.g. Willis, 2002). Clearly, more investigations are needed in order to fully understand best practices with regard to children's perceptions and adjustment to death.

In addition, children without health problems could better understand their peers or siblings who may have chronic illnesses. For example, AIDS educators should provide curricula that specifically address misconceptions on transmission, focusing on the day-to-day behaviours such as sharing toys with a child who has AIDS. Additionally, peers of children with chronic illness who are at risk for negative psychological effects will be likely to benefit from interventions which focus on accurate information sessions, support groups and attention to internalizing behaviours, such as anxiety and depression.

Finally, knowledge and attitudes about medication acceptance and adherence to treatment regimens are likely to be favourably enhanced by addressing misunderstandings about the particular benefits and drawbacks of individual medications. Moreover, interventions that provide information on side-effects, reasons for dosage (and changes in dosage) should also be considered for both parents and children with chronic illness.

Conclusion

Research into children's conceptions of illness, their perceptions of peers with disorders, and their comprehension of medical treatments, is useful for understanding children's development and their views of the world. Interventions to improve each of these aspects often follow from this understanding. Paediatric psychology, having the qualities of both basic and applied research, has given important attention to both in studying children's perceptions and understanding of paediatrics.

Future investigations are greatly needed to enhance understanding of the key variables associated with children's perceptions of chronic illness and death that can be utilized for the development of effective psychological interventions for key related issues, such as maladjustment and poor medication adherence. Specifically, theoretically derived models incorporating a developmental perspective are needed to provide an adequate framework to empirically test more complex models (Wallander & Varni, 1998). Additionally, methodologies and measurement procedures should include perspectives for perceptions across various chronic illnesses in order to identify common characteristics, as well as including under-studied populations, such as minorities and economically disadvantaged groups. Finally, interventions, based on both maladaptive and adaptive perceptions of chronic illness and death, can be developed and evaluated in relation to psychological adjustment.

Coping with bereavement

Margaret Stroebe, Henk Schut and Wolfgang Stroebe

Utrecht University

Over the course of a lifespan, most people will be confronted with the loss of a close relationship: if attachments have been formed, one is likely to have to suffer the consequences of separation. The term 'bereavement' refers to the situation of a person who has recently experienced the loss of someone significant in their lives through that person's death (see 'Coping with death and dying'). The loss of a family member – such as a parent, partner, sibling or child – are typical examples, although the death of other important relationships – such as a meaningful friendship, classmate or good neighbour – may also be significant. Bereavements evoke grief, which can be defined as a primarily emotional (affective) reaction to the loss through death of a loved one. Affective reactions include yearning and pining and intense feelings of distress over the loss of

the deceased person. Grief also incorporates diverse psychological and physical manifestations. The former type of manifestation includes cognitive and social-behavioural reactions such as self-blame and withdrawal from others. The latter includes physiological/somatic reactions, such as head- and stomach ache, and increased vulnerability to diseases. Sometimes mourning is used interchangeably with grief. However, there are good reasons to define mourning as the social expressions or acts expressive of grief that are shaped by the practices of a given society or cultural group. It is worth noting that researchers following the psychoanalytic tradition often use the term 'mourning' rather than 'grief' to denote the psychological reaction to bereavement.

The impact of bereavement

Bereavement leaves many people feeling heart-broken, fearful, uncertain about how to go about their changed lives, and terribly lonely, even when surrounded by others. Most bereaved persons gradually accommodate to their loss, however, and manage to find pleasure in their lives again over the course of time (though many bereaved persons say they 'get used to' rather than 'get over' a loss). At the same time, it is important to recognize that bereaved persons are at elevated risk of developing mental and physical health problems, which may persist long after the loss has occurred (Parkes, 1972/1996; Stroebe & Stroebe, 1987). A minority of individuals are vulnerable to complications in the grieving process itself, for example, chronic grief, which is characterized by protracted grief and prolonged difficulty in normal functioning (Bowlby, 1980). The risk of mortality, though small in terms of the absolute numbers of bereaved persons at elevated risk, is also higher than rates for non-bereaved persons of equivalent age and gender. This 'broken heart' effect pertains across different types of relationships, including spouses and parents who have lost a child (Li *et al.*, 2003; Stroebe & Stroebe, 1993). Not surprisingly, then, bereaved people quite often feel in need of consultations with their general practitioners or seek support from other health care institutions such as the various volunteer and professional counselling or therapy intervention services (Schut *et al.*, 2001) (see 'Counselling').

Given the diversity in bereaved persons' reactions to their loss, it becomes important to establish who is at risk of the diverse detrimental effects. Bereavement researchers have come to use the term 'risk factors', to signify the identification of situational and personal characteristics likely to be associated with increased vulnerability across the spectrum of poor bereavement outcome variables (W. Stroebe & Schut, 2001). For example, high risk subgroups have been identified – admittedly with differing levels of empirical robustness – according to sociodemographic variables (e.g. male gender among spouses; younger rather than older age in general), causes and circumstances of bereavement (e.g. sudden death; child loss), personal factors (e.g. a history of mental disturbance; personality characteristics/relationship difficulties) and concurrent circumstances during bereavement (e.g. economic difficulties that have come about as a result of the death).

Coping with bereavement

It is also important to examine the different ways that people cope with bereavement. Why is it that some persons manage to cope, while others remain devastated by their experience and fail to adapt well? Do these good- versus poor-outcome bereaved people go about their grieving in different ways? Can others help a grieving person to cope with loss? Who needs help with coping? More fundamentally, what is the nature of adaptive coping, and what scientific understanding has been reached on this topic?

Classic theoretical approaches

For most of the twentieth century it was generally believed that to get over the loss of a loved one it was necessary to do one's 'grief work'. Grief work refers to the cognitive process of confronting the

reality of a loss through death, of going over the events that occurred before and at the time of death, and of focusing on memories and working towards detachment from the deceased. The grief work concept was fundamental to the psychoanalytic perspective, formulated by Freud (1917/1957) in 'Mourning and Melancholia', and was subsequently influential not only in major theories of grief, but also in the development of principles and guidelines for bereavement counselling and therapy. Yet, is it enough to say that people who are 'doing their grief work' are coping effectively? In the latter decades of the last century, doubts were raised on a number of levels (Bonanno, 2001; Stroebe, 1992; Wortman & Silver, 1987, 1989). First, the concept of grief work lacks specification. For example, it is difficult to distinguish yearning and pining, which are part of grieving but which are associated with negative outcome (Nolen-Hoeksema, 2001), from grief work, which comprises a constructive confrontation with the reality of loss, one that would then lead to positive outcome. Second, empirical studies have failed to confirm that confronting and working through a loss leads to better outcomes than not doing so, or that avoiding confrontation is necessarily detrimental to adaptation. Third, different 'recipes' for grieving could be found in different cultures, including ones that called for suppression of emotions of grief, a clearly different strategy that was not apparently associated with particularly bad outcomes (Wikan, 1988). Finally, attention has been drawn to two further features of the grieving process itself: it is a complex, dynamic process calling for adaptation to many different life changes, all of which need to be addressed but which cannot be attended to all at the same time: the grief work notion does not cater explicitly for this complexity. Grieving is also exhausting: a person cannot do grief work unremittingly, 'dosage' is necessary, so we need to be aware of the need for emotion regulation and to extend our theoretical modelling to incorporate a more dynamic perspective.

Contemporary theoretical approaches

Contemporary theoretical perspectives postulate finer-grained strategies of adaptive coping with bereavement. Coping is nowadays generally understood to encompass 'the person's cognitive and behavioural efforts to manage (reduce, minimize, master or tolerate) the internal and external demands of the person-environment transaction that is appraised as taxing or exceeding the resources of the person' (Folkman *et al.*, 1986, p. 572). Bereaved people use certain ways of coping to manage the stressful situation that follows bereavement, and the associated negative emotions. 'Adaptive strategies' would then be those that actually lead to a reduction in the negative psychosocial and physical health consequences of bereavement and/or to a lowering of grief. Such definitions may seem straightforward, but it is important to note the difficulties in assessing adaptive coping (see W. Stroebe, 2000). Different strategies may be more effective at different times or for coping with different aspects of bereavement; a strategy may be useful short-term but harmful long-term; it may positively affect physical health but increase distress. Methodologically too, many of the empirical studies that have been conducted to assess effective coping have shortcomings. For example, assessments are not conducted longitudinally (coping strategies need to be assessed at a first measurement point, to predict outcome at a second), and sometimes have even been conducted retrospectively. Furthermore, definitions of

coping strategies or styles often include outcome as well as process variables. For example, some of the scales used to assess emotion-focused coping contain items that confound coping strategy with coping outcome (e.g. including questions about distress or low self-esteem among those on controlling emotions).

Toward identification of (mal)adaptive processes

A number of quite diverse theoretical approaches can be drawn on to identify principles of (in)effective coping with bereavement (for a review, see M. Stroebe & Schut, 2001a). These perspectives range from general stress and trauma theories, to general theories of grief, to models of coping which are specific to bereavement. Each approach has generated empirically testable hypotheses (although far more research is needed to explore the effectiveness of proposed strategies). In addition to elaborating on the grief work process in general, stress and trauma theories have examined processes involving emotion-versus problem-focused coping, confrontation-avoidance strategies, cognitive regulation, the efficacy of communication with others about the loss and the role of revision of assumptions that have been shattered, or making sense and finding meaning in the loss.

General grief-related theories also built on the grief work notion to include examinations of the transformation in the relationship to the deceased and trajectories of adaptation, for example, in terms of psychosocial transitions (e.g. Parkes, 1993) or attachment and recovery processes (Bowlby, 1980; Rubin & Malkinson, 2001). Similarly, Weiss (1988) defined three specific adaptive tasks involved in coming to terms with loss; cognitive acceptance, emotional acceptance and identity change.

Models of coping with bereavement have suggested a number of quite specific processes of (mal)adaptive coping. The best among these studies have adopted well controlled, longitudinal designs. For example, Nolen-Hoeksema (2001) has provided evidence that a ruminative coping style is maladaptive. Rumination was defined as engaging in thoughts and behaviours that maintain one's focus on one's negative emotions and on the possible causes and consequences of those emotions. Rumination was found to prolong distress and to make it more difficult for bereaved people to solve the problems they face following their loss. On the other hand, suppression of grief-related distress has also been shown to be maladaptive (Folkman *et al.*, 1996), although there may be benefits to controlling the emotion of grief (Fralely & Bonanno, 2004; Stroebe & Schut, 1999). Future research needs to tease out precisely when and for whom confronting versus avoiding grief is beneficial versus harmful.

Following a different line of approach, Folkman (2001) adapted cognitive stress theory (Lazarus & Folkman, 1984) to the special characteristics of bereavement, in an effort to derive specific predictions about coping following this particular life event. A key element of Folkman's model was the inclusion of positive indicators of adjustment and delineation of processes which support the positive indicators. Again, longitudinal evidence was provided to show that the co-occurrence of positive with negative affect was not only a correlate, but that positive affect actually had adaptational significance in the coping process: 'The coping processes that generate positive affect and the positive affect itself appear to help sustain renewed problem- and emotion-focused coping efforts in dealing with the chronic stressful condition' (Folkman, 2001, p. 571).

Not only intra- but also interpersonal coping variables have been suggested in theories of adaptation to bereavement, with examinations ranging from studies of bereaved families' interactions, biography reconstruction in family groups, and incremental grief processes dependent on (a)symmetry and (in)congruence within bereaved family groups (M. Stroebe & Schut, 2001a; Winchester-Nadeau, 2001). Looking more specifically at interpersonal processes, investigators have examined the role of disclosure and of types of social support (emotional, instrumental, companionship, etc.) from others as assisting coping with bereavement. Following the extensive work of Pennebaker and colleagues (for a review see Pennebaker & Keough, 1999) which has demonstrated the efficacy of diary writing and spoken disclosure in adjustment to stressful life events, one would expect these manipulations to help in bereavement, which, after all, is frequently considered the most stressful event of all (see 'Emotional expression and health'). Surprisingly, results have been very mixed, with the best-designed studies failing to find any benefits of disclosure among bereaved samples (M. Stroebe *et al.*, 2002). Similarly disappointing have been studies of social support, including the provision of professional support in the form of counselling or therapy. These have also failed to show beneficial effects among samples of normally bereaved individuals. Only in cases of high risk or where there are existing complications (e.g. prior psychological disturbance) has intervention from others been shown to attenuate grief and reduce symptomatology in general (Jordan & Neimeyer, 2003; Schut *et al.*, 2001). Social support has simply been shown to help all people – irrespective of whether or not they were bereaved – but not to buffer the bereaved in particular against the negative consequences of loss (Stroebe, Stroebe, Abakoumkin & Schut, 1996). It seems that the emotional loneliness experienced on the loss of a loved person cannot, then, be assuaged by others, though others may be able to help with tasks arising through the loss. Furthermore, professionals need to channel their intervention toward the most vulnerable among the bereaved.

The dual process model of coping with bereavement

Taken together, we see that many kinds of adaptive tasks have been identified – and some empirically-researched – deriving from very different theoretical approaches. Is it possible to develop an integrative model of coping with bereavement that incorporates many of the elements of these approaches and, most importantly, enables one to incorporate the coping processes that have been identified as (mal)adaptive into a single framework? Two integrative models have been proposed, namely, the Four Component Model by Bonanno and Kaltman (1999) and the Dual Process Model of Coping with Bereavement (DPM) by Stroebe and Schut (1999). Bonanno and Kaltman's model is a broader bereavement model, for example, it includes risk factors, while the DPM focuses more narrowly on the adaptiveness of the coping process itself. Bonanno and Kaltman adopt an emotion theory perspective, while the DPM draws more broadly and explicitly on the earlier theoretical approaches described above. The two approaches are largely compatible. Here we focus on the DPM.

The DPM comprises an attempt to integrate existing ideas into a single framework to enable prediction of adaptive coping and to overcome the shortcomings of the grief work model described

earlier. The DPM defines two broad types of stressor, to cover the range of diverse stressors that grieving people have to deal with, namely, those that are loss- versus restoration-oriented. 'Loss oriented stressors' are those that have to do with the bereaved person's concentration on and processing of some aspect of the loss experience itself. The focus of attachment theory on the nature of the lost relationship would be consistent with this, as would the integration of grief work (grief work is indeed an important part of grieving). 'Restoration-orientation' refers to the focus on the secondary stressors that are also consequences of bereavement. Cognitive stress theory is applicable here: it assumes that a range of sub-stressors may occur (e.g. worries about making ends meet, being able to master the tasks previously undertaken by the deceased). Both orientations are sources of upset and stress, and are involved in the coping process. Both are attended to in varying degrees (according to individual and cultural variations). Thus, one can speak of 'tasks' of grieving but these tasks are more extensive than described previously (see Worden, 1982/1991/2002).

Given that cognitive processes of confrontation-avoidance have been identified as central in coping with bereavement, it is important to integrate an emotion regulation process into the model. Indeed this is also necessitated by the postulation of the two types of stressor, and because of the conceptualization of the grieving process as a dynamic and fluctuating phenomenon. The DPM specifies a dynamic coping process of oscillation, a regulatory process that distinguishes this model from others. It is proposed that a bereaved person will alternate between coping with loss- and restoration-oriented stressors. At times the person will confront and dwell on aspects of loss (or restoration) and at other times avoid them. Oscillation between the two types of stressor is necessary for adaptation. We noted too that grieving is arduous: for successful coping to take place there also, then, needs to be 'time off'. We maintain that it is actually beneficial to the coping process itself to have respite from confronting either type of stressor for a while. What emerges, then, is a more complex regulatory process of confrontation and avoidance than that described and investigated in other models. The structural components of the DPM are depicted in Figure 1.

Clearly, it is also necessary to represent a broader range of cognitive processes in the model including meanings, assumptions and types of expression associated with good versus poor adaptation. Drawing on the cognitive process models of positive versus negative (re)appraisal described earlier, the DPM provides an analysis of cognitions related to the confrontation-avoidance process. Following the previous research outlined above, there are good reasons to argue the need for oscillation between positive and negative affect – in relationship not only to loss- but also to restoration-stressors – as integral to the coping process. For example, persistent negative affect is maladaptive, although negative affect is part of grieving, while somewhat conversely, positive affect sustains the grieving process, but if positive states are maintained relentlessly, grieving is neglected. To illustrate, a chronic griever would be likely to attend relentlessly to negative aspects associated with loss, dwelling on the deceased, failing to take comfort in positive features and ignoring the tasks of restoration that need attending to (or taking a respite from grieving to do pleasant things). Such pathways as these have been integrated within the DPM (Stroebe & Schut, 2001*b*).

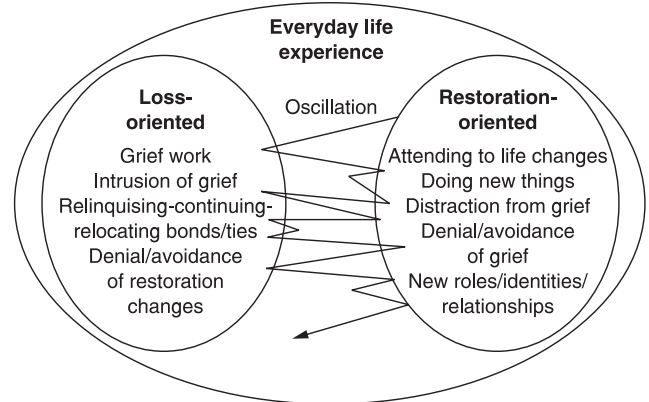

Fig 1 Dual Process Model of coping with bereavement.

Further empirical testing of the DPM is needed, although studies are beginning to find supportive results for some of the parameters (Stroebe, Schut & Stroebe, 2005). Although not a direct test, results of the study by Schut *et al.* (1997) are indicative. It is known that women – at least in traditional western societies – tend to be more emotion-focused and men more problem-focused in their coping. In a blind assignment, Schut offered two types of intervention for bereaved men and women who suffered high levels of persisting distress approximately a year after their bereavement. One type was focused more on emotions, the other on problems. Interestingly, the bereaved women, who were typically more focused on their emotions (loss-orientation), benefited more from the problem-focused intervention, while the bereaved men, more focused on dealing with things through problem (restoration) orientation, benefited most by confronting their emotions.

Conclusions

There are good reasons for arguing the importance of further development and testing of scientific models of coping with bereavement, such as the one illustrated above. Theories provide a sound basis for methodical testing of the validity of assumptions that people have about coping with bereavement: do we need to 'give sorrow words' or 'keep grief within', as the poets disparately claim? Without a systematic analysis it is difficult to ascertain which of these assumptions is correct (we have suggested that neither is; that it is not really that simple!) or, even more importantly, to know whether people's beliefs about what is best for grieving people, are actually correct. Theories are also important for the development of assessment instruments to investigate (mal)adaptive coping with bereavement: 'A rational, theory-driven strategy should be preferred over inductive, empirical approaches which run the risk of coincidental solutions' (Heck & de Ridder, 2001, p. 460). Finally, theoretical approaches to coping with bereavement, backed up by sound empirical testing, should not only teach us more about the nature of grief and grieving, but also enable us to answer questions about effective coping more precisely, and thereby improve understanding of those who suffer extremely from the loss of a significant person in their lives.

Coping with chronic illness

Keith J. Petrie and Lisa Reynolds

The University of Auckland

The increase in chronic illness

Chronic illness is now the predominant disease pattern in most developed countries. Advances in medicine have transformed many previously deadly infectious diseases, such as tuberculosis, pneumonia and influenza into treatable conditions and some have disappeared almost completely. The resulting improved longevity of populations has meant a growth in the burden caused by chronic conditions such as cancer, heart disease, stroke and diabetes. Chronic illnesses often strike in middle- and older-age-groups and bring with them considerable difficulties in adjustment and coping which can severely compromise patients' quality of life. While chronic diseases do kill, most people diagnosed with a chronic illness will live for many years with their condition. Understanding and improving the process of coping with a chronic illness has become an important area of health care.

Adjustments required

The initial psychological adjustments following the diagnosis of a chronic disease generally involve issues related to a loss of function. Individuals at the stage of diagnosis confront the reality that their state of health and function of their body have changed, and are likely to remain impaired. The speed with which individuals confront this loss can be strongly influenced by the nature of the illness. With some chronic illnesses, such as heart disease which is diagnosed following a myocardial infarction, awareness of the presence of the disease is usually sudden. In other chronic illnesses, such as arthritis, the patient may be aware of their disease long before a formal diagnosis is made.

Dealing with the ongoing demands of a chronic illness often requires the learning of new skills and adjustments to daily lifestyle. Patients need to cope with the symptoms of their condition and the requirements of medical treatment, which may mean learning new techniques for managing symptoms or administering therapy and coping with daily life disruption from both symptoms and treatment. Many illnesses, such as insulin-dependent diabetes and end-stage renal disease, require

patients to learn specific techniques for controlling symptoms, such as dialysis in the case of renal disease. Furthermore, an active awareness and monitoring of bodily function may be necessary in diseases like diabetes, where patients are often required to provide 95% or more of their daily care to avoid medical crises (Anderson *et al.*, 1995) (see 'Self-management' and 'Adherence to treatment').

Maintaining intimate and social relationships and developing effective working relationships with medical staff are other important adaptive tasks of living with a chronic illness. Chronic illness can put a strain on these social support networks. Relationships with healthcare staff can be a major source of difficulty in the management of chronic illness. The issue of patient autonomy versus independence from healthcare professionals is often an ongoing problem in long-term treatment programmes. Spouses, in particular, bear a large proportion of the stresses and burdens engendered by the illness. Tasks that the patient normally completed around the home before developing the illness but can no longer manage, need to be assumed by a spouse or other family member. Sometimes this creates feelings of guilt and inadequacy on the part of the patient and feelings of extra pressure and resentment on the part of members of the patient's family.

The restriction in social and other previously pleasurable activities is often an outcome of living with a chronic illness. This change, along with the emotional demands of integrating a new view of the self that includes the chronic illness, result in difficulties in affect regulation and an increased risk of adjustment and emotional disturbances. Individuals with chronic illness are more likely to be depressed than those who do not have a chronic condition, and this relationship has been found to be strongest amongst those who develop chronic illnesses early in life (Schnittker, 2005). However only a minority of patients develop clinical levels of emotional disturbance and this is more common among patients who experience greater levels of pain and disability. Emotional problems, such as depression, often interfere with the adoption and maintenance of rehabilitation programmes and seem to worsen prognosis in many conditions. It is important to note, however, that the emotional response to chronic illness is highly variable

and not all the emotional consequences of chronic illness are negative. The few studies that have investigated positive outcomes, also known as 'benefit finding' (e.g. Carver & Antoni, 2004, Sears *et al.*, 2003), report that individuals have found an increased value in close relationships, greater meaning in day-to-day activities and a greater compassion towards others with difficulties.

The coping process

How well patients adjust to chronic illness can be explained in part by their individual coping responses. 'Coping' is the cognitive, behavioural and emotional ways that people manage stressful situations. Coping has been previously conceptualized by researchers as a trait which is stable across situations, or alternatively, as a process that is strongly influenced by situational factors. However, Lazarus and Folkman's (1984) transactional model has had the largest impact on the current conceptualization of coping with chronic illness. This model sees the patients' coping responses being determined by both their appraisal of the degree of threat posed by an illness, and the resources seen as being available to help them cope in the situation. Coping responses in this model are divided into emotion-focused and problem-focused strategies. The function of problem-focused coping is to actively alter the stressful situation in some way, while emotion-focused coping is directed at regulating the patient's emotional response to a stressor.

Each response can be potentially adaptive or maladaptive depending on the situation. Some emotion-focused strategies show positive benefits across illnesses. Reframing the illness in a positive light, acceptance of the disease, and utilizing social support appear to be adaptive coping strategies across many chronic illnesses. Other emotion-focused strategies such as disengaging from the situation by giving up or avoiding thinking about the illness have generally been related to increased distress and disability (Carver *et al.*, 1993; Dunkel-Schetter *et al.*, 1992; Felton *et al.*, 1984). Problem-focused strategies, which in theory should have a greater adaptive potential, have frequently failed to demonstrate a strong relationship to outcome in chronic illness. However, seeking information about the illness and planning seem to be two strategies that do have the most consistent relationship with positive outcomes (Felton *et al.*, 1984). These strategies seem to have the greatest effect when the stressor is appraised by the patient as controllable (Folkman *et al.*, 1993). The lack of a strong relationship between problem-focused strategies and positive outcomes in chronic illness may be due to a mismatch between situations which are not amenable to change or control and the use of problem-focused strategies by the individual. In such circumstances emotion-focused strategies may be more useful, and recently interventions have been developed for patients with chronic illness to more accurately match the coping strategy to the characteristics of the situation. Such interventions seem to result in reducing the psychological distress associated with managing a chronic illness (Chesney *et al.*, 2003).

Influences on coping

The severity and nature of the disease does not seem to have a consistent relationship to patient coping and adjustment to

chronic illness, whereas the coping process is strongly affected by both psychological and social influences. An important influence is the patient's own subjective understanding of their illness. Leventhal *et al.* (1980) have proposed that cognitive illness representations direct both coping strategies and emotional responses to an illness in a parallel process that feeds back to influence the patient's own illness model. For example, a patient who attributes her hypertension to stress caused by work and who subsequently gives up her job only to find that this has made no difference to her level of blood pressure, may revise her view of the cause of the hypertension. Evidence suggests that particular illness models may be associated with more functional coping strategies and that illness representations may have a critical role in influencing adjustment to a range of common chronic illnesses such as heart disease, cancer and diabetes. In people who have recently had a myocardial infarction, beliefs about cause, timeline, controllability and consequences have been shown to be related to time taken returning to work and attendance at cardiac rehabilitation (Petrie *et al.*, 1996; Cooper *et al.*, 1999) and patients' drawings of perceived damage on their hearts predict recovery better than do medical indicators of damage (Broadbent *et al.*, 2004).

Social and partner support also plays an important role in adjustment to chronic illness. A number of studies have shown social support to be related to better disease outcomes and psychological adjustment in a variety of illnesses (see 'Social support and health'). A large follow-up study of chronically ill patients found social support was beneficial for health over time and this effect was strongest in older patients (Sherbourne *et al.*, 1992). Social support has been associated with better metabolic control in diabetes patients (Akimoto *et al.*, 2004), as well as improved outcomes in breast cancer (Waxler-Morrison *et al.*, 1991), kidney failure (Dimond, 1979) and heart disease (Case *et al.*, 1992). There may also be a gender difference in the way social support operates. In people with heart disease, the protective effects of social support have been less consistent for women. In addition, support can sometimes be too intrusive and people can be deluged with help or conflicting advice causing negative effects on the outcome of chronic illness (e.g. Garrity, 1973). In HIV patients, social conflict has been found to have a stronger association with coping than has perceived support (Fleishman *et al.*, 2000).

The exact nature of the benefits which accrue from social support in the context of chronic illness is not clear. Improved adherence to treatment and better health habits associated with higher levels of social support are likely to be important factors. The role of family and friends noticing changes in the patient's health that need attention may also reduce treatment delay if the illness worsens and the patient needs medical assistance. It seems that patients' perceptions of what actions are helpful are influenced by the social role of the provider. Esteem and emotional support are seen as most helpful when they come from spouses or family (Dakof & Taylor, 1990). Some researchers have suggested that the benefits of social support may not, in fact, derive from its positive aspects but rather from the absence of upsetting or conflictual relationships that interfere with successful function (Coyne & Bolger, 1990).

As well as the critical role of illness perceptions and social support, there is evidence that a number of individual difference variables also influence the coping process. The age of the person, their educational background and personality traits such as optimism can act to influence coping with chronic illness (Carver *et al.*, 1993; Felton *et al.*, 1984). Factors related to the disease itself in terms of its stage, physical characteristics and symptomatology are also important. It is apparent that each chronic illness is made up of a large number of stressors, and patients may apply different coping responses to each of these illness-related problems (Cohen *et al.*, 1986).

Coping interventions

A number of successful intervention strategies have recently been developed for patients suffering from chronic illness. These programmes vary in their focus from being strictly information-based to teaching specific skills which help to address problems faced by the patient. Kate Lorig has developed an intervention based around improving patients' self-efficacy and self-management techniques. It has been adopted in a number of countries as a way of improving the management of chronic illness (Donaldson, 2003). The Chronic Disease Self-Management Programme, also known as the Expert Patient Programme, uses trained patients as leaders of patient groups and draws on the findings of patients' own experience. The groups, which are also being trialled over the internet, focus on improving patients' ability to interpret changes in the disease and its consequences. Group sessions also aim to improve patients' use of medication and utilization of medical and community support as well as pain control and managing the emotional consequences of the illness. The programme encourages patients to set goals and identify effective feedback. Research shows participants experience improved physical activity, reduced symptoms and have significantly less need for medical treatment in comparison with control groups (Lorig *et al.*, 1999).

Mike Antoni and his colleagues at the University of Miami have developed a group cognitive behavioural intervention (see Behaviour therapy and Cognitive behaviour therapy) for a number of chronic illness groups including HIV-infected

individuals, men with prostate cancer and women diagnosed with early-stage breast cancer. This programme, which is adapted for each specific illness group, provides information on the stress response and various coping strategies best matched to deal with specific stressors. Imagery and progressive muscle relaxation techniques (see Relaxation training) are taught to help patients deal with personal stress. Cognitive behavioural techniques are employed to modify maladaptive appraisals and interpersonal social skills are taught to improve the utilization of social support networks. Results from clinical trials show that the intervention increased the incidence of reporting by patients that breast cancer had impacted positively on their lives (Antoni *et al.*, 2001), improved quality of life in men recovering from treatment of prostate carcinoma (Penedo *et al.*, 2004) and improved the use of effective coping and reduced mood disturbance in HIV-infected individuals (Antoni *et al.*, 2001).

While the results from intervention studies provide impressive support for developing coping skills as a treatment, it is difficult to separate the non-specific factors that occur in these group interventions from the specific effects of enhancing coping skills. These group treatment programmes incorporate other aspects such as psychological support and education with the teaching of coping strategies, and further research needs to be done to ascertain the specific benefits of coping training. Intervention studies are a valuable method of testing the coping skills model and they provide a useful way of investigating coping processes over time.

Coping with chronic illness has become an important area for research and intervention in health psychology. Research in this area is likely to become even more important in the future as the large numbers of individuals suffering from such diseases continue to grow. The diagnosis of a chronic illness typically brings with it a number of complex problems, emotional difficulties and changes in lifestyle. The patient's own understanding of the illness and the levels of appropriate social support available to them are key factors in promoting successful long-term coping. Interventions that develop coping strategies and improve the matching of problem-focused or emotion-focused strategies with the situational context seem to provide a promising avenue to improve the quality of life for patients living with a chronic illness.

Coping with chronic pain

Naomi Lester¹, Francis J. Keefe², Meredith E. Rumble² and Jeffrey D. Labban²

²Duke University Medical Center

Chronic pain is a problem that affects millions of individuals every year. Much of chronic pain is associated with significant progressive degenerative disease. Such diseases include arthritis and cancer, and involve prolonged severe pain which may be only partially ameliorated through the use of analgesic medication. This chapter examines the ways in which individuals cope with chronic pain. We describe how pain coping is conceptualized and measured and discuss what has been learned about adaptive and maladaptive methods for coping with chronic pain. We conclude with an exploration of new directions for research in this area.

Coping with chronic pain

Coping has been defined as the process of managing stressful situations, either external or internal, that are viewed as taxing an individual's adaptive resources (Lazarus & Folkman, 1984). The ways in which individuals view or appraise potentially stressful situations is an important component of this process definition of coping. In chronic pain, the ways in which a patient views pain are particularly important in their reactions to pain. Individuals may view pain as unpredictable and feel very little control over pain flares. Conversely, they may view pain as a constant irritation but one that can often be dealt with successfully.

Coping with pain can be thought of as cognitions and behaviours that serve to manage or decrease the sensation of pain and distress caused by pain. Within this basic framework, researchers have formulated several models of pain-coping. We will discuss five such models – the problem/emotion-focused coping model; the active/passive coping model; the cognitive/behavioural coping model; the fear avoidance model; and the acceptance model.

The problem- and emotion-focused coping model

Using the Ways of Coping Checklist (WCCL; Folkman & Lazarus, 1980), Folkman and Lazarus have created a coping model that categorizes coping strategies as either problem-focused or emotion-focused. Table 1 lists sample items from the WCCL. Problem-focused efforts seek to alter the individual's relationship to a stressor. Emotion-focused coping serves to alter one's internal reactions to a stressor. For example, the chronic pain patient faced with the choice of engaging in an activity known to cause pain (say sitting in a cinema for a back pain patient) may use a problem-focused coping strategy such as having a friend pick up a video instead and/or an

Table 1. Items from the Ways of Coping Checklist

Problem-focused coping:
Concentrated on something good that could come out of the whole thing
Made a plan of action and followed it
Seeking social support:
Talked to someone to find out about the situation
Asked someone for advice and followed it
Wishful-thinking:
Hoped a miracle would happen
Wished I could change what happened
Self-blame:
Realized that I brought the problem on myself
Blamed myself
Avoidance:
Went on as if nothing had happened
Tried to forget the whole thing

emotion-focused strategy such as controlling their disappointment by thinking about some other pleasant activity.

The WCCL is a 42-item pencil and paper questionnaire. Individuals are asked to indicate a recent stressful experience and then answer each question. When this questionnaire is used in studies of chronic pain, respondents are usually asked to indicate a stressor associated with their pain condition. Some forms of the WCCL use a 'Yes/No' response format while others employ a scale on which respondents indicate the extent to which they use each coping strategy. There are several scoring methods for the WCCL. One which is frequently used (Vitaliano *et al.*, 1985) adds questionnaire responses to form one problem-focused and four emotion-focused sub-scales. The emotion-focused sub-scales measure seeking social support, wishful thinking, self-blame and avoidance. The problem-focused scale contains items such as 'just took things one step at a time'. The emotion-focused scales are composed of such items as 'asked someone I respected for advice and took it', 'hoped a miracle would happen', 'blamed myself' and 'kept others from knowing how bad things were'.

Research examining the relationships between problem- and emotion-focused coping, and adjustment to chronic pain has been carried out in several groups of arthritis patients (Manne & Zautra, 1990; Parker *et al.*, 1988; Regan *et al.*, 1988). This research suggests that arthritis patients who rely on wishful thinking, and to a lesser extent, on blame and avoidance-coping strategies may experience more depression and greater physical disability

Table 2. Items from the Vanderbilt Pain Management Inventory

Active coping:
Engaging in physical exercise or physical therapy
Clearing your mind of bothersome thoughts or worries
Passive coping:
Restricting or cancelling your social activities
Taking medication for the purposes of immediate pain relief

than those who use fewer of these emotion-focused types of coping. In low back pain patients, Turner *et al.* (1987) found that individuals who relied on seeking social support reported lower pain levels than those who did not use this strategy. In the Turner *et al.* study, problem-focused coping did not relate to pain.

Comment

The problem- and emotion-focused coping model has three major advantages for understanding chronic pain coping. First, research has demonstrated that this coping model is valid not only for pain but for a wide range of stressful conditions (Lazarus & Folkman, 1984). Use of this model thus enables pain researchers to link their research to other recent studies in the literature on coping. Secondly, the questionnaire instrument used to assess problem/emotion-focused coping, the WCCL, is an established instrument which meets reasonable psychometric standards. Thirdly, the WCCL assesses a broad selection of coping strategies. Because of its breadth and utility for measuring both pain-coping and coping with other stressors, the WCCL may be used to compare the ways an individual copes with pain and the ways in which they cope with other stressors.

The active and passive coping model

Another category system, using the Vanderbilt Pain Management Inventory (VPMI; Brown & Nicassio, 1987), creates a model which classifies pain-coping strategies as either active or passive. Table 2 Lists sample items from the VPMI. In this classification system, active coping methods are those that require the individual to take some behavioural action to manage pain. An example of an active strategy would be doing muscle strengthening exercises in response to pain. Passive pain-coping strategies focus more on withdrawing or giving up instrumental control over pain. An example of a passive strategy would be the use of medications in response to pain.

The VPMI is an 18-item pencil and paper questionnaire. Respondents are asked to indicate the frequency with which they use each of the coping strategies when coping with pain of a moderate or higher level of intensity. The active coping scale of the VPMI is composed of items such as 'participating in leisure activities' and 'distracting your attention away from pain'. The passive coping scale contains items such as 'talking to others about how much your pain hurts' and 'taking medication for purposes of immediate pain relief'.

The VPMI has been used primarily in studies of arthritis patients. In one such study, Covic *et al.* (2000) investigated the

relationship between coping, pain, perceived physical disability and depression in rheumatoid arthritis patients. These researchers found passive coping to uniquely predict higher levels of pain. Passive coping was also found to mediate the effects of pain, perceived physical disability and depression. Consistent results were also found in a study examining the relationships of coping and adjustment to rheumatoid arthritis (Strahl *et al.*, 2000). Results indicated that patients reporting the usage of passive coping also reported more impaired physical functioning. Though the internal reliability of both the active and passive coping scales of the VMPI has been demonstrated, the passive coping scale has been shown to be the more valid construct of the two and thus demonstrated more significant relationships (Snow-Turek *et al.*, 1996). However, reports of active coping have been shown to be associated with less pain, depression and functional disability (Brown & Nicassio, 1987).

Comment

The active/passive coping model is appealing because it is simple and straightforward. Treatment efforts based on this model seek to increase active adaptive coping and decrease passive maladaptive coping. The questionnaire instrument developed from this model (the VMPI) is a very brief instrument that enables one to quickly and reliably categorize a patient's coping strategies. One limitation of this model is that some of the strategies that are labelled as passive (e.g. taking medication) require an active effort on the part of the patient (Keefe *et al.*, 1992).

The cognitive and behavioural coping model

Using the Coping Strategies Questionnaire (CSQ; Rosenstiel & Keefe, 1983) to assess cognitive and behavioural coping, Keefe and colleagues have developed a third model of pain-coping. Table 3 Lists sample items from the CSQ. This system parcels coping strategies into a greater number of coping scales. Examples of these scales include, coping self-statements, ignoring pain sensations and catastrophizing about pain. The CSQ also assesses individuals' perceived ability to control and decrease their pain. Studies of patients with osteoarthritis, rheumatoid arthritis and low back pain have indicated that most people with chronic pain use combinations of these methods for coping with their pain (Keefe *et al.*, 1987, 1990, 1991).

The CSQ is a 48-item questionnaire that asks individuals to indicate the extent to which they use each coping strategy when they experience pain. The items are then totalled to create seven sub-scales: diverting attention, reinterpreting pain sensations, coping self-statements ignoring pain sensations, praying or hoping, catastrophizing and increasing behavioural activities. Two higher-order factors, coping attempts and pain control and rational thinking may be calculated from the CSQ responses. The CSQ also assesses respondents' perceived ability to control and decrease their pain.

Research using the CSQ been carried out in several different ways. Some studies have used the seven sub-scales to assess coping, others have used the two higher order factors, and still

Table 3. Items from the Coping Strategies Questionnaire

Diverting attention:	I try to think of something pleasant I count numbers in my head or run a song through my mind
Reinterpreting pain sensations:	I don't think of it as pain but rather as a dull or warm feeling I imagine that the pain is outside my body
Coping self statements:	I tell myself to be brave and carry on despite the pain I tell myself that I can overcome the pain
Ignoring pain sensations:	I don't pay any attention to the pain. I go on as if nothing happened
Praying or hoping:	I pray to God that it won't last long I have faith in doctors that someday there will be a cure for my pain
Catastrophizing:	It's awful and I feel that it overwhelms me I worry all the time about whether it will end
Increasing behavioural activity:	I do something I enjoy, such as watching TV or listening to music I do something active, like household chores or projects

others have re-factored the questionnaire to form additional scales. The CSQ has also been used with a wide variety of pain conditions, including osteoarthritis (Keefe *et al.*, 2000), low back pain (Jensen *et al.*, 2003), rheumatoid arthritis (Covic *et al.*, 2003), fibromyalgia (Hassett *et al.*, 2000), and cancer-related pain (Wilkie & Keefe, 1991). Because of the wide variety of research with this instrument we will confine our description of findings to a more general level. In general, results have indicated that individuals who cope by trying to exert control over pain report less pain, depression and physical disability than those who make less use of this type of coping. Catastrophizing also appears to be a particularly maladaptive way to cope with chronic pain and individuals using this coping pattern appear to be more depressed and have greater functional disability. For example, Turner *et al.* (2002) found that greater catastrophizing was found to be significantly associated with greater pain-related disability and psychological distress in patients suffering from chronic pain after a spinal cord injury. Similarly, a longitudinal study focusing on pain and depression in rheumatoid arthritis patients (Covic *et al.*, 2003) found passive coping strategies, most notably catastrophizing, to be predictive of higher levels of pain and depression.

In examining other sub-scales, Turner *et al.* (2002) found that coping self-statements and ignoring pain were associated with greater psychological wellbeing. Similarly, Keefe and Williams (1990) found that patients who were referred to a pain management programme that endorsed more items from the coping self-statements sub-scale and who reported that they felt they could control and decrease pain, had lower depression.

Comment

The cognitive-behavioural model of coping has had a major impact on chronic pain assessment and treatment. The CSQ is now widely used in clinical pain assessment and in programmatic research examining the efficacy of cognitive-behavioural interventions (see 'Cognitive behaviour therapy'). The CSQ measures a variety of pain-coping strategies as well as identifying a patient's sense of efficacy for controlling pain. This emphasis on both coping and the appraisal of pain controllability fits well with theories of stress coping and provides additional information for the clinicians who are designing programmes to help patients cope more effectively.

The fear-avoidance model

Over the past decade, numerous studies have examined the utility of the fear-avoidance model in explaining adjustment to pain. The fear-avoidance model focuses on two behavioural coping responses to pain-related fear and anxiety: avoidance versus confrontation (Vlaeyen & Linton, 2000). An example of avoidance would be thinking that pain is a signal of damage to oneself and consequently trying to avoid all activities which are pain-related, whereas a more confrontational response would be engaging in activity appropriately considering some pain-related lifestyle changes. Within this model, avoidant responses are thought to lead to the maintenance or intensification of fear as well as to undesirable pain-related outcomes over time through several pathways, including an increase in negative appraisals of pain and its consequences, a decrease in normal activity leading to the disuse of the musculo-skeletal and cardiovascular system, little opportunity for disconfirmation of maladaptive beliefs about pain and its consequences to occur and more opportunity for mood disturbances to increase. This contrasts with confrontational responses, which are thought to lead to better adaptation to pain over time because individuals are engaged in activity and therefore have more opportunities to confront maladaptive beliefs about their pain, more reinforcers in their environment to regulate mood, and more physical activity to maintain functional ability (Vlaeyen & Linton, 2000).

Pain-related anxiety and fear have been assessed most frequently using one of two measures: 1) the Pain Anxiety Symptoms Scale (PASS; McCracken *et al.*, 1992) – a 40-item measure that was designed to assess cognitive anxiety, escape and avoidance, fearful appraisals and physiological anxiety in response to pain and 2) the Tampa Scale for Kinesiophobia (TSK; Kori *et al.*, 1990) – a 17-item measure that assesses fear of (re)injury due to movement. A growing body of research studies has examined pain-related anxiety and fear in patients with chronic low back pain (Crombez *et al.*, 1999; McCracken *et al.*, 1992; Picavet *et al.*, 2002; Verbunt *et al.*, 2003; Vlaeyen *et al.*, 1995), neck pain (Nederhand *et al.*, 2004) and acute low back pain (Fritz *et al.*, 2001; Swinkels-Meewisse *et al.*, 2003). One of the most consistent findings emerging from this literature is that patients scoring high on pain-related anxiety and fear measures report higher levels of disability and poorer performance on physical tasks such as lifting and carrying capacity

and trunk extension and flexion exercises (Burns *et al.*, 2000; Crombez *et al.*, 1999; Fritz *et al.*, 2001; McCracken *et al.*, 1992; Nederhand *et al.*, 2004; Picavet *et al.*, 2002; Swinkels-Meewisse *et al.*, 2003; Verbunt *et al.*, 2003; Vlaeyen *et al.*, 1995). These findings are particularly impressive given that they have been obtained even after controlling for important variables which might explain adjustment to pain such as pain intensity and duration.

Comment

The consistency of findings emerging from studies of the fear-avoidance model is impressive. This model is clinically useful because it links well to exposure-based interventions (see 'Behaviour therapy'). These interventions teach patients to overcome pain-related anxiety and fear through graded exposure to a series of pain-related fears. Preliminary findings from studies using single case designs suggest such interventions are helpful in reducing pain-related anxiety, disability and increasing activity level in patients with chronic low back pain (Vlaeyen *et al.*, 2001; Vlaeyen *et al.*, 2002). Controlled studies are needed to test the efficacy of such interventions with larger samples of chronic pain patients. Future research also needs to examine the degree to which the fear avoidance-model is useful in understanding the adjustment to disease-related pain (e.g. pain due to arthritis or cancer.)

The acceptance model

Recently, there has been growing interest in acceptance as a pain coping approach (McCracken *et al.*, 2004). Interest in acceptance comes from the clinical observation that the lives of many patients having persistent pain are dominated by the struggle to control a problem that is in part uncontrollable. There is growing recognition that maladaptive efforts to control or avoid pain can exacerbate pain and lead to heightened suffering and disability (Asmundson *et al.*, 1999; McCracken *et al.*, 1996).

Recent studies of acceptance and persistent pain have utilized the Chronic Pain Acceptance Questionnaire (CPAQ; Geiser, 1992), a reliable and standardized measure which assesses two dimensions of acceptance: a) willingness to experience pain – the absence of attempts to reduce or avoid pain; and b) activity engagement – the extent to which a person actively pursues valued life activities. McCracken *et al.* (1998) found that patients who scored higher on this measure not only had significantly lower levels of pain-related anxiety and depression, but also had lower levels of disability. These findings regarding acceptance were particularly noteworthy in that they were apparent even after controlling for pain intensity. McCracken and Eccleston (2003) compared the predictive utility of the CPAQ and a commonly used pain coping measure (the Coping Strategies Questionnaire) and found that the CPAQ accounted for almost twice as much variance as coping variables in explaining pain, disability, depression, uptime and work status. Finally, a recent study found that acceptance of pain was predictive of fewer health care visits for pain and pain medication intake (McCracken *et al.*, 2004).

Comment

Although the acceptance model of coping with pain is relatively new, it appears to have promise in fostering our understanding of adjustment to pain. Recent promising findings regarding this model have generated renewed interest in acceptance-based intervention protocols, such as the mindfulness-based stress reduction protocol developed by Kabat-Zinn and his colleagues (1985). To date, no rigorous randomized clinical trial has been conducted to assess the efficacy of acceptance-based interventions for patients having persistent pain. Also, the utility of the acceptance model has largely been examined in patients having chronic pain syndromes (e.g. chronic low back pain) and the utility of this model for disease-related pain conditions is unknown.

General conclusions

Coping efforts which focus on thinking rationally about pain and taking concrete cognitive and behavioural steps to control pain seem to be the most efficacious methods for chronic pain management. Coping strategies which lead the individual to withdrawal or become passive when dealing with pain appear to be the least effective pain management techniques. Research has clearly shown that effective coping can help the chronic pain sufferer to manage pain and maintain higher levels of psychological health. Intervention and treatment programmes which help patients learn new ways of coping with pain have met with considerable success (Keefe *et al.*, 2004).

Our understanding of the ways in which individuals cope with chronic pain and relationships of coping to psychological, physical and behavioural adjustment is not complete. Research in this area is currently exploring the usefulness of new assessment methods such as daily coping diaries and interviews that ask patients to describe, in detail, the thoughts and behaviours which they engage in when coping with pain. In addition, research is now examining the relationships between pain and coping over longer periods of time. Some coping methods may not impact adjustment in the short term but may contribute to disease progression and quality of life over many years time. Chronic disease is now the leading cause of death for individuals in most industrialized nations (see 'Coping with chronic illness') and chronic pain plays a central part in many of these conditions. Future research in this area will help pain researchers and clinicians to design programmes to help individuals learn how to cope with chronic, painful disease.

Coping with death and dying

Colin Murray Parkes

Chorleywood, Hertfordshire

Death is, perhaps, the ultimate test which we face as patients, relatives and members of the caring professions. All of us have to cope with it and, no matter how experienced we become, the coping is seldom easy. Death is often a loss but it can also be a time of peaceful transition. It may represent failure or success, ending or beginning, disaster or triumph. We may try to improve our ways of caring but, whatever the circumstances, death must never become routine.

In recent years, the psychological care of the dying and the bereaved has improved greatly, largely thanks to the work of the Hospices and the various organizations, such as Cruse – Bereavement Care, which provide counselling to the bereaved. Hospices have always seen the unit of care as being the family, which includes the patient, rather than the patient with the family as an optional extra to be taken on if we have time.

The field is a large one and it will not be possible, in the space available here, to give more than an outline of some of the major issues or to review the scientific and clinical research which underlies the theory and practice which I shall describe. The interested reader will find this type of information in the books by Kauffman (2002) and by Kissane and Bloch (2002), also in my own books, Parkes (1996) and Parkes and Markus (1998). A more detailed examination of the theory and practice of the counselling of dying patients and their families is given by Parkes *et al.* (1996).

When people are coming close to death, the professionals may have little or no control over what is happening. Scientific medicine can help us to mitigate some of the pains of dying but, with all our knowledge, 100% of our patients will still die. Despite this, patients and their families continue to turn to us for help. To a large extent, we have replaced priests as the recognized authorities on death, a change of role with which most of us feel uncomfortable.

Death is a social event, it affects the lives of many people. In this circle of people, the patients are the centre of care as long as they are alive; but their troubles will soon be over, those of the family may just be beginning.

Whether or not we think of death as a transition for the patient, it is certainly a transition for the family. Their lives will never be the same again. Death tips the survivors into new situations, new roles, new dangers and new opportunities. They are often forced to learn new ways of coping at a time when overwhelming grief makes it hard for them to cope with old responsibilities, let alone new ones (see 'Coping with bereavement').

The traditional training of doctors and nurses does little to prepare us for the challenges of terminal and bereavement care. We are so preoccupied with saving life that we are at a loss to know what to do when life cannot be saved. Some of us deal with the problem by denying its existence; we insist on fighting for a cure until the bitter end. Sadly, the weapons that we employ too often impair the quality of the life that is left; the end, when it comes, is truly bitter.

Others acknowledge to themselves that the patient is dying but attempt to conceal it from the patient. If they succeed, the patient may die in 'blissful' ignorance, but they often fail. As the disease progresses, the patient looks in the mirror and realizes that somebody is lying. At a time when they most need to trust their medical attendants, they realize that they have been deceived. In either case, the family who survive are denied the opportunity to say 'goodbye', and to conclude any unfinished psychological business with the patient.

Of course, it is not only the professional staff who find it hard to cope with people who are dying; friends, workmates and family members are equally at a loss and they may deal with their own feelings of inadequacy by putting pressure on us to continue treatment long after it can do good or to collude with them in concealing the true situation from the patient. 'You won't tell him he's dying, will you doctor? It would kill him if he found out'. While such remarks may occasionally be justified, they are more likely to reflect the informant's own inability to cope with the truth rather than that of the patient.

In all our work with terminally ill patients and their families, we must consider three psychological problems that complicate

the psychosocial transitions which they face. These are fear, grief and resistance to change.

The problem of fear

Fear is the natural response to any threat to our own life or to the lives of those we love. It has important biological functions in preparing our minds and bodies to fight or to flee. Our entire autonomic nervous system exists to support these ends. Among the many consequences of fear are hyperalertness to further dangers, increased muscular tension, increased cardiac rate and inhibition of digestive and other inessential vegetative functions. In the types of emergency that arose in the environment of evolution, these reactions ensured our survival, but they are seldom of much use to us today.

It would be highly inappropriate for a cancer patient who has been told the nature of his diagnosis to run away or to hit out at the doctor, yet he may have an impulse to do both things. The hyperalertness produced by fear may cause fearful people to imagine additional dangers where none exist. It may also impair their ability to pay attention to anything but the danger itself. If increased muscle tension goes on for long, the muscles begin to fatigue and to ache; such symptoms may themselves be misinterpreted as signs of cancer or whatever disease it is that the person dreads. Similarly, cardiac hyperactivity is often misinterpreted as a sign of heart disease, thereby increasing fear and setting up a vicious circle of escalating fear and symptoms.

All of us have our own ways of coping when we are afraid. Some of us become aggressive, seeking someone or something to blame in the hope that we can rectify the situation. Thus some patients, faced with worsening symptoms, respond by blaming them on the treatment. It is easier to fight a doctor than a cancer. Others use alcohol or other drugs in an attempt to find 'Dutch' courage, a habit which can give short-term relief but may cause fresh problems in the long run.

The logical response to danger is to seek help and, if doctors have failed to cure an illness, we should not be surprised or angry if the patient seeks for a cure from unorthodox practitioners. But cure is not the only thing that people need. Comfort of the non-verbal kind, that a mother can give to a frightened child, is just as welcome to the frightened adult and just as effective in reducing fear. Nurses, who are touching patients all the time, know how powerful a touch of the hand can be. Doctors are often bad at touching, avoiding physical contact with their patients as if the patient's fear might be infectious, which, of course, it is.

When somebody is dying, it is not only the patient who is likely to be afraid, it is everybody around them. This can produce another kind of vicious circle when frightened patients see their fear reflected in the eyes of the people around them. Although most healthy people, asked where they would want die, will say 'at home', the level of anxiety which sometimes surrounds a person who is dying at home often gives good reason to admit them to a hospital or hospice. As one person who had been admitted to a hospice said, 'It's safe to die here!'

Since most people are afraid of dying, we tend to assume that we know why a dying person is afraid. It is tempting to say, 'I understand'. The truth is, none of us can know another's fear and many of

the fears of terminally ill patients have nothing to do with death. Time and again patients have said to me, 'It's not being dead that frightens me, doctor, it's dying'. Most people in our society have not seen anybody die. Their image of death comes from the horror comics and other dramatic and often horrific portrayals of death, which sell newspapers and the like. When people learn about real deaths, it is often the deaths that have been badly handled that get talked about. To many people 'death' means 'agony' and it may come as a surprise to them to learn that, with proper care, pain need not be a problem.

The problem of grief

Grief is the normal reaction to any major loss and is not confined to bereavement. Illnesses such as cancers and AIDS tend to progress in steps. At each setback the patient is faced with another cluster of losses. Initially, the loss of security and body parts affected by the disease constitute the major losses but, in later stages of the illness, increasing disability may cause loss of mobility, occupation and an increasing range of physical functions. In the last phase, the patient faces the prospect of losing life itself and all the attachments that go with it.

Each new loss will tend to evoke intense feelings of pining and yearning for the object that is lost. The person experiences a strong need to cry aloud and to search for ways of retaining some or all of the lost object. A woman may intensely miss the breast that she has lost and find some solace in a good prosthesis or in reconstructive surgery. A man may long to return to work and surprise his workmates by arriving at his place of work despite severe debility. Patients in a hospital regularly pine to go home, and many will do so despite the problems that this may cause to their families.

It is important not to confuse normal grief with clinical depression. Grief is intermittent and, even within an hour or so, people who allow themselves to express grief will feel better, although the pangs will return. Depression, by contrast, is lasting and undermines sufferers, preventing them from doing the very things that would get them out of the slough of depression. The slowing down of thought and movement, and the feelings of worthlessness, which characterize clinical depression, contrast with the restlessness and pining of the grieving person. Other symptoms of depression – anorexia, loss of weight and early morning waking – also occur as part of grieving (particularly if the grief is caused by a debilitating illness).

Diagnosis is important because clinical depression requires, and will usually respond to, treatment with antidepressant medication. Given this help, people who are grieving and depressed often find that, as the depression gets better, they can grieve more easily.

Resistance to change

More problematic is the tendency to deny the reality of the diagnosis, or prognosis, or to avoid facing the implications of this. Many patients make it clear that they do not want to be told about their illness. This is most likely to happen if the doctors are themselves uncertain or are giving conflicting messages. Family members too may find it hard to accept the fact that a loved person's lifespan

is very limited and may be more resistant to facing reality than the patient.

Denial is a defence against overwhelming anxiety, and may enable people to adjust more gradually to the massive changes that threaten their internal world. It is a basic assumption in the minds of most people that we know where we stand. This rather trite statement covers a major but under-rated fact that we can only relate to the world around us because we possess an internal model of that world by which we recognize the world that we meet and plan our behaviour accordingly. This applies at the level of everyday habits (getting up in the morning, walking across the room, laying two places for breakfast, etc.) and at the deeper level of finding meaning and direction in life (wanting to get up in the morning, eat breakfast, etc.).

Major losses render obsolete large sections of our internal world and require a process of restructuring at both levels of functioning. For a while, people who are faced with a discrepancy between the world that is, and the world that should be (on the basis of our experience up to now), continue to operate the old obsolete mode which is, after all, the only model they have. The amputee leaps out of bed and finds himself sprawling on the floor, the widow lays the table for two. Even more common are the habits of thought which lead into blind alleys ('When I get better, I shall go back to work' or 'I must ask my husband about that').

Each time we are brought up short by a discrepancy of this kind, we suffer another pang of grief, intense, painful pining for what we have lost. This forces us to take stock and to begin the long and difficult process of revising our assumptive world. This takes time and it takes even longer for us to revise the basic assumptions that give meaning to life, e.g. that we can find new sources of self-esteem without having to go to work each day, that life in a wheelchair can be quite tolerable or that a widow is not condemned to perpetual mourning.

Because we rely on the possession of an accurate internal model of the world to cope with the world and to keep us safe, we feel, and are, extremely vulnerable whenever we are faced with major discrepancies of this kind. More than at any other time, we need the understanding and protection of people close to us; small wonder that patients and family members grow closer to each other at times of threat and that many people would rather be at home than in a strange or impersonal hospital ward. For those without families, the support of doctors and nurses may be invaluable, but such patients may cling to the security of their home as if this were the only safe place in the world.

The psychosocial transition faced by the dying patient may be more frightening but is usually less complex than the transition faced by the patient's spouse. Having faced the facts of the illness, the patient has not got to learn new ways of coping, acceptance brings its own rewards and the patient will often find that family and other carers are happy to take over responsibility for managing the affairs which previously caused anxiety and stress in the patient's life. 'Don't you worry, we'll look after things now', can be very reassuring to someone who has never previously had the opportunity to 'let go'. Perhaps, because of this, patients who face their illness, and accept that there is nothing more to be done, often enter a peaceful state and achieve a relatively happy conclusion to their lives. They seem to come through the process of grieving more

quickly and completely than their spouses who have to discover a new identity and who will often continue to grieve for years to come.

The problems that arise when we are faced with the need to change our basic assumptions about the world have been explored in more depth by Kauffman (2002).

Coping strategies

Many of the differences between the ways people cope with threats reflect the assumptions and coping strategies that have been found to minimize stress early in life. At times of threat, those who lack the confidence in their own resources may seek help of others, express clear signals of distress and cling inappropriately. Those who lack trust in others, on the other hand, may keep their problems to themselves, bottle up their feelings and blame health care providers or therapies for their symptoms. Their lack of trust makes it necessary for them to control us rather than be controlled by us. A few, who lack trust in themselves *and* others, may keep a low profile, turn in on themselves and become anxious and depressed (Parkes, 2006).

Some people may have learned that the one sure way of getting love and attention is to become sick. In later life they respond to threat by developing hypochondriacal symptoms or exaggerating the symptoms of organic illness. If the threat has been caused by an illness, the interaction of psychological and physical influences may be difficult to disentangle. These interactions have been explored, with sensitivity, by Wilkinson who stresses that we need to learn 'the music that the patient is dancing to, the form of their complaining' (Wilkinson, 2004).

Influencing the transition

All of these strategies reflect insecurity and will respond to reassurance and the creation of a 'secure base', a safe place and a secure relationship in which, little by little, the insecure person can begin to pay attention to and discuss the problems that make them insecure.

To those who lack self-esteem the most important thing we have to offer is our esteem for their true worth and potential. To those who lack trust in others we can show that we understand their suspicion and their need to be in control of us. We act as advisors rather than instructors and show that we accept that trust must be earned: it is not our right to be trusted.

Life-threatening illness can undermine the confidence and trust of us all and the process of revising one's internal model of the world is made easier if the issues are clear and if there is someone nearby who will keep us safe during the period of vulnerability. It follows that members of the caring professions can do a great deal to help people through these psychosocial transitions. Accurate information is essential to planning; hence the reaction of relief that is expressed by many patients when they are told they have cancer. It is easier to cope with the worst than to live in a state of planlessness.

Much has been written about the patient's right to know the truth about an illness, but we must respect his or her right to monitor the amount of new and painful information that he/she can cope with at any given time (see 'Breaking bad news'). It is just as wrong to tell people too much, too soon, as it is to tell them too little, too late. Patients who refuse to give consent to major surgery may just need

a little time to call on the support of other family members before changing their mind. If we respond by threatening them with the dire consequences of their refusal, this may increase their anxiety and delay the final decision.

Similarly, we need to recognize that it takes time to break bad news. To impart the information to a person that they have cancer or AIDS is to inflict a major psychological trauma. No surgeon would think of operating without booking an operating theatre and setting aside sufficient time to do the job properly. The same should apply to all important communication between professional carers and the families we serve.

We need to know whose lives are going to be affected by the information we possess, to decide who should be invited to meet us and where the meeting should take place. This means that someone must draw a genogram, a family tree which identifies each relevant person in the patient's family. Having identified the key people, we must decide who is the best person to talk with them and whether they should be seen together or separately. (Some are so over-protective of each other that they will never ask questions that might cause distress unless they are seen on their own.)

People will remember, for the rest of their lives, the details of the occasions when important news was broken. Even the pictures on the wall are important, and there is a world of difference between the doctor who adopts a relaxed and supportive attitude in a pleasant home-like atmosphere and the busy, impersonal consultant who breaks bad news in a public ward, or in the sterile environment of a treatment room. The placing of chairs at the same level, and at an angle to each other so that human contact is possible and there are no desks or other barriers between us, helps to create the conditions in which communication is possible.

Before telling people what we think they need to know, we should find out what they already know, or think they know, about the situation and what their priorities are. If they use words like 'cancer' or 'death', we should check out that these words mean the same to them as they do to us. 'There are many kinds of cancer, what does the word mean to you?', 'Have you seen anyone die? How do you view death?' will often reveal considerable ignorance and open the door to positive reassurance and explanation. Too often, doctors fail to invite questions and miss the opportunity to help people with the issues that are concerning them most.

Members of the primary care team are in a position to provide continuity of care throughout the illness and bereavement, and are particularly important sources of support. They are likely to be familiar with the social context in which the illness has arisen, to know the family members who are most at risk of adjustment problems and to have a relationship of trust with them that will enable the team to see them through this turning point in their lives. The fact that the primary care team are providing long-term care means that they will often have more time and opportunities to help the family to work things out than other caregivers have.

Eventually the time may come when further active treatment aimed at curing symptoms will cause more problems than it solves. From now on, our concern is more with palliation than with cure and the need for psychosocial care will be greater than ever. The question will arise as to whether to refer the patient to a hospice or specialist home care team. Hospices have focused attention on the need for improved symptom control at the end of life. Although St Christopher's Hospice in Sydenham, the first of the modern style of hospice, was initially restricted to in-patients, the home care which is now provided by most hospices was not long to follow. More recently, support teams have been set up in many hospitals to enable some of the methods of care which have been developed in hospices to be provided in general hospitals, and most hospitals and primary care teams are now able to relieve pain and other distressing symptoms in the later stages of cancer. Less easy to provide is the psychosocial care, which not only relieves the mental suffering of the patient but can help those members of the family whose lives must change, because of the death, to achieve a smooth and satisfactory transition. It is a criticism of existing services in the United Kingdom that the excellent psychosocial and spiritual care which is provided by many (but not all) hospices is not more widely available, and is limited to the final phase of life.

Finally we must recognize that the care of the dying can be stressful for the professionals as well as those for whom they care. A good staff support system is essential and should include the recognition that, if it is all right for patients and their families to cry when they grieve, it should be all right for us too. The 'stiff upper lip' which makes it so hard to help some patients and family members is even more of a problem in doctors (see 'Psychological support for health professionals').

Coping with stressful medical procedures

Yael Benyamini

Tel Aviv University

Stressful medical procedures range from highly stressful ones, such as major surgery and chemotherapy, to simple procedures such as immunizations and blood tests. Though such procedures vary greatly in the degree of physical intrusiveness, pain and discomfort they cause, the stress experienced by patients results not only from these physical factors but also from the subjective meaning of the procedure for the patient and his/her resources for coping (Scott *et al.*, 2001; Wallace, 1985) (see 'Abortion'; 'Coronary heart disease: surgery'; 'Chemotherapy' and 'Intimate examinations'). The physical aspects are interpreted within the subjective framework, which determines the extent of psychological reactions. Therefore, in order to understand how patients cope with these procedures and how to assist them in their effort, health care providers must understand both the objective and the subjective aspects of this experience.

Undergoing a medical procedure entails coping with the procedure itself and coping with the accompanying negative feelings (mainly anxiety). Such feelings are related to the context in which the procedure is carried out, for example, cancer as highly anxiety-provoking (Schou *et al.*, 2004), infertility as a low-control situation (Terry & Hynes, 1998), coronary artery bypass surgery or transplant surgery, which elicit fears due to the uncertainty involved (Heikkila *et al.*, 1999; Jalowiec *et al.*, 1994). Negative feelings also arise from discrepancies between prior expectancies or pre-existing imaginings and the actual procedure (e.g. the difference between the expectation and the reality of giving birth, see Katz, 1993; Slade *et al.*, 1993). Prior experiences also influence reactions to a stressful medical procedure, whether these are prior medical experiences as a child (Pate *et al.*, 1996) or as an adult (for example, undergoing mammography among women who have had a lumpectomy; see Kornguth *et al.*, 2000), recent life stress or even early traumatic experiences (such as the Holocaust; see Schreiber *et al.*, 2004).

Procedures such as surgery require a recovery period. Anxiety related to the procedure can impede recovery from it. Studying the direct predictors or outcomes of such anxious reactions is insufficient (Kopp *et al.*, 2003) since anxiety operates through a variety of behavioural and physiological mechanisms, within a personal and social context (Kiecolt-Glaser *et al.*, 1998). Therefore, this chapter will first briefly review individual differences in coping with stressful procedures as well as the effects of the social and cultural context and then discuss ways to assist patients undergoing these procedures.

Individual differences in coping with medical procedures

Many studies have examined differences in coping styles. One of the most common distinctions is between an avoidant and an active or

instrumental coping style. Typically, studies found avoidant coping with medical procedures and the physical and psychological distress they cause to be related with worse outcomes and active coping with better outcomes among adults (Rosenberger *et al.*, 2004), and adolescents (LaMontagne *et al.*, 2004). Moreover, a maladaptive spiral of distress and avoidant coping can evolve over time (Culver *et al.*, 2002).

Another distinction is between attention focusing and distracting as ways of coping. Distraction by focusing on a specific stimulus could be helpful whereas simply attempting to ignore the situation could result in a rebound effect that leads to more intrusion later on (Fauerbach *et al.*, 2002). Attention focusing has been found to be helpful in some studies (LaMontagne *et al.*, 2000) and detrimental in others (Fauerbach *et al.*, 2002). The inconsistencies may be due to the nature of the stressor with which patients coped: attention to an injury-related procedure could increase post-traumatic responses whereas attention to concrete aspects of a procedure aimed at healing an illness or removing a health threat could decrease such responses.

The attention/distraction distinction has also been studied as a personality disposition, typically labelled as monitoring versus blunting information-seeking style (Miller *et al.*, 1988). In relation to medical procedures, research has shown that relaxation training led low monitors and high blunters to suffer from less surgical pain (Miro & Raich, 1999) and less anxiety due to cancer chemotherapy, possibly because relaxation is a distraction technique (Lerman *et al.*, 1990) (see 'Relaxation training'). High monitors benefited from the provision of detailed information, such as viewing the contraction monitor during labour (Shiloh *et al.*, 1998), and fared most poorly with no preparation at all (Gattuso *et al.*, 1992). Other personality dispositions have also been associated with coping and outcomes of medical procedures (Kopp *et al.*, 2003): Dispositional optimism was related to better recovery and lower rates of re-hospitalization following coronary artery bypass surgery (Scheier *et al.*, 1989, 1999); internal locus of control moderated the relationship between coping strategies and long-term recovery from surgery for scoliosis among adolescents (LaMontagne *et al.*, 2004).

Age differences in coping with medical procedures

Though many findings replicate across ages, there are indications that we need to consider children and adolescents separately (from each other and from adults) when attempting to understand and facilitate their coping with medical procedures. Children's conceptualization of pain, their appraisal of the situation and their ways of coping differ from those of adults (Rudolph, Dennig & Weisz, 1995) (see 'Children's perceptions of illness and death').

Children's approach-avoidance coping may be qualitatively different from adult's approach-avoidance (Bernard *et al.*, 2004) and they may need more preparation and training for coping with medical procedures (Peterson *et al.*, 1999). Their ability to cope at different ages is also a major factor in decisions regarding the best age for elective surgical procedures (Hagglof, 1999). Even within childhood, coping varies by age: older children, compared with younger ones, exhibited more vigilant coping that was related to quicker return to activities following surgery (LaMontagne *et al.*, 1996) and older adolescents' coping, compared with younger ones', was more strongly related to recovery from surgery (LaMontagne *et al.*, 2004). In addition, it is important to remember that children are greatly influenced by their parents' reactions to the situation and ways of coping with it (Salmon & Pereira, 2002). In light of the differences between adults and children in their reactions to procedures, there are also separate instruments that measure individual differences in coping with stressful medical procedures among adults (Krohne *et al.*, 2000) and among children and their parents (Blount *et al.*, 2001).

Gender differences in coping with medical procedures

Women report higher levels of fear than men in reaction to injections and blood sample collection, examinations and symptoms (e.g. Olatunji *et al.*, 2005) and report more pre-operation anxiety than men (Karanci & Dirik, 2003). Women and men often perceive stressful medical procedures differently, sometimes because they are experienced at a different age (for example, cardiac procedures, Hawthorne, 1994). Some procedures have different effects on women's and men's self and body image (Manderson, 1999), and coping with them could be differentially affected by social support in the two gender groups (Krohne & Slangen, 2005). Yet, there has been surprisingly little attention paid to these differences and their implications for planning interventions.

The social and cultural context

Coping with stressful medical procedures entails intensive contact with health care providers in a situation that often involves a lot of uncertainty. Different 'languages' are used in the culture of patients and the culture of providers when talking about health, illness and uncertainty (Becker & Nachtigall, 1991). Patients often interpret statistics and other information in ways that are biased so as to preserve their hopes, whereas doctors judge treatment success across the general patient population (Modell, 1989) (see 'Communicating risk' and 'Healthcare professional-patient communication').

This cultural clash can result in much frustration and feelings of being misled on the part of the patients and in similar feelings of frustration among providers in reaction to their patients' responses. The physician-patient cultural differences can be intensified if they occur within wider cultural gaps, such as a different ethnic or religious background. Sculptures of childbirth from traditional societies typically show several figures surrounding the woman at labour. Drawings of folk healers typically portray an encounter that takes place amidst a small crowd. These depictions of traditional medicine vastly differ from modern clinics and hospitals. The differences they portray can lead to misunderstandings and feelings of

alienation and anxiety among immigrants and patients from more traditional families. In culturally sensitive issues, such as third-party assisted conception procedures (Blyth & Landau, 2004), it is especially important to be aware of ethical considerations that differ around the globe.

The family environment is also of utmost importance to the person coping with a stressful procedure. Family members typically offer a lot of encouragement and support while the patient undergoes the procedure and during initial recovery but may underestimate the length of time required for full recovery and the patient's needs during that time (Feigin *et al.*, 2000). In addition, family care givers have their own fears and therefore their own needs for information and reassurance (Nikoletti *et al.*, 2003). This is especially prominent for female spouses (Mahler & Kulik, 2002).

Finally, the immediate social context also plays a role. The opportunity for social comparison with someone who has already undergone the procedure can provide reassurance and useful information: pre-operative patients assigned to a room at the hospital with a post-operative patient showed less anxiety and a quicker recovery; patients with any roommate recovered faster than no-roommate patients, and cardiac patients assigned to a room with another cardiac patient were discharged sooner after bypass surgery compared with those assigned to a non-cardiac roommate (Kulik, Mahler & Moore, 1996).

Assisting patients coping with stressful procedures: what troubles them?

In order to plan interventions to assist patients, we need to understand the issues that bother them as they face a stressful medical procedure. The common-sense model of illness (Leventhal *et al.*, 1980, 1984) provides a useful framework to illustrate these issues. This model attempts to delineate the principles underlying lay people's perceptions of health threats (see 'Lay beliefs about health and illness'). Research has shown that these perceptions are mostly structured around five dimensions: the identity and symptoms of the health threat; its causes; the timeline; the degree of controllability; and the consequences. In relation to stressful medical procedures, these dimensions suggest that patients are troubled by the following concerns:

- i) *Identity and symptoms* – patients focus on questions such as: What is happening to me? What am I supposed to feel? What will I feel?
- ii) *Causes* – What caused my situation? Why do I need to undergo this procedure?
- iii) *Timeline* – Is this an elective procedure or an emergency one? What happens before, during and after the procedure? How long will I have to wait for the procedure? How long will it take? How much time will it take me to return to my normal routine?
- iv) *Controllability* – Is it mandatory that I undergo this procedure? What are the potential benefits and risks? Who is responsible for the decision to undergo this procedure? What are the alternatives? What information do I need in order to choose among them? How can I regain control and decrease

helplessness? Is there anything I can do to increase the chances of success of the procedure and of quick recovery?

- v) *Consequences* – How serious is my condition? How serious and intrusive is this procedure? What are the expected side-effects in the short and the long term?

Assisting patient coping with stress procedures: planning interventions

Successful interventions must be planned so that they address patients' concerns, as suggested above. A single intervention cannot cover all possible concerns and problems that could arise. Therefore, when planning (and evaluating) such interventions it is important first to characterize the population, the health problem and the context in which it is experienced. In the light of these characteristics, it is important to clearly define criteria for success: Is the goal to decrease anxiety? To lessen the side effects? To minimize patient problem behaviours? To facilitate recovery? To shorten the period of hospitalization? Many studies have evaluated interventions aimed at preparing patients so that they will cope more adaptively with stressful procedures. Their findings suggest several principles and essential components that should be included when planning and administering such interventions.

The provision of information is a necessary component of any intervention in this area. In order to determine which information will be provided and at what level of detail, one needs to consider this from the patient's viewpoint. Patients will need various types of information:

- factual/procedural (what will happen to you)
- behavioural (what do you need to do in preparation for the procedure and for the recovery period; how can you cope most effectively with the procedure itself and its side effects)
- sensory (what will you feel)
- emotional (which emotions will you feel)
- administrative (what do you need to do in order to set this up, receive reimbursement, etc.).

While all of these aspects should be addressed, it is also important to consider the level of detail that is beneficial to the patient: detailed information could 'overwhelm' the patient beyond his or her ability to process it and benefit from it and/or result in increased instead of decreased levels of anxiety. Therefore, for many procedures preparation should be a multi-stage effort. For example, patients undergoing surgery may have different concerns and need different types of information and support pre-operatively, post-operatively and pre-discharge (Gammon & Mulholland, 1996).

Preparation for procedures typically includes mostly verbal information. Providing this information in written form also allows patients to retain it for future reference (see 'Written communication'). The information need not be merely verbal: many hospitals and clinics have used videotapes or tours. It is not clear whether tours are effective for adults (Lynn-McHale *et al.*, 1997) and for children they are even more questionable (O'Byrne *et al.*, 1997). In touring a ward there may be less control over the stimuli to which patients are exposed whereas videotapes allow for pre-planned and well controlled exposure.

In providing information to patients, it is important to attend to the full timeline from the initial deliberation regarding whether to undergo the procedure until full recovery. Naturally, when preparing the patient and his/her family, providers tend to concentrate on alleviating the immediate distress from the procedure they are about to administer by focusing on the procedure itself and the time around it. This focus can lead to disregarding both the difficulties of decision-making and preparation for the procedure, and, even more importantly, the long-term effects. Inadequate preparation for the long-term recovery can result in later patient distress and misunderstanding within the family (Feigin *et al.*, 2000). Even procedures that end positively and are not considered by the health care system to have any long-term effects, such as biopsies that provide reassuring results, require thought about the after-effects: some patients, especially the less educated and the more anxious to begin with, are not easily reassured (Meechan *et al.*, 2005).

Ideally, the information provided should be tailored to the patient's characteristics and preferences. Patients vary greatly in the types of pre-operative information and support they preferred (Mitchell, 1997). Many studies have shown better outcomes when the information matched the patients' coping styles (e.g. Morgan *et al.*, 1998; Shiloh *et al.*, 1998). When children are the patients, it is especially important to provide developmentally appropriate information (Rasnake & Linscheid, 1989). For example, an explanation that 'you will be put to sleep before the procedure' leads them to think that they will feel the same as they do every night in bed. It does not prepare them for the very unnatural way of falling asleep through the use of anaesthetics, which could include a few quite terrifying moments in which everything swirls around them.

The main reason for providing information has always been to reduce anxiety. Information can reduce anxiety by decreasing uncertainty and helplessness and by enhancing feelings of control. Control can also be increased by other means: patients can be more involved in decision-making regarding the preferred procedure. They can be given control over aspects of the procedure and recovery, whenever possible (as in patient-controlled analgesia following surgery; Shiloh *et al.*, 2003). Patients who are more involved could improve the quality of preparation for procedures if they are assertive, ask questions, gather information, do their 'homework', and attend structured preparation sessions. However, it is important to remember that many patients expect to be obedient to medical and nursing staff when they undergo a procedure and they do not always understand that they can exercise active control, even when clearly instructed to do so (Peerbhoy *et al.*, 1998). Patients may also initially accept a more paternalistic approach but over time desire more active involvement in the choice of treatment (Cohen & Britten, 2003).

In addition to preparing the patients, it is important that they receive effective support from their family members and care givers. Negative support can hinder recovery more than positive support and other resources can improve it (Stephens *et al.*, 2002). Therefore, it is important to attend to the perceptions and misperceptions of the situation by the care givers and to provide information and training specifically to the care givers (Mahler & Kulik, 2002). With children, it is essential to train the parents so that they will boost their children's ability to cope effectively instead of

increasing the children's distress (Manne *et al.*, 1992) as well as their own (Zelikovsky *et al.*, 2001).

Concluding comments

The difficulties of coping with stressful medical procedures and the positive effect of adequate preparation for these procedures have been documented for several decades. Since the 1980s sufficient evidence has accumulated showing that preparation interventions, which include not only 'technical' information, but also modeling and teaching coping strategies, improve both physical and psychological outcomes among adults (O'Halloran & Altmaier, 1995) and children (O'Byrne *et al.*, 1997) and are cost-effective. The type of intervention has often been found to be less important than the mere fact that some type of intervention was provided. Yet, many patients are not provided with any type of structured intervention aimed at supporting them in coping with stressful procedures.

This does not mean that they are not provided with any preparation at all: on the contrary, preparation always takes place because providers always give some information and patients always ask some questions. However, such non-structured preparation is much less effective and often not provided at the optimal timing or by the optimal person, as compared with planned and structured interventions.

To summarize, understanding the meaning of the procedure for the patient and his/her family and their specific concerns and planning interventions accordingly can greatly improve patients' coping efficacy and recovery outcomes, at a relatively low cost. Future research should further investigate ways of optimizing such interventions by tailoring them to the patients' subjective perceptions of the procedure and the health threat for which it is intended. In addition, future research should also examine gender differences in coping with stressful medical procedures.

Cultural and ethnic factors in health

John W. Berry¹ and David L. Sam²

¹Queen's University

²University of Bergen

Introduction

Understanding how cultural and ethnic factors relate to health is very much an interdisciplinary enterprise: anthropology, biology, economics, history, medicine, nursing, psychiatry, psychology, rehabilitation and sociology have all participated in the study and application of their own concepts and findings to health. The focus of this chapter however, will be on the contributions of anthropology ('medical anthropology': see e.g. Brown, 1998; Foster & Anderson, 1978; Hahn, 1999; Helman, 2000), psychiatry ('trans-cultural psychiatry': see e.g. Kleinman, 1980; Murphy, 1981; Tseng, 2001; Yap, 1974) and psychology ('cross-cultural psychology': see, e.g. Dasen *et al.*, 1988). In particular, because of the placement of this chapter in the section on 'Psychology, health and illness', and the background of the authors, the approach will be from the perspective of cross-cultural health psychology (Kazarian & Evans, 2001; MacLachlan, 2001; MacLachlan & Mulatu, 2004).

The field of cross-cultural health psychology can be divided into two related domains. The earlier, more established, domain is the study of how cultural factors influence various aspects of health. This enterprise has taken place around the globe, driven by the need to understand individual and community health in the context of the indigenous cultures of the people being examined and served. The second, more recent and very active, domain is the study of the health of individuals and groups as they settle into, and adapt to, new cultural circumstances, as a result of their migration, and the persistence of their original cultures in the form of ethnicity. This enterprise has taken place in culturally plural societies where there is the need to understand and better serve an increasingly diverse population in multicultural societies (Berry, 1997a; Mulatu & Berry, 2001). This separation into work across cultures (internationally) and with ethnic groups within societies is a common one in the field of cross-cultural psychology more generally (Berry *et al.*, 2002). Despite this division, it is a common position that the methods, theories and findings derived from the international enterprise should inform the domestic enterprise. That is, immigrants and members of the ethnic communities should be understood and served in culturally informed ways, and not simply categorized and treated as 'minorities'.

Cultural domain

The broad, international and comparative work linking culture and health has been carried out by medical anthropology, trans-cultural psychiatry and cross-cultural health psychology. Much of this work has resulted from the collaboration of medical, social and

behavioural scientists. The field is thus inherently an interdisciplinary one, and is concerned with all aspects of health; physical, social and psychological.

Three orientations

In this large and complex body of work, three theoretical orientations can be discerned; absolutism, relativism and universalism (Berry *et al.*, 2002).

The absolutist position is one that assumes that human phenomena are basically the same (qualitatively) in all cultures: 'honesty' is 'honesty' and 'depression' is 'depression', no matter where one observes it. From the absolutist perspective, culture is thought to play little or no role in either the meaning or display of human characteristics. Assessments of such characteristics are made using standard instruments (perhaps with linguistic translation) and interpretations are made easily, without alternative culturally based views taken into account.

In sharp contrast, the relativist approach is rooted in anthropology, and assumes that all human behaviour is culturally patterned. It seeks to avoid ethnocentrism by trying to understand people 'in their own terms'. Explanations of human diversity are sought in the ones that a cultural group gives to a phenomenon. Comparisons are judged to be problematic and ethnocentric and are thus virtually never made.

A third perspective, one that lies somewhat between the two positions, is that of universalism. Here it is assumed that basic human characteristics are common to all members of the species (i.e. constituting a set of biological givens), and that culture influences the development and display of them (i.e. culture plays different variations on these underlying themes). Assessments are based on the presumed underlying process, but measures are developed in culturally meaningful versions. Comparisons are made cautiously, employing a wide variety of methodological principles and safeguards, and interpretations of similarities and differences are attempted that take alternative culturally based meanings into account.

Intersection of culture and health

Perhaps the most comprehensive exposition of the way in which culture can influence health and disease was presented by Murphy (1982). He proposed that cultural factors can affect the following aspects: definition, recognition, symptomatology, prevalence and response (by society or healer).

Numerous studies have shown that the very concepts of health and disease are defined differently across cultures; this basic link between culture and health was recognized early (Polgar, 1962) and has continued up to the present time (Foster, 1997; Helman, 2000, Chapter 2). The concept of health has undergone rapid change in international thought, witness the World Health Organization's emphases on the existence of (positive) wellbeing, and not only on the absence of (negative) disease or disability. Of special interest here is the existence of 'culture-bound syndrome' that appears to be unique to one (or a few) cultures (American Psychiatric Association, 2000; Simons & Hughes, 1985).

Recognition of a condition as healthy or as a disease is also linked to culture. Some conditions such as trance are recognized as important curing (health-seeking) mechanisms in some cultures, but may be classified as psychiatric disorder in others (Ward, 1989). Similarly, the expression of a condition through the exhibition of various symptoms has also been linked to cultural norms (Zola, 1966). For example, it is claimed by many (e.g. Kleinman, 1982; Kirmayer, 1984) that psychological problems are expressed somatically in some cultures (e.g. Chinese) more than in other cultures (Tseng, 2001, Chapter 16).

Prevalence studies across cultures have produced very clear evidence that disease and disability are highly variable. From heart disease (Marmot & Syme, 1976; Prener *et al.*, 1991), to depression and schizophrenia (Murphy, 1982; Siegert, 2001), cultural factors such as traditional diet, substance abuse and social relationships within the family all contribute to the prevalence of disease (World Health Organization, 2001, 2002).

The response by society generally (and by the healer) to ill health also varies across cultures. Acceptance or rejection of persons with particular diseases (such as leprosy or AIDS) has changed over time, and differs across cultures (Pick, 1998; Waxler, 1997). Healing practices, based on variations in medicines and beliefs about causations have wide variation in the treatment of both physical and psychological disorder (Hahn, 1999; Murphy, 1981; Yap, 1974).

An attempt has been made to link culture to health, drawing upon some established conceptual distinctions in the behavioural sciences by Berry (1989). Figure 1 shows four categories of health phenomena and two levels of analyses (community/cultural and individual/psychological). Crossing the two dimensions produces eight areas in which information can be sought during the study of links between culture and individual health. The community level of work typically involves ethnographic methods to study the culture, and yields a general characterization of shared health concepts, values, practices and institutions in a society.

The individual level of work involves the psychological study of a sample of individuals from the society and yields information about

individual differences (and similarities), which can lead to inferences about the psychological underpinnings of individual health beliefs, attitudes, behaviours and relationships.

The reason for taking cultural level health phenomena into account is so that the broad context for the development and display of individual health phenomena can be established; without an understanding of this background context, attempts to deal with individuals and their health problems may well be useless, even harmful. The reason for considering individual level health phenomena is that not all persons hold the same beliefs or attitudes, nor do they engage in the same behaviours and relationships; without an understanding of their individual variations from the general community situation, harm may well, again, be inflicted.

Examples of work in the eight areas of interest are common in the research and professional literature. At the cultural level, as we have already seen in relation to Murphy's ideas, the way in which a cultural group defines what is health and what is not, can vary substantially from group to group. These collective cognitive phenomena include shared conceptions, and categories, as well as definitions of health and disease. At the individual level, health beliefs and knowledge, while influenced by the cultural conceptions, can also vary from person to person. Beliefs about the causes of an illness or disability, or about how much control one has over it (both getting it and curing it) shows variations across individuals and cultures (Berry & Dalal, 1994). For example, in one community, the general belief is that if pregnant women eat too much (or even 'normally') there will be insufficient room for the fetus to develop; hence, under-eating is common, and prenatal malnutrition results, with an associated increase in infant disability. However, there are variations across individuals in this belief, with education, status and participation in public health programmes making a difference. In the fishing villages that line Lake Victoria in East Africa, the parasitic disease schistosomiasis is so prevalent that the bloody urine of young males during the full-bloom stage of the disease is considered a healthy sign of approaching manhood. There is no reason to seek medical attention for this ailment (Desowitz, 1981).

With regard to affective phenomena, the value placed on health is known to vary from culture to culture and within cultures across subgroups. For example, Judaic Law prescribes that health is given by God, and it is the responsibility of the individual to sustain it, the value placed on good health is thus a shared belief among practising Jews. However there is a significant variation in the acceptance of this across three Jewish groups; Orthodox Jews have been found to have the highest value, Reformed Jews have a lower value, and Secular Jews have an even lower value on health (Dayan, 1993). And within the three groups, there are further variations according to a number of personal and demographic factors.

Levels of analysis	Categories of health phenomena			
	Cognitive	Affective	Behavioural	Social
Community (cultural)	Health conceptions and definitions	Health norms and values	Health practices	Health roles and institutions
Individual (psychological)	Health knowledge and beliefs	Health attitudes	Health behaviours	Interpersonal relationships

Fig 1 Eight areas of interest in the relationship between culture and individual health.

Pain, in one form or the other is an inseparable part of everyday life, yet, not all social or cultural groups may respond to pain in exactly the same way. How people perceive and respond to pain, both in themselves and in others, is influenced by their cultural and social background (Halman, 2000). Zborowski (1952) examined the cultural component of the experience of pain among three groups of patients at a hospital in New York: Italian- and Jewish-Americans and Protestant 'Old Americans' (of Anglo-Saxon background) and found vast variations. While the Italians and Jews were emotional in their response to pain, and exaggerated their pain experience, the two differed in their attitudes towards the pain. The Italians were more concerned about the immediacy of the pain experience and complained a lot. However, once they were given palliatives and the pain subsided, they quickly forgot about their suffering and returned to their normal behaviour. The Jewish patients on the other hand were more concerned about the implications of the pain to their health. Many of the Jews distrusted palliatives and were reluctant to accept them as they were anxious about 'side-effects', as well as being more concerned about the drug only relieving the pain and not the underlying disease. In contrast, the 'Old Americans' had a 'matter-of-fact' orientation towards pain. They were less emotional in reporting their pain and saw no point in exaggerating it, as it did not help anyone. It was also more common for them to withdraw from the society as a reaction to severe pain.

Health practices and behaviours also vary across cultures and individuals. For example, in respect of nutrition (Dasen & Super, 1988), what is classified as suitable food, and who can eat it are matters of cultural practice. Many high protein 'foods' are not placed in the food category (e.g. grubs, brains) and are avoided, while in other cultures they are an important part of the diet. Within these general cultural practices, however, individuals vary in what they can eat, depending on age, status or food factors related to clan membership. The social organization of health activities into instructions, and the allocation of roles (e.g. healer, patient) is also known to vary across cultures. In some cultures, religious or gender issues affect the role of healer (e.g. only those with certain spiritual qualities, or only males, may become a healer), while in others, the high cost of medical or other health professional training limits the roles to the wealthy. In some cultures, health services are widely available and fully integrated into the fabric of community life (e.g. Aversasturi, 1988; Folland *et al.*, 2001) while in others doctors and hospitals are remote, mysterious and alien to most of the population. In the former case, individual patient-healer relationships may be collegial, in which a partnership is established to regain health, while in the latter, the relationship is likely to be hierarchical, involving the use of authority and compliance.

Psychosocial factors

A second approach to understanding individual health in a broader context has been through the conceptualization and measurement of psychosocial factors (World Health Organization, 1992). While these factors are not usually seen as 'cultural', a case can be made that all known psychosocial factors are also cultural factors, in the sense that they vary substantially across cultures. Hence, they have been treated as cultural variables, and can be understood in terms of

local cultural beliefs, values and behaviours. This position was advocated early (World Health Organization, 1982):

Psychosocial factors have been increasingly recognised as key factors in the success of health and social actions. If actions are to be effective in the prevention of diseases and in the promotion of health and well being, they must be based on an understanding of culture, tradition, beliefs and patterns of family interaction. (p. 4)

Most of these psychosocial factors (World Health Organization, 1992) are known to vary across cultures. For example, the psychosocial factor of specific behaviour patterns (such as the Type A/Type B distinction, or 'burnout') is probably one prevalent in western industrial cultures. Similarly, the influence of lifestyle (including a diet of 'fast foods'), is also likely to be a factor in some societies and not in others. A third psychosocial factor, that of problems of person-environment fit is obviously linked to culture (as a fundamental 'environment'). In particular, the acculturation problems of immigrants and refugees are identified by WHO: these are considered in detail in the next section.

The role of social inequality in health has been emphasized by Wilkinson (1996). It is the maldistribution of resources and wealth within a society, rather than the average level of wealth, that influences an individual's wellbeing. This inequality is often related to a person's cultural or ethnic background; being poor, especially combined with being a member of an oppressed cultural community, is bad for one's health (Desjarlais *et al.*, 1995) (see 'Socioeconomic status and health').

Three of the psychosocial factors refer to excessive stress (relating to close social relations, to the work place, and to broader societal settings). Problems with family and friends are likely to vary according to family organization and type (monogamous/polygamous; endogamous/exogamous; nuclear/extended; matrilineal/patrilineal; matrilocal/patrilocal, etc.). Since these are core contrasts in the ethnographic literature, the type and extent of such problems is likely to be linked to their cultural variations. Similarly, the workplace (the hunt, the garden, the pasture, the factory, the office, the unemployment line), and broader social conditions (poverty, war, famine, imprisonment, being the victim of crime or racism) all vary from culture to culture.

Finally, in the WHO list of psychosocial factors, are the health hazards and protective factors that are present in one's social environment, including: on the one hand, malnutrition, unsafe settings where accidents are likely to occur, and iatrogenic factors and on the other, social support and health promotion programmes (see 'Health promotion').

The degree of cultural variation in the psychosocial factors is plausibly very high, but as yet the extent is not known. It is proposed that such cultural variations be the focus of concerted research.

Ethnic domain

When we focus on the health of culturally distinct groups and individuals, who live in culturally plural societies, we are dealing with the ethnic domain (Berry, 1997a). By 'ethnic' is meant those phenomena that are derived from fully independent cultures; ethnic groups operate with an evolving culture that flows from their

original heritage culture, in interaction with the culture of the larger (dominant) society.

Approach to ethnicity

While ethnic groups are not full-scale or independent cultural groups, it is a working belief of cross-cultural psychology that all the methodological, theoretical and substantive lessons learned from working with cultural groups in the international enterprise should inform our work with ethnic groups (Berry, 1980). That is, we need to know about both their community health conceptions, values, practices and institutions and about how these are distributed as health beliefs, attitudes, behaviours and interpersonal relationships among individual members of the ethnic groups.

Put another way, we are not dealing with 'minorities' that are simply deviant from some 'mainstream', but with communities that deserve to have their health and health needs understood just as well as any other cultural community. In this sense, work on health in the ethnic domain does not differ in principle from work in the cultural domain. However, there is now an important new element, that of contact and possibly conflict, between cultural groups. This is the case in a number of respects: first, the health phenomena of ethnic individuals may be quite different from those of the larger society, and create misunderstanding, confusion and conflict between the two groups. Secondly, these conflicts may themselves generate health problems; and thirdly, the health services of the larger society may not be sufficiently informed, or sensitive, to enable them to deal with either the health problems that are linked to the heritage of the ethnic group, or those that have their roots in the conflict between the two groups in contact (Beiser *et al.*, 1988). Since the first of these issues is very similar to the discussion of the cultural domain, it will not be pursued further here. However, there is one important difference: when a health professional does not understand an individual's health needs while practising in another country, at least the individual may have recourse to an indigenous health system; when this lack of understanding occurs with respect to an ethnic individual, there may no longer be such an alternative service of health support. The second and third issues can be considered using the notions of acculturative stress, and multicultural health.

Acculturative stress

In the literature on the health and wellbeing of ethnic groups and individuals, there was an earlier assumption that the experience of culture contact and change will always be stressful, and lead to loss of health status. As is the case for other forms of stress (as one psychosocial factor), this assumption is no longer supported; to understand why there are variable outcomes to culture contact, the notions of acculturation strategies need to be introduced.

Acculturation was first identified as a cultural level phenomenon by anthropologists (e.g. Redfield *et al.*, 1936) who defined it as culture change resulting from contact between two autonomous cultural groups. Acculturation is also an individual level phenomenon, requiring individual members of both the larger society and immigrants to work out new forms of relationships in their daily

lives. This idea was introduced by Graves (1967), who has proposed the notion of 'psychological acculturation' to refer to these new behaviours and strategies. One of the findings of much subsequent research in this area is that there are vast individual differences in how people attempt to deal with acculturative change (termed 'acculturation strategies'; see Berry, 2003; Berry & Sam, 1997). These strategies have three aspects. Their preferences ('acculturation attitudes'); how much change they actually undergo ('behavioural shifts'); and how much of a problem these changes are for them (the phenomenon of 'acculturative stress'; see Berry *et al.*, 1987).

Perhaps the most useful way to identify the various orientations which individuals may have towards acculturation is to note that two issues predominate in the daily life of most acculturating individuals. One pertains to the maintenance and development of one's ethnic distinctiveness in society, in which people decide how much their own cultural identity and customs are of value and should be retained. The other issue involves the desirability of interethnic contact, in which people decide whether relations with other groups in the larger society are of value and should be sought. These two issues are essentially questions of values, and may be responded to on a continuous scale, from positive to negative. When these two value dimensions are related to each other, four general acculturation strategies are defined. Each is considered to be an option available to individuals and to groups in plural societies, towards which people may hold attitudes; these are assimilation, integration, separation and marginalization.

When there is a negative orientation to the first issue, and a positive orientation to the second issue, the assimilation option is defined, namely, relinquishing one's cultural identity and moving into the larger society. This can take place by way of absorption of a non-dominant group into an established dominant group, as in the 'melting pot' concept.

The integration option (a positive orientation to both issues) implies the maintenance of the cultural integrity of the group, as well as the movement by the group to become an integral part of a larger societal framework. In this case, a large number of distinguishable ethnic groups results, all co-operating within a larger multicultural society (sometimes referred to as a 'mosaic').

When there are no relations desired with the larger society, and this is accompanied by a wish to maintain ethnic identity and tradition, another option is defined. Depending upon which group (the dominant or non-dominant) controls the situation, this option may take the form of either segregation or separation. When the pattern is imposed by the dominant group, classic segregation to 'keep people in their place' appears. On the other hand, the maintenance of a traditional way of life outside full participation in the larger society may derive from a group's desire to lead an independent existence, as in the case of separatist movements. In these terms, segregation and separation differ primarily with respect to which group or groups have the power to determine the outcome.

Finally, there is an option (a negative orientation to both issues) that is difficult to define precisely, possibly because it is accompanied by a good deal of collective and individual confusion and anxiety. It is characterized by being poised in psychological uncertainty between the two cultures, and by feelings of alienation and loss of identity. This option is marginalization, in which groups lose

cultural and psychological contact with both their traditional culture and the larger society.

Inconsistencies and conflicts between various acculturation strategies are one of many sources of difficulty for acculturating individuals. Generally, when acculturation experiences cause problems for acculturating individuals, we observe increased levels of acculturative stress. In an overview of this area of research (Berry, 1997*b*), it was argued that stress may arise, but it is not inevitable. Or as Beiser *et al.* (1988) have phrased it: migrant status is a mental health risk factor; but risk is not destiny.

There are three concepts involved in understanding the roots of acculturative stress. First, acculturation occurs in a particular situation (e.g. an ethnic community), and individuals participate in and experience these changes to varying degrees; thus, individual acculturation experience may vary from a great deal to rather little. Secondly, stressors may result from this varying experience of acculturation; for some people, acculturative changes may all be in the form of stressors, while for others, they may be benign or even seen as opportunities. Thirdly, varying levels of acculturative stress and health problems may become manifest as a result of one's inability to cope with acculturation experience and stressors.

Results of studies of acculturative stress have varied widely in the level of difficulties found in acculturating groups and individuals. Early views were that cultural contact and change inevitably led to acculturative stress; however, current views (Berry & Sam, 1997) are that stress is linked to acculturation in a probabilistic way and the level of stress experienced will depend on a number of factors, such as host society prejudice, coping resources and strategies, education, acculturation strategies and national policies dealing with the issue of cultural diversity.

Research in a number of countries has typically revealed variations in, but sometimes no greater acculturative stress or mental health problems among, ethnic groups than in the general population (Beiser *et al.*, 1988). However, stress is usually lower when integration is being sought (but is highest for marginalization); migration was voluntary, (i.e. for immigrants) rather than forced (i.e. for refugees); there is a functioning social support group (i.e. an ethnic community willing to assist during the settlement process); and when tolerance for diversity and ethnic attitudes in the larger society are positive (Berry, 1997*b*).

In summary, the health outcomes for acculturating individuals are highly variable, and depend on a variety of factors that are under the control of policy makers. Stress, with resultant poor health, can be avoided if certain steps are taken. One of these, to which we now turn, is the development of a pluralistic health care system, one that is knowledgeable about and sensitive to the health needs of ethnic groups and individuals.

Multicultural health

Essentially, the area of multicultural health involves research and action directed towards improving the level of understanding and quality of services available to ethnic groups and individuals who now live in culturally plural societies (Beiser *et al.*, 1988; Mulatu & Berry, 2001).

The research component is driven by the work in the cultural domain and on acculturative stress, and should result in better

understanding of the health, and health needs of ethnic groups. To many observers, it is obvious why this research should be undertaken: it is unethical to presume to provide health services to people one does not understand; it is inequitable to train health service providers to know the needs of only part of the population; and it is unjust (especially in countries with a tax-supported health system) to allocate all of the resources to assist only some of the people.

The action component is directed towards changing the health institutions of the larger society, and the beliefs, attitudes, behaviours and relationships of members of the larger society with respect to these issues. The same framework employed earlier to outline areas of interest in the relationship between culture and health can guide the actions that are required.

To provide one example (from Canada), there is a national organization which promotes the need for multicultural health, with active member organizations in every Province. It advocates curriculum change in all health education programmes, to more fully portray the role of culture and ethnicity in health; it provides in-service workshops on issues of ethnocentrism and racism and on the special needs of immigrants and refugees; and it promotes awareness in the ethnic communities of their rights to health and how to gain access to better healthcare.

Many of these and related activities are supported by governments, in recognition of the value, not only of pluralism, but of healthy pluralism. Experience in many countries suggests that diverse populations can be denied basic services such as health only to a certain extent, and only for a limited period, before social pathologies become manifest, and the health statuses of all members of society deteriorate further.

Conclusions

This chapter has ranged widely over a number of disciplines, across and within cultures, and from research to action advocacy. Despite this diversity, there is a set of core ideas: cultures vary in their understanding and treatment of health; individuals also vary both across and within cultures; this dual variation needs to be taken into account whether working internationally, or with ethnic groups domestically.

It is well understood that health and disease are complex phenomena, and that they are multidetermined. This chapter has necessarily added to this complexity by focusing on the role of cultural and ethnic factors, but it also has attempted to present a systematic overview of their relationships, in addition to a portrayal of what we already know, and what we should, but do not yet know and do. (see also 'Gender issues and health' and 'Lay beliefs about health and illness'.)

Delay in seeking help

Suzanne E. Scott

King's College London

Following the detection of a symptom, the majority of individuals do not seek professional help, but instead do nothing or self-medicate (Freer, 1980). Whilst these responses may play a useful role in limiting the burden on healthcare services for benign and minor conditions, a continuing and important issue is delay in seeking help for symptoms that are indicative of life-threatening diseases. The intention of this chapter is to summarize the theoretical approaches used to study and understand help-seeking behaviour, with particular reference to delay in seeking help for symptoms of cancer and myocardial infarction (as these have been the most widely researched areas), and finally to discuss the implications of this research.

Delay in help-seeking or 'patient delay' (Pack & Gallo, 1938) is the time taken from the detection of a symptom to the first consultation with a healthcare professional for that symptom. This is distinct from 'professional delay' (the time from the first consultation with a healthcare professional regarding a symptom to the receipt of a definitive diagnosis). The overall duration of delay has been divided in such a manner because an undifferentiated measure like 'total delay' (the time from the detection of a symptom to the receipt of a definitive diagnosis) may confound the effects of multiple factors that influence delay (Safer *et al.*, 1979). For instance, the factors that hinder a patient's decision to seek help following the self-discovery of a breast lump may be quite different from those that cause a delay in reaching a definitive diagnosis of breast cancer following the first consultation with a healthcare professional. As such, focusing on separate sub-stages such as 'patient delay' and 'professional delay' provides a more informative and meaningful insight into delay behaviour.

When comparing the time duration for patient and professional delay, it is patient delay that generally constitutes the majority of the overall delay time (Onizawa *et al.*, 2003; Pattenden *et al.*, 2002). Patient delay has been found to have important health-related consequences. For instance, with regard to sexually transmitted

infections, prolonging the duration of the untreated infection will increase the probability of disease progression, its adverse sequelae (e.g. untreated chlamydia can lead to pelvic inflammatory disease, which in turn can cause infertility) and transmission to others (Hills *et al.*, 1993). Similarly, delay in seeking care for airborne diseases such as tuberculosis may be detrimental not only to the individual (due to the increasing severity of the illness over time) but also to the community, as ongoing transmission will continue until effective treatment is administered (Godfrey-Faussett *et al.*, 2002). Patient delay can also lead to a reduction in the efficacy of treatments. For instance, there is a strong relationship between the timing of thrombolytic therapy for myocardial infarction and its efficacy, with early treatment leading to less myocardial damage and reductions in morbidity and mortality (GISSI, 1986; Simoons *et al.*, 1986). Finally, although a link between patient delay and progression of disease has not been established for all cancer sites, the incidence of advanced stage cancer is frequently attributed to delay by patients in presenting to a healthcare professional. Studies with breast cancer patients indicate that patient delay of over 12 weeks is associated with increased tumour size, advanced stage disease at diagnosis and poor survival (Neave *et al.*, 1990; Rossi *et al.*, 1990). Regardless of these detrimental consequences, delay in seeking medical consultation is common (Facione, 1993; Mor *et al.*, 1990). Given the impact of patient delay it is important to understand the decision to seek help and identify the determinants of delay in seeking help.

Measurement of patient delay

Patient delay is typically studied retrospectively, using samples of patients who have recently sought help for the particular symptom or disease being studied. The use of this retrospective data obviously has its limitations with the possibility of error in recall,

particularly for those patients with long delay periods. Nevertheless, analysing the decision to seek help using prospective methodology is not without its drawbacks. Studies examining 'hypothetical help-seeking' or intentions to seek help (i.e. if you noticed a breast lump, when would you seek help?) are problematic, as they do not take contextual and situational factors into account. Such factors are known to play an important role in the decision to seek help. For instance, Safer *et al.* (1979) found that having a recent competing problem (e.g. marriage or divorce) was associated with increased delay in seeking help. Similarly, Dignan *et al.* (1990) reported that mothers with cervical cancer prioritize looking after their child over seeking care for their own symptoms.

Finally, although analysing patient delay as a continuous variable can make greater use of the data, it is common for researchers to specify a duration of patient delay that is considered to be substantial (e.g. patient delay of three months or more) and compare 'delayers' to 'non-delayers'. It should be noted however, that these operational definitions are often arbitrary, in that they may be chosen without thought to their clinical relevance.

Reasons for delay behaviour

It is often assumed that individuals delay seeking medical attention following the self-discovery of symptoms because they fear the diagnosis, or are in denial. However, evidence for an association between fear or anxiety and patient delay is not conclusive (Facione, 1993). Recent research suggests that rather than those who delay seeking help being the most anxious or fearful upon finding symptoms, it is precisely this group who are more likely to seek help promptly (Meechan *et al.*, 2003; Nosarti *et al.*, 2000). Similarly, there is little evidence indicating that denial plays a major role in the delay to seek help (Fisher, 1967). In fact, individuals who delay seeking help often think a great deal about their symptoms and possible treatments and it may be the inability to cope or take action that prevents help-seeking rather than denial (Leventhal, 1970; Safer *et al.*, 1979). This is not to say that denial does not exist but, rather that when denial is evident, it seems to be short lived (see also 'Coping with stressful medical procedures').

In sum, the expanse of literature on help-seeking behaviour indicates that rather than simply denial or fear being responsible for patient delay, a complex matrix of factors influences the decision to seek help following the self-discovery of symptoms. There are three main approaches to the study of help-seeking behaviour, which together provide an understanding of patient delay. These approaches – predispositions, symptom appraisal and the influence of the healthcare system – are now discussed in turn.

Predispositions

The dispositional approach assumes that people have a fairly stable pattern of responses to illness. In this way, some people will nearly always avoid consultation with a healthcare professional, whereas others will be almost 'frequent attenders' at the primary healthcare centre. The dispositional approach seeks to identify differences in patterns of help-seeking and also to determine the reasons for their development. An example of the dispositional approach is the study of gender differences in help-seeking. In the United Kingdom, it has

been reported that compared with women, men are less likely to visit a doctor when they are ill and are less likely to report the symptoms of disease or illness (Department of Health, 2000). Women's rates of utilization of almost all healthcare services are higher than men's (OPCS, 1991) and men often do not seek help until a disease has progressed (Francome, 2000). Men and women also utilize different healthcare services. For instance, women are more likely to visit doctors, nurses, social workers, psychologists or physiotherapists whereas men are more likely to use accident and emergency services (Corney, 1990). However, in their review of men and their health help-seeking behaviour, Galdas *et al.* (2005) noted that there is a significant body of research that argues against gender as a determining factor in help-seeking behaviour and that variables such as occupation and socio-economic status are more important than gender alone.

The dispositional approach has rarely gone beyond description of basic socio-demographic factors or compared the reasons for the dispositional tendencies in seeking help (Mechanic, 1982). Thus, although the dispositional approach can inform us of *who* uses particular health services, it does not provide a full explanation of *why*. Furthermore, the same person with comparable symptoms but at varying times can choose to seek medical care on one occasion but not on another (Mechanic, 1978). Hence, the dispositional approach only offers a limited contribution to the understanding of help-seeking behaviour as the processes of responding to symptoms seems to be more dynamic than this approach suggests. (See also 'Personality and health').

Symptom appraisal

A way of understanding help-seeking behaviour that does focus on the processes leading to the decision to seek help is the symptom appraisal approach. This perspective considers the ways through which people identify and evaluate symptoms, the ways in which people make interpretations of the causes and implications of symptoms, and how these inferences are used in the decision to seek help. The symptom appraisal approach maintains that, following the detection of a symptom, an individual will continue to appraise and then decide whether a symptom means something is 'wrong' and it is this appraisal that will drive the decision of whether professional care is necessary (Safer *et al.*, 1979). Cacioppo *et al.* (1986) drew together theory and research from the fields of social and health psychology to form a general attribution framework that outlines the process of symptom appraisal. This 'Psychophysiological Comparison Theory' is based on two assumptions. Firstly, it is argued that people are motivated to maintain an understanding of their physiological condition because once symptoms are detected we almost automatically assign reasons for their presence. The second assumption notes that this symptom appraisal may not be accurate in terms of the physiological aetiology. For instance, a feeling of discomfort within the mouth may be appraised as a mouth ulcer whereas the discomfort is actually arising from a malignancy of the tongue (Scott *et al.*, 2006).

Based on the work of Safer *et al.* (1979), Anderson *et al.* (1995) proposed that symptom appraisal is the most important stage in the process of seeking medical attention, constituting approximately 60% of total delay. Evidence supporting this proposition comes from both the cancer and myocardial infarction literature.

Patients who do not initially attribute their symptoms to cancer are more likely to delay than those who do interpret their symptoms as indicative of cancer (de Nooijer *et al.*, 2001; Ramirez *et al.*, 1999). Similarly, recent research indicates that the belief that symptoms were those of a heart attack is a predictor of early arrival at hospital (Ruston *et al.*, 1998). Horne *et al.* (2000) found that patients with a mismatch between their expectations of a heart attack and their experiences of a heart attack had significantly longer delays than those whose experiences matched their expectations.

There are many factors that influence the symptom appraisal process. For instance, an individual's past experience of symptoms can guide subsequent symptom appraisal. If a symptom is similar to one that previously turned out to be benign, the individual will be more likely to delay seeking help (Safer *et al.*, 1979). As well as using their own experiences, people can base their symptom interpretation on other people's experiences. The opinion of significant others is often sought prior to seeking help from healthcare professionals. In fact it is estimated that for every medical consultation there are approximately eleven 'lay' consultations usually involving a spouse or close friend (Scambler & Scambler, 1984). These consultations have a number of functions including confirmation that the problem is not trivial, recommendations for home remedies, advice to seek professional help and receipt of 'social permission' to seek care. It has been demonstrated that women with breast cancer who do not disclose the discovery of their symptoms to a significant other are more likely to delay seeking help than those who do make their discovery of a symptom known to others (Ramirez *et al.*, 1999). Timko (1987) notes that sometimes overt encouragement to seek help is not always necessary, as individuals who believe significant others want them to seek help are more likely to do so than those who believe others think they should wait. It should be recognized however, that although the result of consultation with their significant others may act as a trigger to seeking help, the 'lay referral network' (Friedson, 1961) may sometimes be just as erroneous in its symptom interpretation as the individual, and may recommend self-medication when professional attention is actually required.

The nature of the presenting symptoms also has an important role in the evaluation of symptoms. Strong sensory signals such as pain or bleeding lead to shorter appraisal delays (Safer *et al.*, 1979) yet many early symptoms of life-threatening conditions are often devoid of pain and discomfort. When discussing the symptoms of oral and oropharyngeal cancer (e.g. a soreness in the mouth, a red or white patch, persistent mouth ulcer), Guggenheimer *et al.* (1989) noted that they do not appear to be threatening to the patient as they are remarkably similar to those innocuous manifestations which the patient has experienced throughout his or her life. Hence the 'benign' nature of many symptoms does not initiate an immediate realization that the symptoms are indicative of something ominous and in need of professional attention. Demonstrating this point, in their study of delay in help-seeking for the symptoms of myocardial infarction, Horne *et al.* (2000) found that those patients who experienced 'typical' cardiac symptoms (e.g. chest pain, radiating pain, numbness, collapse) experienced shorter patient delay compared with those with more atypical symptoms (e.g. shortness of breath, nausea, vomiting, flu-like symptoms). In the same way, women with breast cancer

whose first symptom is not a breast lump are more than four times more likely to delay than those whose first symptoms do include a lump (Burgess *et al.*, 1998). Finally, those symptoms which interfere with social or personal relations or activities act as triggers for help-seeking (Zola, 1973). For example, if symptoms interfere with an individual's ability to work they will spur the individual to seek the advice of a healthcare professional.

Whilst recognizing that symptom appraisal is a particularly important process in the decision to seek help, it must also be recognized that this process may not be sufficient to complete the process of seeking help. As Anderson *et al.*'s (1995) model of total patient delay suggests, seeking medical attention is a process that involves a number of stages, each governed by a distinct set of decisional and appraisal processes. Once a person has interpreted a symptom as a sign of illness, they will only seek help if they decide this illness requires medical attention ('illness delay'), act on this decision by making an appointment with a healthcare professional ('behavioural delay') and finally make it to the appointment and receive medical attention ('scheduling delay'). Therefore one must also look beyond symptom appraisal to gain a thorough understanding of help-seeking behaviour. (See also 'Symptom perception')

Influence of the healthcare system

The third approach used to study help-seeking behaviour focuses on understanding the influence of the healthcare system on people's decisions to seek help. This perspective purports that modifying the ways in which agencies and professionals are organized can tackle the problem of patients' delay in seeking help (Mechanic, 1982). However, compared with the other approaches used to understand patient delay, this approach has received relatively little attention. Andersen (1968) discussed the concept of 'enabling factors' such as the nature and accessibility of a source of healthcare which can assist or hinder help-seeking behaviour. In support of this notion, poor access to health services is known to influence the decision to seek help for symptoms of breast cancer (Facione, 1993). More recent research has expanded Andersen's work by defining the concept of 'access' and suggesting it is composed of several dimensions that include 'availability' (the volume of existing services), 'accessibility' (the location of the services in relation to the location of the patients) and 'affordability' to the patients (Penchansky & Thomas, 1981). The term 'access' also includes the 'accommodation' of the services, such as the opening hours of primary healthcare practices. This is particularly important given that a deterrent to prompt help-seeking is the inability to take the time off work in order to attend a healthcare professional (McClellan & Reid, 1997). The way healthcare provision is perceived by individuals also influences healthcare use. For instance, perceptions that healthcare is rationed (e.g. due to the implementation of user charges and waiting lists for certain procedures) can impact on the way people use healthcare services such that they 'do not want to bother the doctor' with something that might prove to be trivial (Rogers *et al.*, 1999). Other barriers to healthcare include the nature of the doctor-patient relationship. The perceived closeness of this relationship has been shown to influence patient delay (Henderson, 1965) and patients' previous experiences with physicians have a significant impact on their

subsequent medical help-seeking (Moore *et al.*, 2004). (See also 'Patient-centred healthcare')

Implications for interventions

As delayed help-seeking has detrimental consequences for the individual, the community and the cost of healthcare, it is vital that we understand who delays seeking help and the reasons for those delays, in order to tackle the problem of patient delay. This chapter has outlined the approaches used to study help-seeking behaviour and highlights the importance of psychosocial factors in the decision to seek help. The research on help-seeking behaviour has various implications, particularly with regard to the design of interventions aimed at reducing the duration of patient delay for conditions where patient delay has repercussions on morbidity and mortality.

Although it does not inform us as to why certain groups tend to seek help faster than others, the dispositional approach directs us to those patients who are more likely to delay seeking help. This data is useful in that it can be used to develop 'targeted' interventions to those who are (a) at risk of developing the particular disease and (b) more likely to delay seeking help for symptoms of that disease. This targeting is important as this will ensure that medical services are not overloaded by a large increase in help-seeking for benign symptoms among low-risk groups or 'waste' resources on those who are likely seek help appropriately anyway. However, this tactic can only succeed if there are clearly definable risk factors for the particular disease. For instance, such an approach could be useful for reducing patient delay for symptoms of oral cancer where the main risk factors are oral tobacco use and a high intake of alcohol.

The symptom appraisal approach emphasizes the importance of an individual's own evaluation of his or her symptom(s). Empirical evidence indicates that this process plays a major role in the decision to seek help. The misinterpretation of symptoms has implications for public education in that the importance of symptom appraisal can be used to guide the content of interventions to reduce patient delay. For instance, educational campaigns must

detail the symptoms that are indicative of life-threatening conditions and hence require medical attention. However, because symptoms of serious ailments often mirror those of more common and benign conditions, there is the need not only to educate the public on the symptoms of conditions but also to show them a way of accurately evaluating symptoms when they occur. For instance, although chest pain is a symptom of myocardial infarction, only chest pain that lasts more than 15 minutes should be considered potentially indicative of myocardial infarction (Herlitz *et al.*, 1989). The application of a symptom appraisal based intervention is dependent on there being a clear connection between the disease in question and symptoms specific to that disease. For instance, this approach would be useful for reducing patient delay for early signs of breast cancer where symptoms include a breast lump, discharge and inversion of the nipple, yet less appropriate for delay for early stage prostate cancer where there is no clear link between symptoms and pre-metastatic disease (see also 'Health promotion').

Additionally, we should be aware that although knowledge about symptoms is an important variable in the appraisal of symptoms and the subsequent decision to seek help, this relationship is by no means definitive (Sheikh & Ogden, 1998). In turn, one must consider aspects of the healthcare system that may impact an individual's utilization of services. Here lies the importance of a good doctor-patient relationship, and affordable and available healthcare services, including consideration of opening hours and minimal waiting times. Furthermore, the introduction of additional services such as 'NHS direct' (a 24-hour nurse-led telephone service) has the potential for encouraging those in need of medical attention to seek the care they need, whilst reassuring those who do not need to visit a healthcare professional. Future research should assess the impact of these and other services (e.g. online health information) on the decision to seek help.

Despite the implications of the abundance of literature on help-seeking behaviour, there have been few theory-driven interventions to reduce patient delay. Future attempts should therefore focus on the psychosocial issues shown to be relevant to help-seeking behaviour and embrace the three approaches used to understand patient delay.

Diet and health

Jane Ogden

University of Surrey

Diet and health

Diet influences health through a variety of pathways. This chapter will explore the nature of a healthy diet, how diet affects health and the theoretical perspectives which have been used to understand eating behaviour.

A healthy diet

Although the nature of a good diet has changed dramatically over the years, there is currently a consensus amongst nutritionists as to what constitutes a healthy diet (DOH, 1991). Current recommendations according to food groups are as follows:

- Fruit and vegetables: A wide variety of fruit and vegetables should be eaten and preferably five or more servings should be eaten per day.
- Bread, pasta, other cereals and potatoes: Plenty of complex carbohydrate foods should be eaten, preferably those high in fibre.
- Meat, fish and alternatives: Moderate amounts of meat, fish and alternatives should be eaten and it is recommended that the low fat varieties are chosen.
- Milk and dairy products: These should be eaten in moderation and the low fat alternatives should be chosen where possible.
- Fatty and sugary foods: Food such as crisps, sweets and sugary drinks should be eaten infrequently and in small amounts.

Other recommendations for a healthy diet include a moderate intake of alcohol (a maximum of 3–4 units per day for men and 2–3 units per day for women); the consumption of fluoridated water where possible; a limited salt intake of 6 g per day; eating unsaturated fats from olive oil and oily fish rather than saturated fats from butter and margarine and consuming complex carbohydrates (e.g. bread and pasta) rather than simple carbohydrates (e.g. sugar). It is also recommended that men aged between 19 and 59 require 2550 calories per day and that similarly aged women require 1920 calories per day although this depends upon body size and degree of physical activity (Department of Health, 1995). Diet is linked to health by influencing the onset of illness and as part of treatment and management once illness has been diagnosed.

Diet and health

Diet affects health through an individual's weight in terms of the development of eating disorders or obesity. Eating disorders are linked to physical problems such as heart irregularities, heart attacks, stunted growth, osteoporosis and reproduction (see

'Eating disorders'). Obesity is linked to diabetes, heart disease and some forms of cancer (see 'Obesity'). Research also suggests a direct link between diet and illnesses such as heart disease, cancer and diabetes. Much research has addressed the role of diet in health and, although at times controversial, studies suggest that foods such as fruits and vegetables, oily fish and oat fibre can be protective whilst salt and saturated fats can facilitate poor health.

Diet also has a role to play in treating illness once diagnosed. Obese patients are mainly managed through dietary-based interventions. Patients diagnosed with angina, heart disease or following a heart attack are also recommended to change their lifestyle with particular emphasis on stopping smoking, increasing their physical activity and adopting a healthy diet. Dietary change is also central to the management of both Type 1 and Type 2 diabetes. At times this aims to produce weight loss as a 10% decrease in weight has been shown to result in improved glucose metabolism (Wing *et al.*, 1987). Dietary interventions are also used to improve the self-management of diabetes and aim to encourage diabetic patients to adhere to a more healthy diet (see 'Self-management' and 'Adherence to treatment').

Eating a healthy diet

A healthy diet therefore consists of high carbohydrate and low fat intake and links have been found between diet and both the onset of illnesses and their effective management. Research indicates, however, that many people across the world do not eat according to these recommendations. Data on children's diets indicate that children's diets in the western world do not match the recommendations for a healthy diet. Western children have been shown to eat too much fat and too few fruit and vegetables (see 'Adolescent lifestyle'). Therefore, dietary recommendations aimed at the western world in the main emphasize a reduction in food intake and the avoidance of becoming overweight. For the majority of the developing world, however, under-eating remains a problem resulting in physical and cognitive problems and poor resistance to illness due to lowered intakes of both energy and micronutrients. Recent data from the World Health Organization indicates that 54% of childhood mortality is caused by malnutrition, particularly that which is related to a deficit of protein and energy consumption. Research has also explored the diets of young adults. One large scale study carried out between 1989–1990 and 1991–1992 examined the eating behaviour of 16 000 male and female students aged between 18 and 24 from 21 European countries (Wardle *et al.*, 1997). The results suggest that the prevalence of the fairly basic recommended healthy eating practices was low in this large sample of young adults, particularly in men. The results also provided insights into the different dietary

practices across the different European countries. For example, countries such as Sweden, Norway, The Netherlands and Denmark ate the most fibre; Mediterranean countries such as Italy, Portugal and Spain ate the most fruit and England and Scotland ate the least; and salt consumption was highest in Poland and Portugal and lowest in Sweden, Finland and Iceland. Finally, research exploring the diets of the elderly indicates that, although many younger and non-institutionalized members of this group have satisfactory diets, many elderly people, particularly the older elderly, report diets which are deficient in vitamins, too low in energy and have poor nutrient content.

Research indicates that many people do not eat according to current recommendations. Much research has explored why people eat what they do. This chapter will describe developmental models, cognitive models and the role of weight concern in understanding eating behaviour.

Understanding eating behaviour

Developmental models

A developmental approach to eating behaviour emphasizes the role of exposure, social learning and associative learning.

Exposure

Human beings need to consume a variety of foods in order to have a balanced diet and yet show a fear and avoidance of novel foodstuffs termed 'neophobia'. Research has shown that mere exposure to novel foods can change children's preferences. For example, Birch and Marlin (1982) gave two-year-old children novel foods over a six-week period. One food was presented 20 times, one 10 times, one 5 times, whilst one remained novel and the results showed a direct relationship between exposure and food preference. Neophobia has been shown to be greater in males than females (both adults and children), to run in families (Hursti & Sjoden, 1997), to be minimal in infants who are being weaned onto solid foods but greater in toddlers, pre-school children and adults (Birch *et al.*, 1998).

Social learning

Social learning describes the impact of observing other people's behaviour on one's own behaviour and is sometimes referred to as 'modelling' or 'observational learning'. An early study explored the impact of social suggestion on children's eating behaviours and arranged to have children observe a series of role models with eating behaviours different from their own (Duncker, 1938). The models chosen were other children, an unknown adult and a fictional hero. The results showed a greater change in the child's food preference if the model was an older child, a friend or the fictional hero. The unknown adult had no impact on food preferences. In another study, peer modelling was used to change children's preference for vegetables (Birch, 1980). The target children were placed at lunch for four consecutive days next to other children who preferred a different vegetable from themselves (peas versus carrots). By the end of the study the children showed a shift in their vegetable preference which persisted at a follow-up

assessment several weeks later. The impact of social learning has also been shown in an intervention study designed to change children's eating behaviour using video based peer modelling (Lowe *et al.*, 1998). Parental attitudes to food and eating behaviours are also central to the process of social learning. For example, Klesges *et al.* (1991) showed that children selected different foods when they were being watched by their parents compared with when they were not, Olivera *et al.* (1992) reported a correlation between mothers' and children's food intakes for most nutrients in pre-school children, and likewise, Contento *et al.* (1993) found a relationship between mothers' health motivation and the quality of children's diets.

Associative learning

Associative learning refers to the impact of contingent factors on behaviour. In terms of eating behaviour, research has explored the impact of pairing food cues with aspects of the environment. Some research has examined the effect of rewarding eating behaviour as in 'if you eat your vegetables I will be pleased with you'. For example, Birch *et al.* (1980) gave children food in association with positive adult attention compared with more neutral situations. This was shown to increase food preference. Similarly a recent intervention study using videos to change eating behaviour reported that rewarding vegetable consumption increased that behaviour (Lowe *et al.*, 1998). Rewarding eating behaviour seems to improve food preferences.

Other research has explored the impact of using food as a reward. For these studies, gaining access to the food is contingent upon another behaviour as in 'if you are well behaved you can have a biscuit'. Birch *et al.* (1980) presented children with foods either as a reward, as a snack or in a non-social situation (the control). The results showed that food acceptance increased if the foods were presented as a reward but that the more neutral conditions had no effect. This suggests that using food as a reward increases the preference for that food.

The relationship between food and rewards, however, appears to be more complicated than this. In one study, children were offered their preferred fruit juice as a means to be allowed to play in an attractive play area (Birch & Martin, 1982). The results showed that using the juice as a means to get the reward reduced the preference for the juice. Similarly, Lepper *et al.* (1982) told children stories about children eating imaginary foods called 'hupe' and 'hule' in which the child in the story could only eat one if he/she had finished the other. The results showed that the food that was being rewarded became the least preferred one. This finding has been supported by similar studies (Newman & Taylor, 1992). These examples are analogous to saying 'if you eat your vegetables you can eat your pudding'. Although parents use this approach to encourage their children to eat vegetables the evidence indicates that this may be increasing their children's preference for pudding even further as pairing two foods results in the 'reward' food being seen as more positive than the 'access' food.

The association between food and reward highlights a role for parental control over eating behaviour. Some research has addressed the impact of control as studies indicate that parents often believe that restricting children's access to food and forbidding them to eat food are good strategies to improve food preferences. Birch (1999) reviewed the evidence for the impact of

imposing any form of parental control over food intake and argued that it is not only the use of foods as rewards which can have a negative effect of children's food preferences but also attempts to limit a child's access to foods. She concluded from her review that 'child feeding strategies that restrict children's access to snack foods actually make the restricted foods more attractive' (Birch, 1999, p.11).

Cognitive models of eating behaviour

A cognitive approach to eating behaviour focuses on an individual's cognitions and explores the extent to which cognitions predict and explain behaviour and most research has drawn upon social cognition models particularly the Theory of Reasoned Action (TRA) and the Theory of Planned Behaviour (TPB) (see 'Theory of planned behaviour'). Some research using a social cognitive approach to eating behaviour has focused on predicting the intentions to consume specific foods. For example, a series of studies has explored the extent to which cognitions relate to the intentions to eat biscuits, skimmed milk, organic vegetables and wholemeal bread (Sparks *et al.*, 1992; Raats *et al.*, 1995; Sparks & Shepherd, 1992). Much research suggests that behavioural intentions are not particularly good predictors of behaviour *per se* and studies have also used the TRA and the TPB to explore the cognitive predictors of actual behaviour. For example, Shepherd and Stockley (1985) used the TRA to predict fat intake and reported that attitude was a better predictor than subjective norms. Similarly, attitudes have also been found to be the best predictor of table salt use (Shepherd & Fairleigh, 1986), eating in fast food restaurants (Axelson *et al.*, 1983), the frequency of consuming low fat milk (Shepherd, 1988) and healthy eating conceptualized as high levels of fibre and fruit and vegetables and low levels of fat (Povey *et al.*, 2000). Research has also pointed to the role of perceived behavioural control in predicting behaviour particularly in relation to healthy eating (Povey *et al.*, 2000). The social norms component of these models has consistently failed to predict eating behaviour.

Some studies have explored the impact of adding extra variables to the standard framework described within the social cognition models. For example, Shepherd and Stockley (1987) included a measure of nutritional knowledge, Povey *et al.* (2000) included additional measures of descriptive norms, and perceived social support and recent studies have explored the role of ambivalence in predicting eating behaviour (Sparks *et al.*, 2001). The research in this area points to a consistently important role for attitudes towards a food and a role for an individual's beliefs about behavioural control. There is also some evidence that ambivalence may moderate the association between attitude and intention. However, there is no evidence for either social norms or other hypothesized variables.

A weight concern model of eating behaviour

Food is associated with many meanings such as a treat, a celebration, the forbidden fruit, a family get-together, being a good mother and being a good child (Ogden, 2003). Furthermore, once eaten, food can change the body's weight and shape, which is also associated with meanings such as attractiveness, control and success (Ogden, 2003). As a result of these meanings many women,

in particular, show weight concern in the form of body dissatisfaction, which often results in dieting. The impact of dieting, which has been termed 'restrained eating' on eating behaviour will now be described.

Restrained eating aims to reduce food intake and several studies have found that at times this aim is successful. Thompson *et al.* (1988) reported that in an experimental situation the restrained eaters consumed fewer calories than the unrestrained eaters after both the low and high preloads. This suggests that their attempts at eating less were successful. Similar results have been reported by Kirkley *et al.* (1988) using a food diary approach.

In opposition to these findings, however, several studies have suggested that higher levels of restrained eating are related to increased food intake. In particular, restraint theory has identified the disinhibition of restraint as characteristic of overeating in restrained eaters. The original study illustrating disinhibition (Herman & Mack, 1975) used a preload/taste test paradigm, and involved giving groups of dieters and non-dieters either a high calorie preload or a low calorie preload. The results indicated that whereas the non-dieters showed compensatory regulatory behaviour, and ate less after the high calorie preload, the dieters consumed more in the taste test if they had had the high calorie preload rather than the low calorie preload. This form of disinhibition or 'the what the hell effect' illustrates over-eating in response to a high-calorie preload. More general research has explored possible mechanisms for the over-eating shown by restrained eaters. These include the causal model of over-eating, cognitive shifts, mood modification, denial, escape theory and over-eating as relapse.

i) The causal analysis of over-eating

The causal analysis of eating behaviour was first described by Herman and Polivy who suggested that dieting and bingeing were causally linked and that 'restraint not only precedes overeating but contributes to it causally' (Herman & Polivy, 1988, p. 33). This suggests that attempting not to eat, paradoxically increases the probability of over-eating; the specific behaviour which dieters are attempting to avoid. The causal analysis of restraint represented a new approach to eating behaviour and the prediction that restraint actually caused over-eating was an interesting reappraisal of the situation. Wardle and Beales (1988) experimentally tested the causal analysis of over-eating and concluded that the over-eating shown by dieters is actually caused by attempts at dieting.

ii) Cognitive shifts

The over-eating found in dieters has also been understood in terms of shifts in the individual's cognitive set. Using experimental designs, research has highlighted two alternative cognitive shifts which seem to precipitate a state of over-eating. The first reflects a passive state involving 'motivational collapse' and a state of giving in to the overpowering drives to eat (Herman & Polivy, 1980) and the second reflects a more active state involving cognitions such as 'rebellious', 'challenging' and 'defiant' (Ogden & Greville, 1993). It has been argued that whilst at times over-eating may involve passively giving in to an overwhelming desire to eat, at other times the individual may actively decide to over-eat as a form of rebellion against self-imposed food restrictions.

iii) Mood modification

Dieters over-eat in response to lowered mood and researchers have argued that disinhibitory behaviour enables the individual to mask his or her negative mood with the temporarily heightened mood caused by eating. This has been called the 'masking hypothesis' and has been tested by empirical studies. For example, Polivy and Herman (1999) told female subjects that they had either passed or failed a cognitive task and then gave them food either ad libitum or in small controlled amounts. The results in part supported the masking hypothesis as the dieters who ate ad libitum attributed more of their distress to their eating behaviour than to the task failure. The authors argued that dieters may over-eat as a way of shifting responsibility for their negative mood from uncontrollable aspects of their lives to their eating behaviour.

iv) The role of denial

Cognitive research illustrates that thought suppression and thought control can have the paradoxical effect of making the thoughts that the individual is trying to suppress more salient (Wenzlaff & Wegner, 2000). This has been called the 'theory of ironic processes of mental control' (Wegner, 1994). For example, in an early study participants were asked to try not to think of a white bear but to ring a bell if they did (Wegner *et al.*, 1999). The results showed that those who were trying not to think about the bear thought about the bear more frequently than those who were told to think about it. Similar results have been found for thinking about sex, mood and stigma (see Wenzlaff & Wegner, 2000). A decision not to eat specific foods or to eat less is central to the dieter's cognitive set. This results in a similar state of denial and attempted thought suppression and dieters have been shown to see food in terms of 'forbiddenness' and to show a preoccupation with the food that they are trying to deny themselves. Therefore, as soon as food is denied it simultaneously becomes forbidden and this translates into eating which undermines any attempts at weight loss.

v) Escape theory

Researchers have also used escape theory to explain over-eating (Heatherton & Baumeister, 1991; Heatherton *et al.*, 1991). This perspective has been applied to both the over-eating characteristic of dieters and the more extreme form of binge eating found in bulimics and describes over-eating as a consequence of 'a motivated shift to low levels of self awareness' (Heatherton & Baumeister, 1991). It is argued that individuals prone to over-eating show comparisons with

'high standards and demanding ideals' (p. 89) and that this results in low self-esteem, self-dislike and lowered mood. It is also argued that inhibitions exist at high levels of awareness when the individual is aware of the meanings associated with certain behaviours. In terms of the over-eater, a state of high self-awareness can become unpleasant as it results in self-criticism and low mood. However such a state is accompanied by the existence of inhibitions. The individual is therefore motivated to escape from self-awareness to avoid the accompanying unpleasantness, but although such a shift in self-awareness may provide relief from self-criticism, it results in a reduction in inhibitions thereby causing over-eating. Within this analysis disinhibitory over-eating is indicative of a shift from high to low self-awareness and a subsequent reduction in inhibitions.

vi) Overeating as a relapse

Parallels exist between the under- and over-eating of the restrained eater and the behaviour of the relapsing smoker or alcoholic. The traditional biomedical perspective of addictive behaviours viewed addictions as being irreversible and out of the individual's control. It has been argued that this perspective encourages the belief that the behaviour is either 'all or nothing', and that this belief is responsible for the high relapse rate shown by both alcoholics and smokers (Marlatt & Gordon, 1985). Thus, the abstaining alcoholic believes in either total abstinence or relapse, which itself may promote the progression from lapse to full-blown relapse. In the case of the restrained eater, it is possible that they too believe in the 'all or nothing' theory of excess which promotes the shift from a high calorie lapse to the 'what the hell' relapse characterized by disinhibition. These parallels have been supported by research suggesting that both excessive eating and alcohol use can be triggered by high risk situations and low mood (Grilo *et al.*, 1989). In addition, the transition from lapse to relapse in both alcohol consumption and eating behaviour has been found to be related to the internal attributions (eg. 'I am to blame') for the original lapse (e.g. Ogden & Wardle, 1990).

In summary, diet relates to health both in terms of illness onset, prevention and treatment, however, many people do not always eat in accordance with current dietary recommendations. Psychological research has focused on three main theoretical perspectives to explain eating behaviour. A developmental approach emphasizes exposure and social and associative learning; a cognitive model emphasizes individuals' cognitions; and a weight concern model draws upon the literature relating to restrained eating and the causes of over-eating.

Disability

Timothy R. Elliott¹ and Laura Dreer²

¹Texas A&M University

²University of Alabama at Birmingham

Disability has traditionally been defined by prevailing medical and legal systems across cultures. Less apparent have been social and technological contributions that substantially determine the experience of disability. The many and multidisciplinary definitions of disability in clinical, legal and academic life inadvertently compromise efforts to develop, sponsor and enact effective policy and service for persons who live with disabling conditions (Walkup, 2000).

Theoretical models of disability

The most pervasive definitions of disability have been provided by disciplines associated with healthcare delivery. Contemporary perspectives have evolved in response to the increase of chronic health conditions across societies generally, and from criticisms of the medical model that recognize the broader policy, psychological and socio-economic issues associated with the management of disabling conditions over time and throughout communities.

Medical model of disability

The medical model of disability is the traditional and predominant model. Essentially, healthcare services which flow from this model assume a 'find it and fix it' perspective: health problems are diagnosed and specialized services are prescribed to cure the problem (Kaplan, 2002). This perspective is most effective in the detection and treatment of acute health problems; so effective, in fact, that this model has guided the development and status of medical training, facilities and specialties. The medical model is also responsible for the rapid and effective response to the acute needs of persons with physical disabilities and other chronic health conditions, and the first initiatives to address issues of improved care, survival and quality of life can be attributed to professions who embraced the medical model. In the United States, medical definitions of disability provide the cornerstone for determining disability for legal and occupational purposes (and for determining eligibility for financial assistance; Chan & Leahy, 1999). This model places a clear and unambiguous premium on the diagnosis of a specific cause for a health problem, and on the expert delivery of a curative treatment. These treatments may include rehabilitative services and restorative training to enhance reintegration.

Despite the great benefits this model has endowed upon societies for decades, it has many practical limitations in contemporary applications. In the initial services provided to preserve life and allay acute problems following the onset of a physical disability

(and for acute care needs for those living with disability) the value of the model is readily apparent. However, the model has difficulty accommodating the permanent and chronic trajectory of an incurable condition in which symptoms or impairments may be managed over the lifespan, and preventive and long-term changes in personal behaviour or to environmental constraints may be required for optimal health and quality of life (see 'Coping with chronic illness' and 'Quality of life'). The increasing number of persons with chronic health conditions across cultures is not adequately served by institutions which were designed to focus primarily on the delivery of acute, short-term conditions.

The medical model relies heavily on measures and tests of the disease process, and in this enterprise, the model places a lower value on the subjective report of quality of life and wellbeing, and by extension, to patient input concerning treatment options and recommendations for prescribed regimens. This is due, in part, to the occasional incongruence between subjective reports and objective indicators of disease activity. The successful diagnosis and treatment of acute conditions does not hinge solely on the accuracy or quality of patient input (see 'Disability assessment').

In fairness to the professions allied with the medical model, the measurement of functional ability (e.g. range of motion, impairment in activities of daily living, mobility) now characterizes studies of rehabilitation outcomes and occasionally these measures rely on participant self-report. These instruments still focus on residual deficits associated with the medical diagnosis, and with possible gains in response to the prescribed treatments for affected symptoms (Mermis, 2005).

The course of chronic disease and disability over the lifespan, however, is substantially influenced by behavioural and social mechanisms, and the medical model has limited capacity for assessing and making changes in these important domains. Additionally, the financial costs associated with chronic and disabling conditions have strained healthcare delivery systems grounded in this model. These costs have resulted in attempts to manage losses that include a decrease in available services to many persons with disability, and in a decrease in available insurance coverage for these individuals. Consequently, many persons with disability find greater impairment over time from systems which closely adhere to the medical model, as services are contingent upon reimbursement and the ability of specific programmes and their administrative systems to absorb financial losses incurred in providing services.

These issues have been addressed in contemporary revisions of the model by the Institute of Medicine. These revisions still

rely on diagnostic categories but emphasize greater attention to the processes that place individuals at risk for disability (and secondary complications following disability) including biological, environmental, social, cultural and behavioural factors (Pope & Tarlov, 1991). The needs for active continuous and collaborative partnerships with the consumer, and for increased access to information and customized programmes of assistance are espoused to promote quality of life and optimal health (Institute of Medicine, 2001). In these important revisions of the model, greater emphasis is placed on behavioural and social factors in the ultimate health and wellbeing of persons living with disability.

The WHO model of disability

The limitations of the medical model have been familiar to advocates, consumers and other health care professions throughout the international community. An alternative perspective of disability was developed by the World Health Organization (WHO) in its seminal 1980 report, *International classification of impairments: disability and handicaps*. In this conceptualization, disability was construed across three separate levels of performance at the organ level (impairment), personal level (disability) and societal level (handicap). Although this was a distinct improvement over the medical model, it did not adequately address environmental issues that contribute to disablement and many consumers found the use of the term 'handicap' inappropriate (Heinemann, 2005).

In 2001, the WHO published the *International classification of functioning, disability, and health* (ICF; WHO, 2001). As depicted in Figure 1, the ICF used labels more appropriate to the disability experience and permitted separate ratings along dimensions of body structure and function/impairment at the organ level, activity (vs. activity limitation) at the person level and participation (vs. participation restriction) at the societal level. The scheme conceptualized environmental factors as important contributors of disability. It allows an analysis of disabling features across several dimensions and does not regard a specific medical diagnosis as a concept that determines disability. The WHO model has enjoyed support from many professions, advocates and consumer groups throughout the international community.

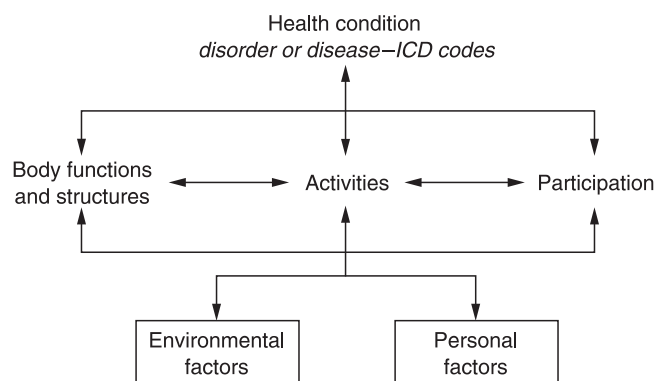

Fig 1 The ICF model of disability.

Alternative models

Several variations of the WHO model have been proposed by specific groups representing particular agencies (e.g. the 'new paradigm' of disability; the National Institute of Disability Research and Rehabilitation, 1999–2003) and from the disability studies literature (the social-constructionist view; Olkin, 1999). These models share a value on the civil rights of persons with disability, the need for access and opportunities for independent living and express a general disapproval of the medical model as a template for policy decisions concerning persons with disability. Disability is conceptualized in these models as a '... function of the person within the environment' (Brandt & Pope, 1997, p. 64). The individual is seen as the organizing core within these models, but impairments are defined and stipulated by the environmental and social contexts; indeed, the environment is construed as the '... major determinant of individual functioning' (Pledger, 2003, p. 281).

Yet these models do not clearly distinguish who qualifies as a person with a disability (or how disability is measured or determined), and they have yet to establish a distinct body of scholarship which systematically posits empirically testable and potentially falsifiable hypotheses that refine theory and advance knowledge (and, as such, lack essential properties required of scientific theories). In fact, some proponents appear to disregard the utility of theory and research in the psychological literature, generally, and construe psychological theory and scholarship as an embodiment of a medical model which conceptualizes disability as a pathological condition insensitive to the impact of environmental and social factors (see Olkin & Pledger, 2003).

Research evidence

Approximately 49.7 million people in the United States live with some type of long lasting condition or disability (U.S. Census Bureau, 2003). Of this number, 9.3 million (3.6%) have a sensory disability involving sight or hearing (see 'Blindness and visual disability' and 'Deafness and hearing loss'); 2.2 million (8.2%) have a condition limiting basic physical activities, such as walking, climbing stairs, reaching, lifting or carrying; 12.4 million (4.8%) live with a physical, mental or emotional condition causing difficulty in learning, remembering or concentrating; 6.8 million (2.6%) live with a physical, mental or emotional condition causing difficulty in dressing, bathing or getting around inside the home; 18.2 million of those aged 16 and older live with a condition that makes it difficult to go outside the home to shop or visit a doctor; and 21.3 million of those aged 16 to 64 live with a condition that affects their ability to work at a job or business. Disability rates escalate with age for both men and women (see 'Age and physical functioning') and 46.3% of people with any disability report more than one disabling condition. Persons between the ages of 16 and 64 are less likely to be employed if they are disabled and 8.7 million people with disabilities are poor (United States Census Bureau, 2003). These data are based on reports from only those persons who responded to the Census 2000 form and thus may significantly under-represent persons living with chronic disabilities in the United States. (See also 'Spinal cord injury').

Chronic health and disabling conditions are increasing throughout the world (World Health Organization, 2002). Within the next 15 years, it is estimated that chronic, disabling conditions and mental disorders will account for 78% of the global disease burden in developing countries (World Health Organization, 2002, p. 13). The disability experience can be influenced across cultures in terms of access to rehabilitative services; cultural stereotypes among service providers; differences in approaches to treating disabilities among different countries; service utilization and healthcare costs among different countries and cultures; disparities in the epidemiology of various disabilities at the international level; differences in governmental policies; collaborative efforts between healthcare providers and grassroots leaders; and differences in values and views of disability in various societies. Differences may also exist in cultural meanings attached to disability and quality of life, in attitudes and perceptions of disability, and the role of the family and society (Landrine & Klonoff, 1992; Murdick *et al.*, 2004) (see 'Cultural and ethnic factors in health').

Many disabilities result from lifestyle factors which include unhealthy behaviours; consumption patterns; inadequate or improper prevention of disease, injuries and accidents and improper management of other chronic health conditions (World Health Organization, 2002). Well known health problems associated with disability include diabetes (American Diabetes Association, 2003), obesity (National Task Force on the Prevention and Treatment of Obesity, 2000), cardiovascular disease (Keil *et al.*, 1989) and multiple visual impairments (Rudberg *et al.*, 1993).

Costs of disability

Disability imposes serious economic consequences (World Health Organization, 2002). Direct and indirect costs associated with disability are expected to escalate with the increasing number of persons who will live with a disability over the next several decades (US Department of Health and Human Services, 2000). On average, persons with disabilities spend more than four times as much on medical care, services and equipment as their non-disabled counterparts (Max, Rice & Trupin, 1995). In general, higher healthcare costs are associated with chronic physical disability; secondary complications; loss in employment productivity; impaired quality of life; care and management of chronic disease and disability along with acute episodes of care associated with such conditions; and problems with psychosocial functioning (Hansen *et al.*, 2002; Kessler *et al.*, 2001; Tugwell, 2000).

Measuring disablement

Measuring different aspects of disability and outcomes associated with rehabilitation services has resulted in a number of empirically based instruments of disability which have advanced the science and practice of functional assessment and health services research (Heinemann, 2005; Mermis, 2005) (see 'Disability assessment'). These instruments are frequently used to 1) evaluate and quantify the extent of physical disability and capacity for self-care, 2) identify limitations for discharge and/or rehabilitation, 3) identify outcomes associated with rehabilitation interventions and 4) inform the identification of goals for rehabilitation. An example of one of the more widely used functional status measures is the Functional

Independence Measure (FIM; Hamilton *et al.*, 1987). The FIM was designed to rate the severity of disability and the outcomes of medical rehabilitation and has been successfully used with a variety of disabled populations.

The WHO models of disability spurred the development of instruments that measure several aspects of optimal adjustment and possible impairment (the Craig Handicap Assessment and Reporting Technique; Whiteneck *et al.*, 1992) and the nature and extent of environmental factors (the Craig Hospital Inventory of Environmental Factors; CHIEF; Craig Hospital Research Department, 2001). Specifically, the CHIEF evaluates physical, environmental and architectural obstacles and other potential barriers (family, access to technology and information, employment issues, governmental policies, etc.).

Clinical implications

Clinical programmes for persons with disability vary according to the working models of disability. Medical perspectives traditionally place greater emphasis on the management of a specific diagnosis and related conditions (see 'Neuropsychological rehabilitation', 'pain management' and 'coronary heart disease: rehabilitation'); other health professions tend to focus their services on the individual with the disabling conditions and the persons who live with him or her, although many of these may recognize the need for policies that address environmental and social impediments. Consumers and their advocates are much more attuned to the demands and issues centred in the environmental and social context, with ensuing recommendations for alterations, accommodation and assistive devices that maximize independent functioning.

The WHO model of disability complements alternative models that represent advocacy and consumer perspectives. Thus, services that promote independent living with improved access to institutions, improve role functioning and mobility reduce disability across the dimensions in the WHO model. This also entails the effective and strategic provision and usage of assistive devices and enhanced computer technologies, and the removal of existing environmental barriers (Scherer, 2002).

Clinical services also benefit from the WHO model. Many legislated policies and services (e.g. vocational rehabilitation) have foundations in the medical model but also reflect advancements and the recognized need for technological assistance, improved access and adequate training and preparation to maximize functioning (Elliott & Jackson, 2005). Although acute medical rehabilitation maintains many characteristics associated with the medical model, service delivery systems and associated policies now urge greater attention to the necessity of collaborating partnerships with persons who live with a disabling condition and to increase community- and home-based services with ongoing access to information and support (Institute of Medicine, 2001; World Health Organization, 2002). Greater emphasis on health promotion for persons with disabling conditions will occur (Rimmer & Braddock, 2002).

Biopsychosocial models of health conditions permeate the psychological literature, generally, and these take into account the interactive effects of disease/disability parameters, psychosocial

stressors and personal and environmental factors which account for varying degrees of adaptation. Biopsychosocial models of disability – usually developed to study adjustment associated with specific disability diagnoses (e.g. spinal cord injury, traumatic brain injury, multiple sclerosis) – proliferate in the rehabilitation psychology literature (see Frank & Elliott, 2000, for several examples). A recent conceptualization of adjustment following disability emphasizes the primacy of subjective, phenomenological appraisals of resources, stressors and contextual issues across diagnostic conditions (Elliott *et al.*, 2002). Appraisals of environmental assets and liabilities, functional abilities and activities are likely to influence self-reports of the dimensions stipulated in the WHO model of disability. Individual differences and other psychological characteristics usually account for greater variance in the prediction of adjustment among persons with disability than in any condition-specific variable (see ‘Coping with chronic illness’ and ‘Coping with chronic pain’).

Psychological interventions have demonstrated considerable impact in the treatment of specific adjustment issues among persons living with disability, and in enhancing role function in certain areas (e.g. return to work; Elliott & Jackson, *in press*; Elliott & Leung, 2005). The WHO model of disability offers tremendous opportunity for psychologists to further demonstrate the respectable utility and impact of research, service and interventions that are informed by psychological theory and expertise, and in this process, offer a more prominent role for psychology (Johnstone, 1997).

Conclusions

The WHO model of disability will emerge as the preferred perspective in the international community, due to its recognition of the many factors that determine the disability experience. This will inevitably increase conflict in western societies that subscribe to a medical model, as policy-makers will debate issues related to reimbursement, resource allocation and the development and management of institutions and service delivery programmes, generally. In these debates policy-makers will encounter influence from stakeholders who have invested in current systems.

Psychology has made important contributions within the traditional medical perspective of disability, and may exert a more influential role within the WHO framework. Psychological expertise in theory, measurement, research design and interventions can contribute to the development of informed, empirically driven and cost-effective health care delivery and policy formation. At times, however, tensions may occur as psychologists conduct theory-based and empirical studies which do not fit well within the medical model (e.g. the effectiveness of home-based interventions that promote wellness) or that seem to place greater weight on individual – rather than environmental – factors (e.g. individual characteristics that contaminate individual self-reports of environmental barriers, or that predict secondary complications and objective indicators of adjustment over time, independent of environmental and medical variables).

Richard B. Slatcher and James W. Pennebaker

The University of Texas at Austin

A longstanding puzzle within psychology and psychosomatic medicine concerns the relationship between the expression of emotions and physical health. Descartes and Shakespeare suggested that not expressing powerful emotions could be unhealthy. Similarly, William James (1890) and Franz Alexander (1950) forcefully argued that inhibiting the expression of strong emotions over time could result in physical health problems through basic biological stress-related channels (see ‘Psychoneuroimmunology’ and ‘Psychosomatics’). Despite these early hypotheses, there is still no overwhelming evidence to support the idea that the suppression of emotional expression is unhealthy and, conversely, that the open expression of emotions is beneficial.

Emotional expression has been viewed by our culture somewhat ambivalently. On the one hand, emotional expression is often viewed as rather uncivilized, as ‘giving in’ to passion (King & Emmons, 1990, p. 864). On the other hand, it is assumed that emotions usually should be let out, that the healthy end to an emotional response is emotional expression. This view is especially common in

the psychological literature. From Breuer and Freud (1895/1966) to the present (e.g. Cole *et al.*, 1996; Pelletier, 1985) the inherent value of naturally expressing one’s thoughts and feelings has been emphasized. Emotional expression is thus viewed as a somewhat unseemly but normal part of everyday life.

While emotional expression is a normative behaviour which is neither good nor bad per se, actively holding back emotion through inhibition may have negative health consequences. Much of the literature examining the links between emotional expression and health has focused on the consequences of inhibition (Cole *et al.*, 1996; Gross & Levenson, 1997; Traue & Deighton, 1999). The findings from these studies suggest that actively holding back thoughts, emotions or behaviours can be a form of stress that exacerbates a number of adverse biological processes, such as increased cortisol production and immune suppression (Traue & Deighton, 1999). By expressing emotions, one may be able to organize and assimilate previously inhibited thoughts and feelings, thus bypassing the need for further inhibition. Several correlational studies have hinted that

such processes may be at work (Cole *et al.*, 1996; Gross & Levenson, 1997; Major & Gramzow, 1999).

Certain life events may be more likely than others to have deleterious health consequences because of their links to emotional expression. Those events that produce the most conflict are ones that are most difficult to share with others – sexual abuse, being fired from one's job, having a stigmatizing disease, marital infidelity and other potentially traumatic experiences (see 'Intimate partner violence' and 'Post-traumatic stress disorder'). Under such circumstances, individuals often try to inhibit thoughts and feelings about their experiences. Often, attempts at thought suppression may actually lead to an increase in thoughts about the very experience that they are trying to erase from memory (Wegner, 1984). Such inhibition, especially if it continues for extended periods of time, can exacerbate stress, and, in turn, lead to declines in immune system functioning and other markers of physical health.

In recent years there has been a rapid growth in research examining emotional expression and health, but a large number of questions remain unanswered. For example, to what extent does the expression of emotions bring about changes in people's psychological and social worlds? Are some people more likely than others to benefit from emotional expression? What are the cognitive, linguistic and social mechanisms that link emotional expression to health outcomes? One method that has been used to test the effects of emotional expression – expressive writing – is particularly relevant to our understanding of the links among upheavals, emotion, language and health. Included in this overview will be a discussion of some of the underlying processes that may help to explain some of the powerful effects associated with emotional expression.

Testing the relationship between emotional expression and health: expressive writing

There are a number of ways in which people are able to express their thoughts and emotions about important events in their lives. Beyond simple venting, perhaps most common is that people talk to others. This translation of an emotional experience into language is also the basis of expressive writing. In 1986, Pennebaker and Beall published the first expressive writing study. In that and subsequent studies, when people were asked to write about their emotional upheavals over a period of 3–4 days for 15–30 minutes per day, they exhibited improvements in physical health relative to controls who had been randomly assigned to write about superficial topics. The initial studies focused on physician visits to the student health centre as an outcome measure. Later studies expanded these findings to various health indicators, such as blastogenesis measures, CD4 counts, liver enzymes and other biological markers (Pennebaker, 1997). About 10 years ago, multiple labs around the world began testing the expressive writing intervention with generally positive results. Meta-analyses of the writing paradigm have suggested that this method produces positive effects for various markers of physical health (Smyth, 1998; Frattaroli, 2006).

In recent years, the number of expressive writing studies has grown exponentially. Multiple studies have examined the

effectiveness of expressive writing in the treatment of AIDS, diabetes, cancer and other physical health problems. A wide variation of writing instructions have been tried across an enormous range of participant populations. As more studies have been conducted, we are now beginning to get a sense of some of the boundary conditions of writing.

Expressive writing is not a panacea. Although an early meta-analysis by Smyth (1998) found that the effect size of writing on objective health outcomes was 0.67, these effects were based on relatively healthy samples. More recent meta-analyses with medical samples suggest that effect sizes for clinical trials are smaller ($d=0.21$) but still significant (Frisina *et al.*, 2004). Because virtually no writing studies could be classified as true RCTs, a recent Cochrane Report concluded that the use of writing as a medical intervention was still in the 'not proven' category (Meads, 2003). But since the Meads report was completed, several promising medical studies have been completed (e.g. Taylor *et al.*, 2003; Petrie *et al.*, 2004; Solano *et al.*, 2003).

Although the overall effect size of the intervention is modest several weeks or months afterwards, given its low cost and minimal adverse effects, the findings continue to be promising. The health benefits for writing are evident in measures of physical and mental health and hold up across samples of widely varying social class, ethnicity, language and cultures. It may be more effective for people dealing with more traumatic than expected upheavals and with events that happened several weeks or months after the event as opposed to immediately afterwards.

Why does expressive writing work? The search for mechanisms

While there is now solid evidence that disclosing emotional experiences can be healthy, one of the more intriguing aspects of this phenomenon has been trying to develop theories that best explain it. Over the years, theoretical views in this area have evolved tremendously. These theories are outlined briefly below.

Inhibitory processes

One of the first theories to explain the effectiveness of expressive writing dealt with inhibition. But direct tests of changes in inhibition following emotional disclosure have yielded disappointing results. For example, participants who claim that they have not previously disclosed their traumas have not differed in health outcomes versus those who have disclosed their traumas (Greenberg *et al.*, 1996). In addition, individuals have great difficulty answering (or even understanding) questions that ask them the degree to which they are actively inhibiting their thoughts, emotions or behaviours (Pennebaker *et al.*, 1988). Thus, at this point, the inhibition model is still unproven.

Cognitive processes

Another explanation for the effects of expressive writing is that the act of converting emotions and images into words changes the way a person cognitively organizes and thinks about an

emotional experience. By integrating thoughts and feelings about an emotional experience, one can then construct a coherent narrative of that experience. Once this integration takes place, the event can be summarized, stored and forgotten more efficiently. Various cognitive models have focused on different facets of cognitive construction and narrative construction. Smyth and his colleagues (1999), for example, have assumed that emotional expression fundamentally organizes an upsetting experience. As an indirect test of this, the authors asked people to write about a trauma in either an organized or an unstructured way. Only the organized writing resulted in health and mood improvements.

Using a different analysis strategy of looking directly at the ways individuals express emotions, several researchers are now finding support for the idea that constructing a narrative over the course of writing about emotional topics helps individuals to better integrate the experience. Specifically, by looking at word usage (e.g. an increasing use of cognitive words over the days of writing), health improvements are efficiently predicted. These word patterns have now been reported in multiple studies (e.g. Campbell & Pennebaker, 2003; Klein & Boals, 2001).

Social integration

Emotional expression, by nature, is an inherently social activity. The ultimate purpose of language is to communicate ideas and thoughts with other people. When someone talks to other people about his or her experiences, it alerts them to the person's psychological state and, ultimately, allows him or her to remain socially tied to them. Conversely, people who have traumatic experiences and do not tell their friends are more likely to live in a detached, isolated state. Consistent with this approach, Rimé (1995) argues that disclosure in the first days or weeks after a trauma has the power to change the quality of a person's social network by bringing people closer together. Disclosure, then, serves as a force of social integration. Rimé suggests that even private disclosure (as well as with writing) helps free a person from the stress of a non-disclosed

event, which ultimately allows for greater social integration. This is consistent with many of the social integration ideas first suggested by Durkheim (1951) wherein mental health was viewed as the result of the relationship between individuals and their social worlds (see 'Social support and health').

Researchers are now examining the social effects of expressive writing. In one pilot study, Matthias Mehl and the second author asked 52 participants to wear a re-engineered tape recorder called the Electronically Activated Recorder (EAR) as a part of an expressive writing experiment (discussed in Pennebaker & Graybeal, 2001). After the writing manipulation, those in the expressive writing group changed how they interacted with others, exhibiting significant increases in interactions with others, use of self-references and the use of emotion words. Similarly, another recent study examined social interaction patterns before and after expressive writing among 95 bilingual participants whose first language was either Spanish or Korean (Kim, 2004). Compared with controls, those in the experimental condition increased in their amount of talking to others in the days following expressive writing. While social integration theory still has not been fully tested, these preliminary findings have been encouraging.

Conclusion

Expressive writing studies have yielded important new ways to think about how emotional expression can encourage mental and physical health improvements. The mechanisms underlying this effect are still unclear but, in all likelihood, there is no single mediating influence between expressive writing and health. Perceptual, cognitive, emotional, linguistic and social processes all undoubtedly contribute and influence each other. Rather than continuing the task of trying to learn which of these features contributes the most or is the most pivotal, future research should draw on all of these processes in trying to maximize the salutary effects of emotional expression.

Expectations and health

James E. Maddux

George Mason University

The major health care challenge in the twenty-first century, as it was at the close of the twentieth century, will be motivating people to make changes in their own behaviour in ways that reduce the risk of health and medical problems and enhance health. These motivational efforts must consist not only of educating people about the positive and negative effects of various behaviours but also, and perhaps more importantly, persuading people that they indeed *can* change their behaviour and teaching them the skills for doing so. For this reason, understanding self-regulation – the capacity of people to think about the future, set goals, develop plans to attain these goals, and regulate their own behaviour based on these goals and plans – will be crucial to solving the health and medical problems of the twenty-first century (see ‘Health-related behaviours’).

Self-regulation consists of several key components, including setting goals, developing plans, monitoring progress towards goals and modifying one’s plans and behaviours in reaction to perceived progress towards one’s goals. At the heart of the ability to self-regulate is the ability to develop expectancies – to use past experience and knowledge to form beliefs about and predict future events (Olson *et al.*, 1996). The expectancy construct is among the most thoroughly investigated constructs in psychology. Expectancies

gained importance with the development of social learning theory, as originally developed by Rotter (1954) (see also Woodward, 1982). As social learning theory evolved, it became more explicitly cognitive, as in Bandura’s (1986) social cognitive theory and Mischel’s (1973) cognitive social learning theory and expectancies were given increasing importance. All of the major models of health behaviour are social cognitive models and feature expectancies as key concepts. Among these are the health belief model (Janz & Becker, 1984), protection motivation theory (Maddux & Rogers, 1983; Rogers, 1975), the theory of reasoned action/planned behaviour (Fishbein & Ajzen, 1975; Ajzen, 1988), (Bandura, 1977), precaution adoption theory (Weinstein, 1988), self-efficacy theory (Bandura, 1977) and the health action process approach (Schwarzer, 1992). These models essentially deal with the same social cognitive determinants while giving them different names and rearranging them in different ways (Maddux, 1993; Weinstein, 1993; Bandura, 2004) (see ‘The Health belief model’, ‘Self-efficacy and health behaviour’, ‘Theory of planned behaviour’).

The influence of expectancies on health behaviour can only be understood if placed in the context of a general model or theory that describes different types of expectancies, their

relationships with each other and their relationships with non-expectancies variables. Fortunately, we do not have to examine every theory in detail to achieve a basic understanding of expectancies and behaviour. Regardless of their differences, these models share several basic principles and hypothesized processes about human behaviour.

The principle of reciprocal causation proposes that environmental events, cognition, emotion and behaviour are mutually interactive influences. People respond cognitively, emotionally, and behaviourally to environmental events, but through cognition they also exercise control over their own behaviour, which then influences not only the environment but also cognitive, emotional and biological states.

The principle of the centrality of cognitive construals proposes that people have powerful symbolizing capabilities which enable them to cognitively construe (construct or build) their worlds. These cognitive construals have the great influence over behaviour and emotions. People attempt to explain events which have occurred and to predict future events so that they can control them. People develop expectancies about their ability to exercise those competencies under specific conditions, and expectancies about the consequences of exercising those competencies in certain situations. These explanations and expectancies greatly influence how people behave. The capacity for cognition also includes the capacity for consciousness, self-awareness, and self-reflection. People observe their own behaviours, thoughts, and feelings. They evaluate their ongoing behaviour based on how well it is working to accomplish their situational aims and objectives.

These cognitive abilities provide people with the tools for self-regulation or self-management. People envision goals and develop plans to attain those goals. They create incentives which motivate and guide their behaviour. They develop standards for their ongoing behaviour, evaluate their behaviour against these standards and then make strategic choices about their behaviour based on these standards.

The principle of the social embeddedness of the self proposes that people define themselves largely by what they think about, how they feel about and how they behave toward other people. The individual's behaviour is influenced and shaped by other people and by what the individual expects other people to think, feel and do in response to his or her behaviour. The most important learning is social learning – what people learn from other people about how to think, feel and behave. The most important cognitions are social cognitions – explanations and predictions about the behaviours, thoughts, and feelings of other people. 'Self' and 'personality' are perceptions (accurate or not) of one's own and others' patterns of social cognition, emotion and action as they occur in patterns of situations. Thus, self and personality are inextricably embedded in social contexts.

Expectancies and health behaviour

Various expectancy theories have proposed a wide variety of expectancies and an even wider variety of labels for the various types of expectancies. Research has linked each of these expectancies in significant ways to health behaviour.

Behaviour–outcome expectancy

A behaviour–outcome expectancy (as it was termed by Mischel, 1973) is a belief about the contingency between a specific behaviour and a specific outcome (result, consequence) or set of outcomes in a particular situation. Other names include expectancy for behaviour reinforcement sequence (Rotter, 1954), outcome expectancy (Bandura, 1977), means–end belief (Kirsch, 1995), action–outcome expectancy (Heckhausen, 1977), response–stimulus expectancy (Bolles, 1972), response–reinforcer association (Rescorla, 1987) and, simply, expectancy (Vroom, 1964). The theory of reasoned action (Fishbein & Ajzen, 1975) and the theory of planned behaviour (Ajzen, 1988) include behaviour–outcome expectancy in the assessment of two major predictors of behavioural intentions – attitudes towards the behaviour and social norms regarding the behaviour. Both constructs are assessed by asking people what outcomes they expect to result from the behaviour in question and how much importance (value) they place on those outcomes (Bandura, 2004). (See also 'Perceived control'.)

Behaviour–outcome expectancies influence health behaviour because people make decisions about their health behaviour based partly on their beliefs about the possible consequences of certain behaviours – such as the belief that using condoms will help prevent sexually transmitted diseases or the belief that regular exercise will help prevent heart disease (Bandura, 2004; Maddux, 1993).

Two kinds of behaviour–outcome expectancies can be distinguished based on two different kind of outcomes: environmental events and non-volitional responses such as a emotional reactions, sexual arousal and pain. A behaviour–stimulus expectancy (or response–stimulus expectancy; Kirsch, 1999) is the expectancy that a behaviour will lead to an environmental event. A behaviour–response expectancy (or response–response expectancy; Kirsch, 1999) is the expectancy that a behaviour will lead to a non-volitional response. Both types are important in understanding health behaviour. People who exercise to reduce risk of heart disease want to prevent these illnesses because they are painful, debilitating and possibly deadly. In addition, the major desired outcomes which lead people to exercise regularly are feelings of physical and psychological wellbeing, and among the major 'costs' associated with exercise are non-volitional responses such as fatigue, discomfort and pain.

Health behaviours are also influenced by social expectations – that is, by how people expect other people to respond (e.g. expected approval or disapproval). Major changes in a person's health behaviour, especially changes in lifestyle such as dietary changes and adopting an exercise regimen, can greatly affect other people, especially friends and family members. Expectancies for approval and support from close others can greatly facilitate behaviour change while expectancies for disapproval and resistance can discourage its initiation and maintenance. Thus, effectively changing sexual behaviour, substance use or abuse, diet and exercise can often depend heavily on a person's ability to manage close relationships and the emotions inherent in these relationships. These social expectancies are examples of behaviour–stimulus expectancies (see 'Social support and health').

Bandura offers an alternative way of categorizing behaviour–outcome expectancies relevant to health behaviour (Bandura, 2004). Physical behaviour–outcome expectancies pertain to the pleasurable and aversive outcomes of the behaviour (behaviour–response expectancies) and to material losses and benefits (behaviour–stimulus expectancies). Social behaviour–outcome expectancies pertain to the social approval and disapproval of other people regarding the behaviour. Finally, self-evaluative expectancies are concerned with one’s own positive and negative reactions to one’s health behaviour and health status (e.g. self-approval/disapproval; self-satisfaction/dissatisfaction). These self-evaluative expectancies can be viewed as either behaviour–response expectancies or behaviour–stimulus expectancies, depending on the extent to which one believes that self-evaluative reactions are within volitional control.

Stimulus–outcome expectancy

Stimulus–outcome expectancies are expectancies that certain events signal the possible occurrence of other events (Mischel, 1973; Bolles, 1972; Rotter, 1954; Vroom, 1964; Heckhausen, 1977). For example, a siren predicts the appearance of a police car, fire engine or ambulance; the worsening of a smoker’s cough may be viewed as a predictor of lung disease; or the presence of a lump in a breast may be viewed as a sign of breast cancer.

Stimulus–outcome expectancies can be divided into two types based on the distinction between environmental events and non-volitional responses. A ‘stimulus–stimulus expectancy’ (Kirsch, 1999) is the expectancy that a stimulus signals the probable occurrence of an external environmental event (e.g. a dark cloud predicts rain). A ‘stimulus–response expectancy’ (Kirsch, 1999) is the expectancy that a stimulus signals the probable occurrence of a non-volitional response (e.g. watching a sad movie might make one cry). Both types of expectancies can influence health behaviour. I may decide not to go running this evening because I believe that the clouds I see predict rain soon (stimulus–stimulus expectancy). A diabetic may avoid regularly testing his or her level of insulin because he finds the procedure painful (stimulus–response expectancy).

Expectancies and outcome value

The power of expectancies over behaviour depends directly on the importance or value (positive or negative) which people place on what they expect. Outcome value is the value or importance attached to specific outcomes in specific situations (Rotter, 1982; Mischel, 1973; McClelland, 1985). Outcomes can be either (external) stimulus events or (internal) non-volitional responses. An outcome can be valued because we wish to attain it (money, better health) or because we wish to avoid it (e.g. pain, fatigue, cancer, obesity). In most social cognitive models of health behaviour, such as protection–motivation theory (e.g. Maddux & Rogers, 1983; Rogers, 1975) and the health belief model (e.g. Janz & Becker, 1984), the perceived severity of the health threat is an outcome value (Maddux, 1993). In the theory of reasoned action/planned behaviour, outcome value is evident in the assessment of attitudes and social norms because both are measured as the product of

behaviour–outcome expectancies and the value of those expected outcomes. The values of outcomes are not static but can change over time. For example, people often begin exercise programmes for the expected physical health and appearance benefits, but over time mood enhancement and social benefits become increasingly important incentives (Hsiao & Thayer, 1998). The importance of outcome value in numerous health-related behaviours has been demonstrated by a considerable body of research (e.g. Strecher *et al.*, 1997; Rogers & Prentice-Dunn, 1997).

Self-efficacy expectancy

A self-efficacy expectancy is a belief in one’s ability to perform a specific behaviour or set of behaviours under specific conditions and to ‘mobilize the motivation, cognitive resources, and courses of action to exercise control’ (Bandura, 1990, p. 316) over a specific task demanded in a specific situation. Self-efficacy expectancies are not competencies. Competencies are what people know about the world and what they are capable of doing in the world (Mischel, 1973). Self-efficacy beliefs are beliefs (accurate or not) about one’s competencies and one’s ability to exercise these competencies in certain domains and situations. Self-efficacy beliefs are not intentions to behave or intentions to attain particular goals. Intentions are what people say they are committed to doing or accomplishing, not what they believe they accomplish. Self-efficacy expectancies are not causal attributions. Casual attributions are explanations for events, including one’s own behaviour and its consequences. Self-efficacy beliefs can influence causal attributions and vice versa because beliefs about competencies can influence explanations of success and failure and because explanations for success and failure will, in turn, influence perceptions of competence (Bandura, 1997). Finally, self-efficacy expectancies are not traits – they are beliefs about the ability to coordinate skills and abilities to attain desired goals in particular domains and circumstances. Self-efficacy beliefs can generalize from one situation or task to another, depending on the similarities between the task demands and the skills and resources required for meeting those demands (e.g. Samuels & Gibb, 2002), but self-efficacy in a specific domain does not emanate from a general sense of efficacy. Measures of traits, such as optimism and perceived control, seem to predict behaviour only to the extent to which they overlap with the measurement of self-efficacy (Dzewaltowski *et al.*, 1990). In addition, measures of global efficacy beliefs have been developed (e.g. Sherer *et al.*, 1982; Tipton & Worthington, 1984) and are used frequently in research, but generally they do not predict behaviour as well as domain-specific self-efficacy measures.

Self-efficacy expectancies influence health behaviour in several ways. First, they influence the health-related goals which people set for themselves. People who feel more self-efficacious set more challenging goals for their health. Second, they influence people’s reactions to the inevitable setbacks which occur when people try to alter long-standing habits or adopt new, healthier habits. People with stronger self-efficacy expectancies are more likely to be resilient and persistent in the face of barriers to change than are people with weaker self-efficacy beliefs, partly because they are less likely to experience the debilitating self-doubt and

despondency that so often results from encountering barrier and setbacks.

Research on self-efficacy has greatly enhanced our understanding of how and why people adopt healthy and unhealthy behaviours and of how to change behaviours which affect health (Bandura, 1997; Maddux *et al.*, 1995; O'Leary & Brown, 1995). All of the major theories of health behaviour noted previously (protection motivation theory; health belief model, theory of reasoned action/planned behaviour; precaution adoption model; health action process approach) include self-efficacy as a key component. Research indicates that self-efficacy beliefs are crucial to successful change and maintenance of virtually every behaviour crucial to health – including exercise, diet, stress management, safe sex, smoking cessation, overcoming alcohol abuse, compliance with treatment and prevention regimens and detection behaviours such as breast self-examinations (Bandura, 2004, 1997; Maddux *et al.*, 1995; Maddux & Gosselin, 2003).

Self-efficacy beliefs not only influence behaviour, but they also influence a number of biological processes which, in turn, influence health and disease (Bandura, 1997). Self-efficacy beliefs affect the body's physiological responses to stress, including the immune system (Bandura, 1997; O'Leary & Brown, 1995) and the physiological pathways activated by physical activity (Rudolph & McAuley, 1995). Lack of perceived control over environmental demands can increase susceptibility to infections and hasten the progression of disease (Bandura, 1997). Self-efficacy beliefs also influence the activation of catecholamines, a family of neurotransmitters important to the management of stress and perceived threat, along with the endogenous painkillers referred to as endorphins (Bandura, 1997; O'Leary & Brown, 1995).

Self-efficacy expectancy is similar to perceived behavioural control, as defined in the theory of planned behaviour (Ajzen, 1988). Both involve beliefs that an individual has the resources and opportunities to execute a behaviour or attain a goal. However, the lack of clarity in the definition and measurement of both self-efficacy expectancy and perceived behaviour control raises some questions. In research, perceived behavioural control has been measured as perceived control over the behaviour and as perceived control over goal attainment (e.g. Ajzen & Madden, 1986; Madden *et al.*, 1992; Schifter & Ajzen, 1985). These are different constructs.

A common source of confusion is the relationship between self-efficacy expectancy and intentions. Sometimes when people say 'I can't' they are referring to beliefs about lack of skills and abilities; at other times they are referring to beliefs about lack of ability to manage discomfort and distress and expressing their resulting unwillingness to do something that may be a simple motor task. This distinction is particularly important in situations in which performing a behaviour may lead to involuntary aversive reactions such as fear, pain or discomfort – situations in which the individual has strong response expectancies for aversive outcomes (Kirsch, 1999). When people anticipate aversive outcomes (e.g. fear or pain) and are not willing to engage in behaviour that may produce those outcomes, their linguistic habit is to say they cannot perform the behaviour (low self-efficacy) rather than they will not perform it. Measures of willingness may simply be measures of intention as employed in the theory of reasoned action. Therefore, in situations in which fear or pain is anticipated, measures of perceived ability to

perform the behaviour (self-efficacy) may be measures of intention to perform the behaviour. This intention is determined primarily by the strength of the person's response expectancies. The mislabelling of intention and perceived ability may occur in other important domains in which people are asked to engage in behaviours that may lead to immediate discomfort, such as dieting, exercising or violating personal norms (Baker & Kirsch, 1991). In situations involving anticipated pain, discomfort or emotional distress (e.g. picking up a snake, asking an attractive person for a date, running a marathon), measures of self-efficacy expectancy for the simple motor behaviours involved in these complex tasks (grasping, talking, running) are strongly influenced by response expectancies and thus are largely equivalent to measures of willingness and intention (Kirsch, 1995). Self-efficacy expectancy for the complex performances (including self-efficacy for coping with disturbing thoughts, anxiety, pain) are not the equivalent of willingness and intention.

Expectancies for proximal versus distal outcomes

One of the major obstacles to changing from an unhealthy behaviour to a healthful behaviour is the conflict between expectancies for proximal (immediate) and distal (future) consequences and in particular the power that expectancies for proximal consequences exert over behaviour. Many unhealthy 'lifestyle' behaviours (e.g. eating and drinking too much, unsafe sex, smoking) are unhealthy only in the long run but are immediately pleasurable and gratifying. Likewise, changing from unhealthy to healthful behaviour (e.g. starting an exercise programme, giving up tasty high fat foods) almost always involves great effort and often results in initial pain or discomfort. This conflict between expectancies makes it difficult for people to adopt safer sexual practices, quit smoking, eat and drink less and exercise regularly. Sex, smoking, eating ice cream, and watching TV in bed are immediately pleasurable and gratifying, while the costs of these behaviours exist only in the imagined and indefinite future. Likewise, giving up these behaviours involves immediate loss of pleasure and an increase in discomfort.

Conclusions

The most important influences on health will continue to be the decisions which people make about healthy and unhealthy behaviour in their daily lives. For this reason it is essential that healthcare professionals become more concerned with teaching people skills for the self-regulation of health behaviour (see 'Cognitive behaviour therapy', 'Health promotion', 'Motivational interviewing', 'Physical activity interventions', 'Self-management', and 'Stress management'). Expectancies are key components of all theories of health behaviour and self-regulation. A complete understanding of the role of expectancies in health behaviour depends on a clearer understanding of the broader social cognitive perspective and the relationships among expectancies and other social cognitive constructs. Research has found that a number of different types of expectancies influence health behaviour in important ways. Self-efficacy expectancies – expectancies about one's ability to engage

in certain health-related behaviours – are probably the most important and influential expectancies.

Understanding of the influence of expectancies on health behaviour depends on understanding important similarities among the behaviours which influence health. Certainly, each health problem and health behaviour presents a unique challenge. For example, efforts to convince middle-aged people to exercise regularly will differ in important ways from efforts to convince sexually active teenagers to use condoms. Despite these differences, however, the processes or mechanisms that explain changes in these behaviours are the same. The expected consequences of exercising or not exercising differ from the expectancies for condom use or non-use, but for both behaviours expectancies for the outcomes

of these behaviours (outcome expectancies) are important determinants. Likewise, convincing older adults that they are capable of engaging in regular exercise and convincing teenagers that they are capable of either abstaining from sex or negotiating safe sex with a partner will require different strategies. In both cases, however, beliefs about personal ability and control (self-efficacy expectancies), will be crucial determinants of success. For this reason, we do not need different expectancies or expectancy-based theories for different health-related behaviours such as specific theories to explain safe and unsafe sexual behaviour, smoking, eating behaviour, and so on. The proliferation of behaviour-specific or problem-specific theories is a waste of intellectual resources and a barrier to theory development and refinement.

Gender issues and women’s health

Jane M. Ussher

University of Western Sydney

The legacy of early critiques of women’s health

Thirty years ago Women’s Health was a field fighting for recognition in a world dominated by androcentric research, theory and clinical intervention. Today it is a rich and vibrant body of work, spanning many diverse disciplines. The health of women is now firmly on the agenda of the World Health Organization, government and research funding bodies, providers of health services and educators. Researchers, theorists and social activists continue to move knowledge and practice forwards, improving service provision for women, at the same time as we reach a greater understanding of ‘what women want’ regarding their health.

Yet it hasn’t always been this way. The last few decades of the twentieth century have seen the publication of a number of groundbreaking studies and critical polemics which highlighted the paucity of knowledge about the health and wellbeing of women. They documented how women’s bodies, women’s minds, and by extension, women’s lives have historically been marginalized, ignored or dealt with in a detrimental way by mainstream health professions. Whole disciplines such as medicine, psychology and psychiatry were subjected to critical scrutiny. It was argued that women’s mental health was defined in relation to man as the norm, and inevitably found wanting as a result. Femininity was pathologized, with mental health treatments merely serving as vehicles of social control, pushing women back into patterns of behaviour and social roles which were sources of distress and despair in the

first place. It was argued that the reproductive body was positioned as a site of illness, irrationality and weakness, used as an excuse for excluding women from an equal place along side men. Or it was posited as a site of medical and psychological intervention, over which women had no choice or control. It was also argued that there was a dearth of knowledge about the normal aspects of reproduction, as psychological and medical research focussed on and reinforced the notion of reproduction as site of deviancy or debilitation, framing the female body within a narrow scientific gaze (Showalter, 1987; Sayers, 1982; Ussher, 1989).

It became clear that vast areas of health research excluded women altogether. For example, work on mid-life concentrated on men, with Erickson's male model of mid-life developmental changes being extrapolated unquestioningly to women, much as Kohlberg's theories of moral development had also been (Gilligan, 1982). Both theories found women lacking. Their deviation from a male norm was deemed deficiency, not difference. Many major clinical trials on heart disease excluded women altogether, as did early research on AIDS. In research on cancer, there has been a focus on the breast and genitals, even though lung cancer surpasses breast cancer as a cause of death for women. Research on all other forms of cancer in women is rare, or gender differences are not analysed when women are included in clinical trials. Research on alcohol use, or on drug use, has also focused almost solely on men until recently – despite the fact that significant numbers of women experience substance abuse, as well as problems from prescribed psycho-active drugs (Lee, 1998; Stanton & Gallant, 1995) (see 'Alcohol abuse' and 'Drug dependencies'). Even when women *are* included in health research, it is only as a narrow and specific group, for in the main the focus has been on middle-class, able-bodied, heterosexual, white women.

These early critiques which focused on the marginalization or exclusion of women's health issues have provided an important legacy for current research, theory and practice. They have highlighted the way in which 'woman' has been constructed in quite specific ways by health professions and researchers. They have documented the way in which women have historically been excluded from shaping the agenda as researchers, clinicians and policy makers, and how this has had a significant impact on the development of knowledge and professional practice in the arena of women's health (Ehrenreich & English, 1979). These critiques provided the foundations for the current field of Women's Health, setting an example and an agenda, simultaneously. Today, in disciplines as disparate as psychology, sociology, cultural studies, women's studies, social work, nursing, anthropology, psychiatry and medicine, scholars and researchers have brought their considerable energies to bear on the question of women's health and a rapidly growing literature on the subject is the result (Lee, 1998). This chapter will examine the gender issues in mental health, as an example of the debates and theoretical issues in this field.

Women's mental health

The existence of gender differences in mental health problems is a well established phenomenon. Prior to puberty, boys are over represented in significantly greater numbers (by a factor of

approximately 4:1) in the whole gamut of psychological or behavioural problems experienced by children. For example, prior to the age of eight, boys predominate in a range of behavioural and psychological disorders, including bedwetting/soiling, feeding and appetite problems, sleep problems, over-activity and restlessness, including reading and writing difficulties, autism, hyperactivity and anti-social behaviour (Crown & Lee, 1999). However, after puberty the situation is reversed. Estimates of the ratio of women to men suffering from disorders such as depression, anxiety and eating disorders range from 6:1–5:3. Community surveys, hospital admissions and statistics on outpatient treatment (both medical and psychological) all concur: women are represented in far greater numbers than men (Bebbington, 1996). The only exceptions are in the diagnosis of schizophrenia, where there are no clear gender differences and of alcoholism, where men dominate. For decades, researchers have searched for the factors underlying this gender difference, claiming that if we can explain it, we will have the key to understanding mental health problems per se. Numerous competing biological, psychological and social aetiological theories have been put forward as a result.

Aetiological theories of childhood mental health and behavioural problems predominantly focus on issues other than gender. Whilst differential rates of diagnosis between boys and girls are acknowledged in discussions of incidence and prevalence, in the main, research and clinical intervention has concentrated on non-gender specific theories. These include factors such as teratogens or perinatal trauma, parental attachment, separation and hospital admission, family discord and divorce, maternal depression, bereavement, school effects, social deprivation and social class, temperament or cognitive factors, such as absence of theory of mind as an explanation for autism (Rutter & Hersov, 1987). Any analysis of differential patterns of problems between boys and girls invariably attributes them to biological differences between the male and female fetus, infant or child, which are said to produce developmental differences between boys and girls that make them more vulnerable in the early years. For example, recent explanations for gender differences in autism posited this problem as being due to sex differences in the brain (Baron-Cohen, 2003).

In the field of adult mental health, biomedical accounts have historically dominated, providing the basis for the widespread use of biomedical interventions, in particular psychotropic drug use. The attribution of symptomatology to 'synaptic events', such as noradrenalin, 5-HT, serotonin, dopamine and acetylcholine neurotransmitters can clearly be applied equally to men and women. The biological explanation for sex differences is seen to be 'female hormones', particularly oestrogen and progesterone, which lead to depression associated with the reproductive life cycle: Premenstrual syndrome (PMS), postnatal depression (PND) or menopausal problems (Studd, 1997).

However, in recent years, the majority of researchers and clinicians have moved away from a strictly biological model, acknowledging instead the role of psychosocial factors in women's mental health. Social or environmental factors which have been reported to be associated with higher reporting of mental health problems include marital status, with married women reporting higher rates of problems than single women or married men; caring roles, with women looking after small children or elderly relatives being

at higher risk; employment status, with work generally providing a protective factor, particularly for working-class women; absence of social support and economic or social power; gender role socialization, which leads to depressogenic attributional styles, and an emphasis on affiliation rather than achievement, leading to vulnerability when relationships are under threat; multiple role strain and conflict, as well as the devaluation of traditional feminine roles; and sexual violence or abuse, in adulthood or childhood (Brown *et al.*, 1986; Baker, 2002; Stoppard & McMullen, 2003). Psychological theories which have been put forward include cognitive vulnerability, specifically the greater likelihood of women to attribute problems to internal, stable and global factors; coping styles; and perception of control (Bebbington, 1998). Psychodynamic theories, including object relations theory and Freudian theory, have been influential in psychotherapeutic circles, as well as in many recent feminist critiques, but have had less impact on mainstream research and practice (see 'Psychodynamic psychotherapy').

Alternative models of conceptualizing, researching, and, if necessary, treating symptomatology have also been developed from within a broadly social constructionist perspective (Stoppard, 1999). Social constructionists challenge the realist assumptions of traditional biomedical and psychological research, arguing instead that subjectivity, behaviour and the very definition and meaning of what constitutes 'health' and what constitutes 'illness' is constructed within social practices and rules, language, relationships and roles: it is always shaped by culture and history (Burr, 1995). Many of the now numerous feminist critiques of women's mental health problems and of the treatment of women within the mental health professions, could be placed under a broad social constructionist umbrella. Feminist critics have argued that misogynistic assumptions about gender roles and normal femininity are used to diagnose and treat women who deviate as 'mad'; that assumptions about the proper position of women within the institution of heterosexuality are used to prescribe notions of normality; that the age-old practice of locating distress or deviancy in the womb (or in reproductive hormones) reinforces notions of woman as more animalistic or biologically driven than man, as well as dismissing all legitimate anger or discontent as the result of 'raging hormones'; and that social and political inequalities, which understandably produce symptoms of distress, are ignored (Ussher, 1991, 2006; Chesler, 1998). This has led to critical feminist analyses of mental health research and treatment; to a deconstruction of the very concept of 'mental illness'; and, more recently, to the development of women-centred research and therapy.

However, one of the main problems is that in adopting a social constructionist perspective, or in arguing that 'mental illness' exists entirely at a discursive level, we are implicitly denying the influence of biology or genetics, or we may appear to relegate the body to a passive subsidiary role, which has meaning or interpretation imposed upon it (Yardley, 1997). Other material aspects of women's lives may also be negated in a discursive analysis: the influence of age, social class, power, economic factors, ethnicity, sexual identity, personal relationships and social support or a prior history of sexual abuse, amongst other factors. Equally, within a social constructionist or discursive approach the 'reality' of mental health problems may appear to be denied; 'mental illness' can appear to be conceptualized as merely a social label or

category. What is needed is a move towards a material-discursive-intrapsychic analysis, where material, discursive and intrapsychic aspects of experience can be examined without privileging one level of analysis above the other.

A material-discursive-intrapsychic analysis of women's mental health

'Material-discursive' approaches have recently been developed in a number of areas of psychology, such as sexuality, reproduction and mental or physical health (Ussher, 1997*b*; Yardley, 1997). This is as a result of both a frustration with mainstream psychology, which has tended to adopt a solely materialist standpoint, thus serving to negate discursive aspects of experience, and dissatisfaction with the negation of the material aspects of life in many discursive accounts. However, the intrapsychic is often left out of material-discursive approaches, for the reason that it is seen as individualistic or reductionist. Equally, when intrapsychic factors are considered (for example in psychoanalytic or cognitive theorizing) they are invariably conceptualized separately from either material or discursive factors. It is time that all three levels together are incorporated into academic theory and practice, in order to provide a multidimensional analysis of women's lives, of mental health and illness as discursive categories and of the mental health symptoms many women experience. So what is meant by a material-discursive-intrapsychic approach?

The level of materiality

To talk of materiality is to talk of factors which exist at a corporeal, a societal or an institutional level; factors which are traditionally at the centre of bio-medical or sociological accounts. This would include biological factors associated with psychological symptomatology; material factors which institutionalize the diagnosis and treatment of mental health problems as 'mental illness' or 'madness'; gender inequalities and inequalities in heterosexual relationships, legitimating masculine power and control. The latter would encapsulate economic factors which make women dependent on men; presence or absence of accommodation which allows women in destructive relationships to leave; support for women of a legal, emotional and structural kind, which allows protection from further harassment or abuse; and the fact that women take on the primary caring role in relationships, at both a physical and psychological level. It would include issues of social class which lead to expectations of 'normal' behaviour for women and men, and which are implicated in educational or employment opportunities available to both, as well as in the way individuals are treated by external institutions such as social services or the mental health professions. The fact of whether children are present in the relationship or not (or are in custody battles withheld), and the material consequences of being married (or not) are also part of this level of analysis. Equally, previous history of sexual violence or abuse is partly a material event; as is family history – the number of siblings, parental relationships and factors such as parental divorce or separation from parents in childhood. There are also many material consequences of experiencing or being treated for mental health problems, in terms of physical or psychological vulnerability,

as well as powerlessness at an economic or societal level. The social isolation which can be a consequence of mental health problems, or which can act to exacerbate its effects is also partly a material issue. Sex, ethnicity and sexuality are also associated with materiality – with the reproductive body, with gendered or sexual behaviour and with physical appearance.

The level of the discursive

To focus on the 'discursive' is to look to social and linguistic domains – to talk, to visual representation, to ideology, culture, and power. What is arguably of most relevance here is the discursive construction of mental illness or madness, of medical or psychological expertise, and the discursive construction of gender, as well as the analysis of the relationship between representations of 'woman' and 'man', and constructions of the particular leads social roles adopted by individual women and men.

As was outlined above, many critics have argued that mental health and illness can be conceptualized as social categories created by a process of expert definition. In this view, it is a discursively constructed label, based on value-laden definitions of normality. What is deemed 'mental illness' in one context, at one point in time, is deemed normal at another (Foucault, 1967). For example, it is the model of normal selfhood that underpins late twentieth century Western notions of mental health, where stability of affect is held up as the norm, and consistent happiness the ideal we should aspire to, which is used to categorize women (and men) as suffering from a mental health problem. Any deviation from this stable norm is deemed illness, a state to be avoided or cured. To illustrate that this is an historical and cultural construct, we only have to look to the model of the self that underpins Eastern models of mental health, such as that found in Buddhist meditation and psychotherapy. Here the illusion of a core consistent 'me', that is always positive and good, is directly confronted (Epstein, 1995). Rather than eradicate 'symptoms', this model would suggest that through the practice of mindfulness, an appreciation of the temporally based dimension of self is arrived at, by paying attention to bodily based experiences and sensations as they occur. There is no reaction or judgement of these experiences or sensations, merely a witnessing of them, leading to awareness that feelings are rarely constant. There is an acceptance of fluctuation and change, but this is not posited as pathological, as needing psychiatric diagnosis or 'cure'.

Equally, within a discursive account, rather than femininity being seen as pre-given or innate, here it is seen as something which is performed or acquired. In the process of becoming 'woman', it is argued that women follow the various scripts of femininity which are taught to them through the family, through school and through the myriad representations of 'normal' gender roles in popular and high culture, as well as in science and the law (Ussher, 1997a). The taking up of the archetypal feminine position, within what has been described as a heterosexual matrix (Butler, 1990), has been seen to put women at risk for mental health problems, as it is a role which requires self-sacrifice, self-denigration and a stifling of independence and desire (O'Grady, 2004). The dominance of phallogocentric scripts of femininity is one of the explanations put forward for why women stay in unhappy, neglectful or violent relationships and arguably one of the explanations for why women internalize marital or family difficulties as depression. Women are taught to gain

happiness through relationships, invariably with men. They are also taught that it is their fault if they can't (Jack, 1991). At the same time, a number of feminist critics have argued that the discursive construction of madness and femininity are closely aligned, thus to be a 'woman' is to be at risk of being positioned as 'mad', particularly if one steps out of line by being violent, sexual or in some other way contravening the feminine role (Chesler, 1998).

The level of the intrapsychic

Intrapsychic factors are those which operate at the level of the individual and the psychological: factors which are traditionally the central focus of psychological analyses of women's mental health problems, outlined above. This would include analyses of the way in which women blame themselves for problems in relationships, and psychological explanations for why this is so, incorporating factors such as low self-esteem, depression, the impact of previous neglect or abuse, guilt, shame, fear of loss or separation and the idealization of both heterosexuality and of men (Baker, 2002). It would include an analysis of psychological defences, such as repression, denial, projection or splitting, as mechanisms for dealing with difficulty or psychological pain. For example, we see evidence of splitting in the way women see themselves, or their man, as 'all good' or 'all bad', with no acknowledgement that everyone can exhibit both positive and negative characteristics at the same time; or in the way women blame themselves, or their bodies, for problems which they experience (Ussher, 2006). It would also include women's internalization of the idealized fantasy of motherhood and of the expectations of being 'woman' in a heterosexual social sphere (Mauthner, 2000). The fear women experience in relation to the threat of violence or abuse in relationships, or in society as a whole, is also an important factor (Yodanis, 2004).

Conclusion

The field of mental health is one where there are clear gender differences between men and women. A number of unidimensional theories have been put forward to explain these gender differences. However, a multifactorial approach which acknowledges a connection between material, discursive and intrapsychic factors is the most appropriate. Mental health problems are thus phenomena experienced by individual women at a material, discursive and an intrapsychic level; we cannot disentangle one from the other. The meaning of mental health to women, and to the experts who research and treat it, has to be understood in relation to the specific historical and cultural contexts in which they are positioned, the material factors impacting on individual women's lives, and the intrapsychic factors which impact upon individual women's experience and negotiation of 'symptoms'. As researchers, clinicians and theorists, we need to move to a position where we can take each of these levels of experience on board, without privileging one above the other. Thus the role of hormones, the endocrine system or physiological arousal, as well as the influence of social stressors, age or economic factors, can be acknowledged and studied in analyses of the aetiology of mental health problems. The existence

of symptoms would also be acknowledged, whether they are psychological or physical, as would the existence of psychological or material factors which might ameliorate symptoms. However, these symptoms or material factors are not conceptualized as independent entities which exist separately from the historical or

cultural context in which the woman lives. They are always positioned within discourse, within culture. 'Mental health problems' are therefore always a product of the symbiotic relationship between material, discursive and intrapsychic factors: one level of analysis cannot be understood without the other. (See also 'Men's health'.)

²University of Sheffield

Development of the health belief model (HBM)

In the 1950s US public health researchers began developing psychological models designed to enhance the effectiveness of health education programmes (Hochbaum, 1958). Demographic factors such as socio-economic status, gender, ethnicity and age were known to be associated with preventive health behaviours and use of health services (Rosenstock, 1974), but these factors could not be modified through health education. Thus the challenge was to develop effective health education targeting modifiable, individual characteristics that predicted preventive health behaviour and service usage.

Beliefs provided an ideal target because they are enduring individual characteristics which influence behaviour and are potentially modifiable. Beliefs may also reflect different socialization histories arising from demographic differences while, at the same time, differentiating between individuals from the same background. If persuasive methods could be used to change beliefs associated with health behaviours and such interventions resulted in health behaviour change then this would provide a theory-based technology of health education.

An expectancy–value model was developed in which events believed to be more or less likely were seen to be positively or negatively evaluated by the individual. In particular, the likelihood of experiencing a health problem, the severity of the consequences of that problem, the perceived benefits of any particular health behaviour and its potential costs were seen as core beliefs guiding health behaviour (see ‘Expectations and health’).

Rosenstock (1974) attributed the first health belief model (HBM) research to Hochbaum’s (1958) studies of the uptake of tuberculosis X-ray screening. Hochbaum found that perceived susceptibility to tuberculosis and the belief that people with the disease could be asymptomatic (so that screening would be beneficial) distinguished between those who had and had not attended for chest X-rays. Similarly, a prospective study by Kegeles (1963) showed that perceived susceptibility to the worst imaginable dental problems and awareness that visits to the dentist might prevent these problems were useful predictors of the frequency of dental visits over the next three years. Haefner and Kirscht (1970) took this research one step further and demonstrated that a health education intervention designed to increase participants’ perceived susceptibility, perceived severity and anticipated benefits resulted in a greater number of check-up visits to the doctor compared with controls

over the following eight months. Thus, by the early 1970s a series of studies suggested that these key health beliefs provided a useful framework for understanding and changing health behaviour.

Structure of the HBM

The HBM focuses on two aspects of individuals’ representations of health and health behaviour: threat perception and behavioural evaluation. Threat perception comprises two key beliefs, namely, perceived susceptibility to illness or health problems and anticipated severity of the consequences of illnesses. Behavioural evaluation also includes two distinct sets of beliefs, those concerning the benefits or efficacy of a recommended health behaviour and those concerning the costs of or barriers to enacting the behaviour. In addition, the model proposes that cues to action can activate health behaviour when appropriate beliefs are held. These ‘cues’ include a diverse range of triggers including individual perceptions of symptoms, social influence and health education campaigns. Finally, an individual’s general health motivation or ‘readiness to be concerned about health matters’ was included in later versions of the model (e.g. Becker *et al.*, 1977). There are, therefore, six distinct constructs specified by the HBM. As Figure 1 indicates, there are no clear guidelines on how to operationalize the links these constructs so the model has usually been operationalized as a series of up to six separate independent variables which can be used to predict health behaviours.

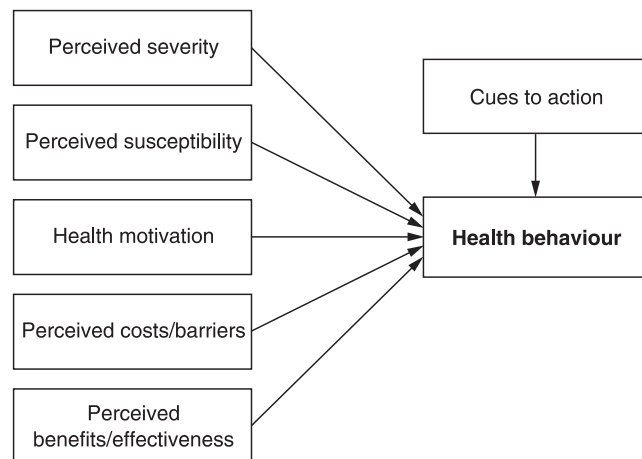

Fig 1 The Health Belief Model.

¹ This chapter is based on a more detailed chapter; Abraham, C. & Sheeran, P. (in press, 2005). Health Belief Model. In M. Conner & P. Norman (Eds.) *Predicting health behaviour: research and practice with social cognition models* (2nd edn.). Buckingham, UK: Open University Press.

Research using the HBM to predict health-related behaviour

The HBM has been applied to the prediction of an impressively broad range of health behaviours among a wide range of populations. Three broad areas can be identified: (a) preventive health behaviours, which include health-promoting (e.g. diet, exercise) and health-risk (e.g. smoking) behaviours as well as vaccination and contraceptive practices; (b) sick role behaviours, particularly adherence to recommended medical regimens; and (c) clinic use, which includes physician visits for a variety of reasons (for a review see Abraham & Sheeran, 2005).

Most HBM studies have employed cross-sectional designs, although Janz and Becker's (1984) review found that 40% of HBM studies were prospective. Prospective studies are important because simultaneous measurement of health beliefs and (especially self-reported) behaviour may be subject to memory and social desirability biases and does not permit causal inferences (Field, 2000). Most studies have used self-report measures of behaviour but some have used physiological measures (e.g. Bradley *et al.*, 1987), behavioural observations (e.g. Hay *et al.*, 2003) or medical records (e.g. Orbell *et al.*, 1995) as outcome measures. While the majority of measures of health beliefs employ self-completion questionnaires, structured face-to-face (e.g. Volk & Koopman, 2001) and telephone (e.g. Grady *et al.*, 1983) interviews have also been employed. Use of random sampling techniques is commonplace and specific representation of low-income and minority groups is also evident (e.g. Becker *et al.*, 1974).

There have been two quantitative reviews of predictive research using the HBM with adults (see Gochman & Parcel, 1982 for review of applications involving children). These reviews adopted different strategies in quantifying findings from research studies. Janz and Becker's (1984) review employed a vote count procedure showing the percentage of times the four main HBM constructs were statistically significant correlates or predictors (in the expected direction) across 46 studies. Across all studies, the significance ratios are very supportive of HBM predictions. Susceptibility was significant in 81% of studies, severity in 65%, benefits in 78% and barriers in 89%. Moreover, the results were also supportive of the model when only the prospective studies ($N=18$) were included. The ratios were 82%, 65%, 81% and 100% for susceptibility, severity, benefits and barriers-based, respectively. Results showed that barriers were the most reliable predictor of behaviour, followed by susceptibility and benefits, and finally, severity.

Unfortunately, limitations of the vote count procedure suggest caution in interpreting Janz and Becker's results. The significance ratios only reveal how often HBM components were significantly associated with behaviour, not how large the effects of HBM measures were on behaviour. Moreover, significance ratios give equal weighting to findings from studies with large and small numbers of participants and do not differentiate between bivariate relationships between a HBM construct and behaviour and multivariate associations.

Harrison *et al.*'s (1992) meta-analytic review of the HBM addressed these methodological issues. Harrison and colleagues originally identified 234 published empirical tests of the HBM. Of these, only 16 studies (i.e. 6.8%) measured all four major components and included reliability checks. This underlines the extent to

which operationalizations of the HBM have failed to measure all constructs or provide psychometric tests of measures. The meta-analysis involved converting associations between HBM constructs and behaviour measures, in each study, into a common effect size, namely Pearson's r . A weighted average of these effect sizes was then computed for each component (see Rosenthal, 1984). Across all studies, the average correlations between HBM components and behaviour were 0.15, 0.08, 0.13 and 0.21 for susceptibility, severity, benefits and barriers, respectively. While these correlations are all statistically significant, they are small in effect sizes terms; individual constructs accounting for only 0.5% to 4% of the variance in behaviour, across studies. Unlike Janz and Becker (1984), Harrison *et al.* found that HBM components had different associations in cross-sectional versus longitudinal designs. Both benefits and barriers had significantly larger effect sizes in prospective than in retrospective research, whereas in the case of severity, the effect size was significantly larger in retrospective studies.

These two quantitative reviews of the susceptibility, severity, benefits and barriers constructs suggest that these variables are very often found to be significant predictors of health-related behaviours but that their effects are small. However, a number of caveats are important. First, the effects of individual health beliefs should be combined and the combined effect may be greater than the sum of individual effects. Second, Harrison *et al.* (1992) adopted very strict criteria for inclusion in their review and the effect sizes they obtained are based on findings from only 3515 respondents. Finally, Harrison *et al.* point out that their effect sizes also show considerable heterogeneity, which suggests that design or measurement differences across studies or different conceptualizations of the constructs influenced the results. Overall then, while tests of the predictive utility of the four main HBM constructs are supportive, poor operationalizations of the model and failure to check both the reliability and the validity of constructs have been significant drawbacks in many studies applying the HBM.

Cues to action and health motivation have been relatively neglected in empirical tests of the HBM. Neither Janz and Becker (1984) nor Harrison *et al.* (1992) included these components because of the paucity of relevant studies. One reason for researchers' failure to operationalize these components may be the lack of clear construct definitions. Cues to action can include a wide range of experiences and so has been operationalized differently by different researchers. For example, Grady *et al.* (1983) found significant associations between the numbers of family members with breast/other cancers and participation in a breast self-examination teaching programme. These authors did not, however, refer to these measures as 'cues to action', while an almost identical variable in Keesling and Friedman's (1987) study of skin cancer prevention was conceptualized in this way.

Measurements of health motivation have generally comprised just a single item, usually expressing general 'concern' about health, though a small number of researchers have developed psychometric scales (e.g. Champion, 1984). Bivariate relationships between health motivation and health behaviour are generally small but statistically significant (e.g. Ali, 2002), with some non-significant exceptions (Umeh & Rogan-Gibson, 2001). Findings from multivariate analyses are mixed, with some studies finding positive relationships (e.g. Ali, 2002) and others finding no association (e.g. King, 1982).

HBM measurement issues

Failures to operationalize the HBM in its entirety may be partly due to the lack of clear guidelines on how HBM constructs should be defined and measured (see Abraham & Sheeran, 2005 for further discussion). For example, there have been suggestions that susceptibility and severity could be combined to form the concept 'threat', and similarly, that benefits and barriers should be subtracted from one another rather than treated as separate constructs (Becker & Maiman, 1975). Consequently, some researchers have used a threat index rather than measure susceptibility and severity separately (e.g. Kirscht *et al.*, 1976) This appears to violate the expectancy-value structure of the HBM and can be seen as an inferior, and perhaps incorrect, operationalization of the model (see Feather, 1982). Moreover, it has been suggested that perceived susceptibility may only become important once perceived severity reaches a certain threshold and that, after that, perceived severity has no further influence on decision-making (Weinstein, 1988). To operationalize this idea Lewis (1994) suggested that threat could be measured using the following equation.

$$\text{threat} = \text{susceptibility} + (\text{susceptibility} \times \text{severity})$$

Similarly, some researchers have combined benefits and barriers in a single index (e.g. Gianetti *et al.*, 1985). This practice raises theoretical and empirical issues. At a theoretical level, Weinstein (1988) suggests that there is a qualitative difference between benefits and barriers, at least in hazard situations, which means that they should be treated as distinct constructs. For example, while barriers relating to taking exercise or giving up salt are certain and concrete (e.g. time and effort, loss of pleasure), the benefits in terms of avoiding hypertension are more hypothetical. At an empirical level, the benefits construct may comprise distinct components, namely the efficacy of the behaviour in achieving an outcome (sometimes called 'response efficacy') as well as possible psychosocial benefits such as social approval. Similarly, the barriers construct may comprise both physical limitations (e.g. ability or expense) and psychological costs associated with its performance (e.g. distress). It seems unlikely that a single index could adequately represent these different outcome expectancies. An empirical approach to resolving this issue is to employ factor and reliability analyses to assess whether, and which, benefits and barriers can be legitimately combined, from a psychometric perspective (e.g. Abraham *et al.*, 1992).

Do HBM measures mediate the effects of demographic factors on health behaviour?

When the HBM was developed it was hoped that the effects of demographic factors such as socio-economic status (SES) could be accounted for, or mediated by (Baron & Kenny, 1986), variation in individuals' beliefs. However, few studies have tested this proposition and available evidence is mixed. Cummings *et al.* (1979) found that SES was not related to health beliefs, though both SES and beliefs were significantly related to inoculation behaviour in bivariate analyses. Orbell *et al.* (1995), on the other hand, found that perceived susceptibility and barriers entirely mediated the effects of social class upon uptake of cervical screening.

Direct (i.e. unmediated) effects were, however, obtained for both marital status and sexual experience. Salloway *et al.* (1978) obtained both direct and indirect effects for occupational status, sex and income and an indirect effect of education upon appointment-keeping at an inner city hypertension clinic. Further research is needed to determine the impact of SES upon health beliefs and behaviour and to discriminate between the effects of cognitions and the effects of factors such as financial constraints, culture of poverty/network effects and health system/provider behaviour barriers on health-related behaviours (Rundall & Wheeler, 1979).

Extending the HBM

Recognizing limitations of the HBM, Rosenstock (1974) suggested that a more comprehensive model of cognitive antecedents could reveal how health beliefs are related to other psychological stages in decision-making and action. King (1982) demonstrated how this might be achieved by 'extending' the HBM in a study of screening for hypertension. She included measures of individuals' causal understanding of high blood pressure derived from 'attribution theory' (Kelley, 1967), which she theorized as determinants of health beliefs that, in turn, prompted intention formation (Fishbein & Ajzen, 1975). Using a prospective design, King found that eight measures, including intention, could correctly classify 82% of respondents as either attenders or non-attenders. Her results showed that measures of perceived severity, perceived benefits and the extent to which respondents identified one or many causes of high blood pressure, accounted for 18% of the variance in behavioural intention, which, in turn, was the best single predictor of attendance. This study is noteworthy because it combined constructs from a number of theories (attribution theory, the HBM and the theory of reasoned action) and created a new model that simultaneously explored the cognitive foundations of health beliefs and sketched a mechanism by which they might generate action (see 'Theory of planned behaviour').

Rosenstock, Strecher and Becker (1988) acknowledged the importance of Bandura's (e.g. 1977) research by proposing that 'self-efficacy' (the belief that one can successfully perform a behaviour) be added to the HBM (see 'Self-efficacy and health behaviour'). Subsequent studies have tested the predictive utility of an extended HBM, including self-efficacy, and generally confirmed that self-efficacy is a useful additional predictor (e.g. Hay *et al.*, 2003). Unfortunately, unlike King (1982), Rosenstock *et al.* (1988) offered no new theoretical formulation specifying interactions between beliefs and self-efficacy. This may have been short-sighted because subsequent research indicated that key HBM constructs have indirect effects on behaviour as a result of their effect on perceived control and intention which may, therefore, be regarded as more proximal determinants of action. For example, Schwarzer's (1992) 'health action process approach' combines constructs from the HBM with those from other social cognitive models. In this model, susceptibility and severity beliefs are construed as antecedents of anticipated consequences (outcome expectancies) and strength of intention while intention and self-efficacy are identified as the most proximal antecedents of action.

Using the HBM to change health behaviour

Accurate prediction is an indicator of veridical explanation. As Sutton (1998, p. 1317) observed, 'models that do not enable us to predict behaviour are unlikely to be useful as explanatory models'. Consequently, considerable effort has been invested in testing the predictive utility of the HBM. However, the model was originally conceived of as a tool to improve health education and so shape health behaviour and it has inspired researchers interested in behaviour change interventions for decades (e.g. Haefner & Kirscht, 1970). We have noted limitations in the predictive utility of the HBM and these findings suggest concomitant limitations in the effectiveness of behaviour-change interventions that target HBM-specified beliefs. Nonetheless, HBM constructs are correlated with a range of health-related behaviours and changing these beliefs may prompt behaviour change (whether or not this involves simultaneous changes in cognitions not specified by the HBM – e.g. intention and self-efficacy). (See 'Health promotion').

Abraham and Sheeran (2005) report a review of evaluations of HBM-based, behaviour-change interventions and highlight 17 such evaluations. Some of these were derived directly from the HBM (e.g. Carmel *et al.*, 1996) whereas others drew upon HBM and other social cognition models in order to target a broader range of cognitions (e.g. Strecher *et al.*, 1994). Some took the form of educational presentations to groups in classes or workshops (e.g. Abood *et al.*, 2003) and/or involved the distribution of leaflets or booklets (e.g. Carmel *et al.*, 1996) whereas others were delivered at an individual level (referred to variously as 'educational' or 'counseling' interventions), and often involved assessment of the recipient's current beliefs before new information and persuasive arguments were presented (e.g. Champion, 1994, Jones *et al.*, 1998). Such interventions are tailored to the individual's cognitions. Computer-generated, individually tailored letters have also been used (Strecher *et al.*, 1994). All of the interventions relied on information provision and verbal persuasion as means to change HBM-specified beliefs. Thirteen of the 17 evaluations found evidence of behaviour change. This is encouraging but, because these evaluations were not selected on the basis of methodological rigour, conclusions regarding effectiveness need to be examined on a study-by-study basis.

Jones *et al.* (1988) provide a good illustration of an evaluation of an HBM-based behaviour change intervention. These researchers report a randomized controlled trial (RCT) of an intervention designed to persuade patients using hospital emergency services to make and keep follow-up appointments with their own doctor. The sample comprised 842 patients with 11 presenting problems (chest pain, hypertension, asthma, otitis media, diabetes, urinary tract infection, headache, urethritis [men], vaginitis [women], low back pain and rash) which did not require hospitalization. An intervention for individual patients was developed. This involved assessment of patients' HBM-specified beliefs and delivery of protocol-based, condition-specific educational messages to target beliefs that were not accepted by recipients. The intervention was designed to increase the patients' perceived susceptibility to illness complications, perceived seriousness of the complications, and benefits of a follow-up referral appointment in terms of avoiding further complications. It was delivered by a research nurse during required nursing care. Four intervention conditions were tested: (i) a routine care, control group, (ii) the individual, nurse-delivered hospital

intervention, (iii) the hospital intervention combined with a follow-up telephone call (iv) a follow up telephone call without the hospital intervention. Only 33% of the control group patients scheduled a follow-up appointment whereas 76% of the hospital intervention group, 85% of the telephone intervention group and 85% of the combined intervention did so. Twenty four percent of the control group kept a follow-up appointment compared to 59% in the hospital intervention group, 59% in the telephone intervention group and 68% in the combination group. Thus, the combination intervention worked most effectively. Jones *et al.* did not conduct a cost-effectiveness analysis, but noted that the telephone intervention alone might be the most effective practical intervention when costs such as staff training and staff time are taken into account.

Abraham and Sheeran (2005) identified a number of shortcomings in HBM intervention evaluations. Evaluation designs have been limited due to the lack of appropriate control groups, lack of randomization to conditions, samples that do not support generalization, and short-term follow-ups. Moreover, the HBM, like other social cognition models, specifies targets for cognition change but does not describe processes responsible for belief change. It is possible to combine models like the HBM with cognition change theories such as cognitive dissonance theory (Festinger, 1957; see Stone *et al.*, 1994, for an empirical example) in order to design interventions with theory-based targets and theory-based intervention techniques. However, this approach is not typical of HBM-based interventions. Consequently, the selection of intervention techniques (as opposed to cognition targets) is often not, or not explicitly, theory-based. In addition, interventions usually comprise a variety of techniques making it unclear which particular technique (or combinations of techniques) are crucial to effectiveness. Finally, in order to establish whether an intervention generates behaviour change because it alters target beliefs, it is necessary both to measure cognitions and behaviour pre- and post-intervention and to conduct mediation analysis (Baron & Kenny, 1986). However, mediation analysis is rarely reported in HBM-inspired intervention evaluations. Consequently, even when HBM-inspired interventions are effective in changing behaviour, it is unclear whether such effects are due to changes in HBM-specified beliefs. In summary, although the HBM has inspired the development of effective behaviour change interventions, the lack of programmatic experimental work means that we are unable to identify a series of belief-changing techniques and, in most cases, unable to say whether effective HBM-inspired interventions work because they change HBM-specified beliefs.

Conclusions

The HBM has provided a useful theoretical framework for investigators of the cognitive determinants of a wide range of behaviours for more than 30 years. The model's common-sense constructs are easy for non-psychologists to assimilate and are easy to operationalize in self-report questionnaires. The HBM has focused researchers' and health care professionals' attention on modifiable psychological prerequisites of behaviour and provided a basis for practical interventions across a range of behaviours. Research to date has, however, predominantly employed cross-sectional correlational designs

and further prospective experimental studies are required to clarify the causal direction of belief-behaviour relationships. The proposed mediation of socioeconomic influences on health behaviour by health beliefs also remains unclear.

The HBM has inspired researchers to develop interventions found to be effective in changing health behaviour. However, given the heterogeneity of evaluation designs, intervention techniques, target behaviours and populations, it is likely that reviews focusing on interventions designed to change particular behaviours for particular populations will be most informative. For example, in a review of 63 interventions designed to increase mammography use, Yabroff and Mandelblatt (1999) found that four theory-based

interventions drawing upon the HBM (e.g. Champion, 1994) increased mammography utilization, on average, by 23% compared to usual care. This is an impressive finding. The review also indicated that theory-based cognitive interventions which did not involve interpersonal interaction (e.g. those distributing letters or videos) were not effective. Meta-analyses of this kind can identify types of intervention and modes of intervention delivery that are effective in changing specified health behaviours. This information could then be used to design experimental studies that isolate particular techniques and combinations of techniques and measure potential mediators, including pre- and post-intervention beliefs.

Health-related behaviours: common factors

Timothy P. Carmody

University of California

Introduction

Any behaviour that affects a person's health status, either positively or negatively, is considered to be a health-related behaviour. Daily habits involving diet, exercise, safety practices and substance use are not only related to the prevention of disease, but also affect the management of chronic illness and degree of disability (Fries, 2002). It is difficult to imagine any activity or behaviour that does not affect our health in some way, either directly or indirectly.

Common health-related behaviours include diet, exercise, smoking, alcohol use, safety practices and participation in health screening examinations such as testing for cholesterol levels, breast and prostate cancer (Fishbein *et al.*, 2001). Among the health-related behaviours most often encouraged in health promotion programmes is regular physical exercise because of its positive impact on health, disease prevention, psychological wellbeing and overall longevity (Johnson, 2003). Regular physical activity is associated with lower death rates for adults of any age, even when only moderate levels of physical activity are performed (Center for Disease Control, 1999).

Regular physical activity decreases the risk of death from heart disease, lowers the risk of developing diabetes, reduces the risk of colon cancer and helps reduce blood pressure (Center for Disease Control, 1999). In 1999, only 65% of adolescents engaged in the recommended amount of physical activity. Even more disappointing, in 1997, only 15% of adults performed the recommended amount of physical activity, and 40% of adults engaged in no leisure time physical activity (Center for Disease Control, 1999). (See 'Adolescent lifestyle', 'Age and physical functioning', and 'Physical activity interventions').

In the United States, over 1.7 million Americans die from heart disease, diabetes, cancer, asthma or stroke (US Public Health Service, 2000). These chronic diseases account for 75% of the \$1.4 trillion that the United States spends on health care (US Public Health Service, 2000). Over 125 million Americans live with one of these chronic diseases and millions of new cases are diagnosed each year (US Public Health Service, 2000). Smoking, exercise, diet and alcohol use contribute to the development of most of these major causes of morbidity and mortality in the industrialized world (McGinnis & Forge, 1993; Smith *et al.*, 2004). However, there are

other behaviours that affect health, which are less obvious to the general public. These latter behaviours pertain to the ways in which people cope with stress and negative emotions (Adler & Matthews, 1994). For example, the way that a person expresses anger may be associated with the development or acceleration of coronary heart disease (CAD) and neoplasms in some individuals (e.g. Adler & Matthews, 1994; Eysenck, 1988; Sparagon *et al.*, 2001) (see 'Hostility, Type A and coronary heart disease'). Similarly, engaging in a pleasurable activity can be health related when such behaviour helps an individual to manage pain, stress or depressed mood.

Whereas behavioural experts have traditionally emphasized the importance of health-related behaviours and methods of behaviour change at the individual level, there is a growing trend to embrace a population-based approach and public health perspective (Smith *et al.*, 2004). Some health-related behaviours (e.g. health screening, diet modification, smoking cessation, drug abuse or safe sex practices) have such an impact on the health of entire populations that they have become the focus of public health education campaigns aimed at promoting health and preventing disease in school, work and community settings (Orleans, 2000; Smith *et al.*, 2004). Such health education campaigns are aimed either at healthy people to promote health maintenance and disease prevention or they target individuals who are already afflicted with illnesses or diseases in order to enhance the quality of their lives, reduce level of disability, delay death or prevent further deterioration. (See 'Community-based interventions'.)

Probably the most important public health education campaign of the past decade has been the worldwide effort to reduce behavioural risk factors associated with HIV infection and autoimmune disorder (AIDS) (Kelly & Kalichman, 2002). Early AIDS prevention efforts focused on safe sex practices and elimination of needle sharing among heroin addicts (Carey *et al.*, 2004). More recent health education campaigns are aimed at promoting adherence to complex antiretroviral combination medication therapies (e.g. Tucker *et al.*, 2004).

In the United States, the Healthy People 2010 campaign (US Public Health Service, 2000) was created as a comprehensive, nationwide approach to health promotion and disease prevention and was designed to serve as a roadmap for improving the health of all people in the United States during the first decade of the twenty-first century. Like the preceding Healthy People 2000 initiative, Healthy People 2010 is committed to the single, overarching purpose of promoting health and preventing illness, disability and premature death (US Public Health Service, 2000). An important goal of the Healthy People 2010 campaign is to eliminate health disparities among segments of the population, including differences that occur by gender, race or ethnicity, education or income, disability, geographic location or sexual orientation (US Public Health Service, 2000). (See 'Cultural and ethnic factors in health' and 'Socioeconomic status and health').

To determine the need for, and effectiveness of, such health education campaigns, public health assessment and surveillance surveys have been developed to monitor health-related behaviours or lifestyle patterns in representative samples. For instance, Walker *et al.* (1987) developed the Health-Promoting Lifestyle Profile (HPLP) which assesses six dimensions of health-related behaviours: self-actualization, health responsibility, exercise, nutrition, interpersonal support and stress management. Likewise, Sugarman *et al.*

(1992) described the Behavioral Risk Factor Surveillance System, a data set based on telephone surveys conducted by state departments of public health in co-ordination with the Center for Disease Control (CDC) to assess progress toward the health objectives for the United States.

Changing demographics of health-related behaviours

The demographics of health-related behaviours have undergone significant change in recent decades (Whitfield *et al.*, 2002). As the average age of the world's population has increased, particularly in industrialized countries, there have been age-related increases in the prevalence of the major causes of morbidity and mortality (e.g. CAD, diabetes, hypertension, cancer, renal disease) and the role that behaviour plays in the prevention, development, and management of these diseases in older adults (Wilcox & King, 1999).

It is well known that the prevalence of chronic diseases and the health-related behaviours associated with those diseases varies across ethnic and cultural groups and socio-economic status (SES) (Whitfield *et al.*, 2002). There has been an increasing recognition of disparities in the prevalence of chronic diseases and health-related behaviours among ethnic, cultural and SES groups (Landrine & Klonoff, 2001). Health disparities related to ethnicity, culture, SES and ageing point to the importance of understanding the effects of contextual factors on health status and health-related behaviours. For example, morbidity and mortality from colorectal cancer is higher among African Americans than other population groups in the United States (American Cancer Society, 2003). Income and education levels are associated with differences in the occurrence of illness and death, including heart disease, diabetes, obesity, elevated blood lead level and low birth weight (US Public Health Service, 2000). It is well known that higher income permits increased access to medical care, enables people to afford better housing and live in safer neighbourhoods, and increases the opportunity to engage in health-promoting behaviours.

The executive summary of the recent report on healthcare disparities (US Department of Health and Human Services, 2003) described the following:

- Minorities are more likely to be diagnosed with late-stage breast cancer and colorectal cancer compared with whites.
- Patients of lower socio-economic position are less likely to receive recommended diabetic services and more likely to be hospitalized for diabetes and its complications.
- When hospitalized for acute myocardial infarction, Hispanics are less likely to receive optimal care.
- Many racial and ethnic minorities and persons of lower socio-economic position are more likely to die from HIV. Minorities also account for a disproportionate share of new AIDS cases.
- The use of physical restraints in nursing homes is higher among Hispanics and Asian/Pacific Islanders compared with non-Hispanic whites.
- Blacks and poorer patients have higher rates of avoidable hospital admissions (i.e. hospitalizations for health conditions that, in the presence of comprehensive primary care, rarely require hospitalization).

Common dimensions of health-related behaviours

Health-related behaviours vary in terms of their duration, frequency, and manner of impact on health (i.e. positive versus negative; direct versus indirect; immediate versus long term). Some health-related behaviours are single actions that occur at a certain point in time and usually involve only one primary decision. Participating in a health screening examination (e.g. mammography, cholesterol, etc.) is an example of this type of health-related behaviour. Other health-related behaviours are long-term habits or patterns of behaviour that continue over an extended period of time and usually involve many decisions. Smoking, physical exercise, dietary habits, Type A behaviour and adherence to complex antiretroviral medication regimens are examples of these long-term health-related behaviours (Smith *et al.*, 2004). Many health-related behaviours such as smoking and alcohol use are not only long-term habits but are also addictive behaviours, characterized by the complex biopsychosocial determinants of obsessive chemical dependence.

Health-related behaviours that affect health in a positive way are sometimes referred to as health-protective behaviours. Examples of health-protective behaviours include eating a low fat diet, engaging in regular physical exercise, using sunscreen, wearing seat belts and engaging in safe sex practices (e.g. wearing condoms). Likewise, some health behaviours have a negative or deleterious effect on health (e.g. eating a high fat diet, sedentary lifestyle, substance abuse and stress-inducing behaviours). Still other health-related behaviours can have both a positive and negative impact on our health. For instance, dietary restraint can facilitate weight loss, but also can result in a restraint–disinhibition pattern of problematic ‘yo-yo’ dieting, weight fluctuation, alcohol use and cigarette smoking associated with health risk (Copeland & Carney, 2003; Herman & Polivy, 1980; Lowe, 1993; Stewart *et al.*, 2000).

Behaviour can influence health either directly or indirectly through its impact on other behaviours. Some health-related behaviours have a direct impact on physical health. Cigarette smoking is an example of this kind of health-risk behaviour (US Public Health Service, 1990, 2000). Other behaviours have an indirect impact on health by way of their association with other behaviours or lifestyle patterns, which in turn have a direct impact on health. For instance, according to one theory, hostility increases coronary risk because of its association with other coronary risk behaviours such as smoking (Scherwitz & Rugulies, 1992; Smith & Christensen, 1992; Smith & Ruiz, 2002). Drug abuse and heavy drinking are examples of health-risk behaviours that have both a direct and indirect impact on health, for example, among individuals infected with HIV by way of their association with non-adherence to antiretroviral medications (Tucker *et al.*, 2004).

Health-related behaviours also vary in terms of the timing of their impact on health. Some behaviours have an immediate impact on health (e.g. accidentally cutting a finger with a knife), others have a long-term effect (e.g. high fat diet, sedentary lifestyle) and still other actions have both immediate and long-term impact on health (e.g. cigarette smoking, dietary restraint, use of sunscreen, regular physical exercise).

Another common feature of health-related behaviours is that they often co-occur. For example, it is well known that alcohol, smoking and coffee consumption are inter-related (Carmody *et al.*, 1985; Istvan & Matarazzo, 1984). Most of the empirical research

has shown a robust association between smoking and alcohol use, and between smoking and coffee consumption. However, there is a dearth of research investigating the co-occurrence of all three of these behaviours (Istvan & Matarazzo, 1984). Similarly, health-protective behaviours can interact with health-risk behaviours. For instance, exercise may provide a healthy substitute for smoking. Some health-related behaviours may become cues for other behaviours (e.g. a cocktail and a cigarette). In some cases, stopping one health-related behaviour may even lead to the onset of another (e.g. quitting smoking leading temporarily to overeating). Likewise, expectancies regarding the relationship between health-related behaviours can influence decisions regarding engaging in those behaviours. For example, Copeland and Carney (2003) found that women who were higher in dietary restraint and disinhibition reported stronger beliefs in the appetite and weight control properties of cigarettes and were more likely to smoke than those who were lower in dietary restraint and disinhibition. Similarly, Stewart *et al.* (2000) found that chronic dieting among female college students appeared to be related to a heavy alcohol use (see ‘Diet and health’).

Given the interactions among health-related behaviours, public health experts have debated whether or not to target multiple behaviours for change concurrently (Prochaska *et al.*, 2004). This debate has emerged in the treatment of tobacco use among alcohol-dependent smokers (Joseph *et al.*, 2003). It has also appeared in studies of health behaviour change aimed at reducing cardiovascular risk. Prochaska and Sallis (2004) compared an intervention that targeted physical activity and nutrition with a second intervention which targeted physical activity alone. Increases in physical activity were similar for the two intervention groups, but dietary change was minimal for the intervention that targeted nutrition in addition to physical activity.

Common determinants of health-related behaviours

Common psychosocial and environmental factors are involved in the development, maintenance and modification of health-related behaviours. The psychosocial determinants of health-related behaviours include cognitive factors (i.e. attitudes, beliefs, expectancies, intentions), individual differences involved in learning and decision-making processes (e.g. hardiness, optimism, locus of control), socio-cultural variables (i.e. influences of family, friends, healthcare providers) and environmental factors (e.g. stressful events, poverty, access to recreational facilities). (See ‘Expectations and health’, ‘Personality and health’, ‘Social support and health’, and ‘Life events and health’.) At a recent workshop sponsored by the National Institute of Mental Health (NIMH), a panel of experts identified eight variables involved in the execution of any deliberate behaviour: intention, environmental constraints, skills, anticipated outcomes, norms, self-standards, emotion and self-efficacy (Fishbein *et al.*, 2001). However, these experts were not able to come to a consensus regarding a single causal model linking these variables to behaviour, causal ordering or strength of inter-relationships among these variables.

Psychosocial and environmental determinants can be categorized in terms of their chronological proximity to a particular health-related behaviour. Determinants which are more distant from the health-related behaviour include biological vulnerabilities,

developmental characteristics, early learning history and other cognitive, social and background variables. More immediate psychosocial precipitants which cue or trigger particular health behaviours also include cognitive, social or environmental factors. Generally, intentions are viewed as most proximal to a specific health-related behaviour (Fishbein *et al.*, 2001).

The initiation, maintenance and modification of long-term health-related behaviours often involve classical (respondent) conditioning, operant and social learning factors such as stimulus control, modelling, positive reinforcement and punishment (Dragoi *et al.*, 2003; Fishbein *et al.*, 2001; Skinner, 1953). Classical conditioning has been shown to be involved in the development of addictive behaviours (e.g. Niaura *et al.*, 1988) and dietary behaviour patterns (e.g. Rozin, 1984). As learned behaviours, health-related behaviours have cues and consequences that influence the occurrence of these behaviours. According to operant learning theory, immediate consequences tend to exert a more powerful influence on behaviour than long-term consequences (Skinner, 1953). Research has shown that the most effective methods for changing health-related behaviours are based on the principles of respondent and operant learning (Bandura, 1986; Epstein *et al.*, 2004). These include self-monitoring, goal specification, stimulus control, self-reinforcement and behavioural rehearsal.

Health-related behaviours also have various cognitive determinants. Some of the cognitive factors thought to be involved in the initiation, maintenance and modification of various health-related behaviours include attributions, expectations, intentions, attitudes and core beliefs (Fishbein *et al.*, 2001). Attitudes have been conceptualized as including both cognitive and affective components. Intentions are usually considered to be the most immediate influence on behaviour as people make rational use of information available to them (Ajzen & Fishbein, 1980). Beliefs and attributions about the determinants of health and expectations about one's ability to control health play important roles in the learning and decision-making processes involved in the development and modification of health-related behaviours (Bandura, 1986, 1997). Expectations about one's ability to accomplish certain behaviours (i.e. self-efficacy expectations) are thought to be important determinants of health-related behaviour (Bandura, 1986, 1997). Self-efficacy has been studied in relation to several health-related behaviours, including diet, smoking, alcohol use, weight control and physical exercise (i.e. Bandura, 1982, 1986, 1997).

Health-related behaviours have also been studied from a personality or individual difference perspective. For example, optimism has been positive associated with health-protective behaviours (McGregor *et al.*, 2004; Scheier & Carver, 1987). Likewise, hardiness (Britt *et al.*, 2001; Funk, 1992; Kobasa, 1979), which has been conceptualized as involving challenge, commitment and control, has been shown to be positively associated with health. Both of these individual difference variables have been investigated in relation to their buffering effects on stress. Type A behaviour pattern (Friedman, 1992; Matthews, 1982; Smith & Ruiz, 2002; Sparagon *et al.*, 2001), health-protection motivation (Prentice-Dunn & Rogers, 1986), dispositional sense of coherence (Antonovsky, 1990; Hoge & Bussing, 2004), sensation-seeking (Zuckerman *et al.*, 1980), introversion–extraversion (Eysenck, 1970) and health locus of control (Strickland, 1989). These individual differences involve patterns of behaviour which are themselves health-related. Likewise,

personality traits may have a moderating effect on other lifestyle risk factors (e.g. Denollet, 1993). The relationships between personality, behaviour and health are complex and largely remain to be elucidated in future multifactorial and longitudinal research.

Health-related behaviours are also influenced by social and cultural factors. For example, peer pressure is a primary factor leading to onset of smoking behaviour in adolescents (Mills & Noyes, 1984). Social support can be an important factor in the development and modification of all forms of addictive behaviours. Social factors can play a role in maintenance of health-risk behaviours (e.g. specific forms of substance abuse) as well as health-protective behaviours (e.g. Kaplan & Toshima, 1990). For example, social support has been shown to be an important factor in smoking cessation and the prevention of smoking relapse (Carmody, 1990). Since social skills can be helpful in eliciting and maintaining social support, such behaviours can also be viewed as health-related.

Ethnic and cultural factors also affect the determinants of health-related behaviours (e.g. Pick *et al.*, 2003). For example, Vaughan *et al.* (2004) compared Hispanic and White mothers regarding paediatric injuries. White mothers reported more injuries among younger children. Among Hispanic mothers, preference for and use of English language were associated with more reported injuries. Their results indicated that risky behaviours, mother's judgement about child compliance and stressful life events were better predictors of injuries than housing quality. However, in the Hispanic group, stress and child temperament explained injury differences between more- and less-aculturated Hispanic families but only partially accounted for differences between White mothers and less-aculturated Hispanics.

Stress has been shown to have a direct impact on the autonomic nervous, neuroendocrine, cardiovascular and immune systems (Selye, 1980). Stress is also associated with health-related behaviours. The manner in which an individual copes with stressful situations can be considered to be a health-related behaviour (Hoge & Bussing, 2004; Lazarus & Folkman, 1984). Stress can also have an indirect effect on health by disrupting health-protective lifestyle patterns. For instance, adolescents who are in more distress are more likely to experiment with addictive drugs and develop chemical dependencies (Mills & Noyes, 1984). Similarly, depression has been associated with difficulty in quitting cigarette smoking (Carmody, 1990; Hitsman *et al.*, 2003; Kassel, Stroud & Paronis, 2003). In fact, stress is the most commonly reported trigger for relapse among chemical-dependent individuals (Marlatt & Gordon, 1985; Shiffman & Waters, 2004) (see 'Stress and health').

Environmental determinants of health-related behaviours include all aspects of an individual's physical surroundings and life circumstances, including exposure to information available to electronic and printed media, proximity to health care and health education resources and access to facilities conducive to engaging in health-protective behaviours such as physical exercise. Socioeconomic status (SES) has generally been regarded as an important determinant of health-related behaviours and overall health status. For example, health-risk factors such as obesity and cigarette smoking tend to be more prevalent among individuals from lower SES backgrounds (US Public Health Service, 1988). The mechanisms involved in determining the association between SES and health are yet to be elucidated (Adler *et al.*, 1994). Legal, economic and regulatory factors also influence health-related behaviours.

For instance, in California and elsewhere in the United States, health economists and policy experts (e.g. Glanz, 1993) have examined the impact of various taxation and other regulatory practices on exposure to environmental tobacco smoke (ETS).

Theories of health-related behaviours

Numerous theories of motivation, learning and decision-making have been applied to the study of health-related behaviours. These theories have been helpful in guiding research aimed at enhancing our understanding of health-related behaviours and developing more effective behaviour-change strategies. However, behavioural scientists have only just begun to apply their theories and methods of studying human behaviour to the fields of health promotion and disease management.

The most widely researched theories of health-related behaviour include: the health belief model (e.g. Kirscht, 1988), subjective expected utility theory (e.g. Sutton, 1982), conflict theory of decisional balance (Janis & Mann, 1968; Velicer *et al.*, 1985), protection-motivation theory (Prentice-Dunn & Rogers, 1986), transtheoretical stages of change model (Prochaska & DiClemente, 1984), theory of reasoned action (Ajzen & Fishbein, 1980), theory of planned behaviour (Ajzen, 1988), and behavioural economics theory (Epstien & Saelens, 2000). (See 'The health belief model', 'Theory of planned behaviour', 'Self-efficacy and health behaviour' and 'Transactional model of behaviour change'.) Each of these theories emphasizes the role of attitudes and beliefs regarding the health consequences of particular behaviours as determinants of health-related decision-making and behaviour. The influence of significant others is also acknowledged as a source of information about subjective norms. These theories are based on the notion that people are rational and that they typically engage in a process of weighing the pros and cons of engaging in any behaviours that affect their health. Traditionally, they have emphasized perceptions of risk but not beliefs about non-risk issues such as self-esteem which also influence decision-making regarding health-related behaviours (Weinstein, 1993).

Most of these theories of health-related decision-making aim toward predicting a single decision (Weinstein, 1993). In contrast, dynamic models assume that the adoption of health behaviours is a dynamic process involving more than one decision rule and usually consisting of several steps or stages (e.g. Prochaska & DiClemente, 1984; Prochaska *et al.*, 1994). An example of such a dynamic model is the transtheoretical stages of change model (Prochaska & DiClemente, 1984) which includes the following stages in the modification of any health-related behaviour: precontemplation (not thinking about change), contemplation (thinking about change in the next six months), action (overt change) and maintenance (continuation of changed behaviour beyond six months). According to this model, specific behaviour-change processes and decision rules tend to be associated with different stages. This transtheoretical model of change has been applied to a variety of addictive behaviours (e.g. smoking, compulsive eating, alcohol use) as well as health-protective behaviours (e.g. weight control, physical exercise, pain management) (e.g. Armitage *et al.*, 2004; Prochaska *et al.*, 1988; Prochaska *et al.*, 1994; Segan, Borland & Greenwood, 2004).

Prochaska *et al.* (1994) studied the stages of change and decisional balance variables in relation to 12 health-related behaviours:

smoking cessation, quitting cocaine, weight control, high-fat diets, adolescent delinquent behaviours, safe sex, condom use, sunscreen use, radon gas exposure, physical exercise, mammography screening and physicians' preventive practices with smokers. Their results supported the applicability of the transtheoretical model of change (Prochaska & DiClemente, 1984) and demonstrated commonalities in terms of the stages of change and decisional balance factors across these 12 health-related behaviours.

Behavioural economics theory (Epstien & Saelens, 2000) focuses on the way in which individuals make decisions about the allocation of time among available behavioural alternatives. This theory has recently been applied to the reduction of sedentary behaviour in obese children by increasing opportunities for more physical activity. In one study (Epstein *et al.*, 2004), significant reductions in percent overweight were observed for obese children participating in treatment programmes in which reduction of sedentary behaviour was promoted either by stimulus control or reinforcement procedures.

The relationship between health risk perception and health-related behaviours is complex (Sjoberg, 2003). For example, people tend to evaluate health risks for themselves differently from risks for others (Sjoberg, 2003). Beliefs about risks associated with certain health-damaging behaviours may not necessarily be associated with the absence of those health-risk behaviours. In a recent survey of health behaviours in young adults in eight countries throughout Europe (Steptoe & Wardle, 1992), the results showed that respondents who engaged in more drinking and smoking behaviour were as aware of the negative consequences of these health-damaging behaviours as people who did not engage in these addictive behaviours. Across the countries surveyed in this study, few relationships were observed between health-risk behaviours and risk awareness. In contrast, beliefs about the positive effects of health-protective behaviours (e.g. eating a low fat diet) were strongly associated with the prevalence of those positive health behaviours.

Since adherence to medical regimen involves behaviour that impacts health, theories of adherence have been useful in furthering our understanding of the psychosocial and environmental determinants of health-related behaviours (see 'Adherence to treatment'). Leventhal and Cameron (1987) summarized five theories of adherence which focused on biomedical, behavioural, communication, decision-making and self-regulatory factors. They advocated for an integration of these theories in adherence research that addresses the patient's history of illness, perceptions, coping strategies and habitual versus reasoned determinants of behaviour change.

Summary and conclusions

I have argued that most of our behaviour is health-related in the sense that most of our actions affect our health, either directly or indirectly. Some behaviours have multiple effects on our health, some positive and some negative. Common psychosocial and environmental factors influence the learning and decision-making processes involved in the initiation, maintenance and modification of health-related behaviours. These include cognitive, socio-cultural, environmental, ethnic/racial and individual difference factors. There has been an increased focus on health disparities related to

cultural, ethnic and SES factors, the investigation of the primary factors underlying these disparities, and the development of strategies for eliminating these disparities.

Long-term patterns of health-related behaviours usually involve various respondent conditioning and operant learning factors that influence multiple decision-making processes. Moreover, health-related behaviours often interact both in terms of their impact on lifestyle and health. These behaviours evolve in a dynamic process that involves many decisions and multiple cognitive, social and environmental determinants. Different sets of psychosocial determinants may be critical at different stages in the development and modification of a particular health-related behaviour.

Several theories have guided and facilitated empirical analysis of contextual and psychosocial determinants of health-related behaviours and processes of change. Nevertheless, behavioural scientists

have only just begun to apply these theories and methods of studying human behaviour to the field of health-related behaviours. Initial successes have been achieved in such areas as smoking cessation, adherence to prescribed medications, regular physical exercise and fitness, safe sex practices, stress management and modification of CAD lifestyle risk factors. However, further theory-based research is needed to enhance our ability to understand, predict and modify health-related behaviours. Among the most promising theoretical approaches are cognitive social learning theory (Bandura, 1986, 1997) and the transtheoretical model of change (Prochaska & DiClemente, 1984) which attempts to integrate key constructs from several theoretical models in order to develop a more comprehensive understanding of health-related behaviours and enhance our ability to promote health-protective behaviour change.

Hospitalization in adults

Rachael Powell and Marie Johnston

University of Aberdeen

Introduction

Hospitalization occurs when symptoms of illness can no longer be tolerated in the individual's domestic environment, when technical investigations need to be performed or when treatments requiring specific equipment or 24-hour patient monitoring are to be undertaken. One might therefore expect that, at least for a substantial minority, hospitalization would be viewed as a source of relief or reassurance, or would hold out the possibility of offering a better understanding of symptoms or even resolution of symptoms. However, in the psychological literature, it is primarily conceptualized as a source of stress. Additionally, discharge from hospital is seen as a stressful time and Ley (1988) has reported high levels of depression in patients in the period following discharge.

This chapter discusses the stressors faced by hospitalized adults and emotional and cognitive responses to hospitalization. The role of health professionals in meeting the needs of hospitalized adults is

considered and the impact of adult hospitalization on family members is examined.

Stressors

The Hospital Stress Rating Scale (Volicer & Bohannon, 1975) describes 49 'events' associated with being in hospital which may be stressful. These events were ranked by 261 medical and surgical patients from the most to the least stressful. The most stressful, thinking you might lose your sight, relates to the threat of illness as does the fourth, knowing that you have a serious illness. Illness course was also identified as an area of concern in chronic bronchitis and emphysema patients by Small and Graydon (1993). Several of Volicer and Bohannon's (1975) high-ranking stressors concern lack of information or poor communication ('not being told what your diagnosis is' (ranking: 6), 'not knowing for sure

what illness you have (7), 'not knowing the results or reasons for your treatments' (9) and 'not having your questions answered by staff' (13)). Major sources of stress in hospital are the investigations and treatments, which may involve pain and uncertainty of outcome (e.g. 'knowing you have to have an operation' (18)) and other studies have found that anticipating painful treatments and procedures is a source of apprehension or distress for the great majority of patients. Other items relate to being away from family and home, e.g. 'missing your spouse' (12) or 'being hospitalized far away from home' (17) or to being in a new environment which lacks privacy and is shared by other people who are ill and receiving treatment (Lucente & Fleck, 1972). Volicer and Bohannon found a high degree of consensus between medical and surgical patients (see also 'Coping with stressful medical procedures' and 'Surgery').

Emotional state

Given the range of perceived stressors, investigation into the emotional state of patients is a logical progression. Many studies use scales that have been developed specifically to measure patients' anxiety about hospitalization but others use scales that have been used to measure mood or distress in other situations and populations. These latter scales have usually been extensively developed and validated and allow comparison of hospitalized patients with normal mood levels, with people undergoing other kinds of threat or with patients who have mood disorders. An important consideration is whether the scale confuses symptoms of the patient's illness or the effects of treatment with somatic mood effects; for example, patients may report feeling lethargic because of thyroid disorder or the after-effects of anaesthesia rather than as a feature of depressed mood. Some scales, such as the Hospital Anxiety and Depression Scale (HADS, Zigmond & Snaith, 1983) have been developed to either separate or omit such somatic items. The HADS has been shown to be reasonably successful in this (Johnston *et al.*, 2000) (see also 'Mood assessment').

Numerous studies show evidence of high levels of psychological distress in hospitalized patients when compared with normal populations, including high rates of clinical emotional disorder. For example, surgical patients assessed on the day prior to surgery show levels of anxiety that, on average, fall between normal levels and levels reported by psychiatric patients with diagnosed anxiety disorder, but are similar to those found in students prior to examinations. Anxiety levels continue to be high after surgery (Johnston, 1980), suggesting that the anxiety is caused not only by the threat of surgery but also by the ongoing discomforts and uncertainties. It is important that staff are aware of and can address emotional state for both the patients' psychological and physical wellbeing. Munafò and Stevenson (2001), for example, found pre-surgical anxiety to consistently predict post-operative outcome. In recent years, the area of psychoneuroimmunology has made great progress in identifying associations between psychological and physical health and has been found to be relevant to patient outcomes after surgery. For example, Broadbent *et al.* (2003) found pre-surgical perceived stress to predict levels of interleukin-1, a cytokine involved in the inflammatory response, in wound fluid collected post-operatively for patients undergoing hernia repair (see 'Surgery').

Cognitions

When the concerns of hospital patients have been examined, it is clear that they have significant worries which are unrelated to the hospital environment, often concerning the welfare of their family at home in the patient's absence or even ongoing everyday worries irrelevant to health and the hospital (Johnston, 1988). Hospital worries may be related to both their medical condition and its treatment. While research has tended to focus on worries about treatment procedures, patients are more likely to be concerned about treatment outcomes or the outcome of the disease whether or not treatment is possible.

Hospitalized patients' concerns are not limited to the hospitalization period itself: Small and Graydon (1993) found that being able to manage their own homes and self-care post-discharge were the most commonly expressed concerns in a small sample of patients with chronic bronchitis and/or emphysema. Leech (1982) found a sense of control to be considered important by 95% of their sample of pre-operative patients with arterial occlusive disease. Only 42% perceived themselves to be in control but, for 82%, it was control over their future rather than lack of control caused by imposed hospital routines that was important. Hence, to some extent, worries are inevitable because of the unpredictable nature of these outcomes, but this is exacerbated by the lack of information available to patients or appropriate coping skills. Studies of psychological preparation for surgical procedures demonstrate that changing cognitions by the provision of information or enhancing the patient's ability to tolerate the uncertainties can reduce the negative effects of the experience (Doering *et al.*, 2000; Johnston & Vögele, 1993).

Individual differences

People who are anxious by disposition are more likely to be highly anxious in the hospital situation than people low in trait anxiety. Hospital and the associated health problems would appear to provide the threatening situations which elicit this underlying personality. People with high levels of anxiety may also use different coping strategies in dealing with the situation (see 'Personality and health').

Coping strategies can be divided into problem-focused and emotion-focused strategies, the former attempting to reduce the impact of stress by removing the source, while the latter aim to minimize the emotional impact without necessarily dealing with the source. It has been suggested that some patients having surgery may try to deal with the threats by using an avoidant strategy which includes minimizing the dangers and directing one's attention to other matters, and such patients would tend to have low scores on tests of anxiety. Initially, it was proposed by Janis (1958) that such a strategy would result in poor outcomes for patient as they would fail to do the necessary cognitive preparation, or 'work of worrying', and as a result would find the post-operative period unexpectedly harsh. Janis proposed that patients with low and high anxiety scores would do badly post-operatively and that a moderate level of anxiety was necessary to achieve optimal preparation. However, empirical studies have not found support for this hypothesis and instead patients having low levels of pre-operative anxiety or those using avoidant coping strategies have done well post-

operatively; it would appear that avoidant coping is adaptive for stressors of relatively short duration (DeGroot *et al.*, 1997; Suls & Fletcher, 1985).

Factors which influence responses to hospitalization may be different in children or in elderly people (see 'Hospitalization in children'). Those with particular clinical conditions may also have different issues to contend with. For example, hospital staff on a surgical ward may have difficulty in ascertaining the level of support necessary for a disabled patient or the supervision and support required by a psychiatric patient.

Roles of health professionals in meeting needs

Psychological preparation

While little work has been done to prepare adult patients for hospitalization per se, there is now very strong evidence that psychological preparation for surgery can result in better outcomes (Johnston & Vögele, 1993). A variety of methods have been used including:

- behavioural instruction: teaching techniques such as breathing and relaxation;
- procedural information: giving patients information about the procedures they will undergo;
- sensory information: giving patients information about the sensations they will experience;
- cognitive coping: teaching methods of re-interpreting apparent threats in a more positive light, using distraction etc.

All of these methods have been shown to be effective. They have been found to improve a wide variety of important outcomes including:

- anxiety
- pain
- pain medication
- behavioural recovery
- physiological indices
- length of stay.

Thus, benefits are not confined to benefits in psychological functioning, but include outcomes of physiological significance and outcomes that affect health care costs.

Surgical patients have also been found to benefit by spending the pre-operative period with patients who have already had the operation they are about to undergo (Kulik & Mahler, 1987). This study suggests that there is considerable potential for improving patient care by organizational as well as direct patient care interventions.

Interventions have also been designed for patients undergoing non-surgical procedures. Such procedures differ from the typical surgical procedure in that the patient is conscious and may be required to co-operate to ensure an efficient and effective procedure. For example, in cardiac catheterization the patient must respond to instructions for breath holding and coughing. Ludwick-Rosenthal and Neufeld (1993) found cardiac catheterization took less time for participants in a high-information group than for those in a low-information group. Sensory information and cognitive coping procedures have also been found to be effective (Kendall & Epps, 1990).

There has been some concern that psychological preparation might be damaging for patients using avoidant coping strategies as the preparation might disrupt the patient's coping. While there is some evidence to support this view, a study by Shipley *et al.* (1978) suggests that the problem can be overcome by giving adequate preparation. Patients awaiting a stressful medical procedure saw a preparatory videotape either once or three times. Those with an avoidant coping style showed higher levels of anxiety during the endoscopy compared with a control group who saw an irrelevant control video, but only when they had seen the video once; they showed neither detrimental nor beneficial effects when they had seen it three times. Patients with attention coping styles showed benefit whether the video was shown once or three times. Thus the more thorough preparation resulted in benefits without the damaging side-effects for the avoidant copers. Ludwick-Rosenthal and Neufelt (1993) found information seekers receiving low-level information prior to cardiac catheterization showed higher behavioural anxiety than avoiders receiving low information or seekers receiving high information. Differences between information avoiders and seekers in the high-information condition were non-significant. See also 'Behaviour therapy', 'Cognitive behaviour therapy', 'Relaxation training' and 'Stress management'.

Communication and information

Patients in hospital depend on staff for their care and treatment, for information about their treatment and progress, and for meeting their basic needs when the patient is severely disabled or restricted even temporarily as in the case of surgical patients. While patients may be diffident about asking for information and the ethos of the hospital may imply that the 'good patient' takes a more passive role, studies have consistently shown that patients are dissatisfied with the amount of information they receive (Ley, 1988). Information provision and support should not be limited to hospitalization itself: D'Angelica *et al.* (1998) found that patients undergoing surgery for pancreatic cancer were satisfied with information provided before surgery and while in hospital, but 27% of patients had unanswered questions about diagnosis and treatment at the time of the survey (mean 13 months post-surgery). Healthcare professionals should be aware that patient satisfaction at the time of contact may not reflect the information needed by patients in the long term.

Doctors and nurses have been wary of giving information which might be misinterpreted or which might alarm the patient, but even in serious illness such as cancer, over 90% of patients want to know about their diagnosis and treatment (Reynolds *et al.*, 1981). Tamburini *et al.* (2003) found cancer patients' most commonly reported need to be the desire to receive more information both about future conditions and about their diagnosis. In patients with motor neurone disease, a disease which is progressively disabling, incurable and eventually terminal, lacking palliative treatments, the majority of patients have been found to report positive aspects to being given the diagnosis (Johnston *et al.*, 1996). In contrast, patients resent finding out important information by indirect means such as overhearing professional conversations.

Healthcare professionals may lack the skills to identify patients' concerns or to communicate effectively (Ley, 1988). Nurses underestimate patients' pain and are poor at identifying which patients are worried about particular matters. Courses to develop

communication skills are now an integral part of the training of doctors and nurses in many colleges.

Professionals may also fail to communicate effectively because communicating bad news or talking to very ill patients is particularly stressful (Parks, 1985). Doctors and nurses are observed to have high levels of stress and may even demonstrate burnout. See also 'Healthcare professional-patient communication' and 'Written communication'.

Family members and significant others

Any individual patient is part of a social network and their hospitalization is likely to impact on friends and relatives who are concerned about the patient's well-being and treatment. Delva *et al.* (2002) found the anxiety levels of relatives of critical care patients to be high: less than 10% of people in 'normal' situations are as anxious or more anxious than these relatives. Titler *et al.* (1991) found feelings of vulnerability to be widely reported by spouses and children of critical care patients and high levels of anxiety and depression have been reported in partners of myocardial infarction patients (Johnston *et al.*, 1999).

For the adult patient population, effects of hospitalization are likely to be particularly severe as adults are often caregivers and/or bread-winners, supporting other family members both emotionally and practically. Hospitalization of an adult can lead to the disruption of home routines and altered relationships (Titler *et al.*, 1991). Children's lifestyle patterns may also be disrupted, leading to decreased school attendance and reduced time with friends (Titler *et al.*, 1991).

Relatives must cope not only with increased pressures resulting from the need to cover the patient's role but also take on the visiting role, finding the time to visit the patient who may be hospitalized at some distance from the family home. Lifestyle changes reported by adult visitors of intensive care patients include fewer hours' sleep and poorer sleep quality, changes in eating patterns and low energy levels (Van Horn & Tesh, 2000). Changes in family roles or responsibilities were reported by 56%.

A number of studies included items assessing the perceived needs of relatives or significant others. Consistently, the need for information emerges as highly important (Delva *et al.*, 2002; Hickey, 1990; Van Horn & Tesh, 2000). It would appear that addressing these informational needs may have a positive impact on the anxiety of significant others. Raleigh *et al.* (1990) assessed the anxiety levels of patients and 'significant others' (relatives or friends accompanying the patients) before and after a pre-operative class for cardiac surgery patients. Prior to the class, the significant others were significantly more anxious than the patients. This anxiety was found to have reduced significantly after the class, with no difference being found between significant others and patients post-test.

Johnston *et al.* (1999) found a cardiac counselling and rehabilitation programme given to both myocardial infarction patients and their partners resulted in lower levels of partner anxiety than a control group up to 12 months later.

Patient welfare is likely to benefit from looking after relatives as healthy family members will be better able to support them both during hospitalization and at discharge. Patients may also be less distressed if their relatives are coping well: in a small experimental study Doerr and Jones (1979) found that patients visited by family members prepared with information about the coronary care unit showed decreased anxiety compared with patients visited by family members without such preparation. The authors concluded that prepared family members transferred less anxiety. It could be, however, that these better informed visitors were more able to fulfill the patients' information needs. Information may also improve the post-hospitalization support given to patients by family members. Johnston *et al.* (1999) successfully improved the knowledge about myocardial infarction of patients and partners. In this study, the majority of partners were women who were likely to have had some control over the patients' diets and so their improved understanding of heart disease had the potential to influence patient health. Taylor *et al.* (1985) found wives who personally performed the same level of treadmill test as their husbands three weeks after the husbands had suffered myocardial infarction perceived the patient's efficacy to be higher than wives who did not perform the task. The combined efficacy perceptions of patients and their wives was consistently found to predict patients' cardiovascular functioning at 11 and 26 weeks, indicating the importance of attending to efficacy perceptions of partners as well as patients when enabling patient recovery. See also 'Social support' and 'Social support interventions'.

Conclusion

Adult patients face a range of stressors on hospitalization which can result in distress and worry and patients may not always employ optimal coping strategies. Some of these stressors, such as illness and having a new environment to contend with, are unavoidable consequences of hospitalization. Others, such as concerns relating to inadequate psychological preparation, insufficient information or poor communication can be addressed with beneficial outcomes. Preparing patients adequately for procedures can be beneficial both for the patient in terms of psychological and physiological outcomes and also for healthcare institutions as healthcare costs may be reduced. The welfare of family members should also be considered by hospital staff. Providing relatives with adequate information and support will not only aid their coping but also benefit the patient as better informed relatives appear to more successfully support the patient.

Hospitalization in children

Thomas Whelan

Monash University

Every year vast numbers of children are admitted to hospital. For example, more than 1 in 10 preschoolers in England (MacFaul & Werneke, 2001) and over 2 million children under 15 years in America (Popovic & Hall, 2001) have a hospital stay each year. Indeed, it has been estimated that around half of the population

in many countries will have at least one hospital admission during childhood (Schmidt, 1997).

Recent advances in medical treatment have meant that an increasing number of children are treated on an outpatient or day surgery basis. As a consequence, a high proportion of child patients

who remain in hospital have complicated or chronic conditions. A further result of improvements in medical practice is that compared with previous decades, children are far more likely to survive birth trauma, severe injuries or illnesses. In the case of childhood cancer, the five-year survival rates have increased from less than 30% in the 1960s to nearly 80% in the late 1990s (Smith & Hare, 2004). Nonetheless, there remains a high emotional cost for children and their parents as many of these patients undergo repeated hospitalizations and prolonged, demanding treatment.

Hospitalized children and their parents have to cope with a variety of stressors. These include factors directly relevant to the illness or injury, such as physical discomfort, loss of autonomy, absences from school, the effects of medication and changes in family interactions. In addition, aspects related to the hospital itself can provoke anxiety including the strange surroundings; separations from family and friends; and unusual, often painful, medical procedures.

Not surprisingly, children have been reported to show a variety of negative behavioural and emotional reactions at some point during a stay in hospital. These have ranged from temporary distress to chronic depression, and have included agitated behaviour, anxiety, withdrawal, enuresis, phobia, altered sleep patterns and appetite problems (Connolly *et al.*, 2004; Papaqostas *et al.*, 2003; Peterson & Mori, 1988). For some children these reactions last long after they leave hospital (Quinton & Rutter, 1976), although for most the effects appear to subside in the weeks soon after discharge (Thompson & Vernon, 1993).

Notwithstanding that most children experience difficulty; some reportedly show behavioural improvements either during or after a stay in hospital (Kotiniemi *et al.*, 1996). Such improvements might be due to the hospital environment being more nurturing than home, the successful treatment of a condition that has been adversely influencing behaviour or a sense of mastery at having managed a difficult experience (Schmidt, 1997; Wright, 1995).

Given the wide variability in the nature and extent of children's responses to hospitalization, over recent decades investigators have focused on examining the factors that influence these reactions. Such research assists in the identification of those who are vulnerable to poor adjustment and leads to the development of individualized interventions to help child patients to cope. Some of the important factors include previous medical experience, developmental status, severity of the illness or procedure, coping style and parental responses.

Influencing factors

Previous medical experience

A child's history of contacts with hospitals and other medical settings has been found to influence responses to subsequent hospital admissions (Yap, 1988). That is, a greater frequency or longer duration of hospitalization can increase the likelihood of negative reactions to following admissions. This is not surprising, as regular hospital admissions and longer stays are likely to be associated with factors such as more serious health conditions and higher levels of medical intervention.

A child's adaptation to illness and hospitalization can also be influenced indirectly through their perception of the experiences of other family members. Healthy children with a history of family

experience of hospitalization, whether this relates to siblings (Murray, 2000) or parents (Eiser & Eiser, 1990), have been found to be more likely to harbour increased concerns about illness and its consequences.

Developmental status

The extent of negative reactions to illness in children appears to be related to levels of development. Young children, those under six or seven years, are more likely to report anxieties and exhibit greater behavioural distress in medical situations than older children (Dahlquist *et al.*, 1994; Melamed & Ridley-Johnson, 1988). Even so, each developmental period has vulnerabilities that influence how stressors are perceived and responses are manifested (Vessey, 2003). Thus, older children still experience negative behavioural reactions to hospitalization.

Bibace and Walsh (1980) attempted to classify children's understanding of health and illness according to phases of development. They suggested that children's concepts of illness can be ordered in a systematic manner, comparable to the stages of cognitive development proposed by Piaget (1952). Although there has been argument regarding the nature of the developmental stages (e.g. Eiser *et al.*, 1990), the notion that there is a developmental trend in children's concepts of illness has been supported by other investigators. Generally, younger and less cognitively developed children offer less complex and more flawed explanations for illness (O'Dougherty & Brown, 1990), are less likely to understand the causes of pain (Bush, 1987), are less able to understand medical procedures and hospitalization (Eiser & Patterson, 1984), are less likely to seek out information about impending medical procedures (Peterson & Toler, 1986), but are more likely than older children to have frightening and guilty misconceptions regarding hospitalization and surgery (Redpath & Rogers, 1984). As well, younger children are likely to exhibit more symptoms of distress when pain and illness occur (Rudolph *et al.*, 1995), have more externally oriented locus of control beliefs about illness (Sanger *et al.*, 1988), and engage in fewer coping behaviours during medical procedures (Manne *et al.*, 1993).

While these differences in children's cognitive abilities and related perceptions have been clearly identified, contemporary investigators (e.g. Rushforth, 1999) caution against an exclusive focus on what younger child patients are unable to do or understand. Such a perspective can lead to the assumption that a child of a certain age is unable to comprehend a particular concept and therefore should not be informed about a condition or its treatment. As noted by Rushforth (1999), even very young children have the ability to achieve a sophisticated level of understanding of their illness experience provided the information is given in a manner and form that is relevant to their level of understanding (see 'Children's perceptions of illness and death').

Illness severity

Other factors that influence the reactions of child patients and their families to hospitalization and surgery relate to the nature of the child's condition and the procedures included in the treatment. In terms of the child's condition, Rennick *et al.* (2002) found that the best predictor of psychological distress six weeks after hospital discharge was the number of invasive procedures (e.g. chest tube

insertion, rectal temperature) that the child experienced. As might be predicted, mothers are more likely to experience distress when a child is hospitalized with a serious condition, such as pneumonia or concussion, than with a moderately serious condition, such as bronchitis (Berenbaum & Hatcher, 1992). Similarly, Roskies *et al.* (1975) reported that emergency admissions were more stressful for parents than were less urgent hospitalizations.

However, as O'Dougherty and Brown (1990) observed, estimations of a child's likely reaction to illness or medical procedures cannot be predicted simply by the severity of illness or the nature of the treatment. Even relatively minor treatments, such as immunizations (Hatcher *et al.*, 1993) and same-day hospital procedures (Faust *et al.*, 1991) can be extremely stressful for children and their parents. It appears that more important than the actual illness or its treatment is how the experience is perceived by the patient and his or her family.

Coping style

Research dealing with the reactions of adult and child patients to aversive medical procedures has highlighted the role of personal styles of coping (e.g. Montagne, 2000). Although there are a variety of coping styles, there is usually a dominant pattern characterized by approach or avoidance behaviours. Patients who predominantly approach, variously classified as 'sensitizers', 'vigilants' or 'active copers', seek out information, consider it, and attempt to prepare themselves for the procedure. Whereas more avoidant patients, labelled as 'repressors', 'deniers' or 'avoiders', tend to reject information, deny stress and attempt to focus on thoughts unrelated to the medical intervention (Martelli *et al.*, 1987; Myers, 1995).

As with adult patients, studies with children have indicated consistently that being at the active end of the active-avoidant scale is associated with more beneficial behaviours (see review by Rudolph *et al.*, 1995). Active copers have been found to be more co-operative with hospital staff and to have higher tolerance for pain (Siegel, 1981), to be less distressed following surgery (Hubert *et al.*, 1988) and to show more adaptive responses prior to medical procedures (Peterson & Toler, 1986).

Nonetheless, the research to date suggests there is not a definitive one-to-one correspondence between a child's coping style and his or her adjustment. According to LeRoy *et al.* (2003), the critical dimension appears to be the extent to which a child has a plan for dealing with a procedure. For example, behaviours associated with positive adjustments include active information seeking and exploration of the medical setting, but might also include deliberate avoidance or distraction (see also 'Hospitalization in adults').

Parental responses

A crucial factor in a child's response to medical events is the reaction of his or her parents. Mothers and fathers of child patients have reported experiencing a range of negative reactions to their child being in hospital. In fact, Ogilvie (1990) indicated that parents often perceive their own anxiety as greater than that of the child. This has been supported by the observation of Thompson and her colleagues (1996) that when children were undergoing assessments for lung transplantations, the parents were far more likely to indicate clinically significant levels of distress. The anxiety of parents might not always be obvious, even when it is extreme.

As several investigators (e.g. Boyer & Barakat, 1996) have noted, parents can conceal or play down their concern, perhaps in order to present a 'brave face' for their child.

The impact of their child's hospitalization can affect parents long after discharge. Investigations (e.g. Board & Ryan-Wenger, 2002) have suggested that the diagnosis and subsequent treatment of children with serious conditions can precipitate symptoms of post-traumatic stress in their parents. One study of child survivors of cancer has shown that up to two years after treatment, parents were three times more likely than the child patients to report severe post-traumatic stress (Kazak *et al.*, 1997) (see also 'Post-traumatic stress disorder').

When a parent expresses negative reactions to the child's illness or hospitalization, this is likely to impact on the child's ability to cope (DuHamel *et al.*, 2004; Melnyk & Feinstein, 2001). Studies across a variety of medical situations have indicated that when a mother's anxiety is high her child's co-operative behaviour decreases and the child is likely to show increased anxiety. Alternatively, a child's co-operative behaviour increases and anxiety decreases when the mother's anxiety is low (Cameron *et al.*, 1996; Mabe *et al.*, 1991).

In an effort to understand how this communication of emotion takes place, a range of specific parental behaviours have been investigated. Behaviours with a more emotive emphasis have been linked with children's poorer responses to the stress of hospitalization and medical procedures. This includes rejection, over-indulgence, over-protection (Carson *et al.*, 1991), agitation (Bush *et al.*, 1986), non-involvement (Wells & Schwebel, 1987), reinforcement of complaining or of illness behaviour (Gidron *et al.*, 1995), and criticizing or apologizing to the child (Blount *et al.*, 2003). Alternatively, parenting behaviours encouraging a child's active coping, such as the use of information, positive reinforcement, humour or distraction have been found to be associated with the child engaging in more adaptive responses (Bush *et al.*, 1986; Vance & Eiser, 2004). Blount *et al.* (1990) found that when parents varied their behaviour to suit different phases of the procedure (e.g. using distraction during anticipatory phases and encouraging the child to breathe during painful phases), children were more likely to have lower levels of distress.

Clearly, reducing parental anxiety is an important goal for health-care professionals. It has long been recognized that better communication between parents and caregivers, and emotional support of parents can reduce their child's anxiety both before and during medical procedures. Unfortunately, while researchers have focused on the influence of the mother-child dyad on children's reactions to hospitalization, little examination has been directed to father-child or sibling-child interactions. In addition, investigations of factors that enable families to achieve positive changes would be of value. For example, researchers have suggested that a child's illness and hospitalization can provide opportunities for parents and siblings to enhance their understanding of illness, increase their sense of competence in caring, expand their social networks to include families with similar concerns to their own, and strengthen family coping behaviours (Kotiniemi *et al.*, 1996; Perrin, 1993).

Children's coping with medical events

After some 50 years of research, there is a greater awareness of the specific needs of child patients. As a consequence, a variety of strategies have been developed to help children and their parents

to cope. These methods have ranged from broad-based approaches that affect large groups of patients to more individualized interventions.

Hospital setting and policies

One area where there has been widespread change is in hospital practices related to parent access. Until the 1960s, children endured extended separation from their parents as reflected in the following visiting regulations.

Patients are not allowed visitors unless they have been in the hospital for a period of 4 weeks, after which time only the parents or guardians (no friends or relatives are allowed) are permitted to visit on each alternate Sunday in each month, between the hours of 2 p.m. and 3.30 p.m. Parents or guardians of patients dangerously ill are allowed to visit as often as the Doctors consider necessary.¹

Today, typically hospitals have unrestricted access in that parents can remain with their child overnight, be present during medical procedures while the child is conscious and participate in the daily care of their child. Clearly, these family centred practices are preferable to the previous restrictions. To be of real benefit, however, they have to be adequately supported. For example, in order for parents to stay overnight they require suitable facilities and parents who choose to be present during difficult procedures need effective preparation to enable them to direct their full attention to caring for their child.

Another broad-based strategy to help children to cope involves consideration of the hospital environment, such as the design and layout of facilities, and the use of visual displays. Surprisingly, this area has received little attention from researchers in the psychological literature. Generally, efforts to make the environment more familiar and home-like are beneficial. The availability of play areas and materials is important so that children can have spaces where they are free from medical procedures, can express themselves and find enjoyment.

Of course, the continued development of medical treatments that minimize pain is essential to children's coping, as is providing child patients with appropriate levels of pain medication (Ellis *et al.*, 2002). Where possible, affording children with the opportunity to participate in decision-making regarding their care and treatment can help them to gain a sense of control over a situation that might otherwise be overwhelming (Kuther, 2003).

Not surprisingly, children's coping with medical events is influenced by the nature of the interactions they have with health professionals. In order to assist children, staff need to be aware of the potential effects of hospitalization and of factors that can influence a child's vulnerability to maladaptive reactions. Most importantly, staff need to be willing and able to invest time in attending to children's emotional as well as their physical needs (Wright, 1995).

Psychological techniques

A wide range of more individualized psychological techniques has been developed to help child patients and their parents cope with difficult medical events (see reviews by Melnyk *et al.*, 2004;

Powers, 1999). Outcome studies have indicated that these approaches result in specific benefits to child patients and their families, including reduced anxiety and fewer problem behaviours. Most strategies can be classified into three groupings: information provision; modelling; and cognitive behavioural techniques (Whelan & Kirkby, 1998).

The types of information that can be offered to patients can be categorized as procedural (i.e. what will happen to the child), sensory (i.e. what the child will see, hear and feel) and behavioural (i.e. what the child can do). Providing such information is thought to reduce anxiety by clarifying expectations and encouraging a sense of control (Wallace, 1984). The effective provision of information is particularly important for child patients given their potential for having distorted beliefs about impending medical events (Cohen *et al.*, 2001). Information can be provided to children through a variety of formats including written material, instruction from hospital staff, hospital tours and play therapy (see also 'Written communication').

The modelling technique is based on the research of Bandura and his associates (e.g. Bandura & Menlove, 1968) who demonstrated the efficacy of using vicarious processes to reduce children's fears about a variety of stressors. In a hospital setting, this involves exposing the child to fearful events in an upcoming procedure through a model (a peer in a film, a storybook character or a toy figure). Seeing the model demonstrate effective coping enables the child to prepare his or her own adaptive behaviours. A wide range of benefits have been reported for child patients (and their parents) who have undergone modelling-based preparation (Melamed & Ridley-Johnson, 1988). These benefits, however, are influenced by variables such as a child's age (Melamed *et al.*, 1976), the timing of preparation (Melamed *et al.*, 1976), previous hospitalization (Melamed *et al.*, 1983) and parental presence during preparation programmes (Robinson & Kobayashi, 1991) (see also 'Behaviour therapy').

In recent decades, investigations of treatments to help children deal with distress related to medical events have focused on cognitive behavioural techniques (Powers, 1999). This approach includes a variety of components that have the advantage of assisting children with distress both before and during medical procedures. Typical components have included breathing exercises and other forms of relaxation and refocusing (e.g. blowing bubbles, playing with toys, reading pop-up books, practising progressive muscle relaxation), imagery and coping statements. Coaching (i.e. prompting the child to engage in coping skills) by the parent or medical staff during the procedure has also been a typical aspect of treatments. Other common elements include reinforcement for using coping skills and behavioural rehearsal (Powers, 1999) (see also 'Cognitive behavioural therapy' and 'Relaxation training').

Although there appears to be widespread recognition of the value of psychological preparation among health professionals, unfortunately, often the most effective interventions are not available for children and their parents (Koetting O'Byrne *et al.*, 1997; Whelan & Kirkby, 1995). In a survey of 123 pediatric hospitals in North America, Koetting O'Byrne *et al.* (1997) found that the most common types of preparation offered were those likely to be less effective, such as hospital tours, printed materials and narrative preparation. Only half of the hospitals studied reported that they taught coping techniques and 48% used films in preparation for surgery. In addition, it appears that such programmes have

¹ Policy statement of the Royal Children's Hospital 1947, Melbourne, Australia

been vulnerable to financial restrictions at times of economic stringency. This is despite empirical evidence that structured preparation programmes provide substantial financial advantages through shorter hospital stays, reduced post-surgery complications and decreased medication usage (Groth-Marnat & Edkins, 1996). Given the desirability of preparation programmes in terms of reductions in stress for families and economic savings, future investigations should provide further cost-benefit analyses, and just as importantly, investigate ways to best communicate these findings to health institutions.

Conclusion

Much has been learnt about the psychological impact of hospitalization and illness on children. Even so, recent changes in hospital practices have meant that this research needs to be updated. For example, compared with the previous decade, today there are shorter hospital stays, more invasive procedures completed in outpatient settings, different staffing patterns, more children treated outside paediatric units and greater expectations that parents will be involved in patient care (Vessey, 2003). As yet, the full impact of these changes is not understood. Given the increasing funding and resource pressures faced by hospitals, along with advances in medical technology, it is likely that there will be further changes. As cautioned by Wright (1995), in order to continue the gains of efforts to minimize the adverse consequences of hospitalization, any subsequent modifications need to be considered in terms of the possible effects on children's behaviour.

A salient weakness with much of the literature on hospitalization in children has been a failure to adopt theoretical frameworks. The reactions of children cannot be explained by examining contributing factors in isolation from one another. In the future, it is important that investigations determine how variables interact to produce children's responses (Vessey, 2003). Similarly, there has been a failure to evaluate psychological interventions within clearly developed theoretical contexts. As a result, the processes by which the strategies have exerted their effects have been poorly understood. It is hardly surprising that in clinical settings the usual approach has been to provide '... a smorgasbord of intervention techniques' (Ludwick-Rosenthal & Neufeld, 1988, p. 326) with the assumption that one or more features of the treatment will facilitate a child's adjustment. Investigations that provide a clearer identification of the effective components of interventions are more likely to produce cost-effective treatments. Such research could include an examination of factors that moderate the effects of interventions (e.g. age or temperament) on child and parent outcomes. Furthermore, specific treatments could be developed for specialist patient groups, such as the substantial numbers of children who are emergency admissions or health system 'veterans' with multiple hospital stays.

Finally, much of the research on the effects of hospitalization on children has been conducted in developed nations that have relatively well resourced health systems. Few studies have been reported from developing countries. Investigations are required to determine the special requirements of hospitalized children in these nations and to develop culturally relevant models of care.

Hostility and Type A behaviour in coronary artery disease

Willem J. Kop¹ and David S. Krantz²

¹University of Maryland Medical Center

²Uniformed Services University of the Health Sciences

Historical perspective and early research

Systematic research on behavioural patterns related to increased risk of coronary artery disease (CAD) and its clinical manifestation as myocardial infarction was initiated by Friedman and Rosenman in the 1950s. The Type A Behaviour Pattern (TABP) was documented to be predictive of future myocardial infarction. TABP is defined as: 'an action-emotion complex that can be observed in any person who is aggressively involved in a chronic, incessant struggle to achieve more and more in less and less time, and if required to do so, against the opposing efforts of other things or persons ...' (Friedman & Rosenman, 1959). Later research (reviewed below) has documented that hostility may be the 'toxic' component of TABP. Type A behaviour is characterized by an excessive competitive drive, impatience, hostility and vigorous speech characteristics. The complement of TABP was called Type B behaviour and was described as the relative absence of Type A characteristics.

The early reports by Friedman, Rosenman and co-workers have resulted in numerous epidemiological and experimental

investigations on the relationship between TABP and manifestations of coronary artery disease. In the 1960s and 1970s, most epidemiological studies supported the association between TABP and risk of future coronary artery disease (CAD) in men and women. The magnitude of these associations was comparable to that of traditional risk factors for CAD and also independent of these factors, such as hypertension and elevated lipid levels. One major study in this area was the Western Collaborative Group Study (WCGS) in which 3200 males were followed up for 8.5 years (Rosenman *et al.*, 1975). It was observed that individuals with Type A behaviour were more than twice as likely to suffer CAD disease than their Type B counterparts. Another important study was the Framingham Heart Study (Haynes *et al.*, 1980), where Type A behaviour was found to be predictive of CAD among men with white-collar professions and in women working outside the home. These findings led a review committee of the National Heart, Lung, and Blood Institute to construe Type A behaviour as a risk factor for CAD in middle-aged US citizens (The review panel on coronary-prone behaviour and coronary heart disease (NHLBI), 1981). Later studies, however, failed to show an

association between TABP and clinical coronary disease (for review see Matthews & Haynes, 1986) (Matthews & Haynes, 1986). These negative findings have contributed to deconstructing the TABP, examining its culprit aetiological mechanisms and searching for components of TABP that did predict adverse CAD outcomes.

Evidence suggested that 'hostility' is the 'toxic' component of TABP (e.g. (Helmer *et al.*, 1991)). Similar to TABP, hostility is defined as a psychological trait. Hostility is characterized by a negative attitudinal set, a cynical view of the world, an antagonistic style and the presence of negative expectations as to the intentions of other people (Siegman & Smith, 1994). The attitudinal trait of hostility is distinct from anger, which is an emotional state and often leads to aggressive behaviour. Type A behaviour and hostility relate to anger in the sense that thus-affected individuals experience an elevated number of anger experiences. Therefore, Type A behaviour, hostility and trait anger share common characteristics, but they are also independent to a considerable degree (Smith *et al.*, 2004; Kawachi *et al.*, 1998). However, equivocal results in the TABP/hostility literature have remained and may depend in part on whether or not the assessment tools incorporate behavioural observations, rather than measuring self-reported personality traits (see also 'Personality and health').

Assessment of Type A behaviour and hostility

A Structured Interview (SI) was developed to improve Type A behaviour assessments. The SI interrupts and challenges the interviewee to evoke behavioural responses such as vigorous speech and competition of control over the conversation. Apart from the behavioural observations, the SI also enables content analysis of the answers. Because the clinical assessment of overt and non-verbal behaviour is an essential part of this technique, special training is required to administer and score the SI. In addition, Friedman and colleagues also developed a scoring technique based on videotaped TABP interviews.

As alternative assessment procedures, several self-administrated questionnaires have been developed (e.g. the Jenkins Activity Survey (JAS: (Jenkins *et al.*, 1971); Bortner Type A scale ((Bortner, 1969); and the Framingham Type A scale (Haynes *et al.*, 1980)). Because Type A questionnaires rely solely on self-report, only modest correlations are observed between the SI and self-report questionnaires (Engelbreton & Matthews, 1992).

Hostility is most commonly assessed with the Cook–Medley Hostility Inventory (Cook & Medley, 1954). The Cook–Medley scale is a 50-item self-report questionnaire derived from the Minnesota Multiphasic Personality Inventory. Several papers report on sub-factors that may comprise the Cook-Medley questionnaire, of which 'cynicism', 'aggressive responding', and 'hostile affect' appear to have the strongest relationships with CAD (Barefoot *et al.*, 1989). Also, other questionnaires are available to assess hostility (e.g. the Buss–Durkee Hostility Scale; (Buss & Durkee, 1957)).

A better alternative for the assessment of hostility as CAD risk factor is based on interview analysis of the Structured Interview (initially developed to assess TABP). Two interview-based measures of hostility exist: the Potential for Hostility, and the Interpersonal Hostility Assessment Technique (IHAT (Haney *et al.*, 1996; Brummett *et al.*, 2000)). The IHAT includes four components: irritation, indirect challenge, direct challenge and hostile

withhold/evade. Irritation is scored for irritated tone, impatience or exasperation with the interview or interviewer, arousal while re-experiencing negative life events, condescension or snide remarks, harsh generalizations and punched words with angry emphasis. Indirect and direct challenges refer to indirectly versus explicitly challenging the questions or the interviewer. Hostile withholding/evading refers to respondents' avoidance or refusal to answer a question. The total IHAT ratings tend to be positively skewed, and approximately 10% CAD of patients show no hostile behaviours. Total IHAT ratings are associated with aforementioned SI-based clinical ratings of Potential for Hostility ($r = 0.32$). IHAT scores are stable over a four-year period (intraclass $r = 0.69$), reflecting the trait-nature of hostility.

Many studies show that questionnaire- and interview-based measures of hostility share common variance, but classifications of individuals may vary considerably. This is, as in the aforementioned methods of TABP assessment, likely to be caused by the fact that the SI classification is dependent on behavioural observations such as speech characteristics, whereas the Cook–Medley depends on self-reports of a cynical or a hostile demeanor.

Equivocal results obtained in Type A behaviour and hostility research

The Multiple Risk Factor Intervention Trial (MRFIT) and a subsequent longer follow-up analysis of the WCGS revealed the most compelling evidence against the association between TABP and subsequent manifestations of CAD. In the MRFIT study (Shekelle *et al.*, 1985), both the SI and the JAS were administered in high-risk men, and neither was associated with future cardiac disease. Ragland and Brand (Ragland, 1989) reported on the recurrence of myocardial infarction in men who participated in the WCGS and who survived their first myocardial infarction. Unexpectedly, Type A behaviour was found to be protective in this sample. Thus, the predictive value of Type A behaviour in populations with elevated risk of coronary disease remains controversial. Furthermore, since 1979, virtually no positive reports have been published that support the relationship between questionnaire-assessed Type A behaviour and CAD. Recent reviews also suggest that the contribution of hostility is relatively low compared with other psychosocial risk factors such as depression and social isolation (Hemingway & Marmot, 1999) (Myrtek, 2001; Miller *et al.*, 1996) (see also 'Social support and health').

The question could be raised as to whether hostility and TABP are still important constructs for cardiovascular health. The answer to this question is probably confirmative, although the emphasis has definitely changed in the past 10 years (see (Riska, 2000)). There are several reasons why it remains important to consider hostility and TABP in behavioural medicine. First, methodological issues are important in the interpretation of the studies with negative results. Studies that revealed negative findings regarding TABP and prediction of future cardiac disease investigated 'high-risk' populations. Because Type A behaviour may be related to the presence and persistence of several coronary risk factors and adverse health behaviour (e.g. smoking, unhealthy diet, etc.), this may attenuate the observed covariate-adjusted association between TABP and cardiac disease in high-risk populations. Second, several negative studies

included patients who participated in treatment trials (either pharmacological or behaviour modification), which may have biased recruitment and reduced the magnitude of the associations observed between TABP and cardiac disease. Recent developments in informed consent procedures, which include more time and are inconsistent with a hostile attitude, may have further enhanced this bias. Third, hostility and TABP may be associated with specific non-survival of first cardiac events. That is, Type A persons who suffer their first myocardial infarction may be less likely to survive this incident than Type Bs. If this is correct, then study samples that are limited to survivors of myocardial infarction do not include the high-risk Type A individuals. Finally, the original description of TABP had a primary behavioural observational perspective without a consistent aetiological theory. The inclusion of personality traits as theoretical perspective has resulted in negative findings and deconstruction of the TABP concept. As reviewed below, quantification of the behavioural aspects of hostility and TABP is likely to reveal important novel information in CAD pathophysiology and risk stratification.

Hostility and Type A behaviour as related to coronary disease

Measures of hostility derived from the Structured Interview are predictive of severity of coronary artery disease in samples where global Type A behaviour was not similarly predictive (Dembroski *et al.*, 1989). On the other hand, the Cook–Medley questionnaire does not unequivocally predict severity of CAD see (Siegman & Smith, 1994). One study (Siegman, Dembroski & Ringel, 1987) suggests the particular importance of the behavioural manifestation of hostility in the relationship with CAD severity.

Several longitudinal studies have addressed the predictive value of hostility in the development of clinical manifestations of CAD. SI-assessed hostility predicts cardiac events in initially healthy subjects and in patients at high risk of coronary disease who were participants in the Recurrent Coronary Prevention Project (RCPP; (Friedman *et al.*, 1986)) and the MRFIT study (Dembroski *et al.*, 1989). A recent analysis of the MRFIT data confirmed the role of interview-based hostility on cardiac events (Matthews *et al.*, 2004).

The Cook–Medley questionnaire has yielded mixed results in follow-up studies of healthy individuals. This may partially result from the particular circumstances in which participants completed the inventories (often as part of a job or university selection procedure), and the use of very long follow-up durations (frequently more than 20 years). Apparently, the behavioural component of hostility – which is more likely to be detected by the SI – is an essential feature in the elevated risk of cardiac end-points (Siegman & Smith, 1994). It is noteworthy that both cross-sectional studies and longitudinal studies support the notion that the relationship between hostility and coronary artery disease is most evident among individuals younger than 60 years of age. This may reflect the fact that younger hostile persons encounter provocative situations more often than older individuals.

Psychobiological mechanisms

Acute psychological stressors result in elevations in heart rate, blood pressure, increases in blood lipids and catecholamines and also

in platelet activity and blood clotting factors. The primary mechanism accounting for associations between TABP/hostility and CAD involves increased physiological response to environmental stressors among hostile individuals (Williams, Jr. *et al.*, 1991; Krantz *et al.*, 1988). For example, in a recent study we documented that hostility, particularly hostile affect, was associated with endothelial dysfunction during a mental challenge task (Gottdiener *et al.*, 2003).

High blood pressure may promote damage to the coronary vessel wall, especially at sites where turbulence in coronary blood flow exists (e.g. branching points). In the setting of this mild coronary injury, deposition of lipids may occur which further enhances vascular damage. The progression of CAD is determined by an intermittent process of gradual coronary atherosclerosis combined with blood clot formation and degradation that may finally develop into coronary obstruction and, consequently, clinical manifestations of coronary disease. Inflammatory processes are likely to play an important role in this process. Different disease stages are associated with characteristic pathophysiological processes, which can be affected by psychological factors via neuroendocrine and autonomic nervous system pathways (Kop *et al.*, 1994).

A series of animal studies by Kaplan, Manuck and colleagues, found that high dominant male monkeys (macaques) in socially unstable circumstances showed more coronary atherosclerosis at necropsy (Kaplan *et al.*, 1982). In other studies, this research group established that individual differences in the consequences of aggressive behaviour can be explained in part by the psychosocial context in which these behaviours are displayed.

As for Type A behaviour and hostility in humans, several reports support the contention that psychobiological over-reactivity is characteristic of hostile individuals, particularly when these individuals are exposed to situations that elicit hostile behaviour. Thus, prolonged exposure to elevated stress responses in blood pressure, heart rate, catecholamines, blood clotting factors and inflammatory processes may account for the elevated risk of disease progression in hostile individuals.

It is conceivable that the consequences of a chronic hostile attitude are not limited to physiological changes that promote CAD, but also involve psychological repercussions of hostility. Glass proposed a psychological model in which Type A individuals were hypothesized to experience a state of frustration and exhaustion, a ‘prodromal depression’, preceding myocardial infarction (Glass, 1977). The basic assertion was that Type A individuals exert intense efforts to control stressful events. These active coping attempts eventually extinguish and lead to frustration and psychological exhaustion. This notion provides a model accounting for why Type A behaviour and hostility may interact with constructs such as depression and exhaustion, which are also factors that may affect the progression of coronary artery disease (Carney *et al.*, 1988; Kop *et al.*, 1994). We have found that trait anger and exhaustion have additive effects in predicting clinical events after coronary percutaneous interventions (Mendes de Leon *et al.*, 1996) (see also ‘Psychoneuroimmunology’ and ‘Stress and health’).

Modification of hostility and Type A behaviour

Positive effects of behaviour modification in CAD patients have been reported in several investigations. The majority of these studies

have been directed at reducing Type A behaviour. Because hostility appears to be a significant feature of Type A, these studies are applicable to strategies aiming at modifying hostility. Type A and hostile persons may be more prone to develop CAD because of (a) an overall increased cardiovascular reactivity, and (b) frequent exposure to conditions in which anger occurs. In addition, TABP/hostility is related to a reduced availability of stress-decreasing resources such as social support, which partly results from the antagonistic behaviours portrayed by hostile individuals. In general, intervention studies indicate that control over angry emotional experiences can be enhanced by 'behavioural' approaches (e.g. addressing issues such as patience when driving, taking sufficient time for daily meals), whereas the hostile attitude might be altered using 'cognitive' strategies (i.e. managing unreasonable expectations and ideas) (Kop, 2004).

In general, hostility interventions are conducted in a group setting consisting of approximately 10 participants. First, an attempt is made to gain insight into the triggers of anger-provoking incidents. Usually, participants are asked to self-monitor their behaviour to determine the circumstances in which anger or irritation occurs. Second, new strategies to cope with aggravating situations are introduced, such as learning to voluntarily insert a delay between the provoking incident and the reaction to it. At later stages of the intervention, a cognitive approach is taken, where unrealistic beliefs and expectations are addressed and modified. This may eventually result in opportunities to address provoking situations in a 'problem-solving' way.

The efficacy of these interventions is supported in a number of studies. For example, in the RCPP the number of re-appearing myocardial infarctions was significantly lower in patients who received Type A intervention (7.2% versus 13.2%, during three years of follow-up (Friedman *et al.*, 1986). A substantial decrease in Type A behaviour occurred far more often in a Type A treatment group than in a control group. Moreover, patients who were successful in considerably decreasing their Type A behaviour, suffered a re-infarction four times less than those who failed to do so (Mendes de Leon *et al.*, 1991). Recent clinical applications of these interventions incorporate various components of 'negative affectivity' in cardiac rehabilitation programmes, including depressive symptoms, exhaustion and anxiety (for review see (Kop, 2004).

Recent trends and future research

The study of hostility and TABP has received increasing international attention. Population trend analyses suggest that TABP not only decreases with progressing age, but also that population trends display an overall reduction in TABP (Kojima *et al.*, 2004; Smith & Sterndorff, 1993). These trends may reflect changes in global socio-economic patterns and changes in public health that have addressed components of TABP as a target (for an excellent Foulcaudian perspective see (Riska, 2000). Increased attention for negative emotions and TABP in the workplace (Brummett *et al.*, 2000) and

assessment of Type A and its biobehavioural cardiovascular risk factors in children and young adults (e.g. (Raikkonen, Matthews & Salomon, 2003) may have additionally contributed to this decrease.

Assessment and treatment of hostility, TABP and other psychosocial risk factors in women have received increasing scientific attention (Eaker, 1998). Some evidence suggests an interaction between TABP and the use of hormone replacement in post-menopausal women (Chaput *et al.*, 2002). Hostility may also differentially affect men versus women in acute responses to social challenge (Smith & Gallo, 1999) (see 'Gender issues and women's health'). Despite potential differences in biopsychological pathways, prospective studies indicate that hostility is predictive of adverse cardiovascular health outcomes in post-menopausal women. More research is needed, however, to examine the interaction between gender with race and ethnicity in determining associations between psychosocial factors and cardiovascular disease.

Results indicate that psychological interventions are capable of reducing negative emotions and antagonistic behaviour patterns. However, evidence is not consistent as to whether these psychological improvements lead to a reduction of cardiovascular risk. Further studies are needed to investigate the biological and health behaviour concomitants of hostility. For example, it has been suggested that a relative depletion of the neurotransmitter serotonin is characteristic of hostile individuals. This deficiency has also been purported for other psychological measures associated with CAD, of which depression is the most well established. Some evidence supports the role of genetic factors in both hostility and its biological correlates e.g. (Sluyter *et al.*, 2000). It may therefore be that a combined behavioural and pharmacological approach proves to be successful in ameliorating hostility. In the prevention of CAD-related events, hostility may not be the primary target for intervention because its modest predictive value for adverse cardiovascular outcomes (Myrtek, 2001; Miller *et al.*, 1996). The assessment and treatment of the behavioural component of hostility and TABP appears to be more important than their underlying personality dimensions. These psychological measures need to be evaluated from a socio-cultural perspective that may change over time. Nonetheless, interventions that reduce hostile behaviours and attitudes may enhance both quality of life and alter concurrent psychological CAD risk factors such as acute stress responses and depressive symptoms in individuals at risk of coronary disease.

Risky behaviours promote and healthy behaviours reduce disease risks

The evidence is clear: risky behaviours can lead to health crises and healthy behaviours can delay and avoid health crises. Cigarette smoking increases the probability of multiple types of cancer in addition to lung cancer, including cancers in organs as far from the mouth and lungs as the cervix. Cigarette smoking also greatly increases the likelihood of cardiovascular disease. Yet lung cancer has now exceeded breast cancer as a cause of death among women. Obesity is a risk factor for a broad range of diseases (Thompson & Wolf, 2001) and we are facing an epidemic of Type 2 diabetes, formally seen among the elderly and now increasingly diagnosed among teenagers (Mokdad *et al.*, 2001). The epidemic is occurring in spite of the clear evidence that weight loss and exercise can reduce the risk of diabetes. A multi-centre trial with over 3000 participants, each of whom was at high risk for becoming diabetic, found that exercise and dietary changes resulted in a 58% reduction in the number of individuals becoming diabetic whilst medication resulted in a 31% reduction relative to a control group receiving placebo (Knowler *et al.*, 2002). In short, despite knowledge of risk many people smoke, eat unhealthy, high fat, high calorie foods and are physically inactive. Knowledge of risk does not translate into risk avoidant behaviour (see also ‘Health related behaviours’).

Adherence is poor

Is the failure to adhere to recommended and effective preventive, disease-controlling and curative behaviour due to lack of intentions (Ajzen & Fishbein, 1980) or due to a failure of confidence in one’s ability to perform the required action? (Bandura, 1986) (see ‘Theory of planned behaviour’ and ‘Self-efficacy and health behaviour’).

As many as half of the patients whom clinicians encounter on a daily basis are partially or completely non-adherent to the recommended treatment for hypertension; to the use of medication that reduces the frequency and intensity of asthma attacks (Halm *et al.*, 2006); to the use of medication that lowers blood sugar levels and to recommendations to take preventive measures including avoiding risky behaviours to prevent diabetes or control its complications (Phillips *et al.*, 2001). Many who fail to adhere fully to medically prescribed treatment are fully capable of forming intentions to act and acquiring the skills needed to follow through and adhere to ‘alternative’ or complementary treatments (Astin, 1998). Whether one is old or young, a graduate degree in biology or psychology is not essential for taking a diuretic each morning to control blood pressure or using a corticosteroid inhaler once a day to control the pulmonary inflammation which is a source of vulnerability to attacks of asthma. An important set of questions remains to be addressed concerning why people do not adhere to treatment to prevent and control illness threats when the behaviours recommended are well within their mental and physical competencies. Unfortunately, many investigators who use measures of intentions and efficacy to predict behaviour offer little practical or theoretical guidance as to how intentions or efficacy are created in adherent patients and which factors are involved when intention and efficacy are present but unrelated to action; both types of information are important for behavioural intervention. Correlations of behavioural measures with intention and/or efficacy are insufficient evidence for causation and insufficient guides for intervention; i.e. correlation should not be confused with causation (Pedhazur, 1997) (see ‘Adherence to treatment’).

Social learning and self-management

Historically, social learning models have provided the main source of guidance for creating and testing behavioural interventions.

The pioneering work of Lorig and colleagues (Lorig *et al.*, 2001) has shown that identifying and creating motivational resources and performance skills improves patient management of chronic illnesses. Social learning approaches and cognitive behavioural models were the basis for the highly effective behavioural interventions used in the diabetes prevention trial (Knowler *et al.*, 2002). Although the behavioural intervention was highly effective and exceeded the efficacy of the drug Metformin in deterring the transition from risk to diabetes, it had a serious downside; it was extremely intensive. Altering participant's lifestyles required as many as 16 lengthy face-to-face contacts and multiple phone contacts with well trained change agents. The cognitive behavioural treatment effective for the initiation and maintenance of the life style changes, i.e. alterations in eating and exercise patterns, effective for avoiding diabetes onset were clearly too expensive to implement within the current health-care system. Is there a short cut? Is there a way of educating and teaching patients with 'less that is more'? (see also 'Behaviour therapy' and 'Cognitive behaviour therapy').

Common-sense and self-management

Clinicians who listen carefully to what their patients say and examine patient responses in focus groups, report that many patients may see little reason for adhering to treatment. Why, patients ask, should they take a hypertension medication when they feel perfectly fine? And why should they inhale a corticosteroid when the papers are filled with stories about the risk of steroids for athletes? These actions make no sense given patients' perceptions and beliefs about their health status, the diseases they supposedly have and the benefits and risks of treatment.

The beliefs people hold about specific diseases and treatments are based upon a combination of what they hear from people around them, their understanding and misunderstanding of what practitioners tell them, their observations of other persons, and their perceptions and experience with their own physical and emotional states. These beliefs form a repertory of 'common-sense' knowledge; they are beliefs that are supported by social consensus and information from practitioners and the individual's repository of experience and ongoing perceptions of illness symptoms, duration, causes, efforts at control and consequences (Leventhal *et al.*, 1980, 2003). As Festinger (1954) proposed decades ago, social information is less likely to persuade when the recipient of the message believes they have objective evidence to back their own beliefs. You cannot convince me that I am holding a sheet of paper if the sheet is a shiny, metallic grey, is difficult to bend and impossible to tear. Similarly, you will have a hard time convincing me that I have a disease called hypertension if I have no symptoms and feel perfectly well (Meyer, Leventhal & Gutmann, 1985), or that I have asthma when I have no symptoms and am not having an attack (Halm *et al.*, 2006). Also, does it make sense to use a prescribed medication to treat a condition or illness that currently I do not have? My common-sense representation of my somatic status does not call for medication.

Representations of illness and treatment

Studies have identified five domains of illness representations that form a base for initiating, maintaining and evaluating the

efficacy of preventive or treatment behaviours (Leventhal *et al.*, 1980): the identity of the illness (its symptoms and label), its time-line (acute or chronic), its cause (genes, exposure to virus, etc.), control (can it be prevented, cured or controlled?; Lau & Hartmann, 1983) and consequences (pain, dysfunction, economic and social losses). Treatments also have representations. Treatment representations can be described by summary features, that is they can be perceived as necessary and/or as sources of side effects and risk (Horne, 2003), and they can also be represented in greater detail in the five domains; e.g. their identity or names and symptoms (surgery has wound-healing pain), time frames (antidepressants take weeks to alter mood), causal routes of action (surgery removes tumours), consequences (weeks of debilitation), and control (effectiveness for preventing, curing or controlling a disease).

The factors in each of the domains are represented in both abstract and in concrete, experiential form, my illness has an abstract label (hypertension) and concrete symptoms (nervousness, warm face, etc.), my anti-depressant has an abstract time frame (weeks to improve mood) and a concrete time line (I can feel the (side) effects of the medication within hours), and my illness has consequences that I can verbalize or literally see as vivid images in my mind's eye (Gibbons & Gerrard, 1997). The abstract and concrete levels of the factors comprising the representations need not be consistent with one another. For example, both patients and non-patients attribute symptoms to conditions that are asymptomatic (more patients do so than do non-patients); warm faces, nervous tension, heart beating, etc. are misperceived as symptoms of chronic elevations of resting levels of blood pressure (hypertension) although resting levels are asymptomatic (Baumann *et al.*, 1985) (see also 'Symptom perception'). Adherence to treatment for hypertension is higher among patients who perceive treatment as having a positive effect (reducing) on their symptoms; patients are less likely to adhere when they do not perceive these benefits (Meyer *et al.*, 1985).

Heuristics give meaning to somatic experience

The speed and ease with which events (symptoms, functional changes) are labelled (a cold, asthma), evaluated (benign, life-threatening) and affectively responded to can obscure the many heuristics or rules-of-thumb involved in the evaluative process. Symmetry, the bi-directional process of labelling symptoms and finding symptoms when labelled, appears to be a fundamental feature in the formation of representations whether these be representations about illness or treatments. For example, when given false feedback suggesting their blood pressure is elevated, non-hypertensive undergraduates report the same symptoms and reduced health status as reported by hypertensive patients (Bauman *et al.*, 1985; Croyle, 1990), and absence due to sickness was more frequent among aware hypertensives and among falsely aware hypertensives who perceived a high symptom level, compared with both normotensives and unaware hypertensives (Melamed, Froom & Green, 1997). Heuristics facilitate decision making when dealing with ambiguous and highly salient cues (symptoms, pain) and the emotional distress that may arise in the context of ambiguity and limited information. Heuristics such as symptom pattern (chest pain or pressure is the symptom pattern for heart attack and is perceived to be more typical of men), location

(breathlessness is a problem of the lungs not the heart), duration (after three days it may be serious), and novelty (never had it before – better it check it out), provide provisional ‘diagnostic meanings’ and suggest the need for seeking care (Woloshynowych, Valori & Salmon, 1998). More complex heuristics that are involved in decisions as to whether symptoms are a sign of illness or a non-illness condition include the age-illness heuristics (mild, chronic symptoms are likely to be seen as signs of age not illness), and the stress-illness heuristics (when under high stress symptoms are likely seen as indicators of stress not illness). The full meaning of a symptom and/or illness evolves over time and the evolution is speeded by the success or failure in the control of symptoms by self selected or medically recommended treatments (see ‘Self-management’).

Social factors shape representations of disease and preventive and treatment behaviours

Social influences play a critical role in health behaviours for the prevention, treatment and control of disease. Social factors can operate by creating or moderating the impact of more specific health beliefs, and they can have direct effects on health behaviours. Social comparisons are involved in the interpretation of symptoms and decisions to seek medical care; (Lau & Hartman, 1983), multiple studies find that virtually all elderly individuals discuss symptoms with other persons and virtually all people seeking medical care have been told to do so by someone (Cameron, Leventhal & Leventhal, 1993). Social comparisons reinforce beliefs about exposures to pathogens, reinforce the interpretation and meanings assigned to symptoms with specific patterns and can increase uncertainty and concerns about novel symptoms (Taylor, 1983). Comparison can also provide reassurance of the safety of needed and potentially threatening treatments such as bypass surgery by minimizing the emotional distress associated with threat-induced images of surgical mutilation and pain (Kulik & Mahler, 1987). Consistent with the basic premise of the common-sense model and with the multitude of studies of observational learning (Bandura, 1969), information from individuals who have experienced treatment and struggled with disease, communicates the lived experience of the source. For example, misconceptions about cancer are more prevalent among Latinos than Anglos, in part because they fit a Latino fatalistic cultural theme (Pérez-Stable *et al.*, 1992).

Putting it all together

Many data analytic tools such as multiple regression analysis tend to emphasize the contribution of single factors to specific behavioural and health outcomes. Studies report the effect of particular personal beliefs and/social influences on action, the effect of each factor is assessed independent of the contribution of others. Conceptual models however, make clear the need for further integration. Qualitative studies suggest that people develop integrative narratives of their illnesses, which transcend the details of the illness experience and dynamically combine a wealth of information from somatic cues, mass media and input from their practitioners (Docherty and McColl, 2003; Hunt *et al.*, 1989). Theoreticians have proposed that specific beliefs have beneficial effects on preventive and treatment behaviours when the set is consistent or coherent

(Moss-Morris *et al.*, 2002; Antonovsky, 1993) or generates a sense of overall competence or self-efficacy for behavioural management (Bandura, 1986). The common sense model identifies several types of coherence or consistency that are important for preventive and treatment actions.

Coherence: Abstraction bind concrete experience

Concrete experiences are tied to specific points in time, they are time bound. For example, a patient interviewed in hospital reported experiencing ‘fatigue two days ago, breathlessness a few hours later, a collapse on the floor at home, a day later, and the panic of inability to breathe and walk, an hour before appearing at the hospital emergency department for treatment’; these were perceived to be distinct, separate events as they were not understood to be indicators of congestive heart failure, CHF (Horowitz *et al.*, 2004). Because the experiences are not bound together by a common concept, the patient did not seek care when she collapsed and did not see the collapse as a sign that she would soon need emergency treatment. The patient suffering from CHF was hospitalized because she did not see the connections among these experiences and did not attend to or treat the milder chronic symptoms to avoid later collapse. Appropriate linkages are critical for symptom management and inappropriate linkages risky. This idea is critical for prevention as well as for treatment. It is fine to feel good, but feelings are sensitive to many factors and they do not necessarily indicate good health. One can feel relaxed and ‘high’ after exercising, vigorous exercise can be an antidote to depression and have health benefits. However, one can also feel relaxed and high while inhaling a cigarette, an antidote to depression with a health risk.

Coherence among representations

A second aspect of coherence is the fit between the representation of a disease threat and the representations of the behaviours selected for prevention and control. If stress is perceived as the cause of hypertension, stress reduction rather than medication makes more sense and lowering stress will be supported as an effective means of controlling hypertension as it will result in the reduction of psychophysiological symptoms that are perceived to be signs of elevated blood pressure. Little effort is needed to retrieve examples of ‘good fit’ ranging from rubbing sore muscles, salving a rash or drinking a household remedy to deal with stomach cramps and gas. Each focuses behaviour on the location and presumed cause of the symptoms, signs and physical distress.

Coherence and the selection of indicators

Common-sense representations of illnesses and preventive and treatment behaviours are control systems. Coherence in a system that is bi-level, i.e. abstract and concrete, requires a sense of ‘good fit’ at each level and between levels. Coherence at the perceptual or concrete level requires evidence that behaviour affects a perceptual cue, e.g. symptoms, taste, momentary moods and emotions of satisfaction and/or satiation, etc. Satisfaction of goal attainment at the concrete level may not produce movement toward goals at the abstract level. Selection of appropriate concrete cues, where somatic cues exist, or transferring monitoring

from somatic to external indicators (from symptoms to objective readings of blood sugar or blood pressure) is critical for insuring that movement at the perceptual level will achieve abstract goals.

Coherence among illness/treatment representations, the self and social context

Two sets of questions need to be addressed concerning the fit among representations of illness threats and procedures for prevention and control with representations of the self and representations of the social context (Gibbons & Gerrard, 1997). Strategies for resource management that have been acquired over the life span, such as conservation of resources or “use it or lose it (exercise)” are perceived to be essential for preserving function. These strategies will affect the perception of how best to approach management of specific illness threats (Leventhal & Crouch, 1997). Belief that conservation is critical to avoid recurrence of heart attack encourages non-adherence to active rehabilitation programmes and hypervigilance and over-utilization of medical care in

response to chest complaints (Aikens *et al.*, 1999). The perceived vulnerabilities and strengths of the self, based upon perceived resemblances of the self and specific others and their vulnerabilities, will moderate the interpretive process. Finally, cultural beliefs provide specific ways of interpreting the meaning or identity of somatic complaints including their causes, consequences, time frames and modes of control. These broader beliefs interact with and moderate the interpretation and meanings of somatic experiences and affect the selection of practitioners to assist in prevention and control.

Techniques for studying coherence are not well understood or developed. It is clear that we have a lot to do and much to learn. Forward movement will require new methods for describing representations, heuristics and action and interventions designed to influence particular factors in the landscape of beliefs presumed to affect health behaviours and health outcomes. Forward movement will require close collaboration among psychologists, physicians, cell biologists and other social scientists as well as the design of studies that create and translate findings from the clinical setting to the laboratory and back again.

Life events and health

Tirril Harris

St. Thomas' Hospital Campus

Introduction

The notion of life events adversely affecting health is deeply embedded in popular consciousness. However among theorists there have been interesting variations. Some early thinkers pursued general theories involving homeostasis, viewing disease in terms of 'illness as a whole'. The best known were Cannon's (1932) fight-flight reaction and Selye's (1956) general adaptation syndrome. These detailed a number of biological responses to environmental demands, presenting them as an orchestrated pattern, almost regardless of the specific nature of these demands. These generalized patterns included responses which were easy to measure in early psychological laboratories, such as heart rate or sweating, and this may partly have accounted for the interest shown in this model of illness. Others pursued theories involving more specificity, believing that particular disorders arise from specific circumstances. During the 1950s this was accepted by followers of Franz Alexander and the school of psychosomatic medicine. Another example was Flanders Dunbar's influential set of ideas that specific personality types were more vulnerable to certain illnesses (Dunbar, 1954). The specificity considered nearly always involved the person's underlying attitude rather than the specific way the environment impinged in the form of a life event. However more recent research has suggested the value of examining the latter in relation to particular health outcomes and this chapter

aims to convey this perspective (see also 'Personality and health' and 'Stress and health').

Life events, difficulties and meaning

One important difference between various perspectives on stress involves what may be called their conceptual level of stress analysis. Five such levels can be distinguished:

- i) Microunit: incidents such as insults, which in aggregate amount to an experience at the next level, such as an estrangement.
- ii) Unit: the basic life event of most research instruments – an estrangement, house-move, job-change, or death.
- iii) Specific qualities of units: what type of event? a loss, humiliation, danger, frustration, challenge, or intrusion? Would it induce guilt or fatigue in most people?
- iv) General qualities of units: less specific characteristics such as positive/negative, severely versus mildly unpleasant.
- v) Person's summary score (not all instruments): where scores are allotted individuals may be characterized in terms of their total experience – say of severely unpleasant events – during a given period.

Level (i), the incident level, is usually identified with the Hassles and Uplifts scale (Kanner *et al.*, 1981). While the distinction between

hassles and uplifts suggests the positive/negative distinction at level (iv), many studies looking at health outcomes with this instrument ignore the effects at level (ii) and it thus becomes difficult to interpret how much stress a person is under at level (v). In other words by concentrating attention on altercations with parking attendants and troubles getting computers to function, this instrument is in danger of missing the impact of more serious experiences such as children leaving home. Most instruments however do operate from level (ii), although the location of inclusion thresholds varies between them. The earliest measure, the Schedule of Recent Experiences (SRE: Holmes & Rahe, 1967) sees life events as anything involving significant change/readjustment, but leaves the estimate of this significance entirely to the respondent: the latter has the ultimate say as to whether a 'serious illness' or a 'loss of someone close' has occurred. This allows bias to creep into the data (collected according to a checklist of 67 events), as the more anxious respondents will define as 'serious' illnesses which more sanguine personalities will consider only minor (say a bout of bronchitis), and respondents who have become depressed look back and redefine their neighbour who has moved to Australia as 'very close', while those who have not suffered depressive onset may continue to feel friendly but not romanticize the degree of closeness of the relationship before the move (Brown, 1974).

The SRE then moves straight up to level (v). Each event on the checklist has been allotted a 'typical life-change unit score' from 0 (no change/distress likely) to 100 (maximum change/distress). Scores for each experience are then summed to give each individual a total score, and this, rather than the occurrence of more specific experiences, is the most frequently used measure employed in analyses of the SRE's impact on health outcomes. Another major disadvantage of this approach is its failure to deal with the meaning of events for individuals: a planned first pregnancy in a secure marital and financial situation has a totally different meaning from an unplanned pregnancy for a single parent where there are already three children, cramped housing and a shortage of money, but both would get the same 'pregnancy' score on the checklist system.

Approaches to stress measurement such as the Life Experiences Survey (Sarason *et al.*, 1978) or the Life Events Inventory (Tennant & Andrews, 1976) which do consider level (iv) can, of course, take account of the difference in the 'undesirability' between two such pregnancies. But they usually leave it entirely to the respondent to define 'undesirable', and here again there are dangers of bias in that sick and well sub-groups may well vary systematically in their self-defined threshold for this. One approach, the Life Events and Difficulties Schedule or LEDS (Brown & Harris, 1978) attempts to capture such variations in the 'context' of the pregnancy without specifically taking account of the actual emotional appraisal of the individual concerned. For this *contextual* method of rating a judgement is made by the investigator about the likely meaning of each event for the person concerned, on the basis of what most people would feel in such a situation, given biography, prior plans and current circumstances, but ignoring what he/she reports as the actual response. Based on a semi-structured face-to-face interview, obtaining a full coherent account of any relevant incident, the interviewer uses a set of previously developed rules embodied in training manuals to decide which of 68 different types of possible event or ongoing difficulty can be

included as having occurred during a defined period (level ii). The verbal interview and the detailed manuals permit an assessment of key stressors which often involve secrets and lies, unbiased by respondent appraisal. They also give the LEDS three other advantages:

- a) an ability denied to simple questionnaires to deal more precisely with the relative timing of stressor and onset/exacerbation of disorder, by allowing cross-questioning and backtracking during the interview; relating symptoms to each other, and to events such as National Holidays (as well, of course, as to other stressful events under study).
- b) a wealth of narrative material which supplements specific probes designed to make distinctions at level (iii) as well as at level (iv), and thus allows analysis by specific sub-types of unpleasant event. This permits exploration within the debate outlined earlier between general and specific theories of the impact of stress on health.
- c) a check on various types of investigator bias, along with control over respondent biases, through manuals with extensive lists of precedents and through consensus meetings with other research workers who are unaware of the subject's symptoms and reactions. This also ensures high rates of inter-rater reliability (Tennant *et al.*, 1979; Parry *et al.*, 1981).

More recently a number of other instruments have adopted this type of contextual interview approach (Dohrenwend *et al.*, 1990; Brugha & Cragg, 1990; Sandberg *et al.*, 1993; Costello *et al.*, 1998) or systematized the approach already employed (Paykel, 1997; Wethington *et al.*, 1996). Because of these advantages the remainder of this chapter will concentrate on findings using this contextual approach (see also 'Stress assessment').

Vulnerability to the impact of life events and difficulties

Reference to the multi-factorial nature of illness aetiology has become like grace before meals, often repeated but rarely followed through. Research still tends to focus on one factor while paying lip service to the others. It will be argued here that the impact of life events on health can only be understood in the light of knowledge about what makes some people more likely than others to become ill after particular types of stressor. In other words without an understanding of vulnerability, understanding of the relationship between stress and health will remain limited.

Early work with the LEDS in Camberwell, London in the late 1960s focused on depressive disorder. Parallel findings in patient and random community female samples identified 'severe events and major difficulties' as factors provoking onset of depression. These *provoking agents* constitute only a small minority of all stressors recorded by the LEDS instrument and largely involved interpersonal crises, such as discoveries of partners' infidelities, children's stealing or estrangements from former good friends or family, but depression was also linked with more material stressors such as threats of eviction or unemployment. It was noteworthy that events such as house moves, not rated severe because they involved only hassle and were only mildly unpleasant, were not associated with depression. Nor were events which were severe in the short but not the

long term, such as a child with a threatened diagnosis of meningitis which turned later out to be migraine. Although extremely distressing during the first few days, such 'non-severe' events were, by definition, largely resolved by the end of two weeks.

A thorough exploration of the background and social network variables suggested that four 'vulnerability factors' might be at work. Two of them involved lack of supportive relationships, the first with a partner currently, the second in the past – loss of mother by death or long-term separation before age 11. The other two – lack of employment and household containing three or more children – were closely linked with current roles, suggesting that women trapped at home were more vulnerable (see also 'Socioeconomic status and health' and 'Social support and health'). Speculation on the common theme uniting these four factors suggested they were all likely to be associated with an intrapsychic state such as poor self-esteem or low mastery. This would cause minor feelings of depression (likely in anyone experiencing such events) to generalize into the full-blown clinical state (for detailed discussion see Brown & Harris, 1978). Subsequent findings offered five types of confirmation concerning this intrapsychic mediator:

- 1) In a later sample self-esteem was deliberately measured at first interview and at follow up those who had shown *negative self evaluation* were nearly three times more likely than the rest to become clinically depressed after a provoking agent (Brown *et al.*, 1986).
- 2) Further exploration of the nature of the provoking agents revealed that it was really losses involving humiliation/entrapment that played the key role, echoing the theme of low self image/powerlessness (Brown *et al.*, 1995; Broadhead and Abbas, 1998; Abbrev Kendler *et al.*, 2003).
- 3) 'Fresh start' events found to precede depressive remission (Brown *et al.*, 1992; Leenstra *et al.*, 1995) seem to represent the opposite process, a sense of renewed self-worth, power and hope.
- 4) The well known doubling of rates of depression among women has been related to differing types of severe events involving their greater entrapment in domestic roles as compared with men (Nazroo *et al.*, 1996).
- 5) The contribution of the third and fourth vulnerability factors seemed to change with alterations in women's roles by the year 2000. With increasing proportions of women in the labour force, though part-time employment is still protective, full-time work no longer is, especially for single mothers (Brown & Bifulco, 1990). Moreover the greater availability of contraception that is free and easier to use, of legal abortion and of nursery places means that having as many as three children is no longer associated with lesser mastery (i.e. of fertility), with being trapped at home nor with depression (Brown, personal communication 2000).

This brief account of the historical development of the LEDS perspective on depression shows how increasing refinement from the side of vulnerability – the move from gross demographic factors such as lack of employment or supportive partner to the allied low self-esteem – can lead to increasing specificity in the nature of the life events seen as critical: from 'severe' in level (iv), to 'humiliation' in level (iii), a type of stress even more likely to resonate with negative self-evaluation than would non-humiliating losses such as adult

children emigrating because of promotion, or markedly reduced family income because of employer's bankruptcy leading to job loss.

Specificity of life-event stress resonates with specificity of vulnerability to produce specific illnesses

The LEDS has now been used to investigate a range of disorders, both psychiatric and somatic, and while there is no space here to go into details it may be of use to highlight particular causal chains which seem to have been identified.

- a) Humiliation/entrapment, low self-esteem and depression (see above).
- b) Danger, vigilance and anxiety disorder (Finlay Jones, Chapter 3 in Brown & Harris, 1989).
- c) Intrusiveness, sensitivity to criticism and schizophrenia (Awaiting further confirmation, Brown & Harris, 1989, chapter 16, p. 451).
- d) Pudicity (or events involving sexual shame) and restricting anorexia nervosa (Schmidt *et al.*, 1997).
- e) Goal-frustration, striving stubbornness and peptic ulcer disease (Craig, Chapter 9 in Brown & Harris, 1989).
- f) Goal-frustration/work difficulties, irascibility/type-A and myocardial infarction (Neilson *et al.*, in Brown & Harris, 1989, Chapter 12).
- g) Challenge, dedication and secondary amenorrhea (Harris in Brown & Harris, 1989, Chapter 10).
- h) Conflict over speaking out, punctiliousness and functional dysphonia (Andrews & House in Brown & Harris, 1989, Chapter 13).
- i) Severe events and functional illness: abdominal pain, menorrhagia and somatization: A number of LEDS studies suggest that the old distinction between functional and organic disorder still has some value. In one early study with patients undergoing appendectomy, pathologists' reports on the appendices were only consulted long after the life events had been rated (Creed in Brown & Harris, 1989, Chapter 8). This lends all the greater credibility to his finding that the same type of severe events associated with depressive onset were more than twice as common in the nine months before appendectomy for those without appendicitis as for both those with acute inflammation and those in a community comparison group. The author suggested that pain in the absence of inflammation may form part of a cluster of psychiatric symptoms in response to a more severely threatening event, as may increases in gut motility (also invoked to account for functional abdominal pain). Further research with a range of gastrointestinal disorders confirmed this perspective (Craig, *op. cit.*). Again those without signs of tissue damage showed a raised proportion with at least one of the severe events associated with depression, while those with other 'organic' conditions resembled the community comparison group. A similar patterning was found for functional menorrhagia, although here the high number with depression meant that a large number of these severe events were humiliations and losses (Harris, *op. cit.*). One study of somatization took particular care to distinguish somatizers with functional somatic symptoms from other mixed physical/psychiatric cases (Craig *et al.*, 1993). Its findings not only

confirmed the picture of preceding severe depressogenic-type events but also highlighted another parallel with depression – a high rate of neglect by parent figures in childhood. However, as children, somatizers in addition, and more often than pure psychiatric cases, had experience of either their own or their parents' physical illness. The authors suggest that these produced the somatizers' particular form of coping with the loss of hope consequent upon the provoking event, namely presenting with a physical symptom, which might have become their habitual way to elicit care and support.

Severe events have also been implicated in the development of such 'organic' conditions as multiple sclerosis (Grant in Brown & Harris, 1989, Chapter 11), stroke (House *et al.*), diabetes mellitus (Robinson & Fuller, 1985) and disease progression in HIV infection (Evans *et al.*, 1997). The evidence for their role in onset/relapse of breast cancer is contradictory (Ramirez *et al.*, 1989), (Barraclough *et al.*, 1992; Chen *et al.*, 1995; Geyer, 1991; Protheroe *et al.*, 1999) (see also 'Psychosomatics').

These findings also suggest that depression may mediate between the occurrence of severe events and the onset of somatic illness, but that this could operate in at least two different ways. First, even though there is no organic tissue damage, it may render people more likely to interpret themselves as ill along the following lines:

Events and difficulties ————— Psychiatric Caseness
 ————— Increased sensitivity to physical
 abnormality/pain without gross organic damage

Second, the results on multiple sclerosis and breast cancer suggest the possibility of a chain of the following kind:

Provoking agent ————— Depression of at least
 borderline – case level ————— Disorders
 consequent on decreased immunological competence

Both of these pathways might be seen as characterized by a measure of 'disengagement' from usual functioning. In other instances, anxiety, anger, and tension may operate as mediating factors, and these might be considered disorders of 'overengagement', such as

ulcers, heart disease and even secondary amenorrhoea (see also 'Coronary heart disease: cardiac psychology').

These diagrams highlight the need to specify the intervening physiological mechanisms serving to relate the emotional meaning of the stress experienced to the biochemistry of the disease. Henry and Stephens (1977) have counterposed the pituitary–adreno–cortical (PAC) and the sympatho–adreno–medullary (SAM) systems, relating the former to conservation–withdrawal (like 'disengagement') and the latter to the fight–flight complex of reactions to stress (more like over-engagement). Calloway and others (1984) reported higher levels of urinary-free cortisol in those of their depressed patients who had undergone a severe event before illness onset, though other reports of basal salivary cortisol in those with recent life events have been conflicting (confirmatory by Strickland *et al.*, 2002; negative by Harris *et al.*, 2000, who did however find higher baseline morning cortisol predicted depressive onset independently of other psychosocial factors). Changes in corticosteroid levels may have 'extensive and complex effects upon the immune system' (Stein *et al.*, 1981), suggesting that studies of physical illness resulting from disorders of immune function should pursue hypotheses involving humiliation, loss, low self-esteem and depressive response (see also 'Psychoneuroimmunology').

In summary, the specificity perspective on life events and health promises to encourage a multi-factorial approach, in which data on life events, meaning and psychosocial vulnerability should be collected alongside detailed physiological data.

Acknowledgements

The life events research described was originally conceived by Professor George Brown, and largely supported by the Medical Research Council. I am indebted to all the members of the research team who have participated in the data collection over the last 20 years, to Laurie Letchford and Sheila Williams for work with the computer and to all those who have taken the trouble to respond to our questions by telling of such painful and private experiences.

Men's health

Christina Lee¹ and R. Glynn Owens²

²The University of Auckland

Why men's health?

Research in psychology, health and medicine has traditionally focused on men, to the neglect of women, but in the process men

have tended to be treated as if they were 'standard human beings', and the effects of the gendered nature of society on men's health have been ignored. This chapter takes the view that a social perspective on men's health needs to focus on gender: what, other than

biology, does it mean to be a man in contemporary society, and how might social and cultural expectations of masculinity affect men's behaviour, their relationships and their physical and emotional health? Systemic gender inequities in income, social responsibilities, social power and access to resources are as influential on men's lives and health as they are on women's (see also 'Gender issues and women's health').

Contemporary men are, to varying degrees, caught between the demands of two sets of social expectations, neither of which is readily compatible with contemporary reality (e.g. Copenhaver & Eisler, 1996). Theorists of masculinity argue for the existence of multiple 'masculinities' reflecting the lives of men from varied ethnic backgrounds, social classes and sexual orientations (e.g. Connell, 1995; Mac an Ghail, 1996). In this chapter, we concentrate on two main social constructions of how men should behave. We contrast the traditionally dominant model of 'hegemonic masculinity' – that model of masculinity which society privileges as 'true' maleness – with modern, egalitarian perspectives on men's 'new' gender roles.

'Hegemonic masculinity' refers to the traditional, patriarchal view of men's behaviour: a man is characterized by toughness, unemotionality, physical competence, competitiveness and aggression. By contrast, modern views of gender relations downplay differences between the sexes, recognizing that many gendered aspects of life are arbitrary, and prescribing that men should find more egalitarian ways of living. This apparently more equitable and permissive model of gender is also problematic, in that it neglects economic, cultural and social forces, ignoring the fact that individual choices are rarely free of constraint.

We argue that neither of these prescriptive masculinities is easy to achieve, that their incompatibilities mean that however a man chooses to lead his life will in some sense be 'wrong', and that one result of this tension is damage to men's health. This emphasis on gender means that a focus on specific illnesses and risk factors is less important than an analysis which deals with the social nature of gender. From a social science point of view, what is important is not that men get prostate cancer and women get breast cancer: it is that men's and women's lives, the contexts within which they experience health and illness, are very different from each other.

Health behaviours and health service use

One of the best established gender differences in health is that men's life expectancy averages three years less than women's (Population Reference Bureau, 2003). However, the size of the gender gap varies between regions. In Eastern Europe, men's life expectancy is 11 years less than women's, while in countries such as Afghanistan, Pakistan and Nepal, it is equal to or greater than women's. This suggests a need to look beyond essential biological differences to explain differences in life expectancy.

Males are certainly biologically weaker than females, as is demonstrated by consistently higher neonatal death rates among males than females. But other causes of death have more complex explanations. For example, coronary heart disease is a leading cause of death for both men and women (e.g. Australian Bureau of Statistics, 2000), but men die younger than women. Explanations exist at biological, behavioural and sociocultural levels. At a biological level, men lack the protective effect of

oestrogen (Dubbett & Martin, 1988). But at the same time, hegemonic masculinity encourages men to adopt attitudes and behaviours which increase risk of coronary heart disease. These include hostile and competitive social relationships, high fat, high alcohol diets and other harmful attitudes and behaviours, chosen at least in part because they enable enactment of a 'male script' (Helgeson, 1995).

The evidence that men lead less healthy lifestyles than women is well established, but is rarely interpreted from a perspective that acknowledges the social pressures on men to conform to unhealthy gender-based stereotypes. Men who make less than optimal health choices are seen as individually responsible. This has led to lack of efforts to improve men's health behaviours, and an assumption that such efforts will be unsuccessful (Courtenay, 1998).

Hegemonic models of gender position a concern for one's health as feminine; men are 'naturally' unresponsive to pain and unconcerned with minor symptoms (Petersen, 1998). Surveys across countries and age groups demonstrate that men engage in more health-damaging behaviours and women in more health-protective behaviours (e.g. Courtenay *et al.*, 2002; Stronegger *et al.*, 1997; Uitenbroek *et al.*, 1996) (see 'Health-related behaviours').

Men make less use of health care and screening services than women, even when gynaecological services are accounted for (e.g. Stoverinck *et al.*, 1996), are slower to acknowledge symptoms of illness (e.g. Gijsbers van Wijk *et al.*, 1999), and are more likely to be 'sent' by their spouse (e.g. Seymour-Smith *et al.*, 2002). This is particularly the case for psychological services; boys are more likely than girls to be taken to a psychologist by parents, but men are less likely than women to seek psychological services for themselves (Jorm, 1994).

Men know less about health than women, and cultural institutions position women as responsible for men's health. Lyons and Willott (1999), for example, have analysed the way in which popular media direct information about men's health towards women, reinforcing the notion that men are incapable of caring for their own health. Loss of a partner, whether through divorce (Umberson, 1992) or widowhood (Clayton, 1990), is associated with more negative changes in health behaviours for men than for women (Byrne *et al.*, 1999). Women's culturally determined willingness to take care of men's health may appear to benefit men but in fact serves to reduce their freedom to make lifestyle choices.

Young men are disproportionately at risk of injury and accidental death (Smith, 1993); they have low levels of health-promoting behaviour and high rates of risky behaviours. Courtenay (1998) has argued that young men should not be dismissed as wilfully negligent of their health, but that social influences should be acknowledged in gender-specific health interventions to help young men make the transition to adulthood safely (see 'Adolescent lifestyle').

Risky behaviour

The major sex differences in death rates are not in disease but in accidents and violence. Hegemonic models of masculinity encourage men to expose themselves to danger, reflecting cultural

constructions which regard these characteristics as superior despite their obvious capacity to harm (Petersen, 1998).

Injuries are significant public health problem (Krug *et al.*, 2000) but social discourse constructs accidental injuries as isolated incidents, rather than the result of gendered patterns of behaviour. Gender differences in risk of accidental injury or death are apparent from early childhood. Several national surveys (e.g. Danseco *et al.*, 2000; Lam *et al.*, 1999) show that boys are twice as likely as girls to be injured or killed in accidents. Adult men are around three times as likely to die from injuries than are women (e.g. Li & Baker, 1996), and these death rates are paralleled by rates of morbidity, hospitalization and disability (e.g. Gardiner *et al.*, 2000).

The excess of men in accidental injury and death statistics is observable whether one focuses on occupational (e.g. Gerberich *et al.*, 1998; Wong *et al.*, 1998), traffic-related (Li & Baker, 1996; Li *et al.*, 1998) or sporting and recreational (e.g. Williams *et al.*, 1998) settings. But in each area of activity, men's higher rates of injury are explicable not by individual men's carelessness but by men's higher exposure to risk. When one accounts for gender differences in exposure, the differences disappear. Thus, it is not the risk behaviours of individual men that require understanding, but the social forces which lead to gender differences in choice of occupation and recreational activity.

Suicide is around four times as common among males than among females at all age groups in all western countries (e.g. Lee *et al.*, 1999), although this gender difference does not appear in Asian countries (e.g. Yip, 1998). Lee *et al.* (1999) showed that suicide rates are highest among migrant, indigenous, gay and other minority men. Marginalization, poverty and social isolation appear to affect men more strongly and negatively than they do women (e.g. Taylor *et al.*, 1998), possibly because such experiences are seen as indicating men's failure to fulfil traditional role expectations of being protector and provider. Higher rates of suicide among men, and young men in particular, are related to higher levels of use of alcohol and other drugs (e.g. Lester, 1995) and risk-taking more generally (Langhinrichsen-Rohling *et al.*, 1998) (see also 'Alcohol abuse' and 'Suicide').

Social roles and health

There is no men's literature that parallels the extensive research on multiple roles in women's lives (e.g. Repetti *et al.*, 1989). Research on social roles has focused on the difficulties faced by women who combine paid work, domestic labour, care of children and care giving for frail or elderly family members (e.g. Doress-Worters, 1994; Lundberg, 1996). By contrast, there appears to be an assumption that men have only one role, that of paid worker, that any other roles are secondary and can be abandoned at any time, and that all men have a full-time unpaid helper who manages all other aspects of their lives. Such assumptions, obviously, do not reflect reality, and many men experience stress and stress-related illness as a result of conflict between social expectations and the reality of their personal and family lives (e.g. Duxbury & Higgins, 1994; Milkie & Peltola, 1999).

A central tenet of hegemonic masculinity is the assumption that a 'real' man will have a full-time, permanent job that supports his family financially (Price *et al.*, 1998). This myth is no longer tenable, but continues to influence both men's and women's concepts of successful masculinity. Men who do not conform to this stereotype are stigmatized and often find it difficult to avoid low self-esteem (e.g. Willott & Griffin, 1997); while the job market has changed, there is an assumption that men without full-time permanent employment are somehow responsible for this. Several studies of the impact on men and their families of systemic unemployment have demonstrated negative effects on men's health, self-esteem and relationships with their families (e.g. Davis, 1993; Dixon, 1998; Lobo & Watkins, 1995) (see 'Stigma').

Unpaid domestic labour is primarily a female activity (e.g. Baxter, 1997). Fathers who do contribute to household labour are most likely to involve themselves with childcare (e.g. Deutsch *et al.*, 1993). Men in role-reversed households enjoy this role but find it difficult, both to define and to carry out (Grbich, 1995; Smith, 1998). Men's active involvement in family life tends to lead to better relationships with their partners and children (e.g. Bailey, 1994; Brody, 1999). However, both broader social structures and individual gender socialization make an equitable approach to parenting and to household labour extremely difficult to put into practice (Smith, 1998).

The majority of men have positive views about fatherhood and family life. Men, like women, generally grow up with the expectation that they will have children (Grewal & Urschel, 1994) and are frequently distressed if they find they are infertile (Webb & Daniluk, 1999). It is argued (e.g. Hawkins *et al.*, 1993) that a closer involvement by fathers in parenting leads to more positive personal development among men, as well as a closer match between men's and women's adult life trajectories, which maintains the quality of their marital relationship (e.g. Kalmijn, 1999).

There is little research that examines the emotional effects on men of becoming fathers, with the focus tending to be on the effect on children of the presence or absence of a father figure in the home (e.g. Clarke-Stewart *et al.*, 2000). The evidence suggests that the majority of parents, both fathers and mothers, find the transitions associated with new parenthood to be challenging and difficult. Ballard *et al.* (1994) found that 9% of fathers were depressed six weeks after the birth, and 5% at six months. Fathers are at greatest risk of depression if their partners have received a diagnosis of depression, while fathers' adjustment problems, like mothers', are strongly related to lack of social support and high levels of economic and work-related pressure (Zelkowitz & Milet, 1997).

Just under half of all first marriages will end in divorce, and the rate for second and subsequent marriages is even higher (e.g. Thompson & Amato, 1999). Divorce and separation are initiated by women more often than by men (Stevens & Gardner, 1994). Men are less likely than women to be emotionally prepared for separation, and divorced men experience worse physical health and have less healthy lifestyles than married men, but this may be explained by pre-existing differences in variables such as alcohol use and aggressiveness, which predispose men towards relationship breakdown (Cheung, 1998). Men who want to

continue to maintain a relationship with their own children face structural and systemic barriers (Pasley & Minton, 1997). Negotiating satisfactory roles and relationships as non-custodial parents, stepfathers and single fathers is a challenge for which there are few successful role models (Pasley & Minton, 1997).

Other issues

The field of men's health covers an enormous range of topics (see Lee & Owens, 2002*a,b*), and space does not permit a consideration even of some of the most important. These include men's sexuality and sexual behaviour, both for heterosexual men and for those with alternative sexual orientations or preferences. They also include issues relating to body image, including eating disorders and the non-medicinal use of steroids. Other topics are the roles and reactions of men in issues surrounding contraception, fertility problems, miscarriage and abortion. There are also issues surrounding criminality and assault, both as perpetrators and as victims. Another area is the particular challenges faced by men leading gay or other alternative lifestyles, and gendered issues surrounding ageing, retirement, frailty, family care giving, widowerhood and facing death are also important.

Conclusion

The purpose of this chapter has been to present an argument for a particular perspective on men and their health: that of focusing on socially constructed concepts of gender and the impacts that these have on individual men's behavioural choices and thus on their health. This may be contrasted with a more traditional, reductionist and 'piecemeal' approach to men's health: the identification of specific, isolated topics to be investigated individually without attention to the social or cultural context.

Strategies to improve men's health can only be developed if gendered differences in behavioural choices are taken seriously, and the underlying differences in men's and women's social worlds adequately explored. This chapter has attempted to demonstrate that men are affected by a sexist and heterosexist society, and by the stereotypes promoted by hegemonic and prescriptive notions of masculinity. Men's choices are further constrained by a social context that values them for their economic productivity rather than for their ability to sustain positive relationships. Research on men's health needs to take these issues into account. Men's lives need to be examined in context, with an awareness of the diversity of men's experiences, in order to develop an inclusive and socially relevant understanding of men's health.

Noise: effects on health

Staffan Hygge

University of Gävle

Noise: nature and measurement

Noise is often defined as unwanted sound or sounds that have an adverse effect on humans. What is sweet music for one person may be noise to someone else. Thus, noise is a psychological construct influenced both by physical and psychosocial properties.

Sound is created by the rapidly changing pressure of air molecules at the eardrum. A single tone, such as that from a tuning fork, can be depicted as a fixed wavelength sinusoidal pressure distribution across time. The number of pressure cycles per second, measured in hertz (Hz), is the basis for the sensation of pitch. A healthy young ear is sensitive to sounds between approximately 20 Hz and up to 20 kHz. The amplitude of the sine wave is perceived as loudness. To accommodate the wide dynamic power range of the human ear a logarithmic magnitude scale for sounds has been introduced. Its unit is the decibel (dB). Adding two independent sound sources of the same dB-level will yield a sum that is ≈ 3 dB higher than one of them alone. The subjective effect of a change in 3 dB amounts to a just perceptible change. A change of around 10 dB is needed to experience the sound as twice as loud.

The hearing threshold for pure tones is lowest in the frequency range 500–4000 Hz, which also is the range where human speech has its maximum energy content. In order to compensate for the ear's frequency sensitivity, and to make units that are comparable across the audible frequency range, standardized weighting curves or filters have been defined for sound level meters (see Fig. 1).

The A-filter, which is the most commonly used filter, is intended to mirror hearing thresholds. The B- and C-filters were made to mirror the ear's sensitivity to intermediate and high intensities, and the D-filter was designed to penalize sounds in the frequency ranges important for human speech. When the low frequency components of a sound dominate, such as in HVAC-noise, dBA underestimates perceived noise.

Several indices have been suggested to represent fluctuating sounds across time. A simple one is that of maximum level, L_{\max} , which can be combined with a number index for how many times a certain L_{\max} -level has been exceeded. The L_p -measure, as in L_1 and L_{50} , states the percentage of time a certain value (in dB, dBA etc.) is exceeded. The equivalent continuous sound pressure level, L_{eq} , is the average constant level across the time period that represents

Fig 1 Standard A-, B-, C- and D-weighting networks for sound level meters.

the total energy of the fluctuating variable sound. L_{eq} -levels are commonly used for codes and regulations and can be weighted to dBA, dBB etc. Because of its logarithmic nature the L_{eq} -measure is strongly influenced by high peak values, but very insensitive to increases in background sound levels.

Many other indices have been proposed (cf. Kryter, 1985). These include attempts to incorporate masking, critical bands, rise-time, predictability, fluctuations and the design of ratio-scales for the measurement of annoyance and perceived loudness.

Auditory health effects

Hearing impairment

Prolonged exposure to intense sounds results in noise-induced hearing loss. Three types of noise induced hearing losses can be distinguished: (1) temporary threshold shifts (TTS); (2) permanent threshold shifts (PTS); and (3) acoustic trauma. TTS show an increase with SPL-levels and exposure time, starting at about 70 dB for noise in the frequency bands around 4 kHz and about 75 dB for bands around 250 Hz when the noise is present for several hours. TTS is reversible but requires silent periods to recover. PTS is the effect of prolonged exposure to high intensity sounds with insufficient silent recovery periods in between. The effect to the inner ear is the irreversible destruction of hair cells. To reduce the risk of PTS most western countries have restricted sound exposure in the work environment to 85 or 90 dBA for eight hours a day, five working days a week for several years when no hearing protection is worn. However, that is not a decision purely guided by the concern to avoid hearing loss, since it has been estimated that around 10% of those so exposed to 85 dBA will accrue a hearing loss. The figure is estimated to drop to 4% if the levels are reduced to 80 dBA. Thus, converging evidence suggests exposure levels of around 75 dBA will be safe from the point of hearing impairment, temporary or permanent.

Noise-induced acoustic trauma involves very short exposure to very intense sounds, such as riveting, gunfire, explosives, toy pistols and clicking toys. These impulse sounds are treacherous because of their short duration, which falls short of the integration time of the brain, but not of the inner ear. Thus, their perceived loudness is much lower than the damage caused to the hair cells in the inner ear.

Degree of hearing impairment is assessed by audiometry, which normally consists of measuring hearing thresholds for pure tones in the frequency range 500–8000 Hz. The resulting audiograms are evaluated against standardized age-corrected audiograms for unimpaired hearing. Hearing impairment caused by broadband noise often starts in the frequency range 3000–6000 Hz, with a downward spread to 500–1000 Hz as the impairment grows worse. A slight impairment in the 3000–6000 Hz range does not much affect speech comprehension in an otherwise silent environment. However, when the frequency ranges from 2000 Hz and downwards is affected, speech comprehension is markedly reduced. Hearing impaired persons and persons who do not fully master the language spoken may need up to a 10 dB better signal-to-noise ratio than normal hearing persons to understand speech.

During recent decades, noisy leisure activities rather than industrial work noise, have become more important as contributors to hearing impairment. In particular guns and rifles, explosives, chain-saws, lawn-mowers, snow mobiles, water scooters, loud concert and disco music and certain toys with loud click sounds may cause hearing impairment by itself or by blocking recovery from TTS accrued at work (see 'Deafness and hearing loss').

Non-auditory health effects

The World Health Organization defines health as the state of complete physical, mental and social wellbeing, not merely as an absence of disease and infirmity. Therefore, the health effects of noise include a broader array of adverse effects than damage to organs and tissue.

Stress reactions and cardiovascular disorders

Noise has often been implicated as a contributing cause to the development of stress reactions and cardiovascular disorders. Correlational studies report higher systolic or diastolic blood pressure (BP) or elevated stress hormone levels in hearing-impaired or noise-exposed industrial workers (Evans & Cohen, 1987). Children and adults chronically exposed to aircraft noise have been found to have higher BPs and elevated levels of stress hormones compared with controls matched on sociodemographic characteristics (Cohen *et al.*, 1986). Correlational and cross-sectional studies suffer from methodological flaws, primarily from possible selection bias and inability to rule out other possible causes for the stress reactions and cardiovascular disorders, such as a hazardous chemical environment and other stress inducing work-related factors. Experimental studies, which for practical and ethical reasons must be restricted to acute rather than chronic noise effects, show noise effects on several non-specific physiological measures associated with stress reactions, including BP, heart rate, stress hormone output and vasoconstriction. These reactions habituate to a large extent and thus it is not clear how they can build up to a chronic effect (Evans & Cohen, 1987). However, stress reactions to chronic noise exposure have been shown in an experimental study by Peterson *et al.* (1981). Rhesus monkeys were exposed to loud noise for nine months. BPs increased by one third and high BP-levels were maintained for a one-month follow-up period after noise cessation.

It is probably fair to conclude that chronic exposure to high intensity noise increases the risk of cardiovascular problems. Because of this and of fairly well controlled studies where noise has also been shown to increase secretion of stress hormones (Stansfeld & Lercher, 2003), also in children, it can be claimed that noise plays a role in a general stress response. Since detailed dose-response relationships are not fully specified this conclusion must be restricted to high-intensity noise at this point (see also 'Stress and health'). With regard to other medical symptoms reportedly linked to noise, e.g. ulcers, miscarriage, weight at birth, consumption of medication, visits to doctors, infectious diseases, the evidence is still too meagre to be conclusive (Cohen *et al.*, 1986).

Mental health

Since noise affects annoyance and prolonged annoyance may cause mental problems, it has been argued that noise may impair mental health. Studies on mental health or mental hospital admissions around Heathrow airport in London, Schiphol in Amsterdam and the different airports in Los Angeles, give correlational support for such claims. However, in most of these cases critics have shown that stringent and proper controls for sociodemographic variables diminish the correlations between noise levels and various indices of mental health. Thus, the results are conflicting and there is as yet no solid empirical basis for arguing a strong direct effect of noise on mental health (Stansfeld & Lercher, 2003).

Sleep

Sleep and sleep quality is among the most noise-sensitive human activities. From laboratory studies it has been concluded that 20–35% of normal and self-reported noise sensitive persons have problems falling asleep, change sleep stage or are awakened by a number of peaks as low as 50 dBA (Öhrström, 1993). There seems to be some agreement that peak levels below 40 dBA or equivalent noise levels below 35 dBA L_{eq} , do not have much effect on sleep. However, field studies indicate much less noise induced sleep disturbance (Griefahn & Schuette, 2003), which partly may be due to less refined sleep recording techniques in the field.

People who are drowsy or sleeping have difficulties in actively identifying and recognizing sounds, and consequently they have a problem in adapting or habituating to sounds. Children change sleep stages less often than adults because of noise and are less easily awakened than adults, but the opposite is true for the elderly. Effects of sleep deprivation on task performance the next day vary with the difficulty of the task, but no conclusive dose response relationships can be stated at this time (see ‘Sleep and health’ and ‘Sleep disorders’).

Performance and cognition

The traditional findings from laboratory noise studies are that fairly high noise levels (80–90 dB in intermittent bursts) are needed to show effects on attention, signal-detection, vigilance, short term-memory etc. (see reviews by Broadbent, 1983; Jones, 1990; Smith, 1993; Hygge, Jones & Smith, 1998). However, recent studies, both in the laboratory and in the field, have changed that picture both by scrutinizing the nature of the disturbing sound and by introducing more cognitively demanding tasks (reading, memory). Further, during the last decade noise impacts on children’s cognition have been a focus of attention.

In experiments on speech-like noise and short-term memory serial recall, a set of 7–9 digits or letters is presented visually at a fixed rate. A rehearsal period is inserted between the presentation of the last item in the set and a prompt to reproduce the series in correct order. Speech in the rehearsal period, even devoid of semantic content such as a foreign tongue, or vocals in a song, interferes with recall, but broadband noise does not (see overviews by Jones & Macken, 1993; Jones & Morris, 1992). The effect is stable across sound levels ranging down to around 50 dBA, and has been shown to extend to a range of non-speech sounds that have speech-like

level fluctuations (Hughes & Jones, 2003). However, the serial nature of the memory task seems to be crucial. The effects of irrelevant speech on more cognitive tasks such as proofreading and understanding are not as marked and are less consistent.

Classroom experiments of recall memory in children aged 12–14 years one week after a 15-minute learning session in noise (Hygge, 2003) showed impairment from aircraft and road traffic noise at 66 dBA L_{eq} and from aircraft noise at 55 dBA L_{eq} . No impairment was found from exposure to train noise and verbal noise, nor did any of the noise sources affect long-term recognition. In a larger study of noise effects on many different memory tasks, with children, young adults, middle aged and older teachers (Boman *et al.*, 2005) it was shown that language-based memory for texts was more sensitive to noise impairment than other memory tasks, that road traffic noise and irrelevant speech was about equally harmful, and that the relative noise impairment was roughly equal across age groups.

The results from these laboratory studies fit nicely with findings from field studies of children living in the vicinity of some European airports. In a longitudinal prospective study around the old and new airports in Munich (Hygge *et al.*, 2002), noise-exposed children at the old airport were found to improve their initially lower cognitive performance in memory and reading compared with that of the control group after the airport closed down. At the new airport, the reverse was true. Before the opening of the new airport, there were no differences in reading and memory tasks between the prospective noise-exposed group and their quiet control group, but after the new airport had opened the noise-exposed children started to lag behind their controls. In a cross-sectional comparison between three European airports, Stansfeld *et al.* (2005) found similar effects of aircraft noise exposure, but not for road traffic noise exposure.

The vulnerability of language acquisition and mastery, memory and reading to noise exposure, particularly in children, fits in well with findings from other cross-sectional studies of school achievement and cognitive performance in noisy and less noisy areas (Evans & Lepore, 1993).

In a well known series of experiments, Glass and Singer (1972) reported performance after-effects on the number of times their subjects attempted to solve insoluble geometric puzzles and proof-reading errors. The noise they used was a mixture of office machines and foreign languages presented in aperiodic bursts in intensity ranges from 60–108 dBA depending on experiment. Their main findings were that the noise had deleterious effects on post-noise behaviour when the noise was uncontrollable or unpredictable by the subjects. The introduction of perceived control by making the noise predictable or controllable eliminated the adverse noise effect even when compared with a silent control group. These adverse effects of uncontrollable and unpredictable noise have been replicated in several studies for various types of noise, as well as for stressors other than noise (Cohen, 1980). Thus, research on the after-effects of noise points to psychological coping mechanisms that may be basic and central to others stressors as well.

Social behaviour

In the laboratory, noise has consistently interacted with anger in provoking aggression as measured by the delivery of electric

shocks to a confederate of the experimenter (Cohen & Spacapan, 1984). That is, the presence of noise at the time of aggression is not by itself sufficient for increased aggression, but when the subject is made angry the presence of noise adds to the aggression shown. For helping behaviour, a mixture of experimental studies in the field and the lab show less helping when exposed to noise. However, the noise effect on helping is not as consistent and marked as that on aggression.

Theoretical accounts of the noise effects

There are detailed and well documented empirical findings of how physical energy of a certain intensity, frequency composition, duration, onset-time etc. causes certain amounts of hearing impairment, but there is no good comprehensive theory as to why and how.

Stress theories adapted to explain noise effects have two sides to them. One side explores the physiological effects, the other the psychological outcomes. The physiological theories have pointed to the roles played by epinephrine and norepinephrine secretion in the activation of the sympathetic-adrenal medullary system, and to hormone output from the pituitary-adrenocortical axis (Evans & Cohen, 1987). Psychological stress theories such as Lazarus (1966) view the person's psychological appraisal of a stimulus as threatening as a first stage, followed by a stage where the individuals evaluate their resources to cope with the threat. If they perceive that they can cope, no stress response occurs, but they may later reappraise their coping ability. If they do not perceive that they can cope or are uncertain, stress is experienced (see 'Stress and health').

Psychological theories of the performance effects of noise have relied primarily on two constructs: arousal and informational load. Arousal refers to nonspecific brain activity signifying different levels of general alertness. The Yerkes-Dodson law (Kahneman, 1973) of arousal and performance assumes an inverted U-relationship

between performance and arousal. Too high or too low arousal, with reference to the optimum level, impairs performance, but the exact optimal level depends on the difficulty of the task and individual skill in carrying out the task. Arousal theory and the inverted U-hypothesis suffer from several shortcomings (Hockey & Hamilton, 1983), including the multidimensionality of the construct and the problem of finding data-independent locations of the optimum level. On the other hand it is a convenient theoretical vehicle to accommodate combined and interactive effects of many different stressors, noise just being one.

Another line of theorizing (Smith, 1989) has emphasized a dominant strategy selection, and reduced efficiency in the control processes while working in noise. In information overload models (Cohen *et al.*, 1986), an emphasis is put on shrinking cognitive capacity as a result of attention allocation during noise and stress exposure, and the individual's adaptation to demands on information processing. One implication of this theory is that cumulative cognitive fatigue effects should show up as residuals also after the cessation of the noise, as in after-effects of non-controllable noise. Another important implication of the model is that both noise itself as a stressor plus individual efforts to cope with the noise can create adverse effects. Recently, there has also been some theoretical advancement into the area of noise and its effects on memory structure (Enmarker, Boman & Hygge, 2006).

Further reading

Pain: a multidimensional perspective

Dennis C. Turk and Tasha Burwinkle

University of Washington

Pain has been the focus of philosophical speculation and scientific attention since earliest recorded times. Yet, despite its history, advances in knowledge of neurophysiology and biochemistry, and the development of potent analgesic medications and sophisticated invasive modalities that have evolved, pain relief remains elusive. On average fewer than 50% of patients obtain at least a 30% reduction in pain following treatment with potent medications, pain reduction following rehabilitation averages around 30% (Turk, 2002a). Pain remains a perplexing and challenging problem for pain sufferers, their significant others, healthcare providers and society.

Although pain is an almost universal experience, there is little consensus even with regard to how to define it. Historical debates have raged back to the time of the ancient philosophers as to whether pain was a purely sensory or uniquely affective phenomenon. Arguments have persisted and the conceptualization of pain has more than philosophical consequences; it will affect how pain is assessed and how and even whether pain is treated.

One factor that has contributed to the debate about what pain is relates to the fact that it is a subjective experience. Unlike temperature, there is no 'pain thermometer' to determine the extent of pain that an individual has or should have. The only way to know how

much pain someone has is to ask them and to make inferences from observation of their behaviours (see 'Pain assessment'). Another difficulty with understanding and treating pain is that it is associated with many diseases and may result from diverse sources of pathology. Moreover, the report of pain is common even in the absence of definitive physical pathology.

Another factor that has contributed to confusion relates to differential characteristics of pain. For example, pain is frequently viewed along a time continuum; acute pain, defined by its relatively brief duration (e.g. days), to sub-acute pain (e.g. months), to chronic (years) (Turk & Okifuji, 2001). Other specific variations or classifications are noted. People with migraine have episodes of severe pain that may last for hours interspersed with periods where the individual is pain free – recurrent acute pain. Pain is also associated with malignancies. This is a unique category due to the special meaning attributed to potentially lethal conditions although the mechanisms involved may be no different than those involved with other pain syndromes (Turk, 2002a).

Other distinctions are made between pain associated with neurological damage (neuropathic pain), musculoskeletal perturbations (nociceptive pain) and visceral pain having components of both (Woolf & Mannion, 1999).

The distinction between those whose symptoms are attributed to physiological in contrast to psychological factors (psychogenic) has a long history. Sub-groups of patients based on type of onset, for example, traumatic versus idiopathic have also been discussed (Turk *et al.*, 1996).

The ways of classifying subtypes of pain and pain sufferers are important because they illustrate the differential contributions of affective, cognitive and behavioural, as well as sensory factors. The transient pain associated with a time-limited procedure (e.g. needle injection) is not likely to generate the same degree of emotional arousal as pain such as the chronic pain associated with cancer. Patients with acute pain may be aware of the cause of the pain and expect resolution in a known timeframe; whereas for patients with chronic back pain, the cause may be unknown, the time course is indefinite and treatments are inadequate. Interpretations of the meaning of the pain and expectancies for the future will influence behavioural responses; and it has been shown to influence physiology associated with the transduction of sensory information which is interpreted as pain (e.g. Flor *et al.*, 1985) as well as neurotransmitters (Bandura *et al.*, 1987).

Focus on chronic pain

For the person experiencing chronic pain, there is a continuing quest for relief that often remains elusive, leading to feelings of helplessness, hopelessness and depression. Significant others share the frustration as pain persists in their loved one with no end in sight. Healthcare providers share these feelings of frustration as patients' reports of pain continue despite the provider's best efforts. On a societal level, pain creates a significant burden in lost productivity and disability benefits. Third-party payers are confronted with escalating medical and disability costs and experience irritation when patients remain disabled despite extensive and

Table 1. Pain: magnitude of the problem

Prevalence of chronic pain	<ul style="list-style-type: none"> • Almost 1 in 5 adult Americans (30 million) experience chronic pain (Joranson & Lietman, 1994) • Thirty-one million Americans have low back pain at any given time (Jensen <i>et al.</i>, 1994) • Over 11 million American suffer from recurring episodes of migraine headaches (Stewart <i>et al.</i>, 1991) • One in four Americans (23%) experience joint pain daily or every few days (Arthritis Foundation, 2002) • 46% of women and 37% of men experience pain daily (Arthritis Foundation, 2002) • Back pain ranks 6th among all reasons for office-based physician visits, accounting to 17.4 million visits (23% of all visits) per year (Cherry <i>et al.</i>, 2001) • Approximately 23 million Americans suffer from CLBP (Latham & Davis, 1994), and it is responsible for 40% of all visits to orthopaedists and neurosurgeons (Cavanaugh & Weinstein, 1994)
Costs of chronic pain	<ul style="list-style-type: none"> • Annual direct costs associated with migraine in the US have been estimated at \$1 billion, while indirect costs amount to \$13 billion (1993 prices) (Hu <i>et al.</i>, 1999) • Patients with rheumatoid arthritis are estimated to incur over \$14 billion (2000 prices) in medical expenditures and work loss (Lubeck, 2001) • The costs of low back pain are estimated to be \$50 billion yearly (Back Pain Patient Outcomes Assessment Team, 1994) • Costs attributed to chronic pain (e.g. treatment, lost work days) are \$215 billion per year in the United States (American Academy of Orthopaedic Surgeons, 1999)
Workdays lost due to chronic pain	<ul style="list-style-type: none"> • Clinic-based patients with migraine lose 19.5 workday equivalents per year (Gerth <i>et al.</i>, 2001) • Among US workers, everyday pain accounts for 50 million sick days per year (Louis Harris and Associates, 1996) • More than 1 million Americans were out of work in 1999 because of musculoskeletal pain (National Research Council, 2001)

expensive treatment and rehabilitation efforts. In short, pain is a major health problem in society that affects millions of people and costs billions of dollars (Table 1).

With such astronomical figures, it is easy to lose sight of the incalculable human suffering accompanying chronic pain for both pain sufferers. The emotional distress that is prevalent may be attributed to a variety of factors, including inadequate or maladaptive coping resources; iatrogenic complications; overuse of medication; disability; financial difficulties; litigation; disruption of usual activities; inadequate social support and sleep disturbance. Moreover, the experience of 'medical limbo' – that is the presence of a painful condition which eludes diagnosis and which carries the implication of either psychiatric causation or malingering, on the one hand, or an undiagnosed life-threatening disease on the other – is in itself the source of significant stress which can initiate, exacerbate and maintain emotional distress.

In sum, chronic pain is a demoralizing situation that confronts the person not only with the stress created by pain but with a cascade of ongoing stressors that compromise all aspects of the life of the sufferer. Living with chronic pain requires considerable emotional resilience, tends to deplete emotional reserves and taxes

not only the pain sufferer but also the capacity of significant others to provide support (see 'Coping with chronic pain').

Alternative conceptualizations

In order to understand the basis for the current treatment of pain, it is useful to consider several alternative conceptualizations. These can be loosely grouped into single factor models that focus on a particular cause of the symptoms (i.e. the biomedical, psychogenic, motivational and behavioural models) and multidimensional models that emphasize the contributions of a range of factors that influence patients' experiences and reports of pain (i.e. Gate Control Theory and the biopsychosocial model).

Biomedical model

The biomedical (sensory) conceptualization of pain dates back thousands of years and is based on a simple linear view that predicated on a close correspondence between a biological state and symptom perception. From this perspective, the extent of pain severity is presumed to be proportionate to the amount of tissue damage. As a consequence, treatment consists of eliminating the physical cause of the patient's pain or disrupting the putative pain pathways.

There are several perplexing features of persistent pain that do not fit cleanly within the biomedical model. A particular conundrum is the fact that pain may be reported even in the absence of identified physical pathology, such as is the case of back pain. Conversely up to 35% of people with observed pathological processes remain asymptomatic (e.g. Jensen *et al.*, 1994). It has been suggested that the presence of pain may alter the peripheral and central nervous systems such that they become hypersensitive to normally non-noxious stimuli or it may lower the threshold for noxious stimuli to be perceived as painful (Woolf & Mannion, 1999). Methods for detecting the underlying mechanisms involved in humans are not well established and the postulated changes in the nervous system remain to be demonstrated (Terman & Bonica, 2001).

Psychogenic model

As is frequently the case in medicine, when physical explanations prove inadequate, psychological alternatives are imputed. If the pain reported is 'disproportionate' objective physical pathology or if the complaint is recalcitrant to 'appropriate' treatment, then it is assumed that psychological factors must be involved. Several variants of psychogenic aetiologic models have been proposed. For example, a postulate of a 'pain-prone' personality (Engel, 1959) suggests that persistent complaints occur in people who are predisposed to experience pain due to maladaptive child-rearing practices, physical or sexual abuse and longstanding personality characteristics.

Based on the psychogenic perspective, assessment of chronic pain patients is directed towards identifying the psychopathological tendencies that instigate and maintain pain. Treatment is geared towards helping patients achieve 'insight' into the psychological contributors (e.g. Basler *et al.*, 2002). Empirical evidence to support this model is scarce. In fact, evidence suggests although emotional distress is prevalent in chronic pain patients (M. Sullivan &

Turk, 2001), the emotional distress observed more typically occurs in response to pain and not as a causal agent (e.g. Fishbain *et al.*, 1997) and may resolve once pain is adequately treated (Wallis *et al.*, 1997). Furthermore, there is no evidence demonstrating that insight-oriented psychotherapy successfully reduces symptoms for the majority of patients with chronic pain. The psychogenic model is silent on the observation that a substantial majority of people who have been exposed to potentially destructive and traumatic childhood experiences never develop chronic pain syndromes.

Motivational model

The motivational perspective, ascribed to by many third-party payers, suggests that a pain complaint in the absence of physical pathology indicates that the patient is intentionally seeking secondary gains (malingering, exaggerating) such as attention or financial compensation (Fishbain, 1994). In this case, treatment consists of denial of disability payments that is believed to resolve symptom complaints. There is scant evidence, however, to support this claim (Mendelson, 1982).

Classical (respondent) conditioning

In the classical or 'respondent conditioning' model, if a painful stimulus is repeatedly paired with a neutral stimulus, the neutral stimulus will come to elicit a pain response. For example, a patient who received a painful treatment from a physical therapist (PT) may become conditioned to experience a negative emotional response to the presence of the PT and to any stimulus associated with painful stimuli. The negative emotional reaction may instigate muscle tensing, thereby exacerbating pain, and further reinforcing the association between the PT and pain. Fear of movement has been reported to be more disabling than the pain itself (Crombez *et al.*, 1999).

Treatment based on this model consists of repeatedly engaging in behaviour (e.g. exposure) that produces progressively less pain than was predicted (corrective feedback), which is then followed by reductions in anticipatory fear and anxiety associated with the activity (i.e. desensitization) (Vlaeyen *et al.*, 1995). In this way, patients progressively increase their activity, despite fear of injury and discomfort associated with the use of deconditioned muscles.

Operant conditioning

The operant conditioning model (Fordyce, 1976) proposes that when an individual is exposed to a stimulus that causes tissue damage, the immediate response is withdrawal and attempts to escape. This may be accomplished by observable behaviours such as avoidance of activity believed to cause or exacerbate pain, help-seeking and so forth. The operant model does not concern itself with the initial cause of pain. Rather, it considers pain a subjective experience that may be maintained even after the physical cause of pain has resolved. The operant model focuses on expressions of pain ('pain behaviours' – e.g. limping).

According to the operant model, positive reinforcement (e.g. attention from others, avoidance of undesirable or feared activities) may maintain the pain behaviours even in the absence of

nociception itself. In this way, respondent behaviours that occur following an acute injury may be maintained by reinforcement.

The behavioural principle of stimulus generalization is also important as patients may come to avoid more and more activities that they believe are similar to those that previously evoked pain. Reduction of activity leads to greater physical deconditioning, to more activities eliciting pain and consequently to greater disability. Moreover, it is likely that the deconditioning resulting from reinforced inactivity can result directly in increased noxious sensory input. Muscles that were involved in the original injury generally heal rapidly but due to under-use of these muscles, they become weakened and subject to noxious stimulation when called into action. Studies have provided evidence that supports the underlying assumptions of the operant model (e.g. Keefe *et al.*, 1992). The operant model has, however, been criticized as inadequate (e.g. Schmidt *et al.*, 1989).

A fundamental problem with the operant approach in practice is the emphasis on pain behaviour rather than pain per se because observed behaviours are then used as the basis to infer something about the internal state of the individual – that the behaviours are communications of pain (Turk & Matyas, 1992). In this case, however, there is no way of determining whether the behaviour results from pain or from a structural abnormality. Limping, for example, from the operant perspective, is viewed as a pain behaviour; however, this is an inference. It is possible that limping is the result of physical pathology and has no direct association with pain. (See also ‘Behaviour therapy’.)

Social learning model

According to the social learning model, the acquisition of pain behaviours occurs through observational learning. Children, for example, learn how others respond to pain. Based on these ‘models’, they may be more or less likely to ignore or over-respond to symptoms they experience (Craig, 1986). Expectancies and actual behavioural responses to painful stimulation are based, at least partially, on prior social learning history. Even physiological responses may be conditioned during observation of others in pain (Vaughan & Lanzetta, 1980).

Incompleteness of common models

The models briefly described are not wrong; rather they are incomplete. The inadequacies of these models have initiated attempts to reformulate thinking about pain. Healthcare providers, lay people and third-party payers have long considered pain as being synonymous with physical pathology. It is important, however, to make a distinction between nociception, pain and suffering.

‘Nociception’ refers to the peripheral sensory stimulation in nerves that conveys information about tissue damage. This information is capable of being perceived as pain. ‘Pain’, because it involves conscious awareness, selective abstraction, appraisal, ascribed meaning and experience, is best viewed as a perceptual process. ‘Suffering’ includes interpersonal disruption, psychological distress and a myriad of other factors associated with perception of the impact of pain on one’s life and future (Turk & Fernandez, 1997). From this description, it should be apparent that there is no direct

link between nociception, pain and suffering. Rather, the extent of pain and suffering is associated with an interpretive process.

The variability of people’s responses to nociceptive stimuli and treatment is more understandable when we consider that pain is a personal experience influenced by attention, anxiety, prior learning history, the meaning and other physiological and environmental factors, as well as physical pathology (Turk & Monarch, 2002). Biomedical factors, in the majority of cases, appear to instigate the initial report of pain. Over time, however, psychosocial and behavioural factors may serve to maintain and exacerbate levels of pain, and influence adjustment and disability. Following on from this view, pain that persists over time should not be viewed as either solely physical or psychological; rather, the experience of pain is maintained by an interdependent set of biomedical, psychosocial and behavioural factors.

Gate control model

The gate control model contradicts the notion that pain is either somatic or psychogenic, rather it postulates that both factors have potentiating and moderating effects. Melzack and his colleagues (Melzack & Casey, 1968; Melzack & Wall, 1965) emphasize the modulation of pain by peripheral and central nervous system processes. Prior to this formulation, psychological processes were largely dismissed as reactions to pain. Melzack and Casey (1968) differentiated three systems related to the processing of nociceptive stimulation – motivational–affective, cognitive–evaluative and sensory–discriminative – all thought to contribute to the subjective experience of pain.

After the gate control model was first described in 1965, no one could try to explain pain exclusively in terms of peripheral factors. However, the physiological details of the gate control model have been challenged (e.g. Price, 1987). Nevertheless, it has had a substantial impact on basic research and in generating treatment modalities.

Biopsychosocial model

Although the gate control model introduced the role of psychological factors in the maintenance of pain symptoms, it focused primarily on neurophysiology. The biopsychosocial model, by extension, adds in cognitive, affective and behavioural components of pain and it views illness as a dynamic and reciprocal interaction between biological, psychological and sociocultural variables which shape the person’s response to pain (Turk & Monarch, 2002).

The biopsychosocial model is unique, in that it takes into consideration the influence of higher order cognitions. It accepts that people are active processors of information, and that behaviour, emotions, and even physiology are influenced by interpretations of events, rather than solely by physiological factors. People with chronic pain may therefore have negative expectations about their own ability and responsibility to exert any control over their pain. Moreover, pain sufferers’ behaviours elicit responses from significant others that can reinforce both adaptive and maladaptive modes of thinking, feeling and behaving.

The biopsychosocial model has led to the development of treatment interventions based on a cognitive–behavioural perspective (Turk, 2002b). According to this perspective, patient’s attitudes,

beliefs and unique schema filter and interact reciprocally with emotional factors, sensory phenomenon and behavioural responses. Moreover, patients' behaviours elicit responses from significant others that can reinforce both adaptive and maladaptive modes of thinking, feeling and behaving.

Similar to the operant model of chronic pain, the most important focus of the cognitive-behavioural perspective is on the pain sufferer, rather than on only symptoms or pathophysiology. Unlike the operant model, however, the cognitive-behavioural perspective places a great deal of emphasis on people's idiosyncratic beliefs, appraisals and coping repertoires, as well as sensory, affective and behavioural contributions, in the formation of pain perceptions.

For chronic pain sufferers, certain ways of thinking and coping are believed to influence the perception of nociception, the distress associated with it, or factors that may increase nociception directly. Pain that is interpreted as signifying ongoing tissue damage or life-threatening illness is likely to produce considerably more suffering and behavioural dysfunction than pain that is viewed as being the result of a minor injury, although the amount of nociceptive input in the two cases may be equivalent.

In addition to triggering or aggravating nociception directly, psychological factors also have indirect effects on pain and disability. Chronic pain sufferers can develop ways of thinking and coping that in the short-term seem adaptive, but in the long-term serve to maintain the chronic pain condition and result in greater disability. As noted, because the fear of pain is aversive, the anticipation of pain is a strong motivator for avoidance of situations or behaviours that are expected to produce nociception. Moreover, the belief that pain signals harm further reinforces avoidance of activities believed to cause pain and increase physical damage. Through the process of stimulus generalization, more and more activities are avoided to prevent exacerbation of pain. The undesirable result of this avoidance is greater physical deconditioning and increased disability.

Inactivity may also lead to preoccupation with the body and pain and these attentional changes increase the likelihood of amplifying and distorting pain symptoms and perceiving oneself as being disabled. At the same time, the pain sufferer limits opportunities to identify activities that build flexibility, endurance and strength without the risk of pain or injury. Moreover, distorted movements and postures used to avoid pain can cause further pain unrelated to the initial injury. Avoidance of activity, although it is a seemingly rational way to manage a pain problem, can play a role in facilitating nociception and disability when maintained for extended periods (Vlaeyen *et al.*, 1995).

When chronic pain sufferers develop negative expectations about their own ability to exert control over their pain, these expectations instantiate feelings of distress when 'uncontrollable' pain interferes with participation in activities. Pain sufferers frequently terminate efforts to develop new strategies to manage pain and instead turn to passive coping strategies such as inactivity and self-medication to reduce emotional distress and pain. They also absolve themselves of personal responsibility for managing their pain and instead rely on significant others including healthcare providers. Those who feel little personal control over their pain are also likely to 'catastrophize' about the impact of pain-flare episodes and situations that might initiate or exacerbate pain. Catastrophizing includes over-evaluating

Table 2. Characteristics of treatments based on the Cognitive-Behavioural perspective

<ul style="list-style-type: none"> • Problem-oriented • Behaviourally focused • Time-limited • Educational • Collaborative (patient and health care provider work together) • Make use of in-clinic and home practice to identify problems and consolidate skills • Emphasize maintenance and generalization

and over-reacting in a negative, maladaptive manner, as if even relatively small problems were major catastrophes (Sullivan *et al.*, 2001). Catastrophizing has been related to greater pain, disability and emotional distress independent of physical pathology (Severeijns *et al.*, 2001).

Thus, pain sufferers often develop negative, maladaptive appraisals about their condition and personal efficacy in controlling their pain. Problems associated with pain reinforce their experience of distress, inactivity and over-reaction to nociceptive stimulation. In contrast, persons who believe that they are able to control the situations that contribute to pain flare-ups are more resourceful and are more likely to develop strategies (the self-management strategies described below) that are effective in limiting the impact of painful episodes and thus are able to reduce the impact of the pain problem.

To summarize, the cognitive-behavioural perspective takes a broad view of pain that focuses on the person and not just the symptom. Persistent pain, like any chronic disease, extends over time and affects all domains of the person's life. Rather than focusing on cognitive and affective contributions to the perception of pain in a static fashion, as in the gate control model, or exclusively on behavioural responses and physical pathology as the sensory and operant conceptualizations, respectively, do, the cognitive-behavioural conceptualization posits the interaction of ongoing physical, cognitive, affective and behavioural factors (Turk, 2002b).

The cognitive-behavioural perspective offers a heuristic way of thinking about people who suffer from chronic pain. There has been a growing body of evidence supporting the efficacy of treatment based on the cognitive-behavioural perspective for diverse chronic pain syndromes (Morley *et al.*, 1999); however, there is wide diversity of the specific techniques incorporated with treatment. Table 2 lists features that appear to be consistent across the different treatment protocols that can be ascribed to the cognitive-behavioural perspective and Table 3 the targets of intervention (Turk, 2002b). The methods used to accomplish these vary. (See also 'Cognitive behavioural therapy' and 'Pain management'.)

Summary and concluding comments

The unidimensional models of pain that focus on only one aspect of pain, whether it be sensory, affective or behavioural, seem inadequate to explain such a complex phenomenon. More recently

Table 3. Targets of Cognitive-Behavioural treatment

- Reconceptualization of patients' views of their problems (pain and others) from overwhelming to manageable (Combat demoralization)
- Convince patients that the skills necessary for responding to problems more adaptively will be included in the treatment (Enhance motivation and outcome efficacy)
- Change patients views of themselves from passive, reactive, and helpless to active, resourceful, and in control (Foster self-efficacy)
- Ensure that patients learn how to monitor their thoughts, feelings, behaviour, and physiological reactivity and learn the interrelationships among these (Break-up maladaptive patterns)
- Teach patients how to and when to use necessary overt and covert behaviours required for more adaptive responding (Skills training)
- Encourage patients to attribute success to their own efforts
- Anticipate problems and discuss these and ways to cope with them (Facilitate maintenance and generalization)

attempts to integrate the range of medical-physical, psychosocial and behavioural factors within a broad multidimensional framework

have been made and a body of research appears to support the appropriateness of these conceptual models, at least in chronic pain.

Patients all come to treatment with diverse sets of attitudes, beliefs and expectancies. Research suggests that the importance of addressing these subjective factors is likely to influence how patients present themselves and respond to treatments offered. Viewing all patients with the same medical diagnosis as similar is likely to prove unsatisfactory. It would seem prudent to (1) attempt to identify pain patients' idiosyncratic beliefs, (2) identify the environmental contingencies of reinforcement, (3) address those beliefs and environmental relationships that are maladaptive, and (4) match treatment interventions both to physical characteristics of the diagnosis and also to relevant psychosocial and behavioural ones (Turk, 1990).

Perceived control

Kenneth A. Wallston

Vanderbilt University Medical Center

Perceived control (also referred to as an internal locus of control orientation, perceived personal control, perceived competence, self-efficacy or a sense of mastery) has been defined as the belief that one can determine one's own internal states and behaviour, influence one's environment and/or bring about desired outcomes (Wallston, Wallston, Smith & Dobbins, 1987). If people say that things are under their control, they are saying that they are able to determine or influence important events or situations (Walker, 2001), including their own actions or those of other people.

Perceived control has long been 'recognized as a central concept in the understanding of the relationships between stressful experience, behaviours and health. Experimental investigations indicate that control over aversive stimulation has profound effects on autonomic, endocrine and immunological responses, and may influence the pathological processes implicated in the development of cardiovascular disease, tumour rejection and proliferation, and the acquisition of gastrointestinal lesions' (Steptoe & Appels, 1989).

It is critical to understand the distinction between actual control – the objective responsiveness of an event to influence by human or other factors – and perceived control which might bear little correspondence to reality. The mental and physical health benefits which have been associated with control have been related more to the subjective perception that control exists than to the objective determination of that control. A person's wellbeing is a function of the degree to which they feel in control, not how much they are in control. Actual (or veridical) control may be sufficient to lead to a perception of control, but it is not necessary. Perceived control in the absence of actual control has been termed 'illusory' control (Glass & Singer, 1972; Taylor & Brown, 1988; Taylor, 1989): it is the perception (or illusion) of control that mediates the health effects, not the actual control itself.

Primary and secondary control

Rothbaum, Weisz & Snyder (1982) distinguished between two types of control. In primary control, individuals directly influence their outcomes by acting upon the environment or situation to make it conform to their individual needs. In secondary control, individuals change themselves to better conform to the situation in order to compensate for the inability to engage in primary control. According to Rothbaum *et al.* (1982), there are many sub-types of secondary control:

- predictive control – adjusting one's expectancies based on knowledge of what will occur
- illusory control – taking credit for the control even when it is not there

- vicarious control – aligning oneself with powerful other entities who exercise control
- interpretive control – deriving meaning from otherwise uncontrollable situations.

Heckhausen & Schulz (1995) built their lifespan theory of control upon the typology of primary versus secondary control, but added two other dimensions: functional versus dysfunctional and veridical versus illusory. In their view, primary control has functional primacy over secondary control. They argue that the major function of secondary control is to minimize losses in, maintain and expand existing levels of primary control. At each period of the life course, individuals experience different opportunities and constraints leading to shifts and trade-offs between primary and secondary control strategies.

The distinction between primary and secondary control nicely matches Lazarus and Folkman's (1984) distinction between problem-focused and emotion-focused coping. Compas and his colleagues have taken this one step further by distinguishing between primary control coping and secondary control coping, both of which lead to better outcomes than disengagement coping (see Connor-Smith & Compas, 2004). One function of coping, whether by acting directly on the environment or on one's own reactions to events, is to maintain or regain a sense of control. There is a reciprocal causal relationship between perceived control and coping behaviours; a sense of control leads to effective coping behaviours (and, thus, to the outcomes of those behaviours). At the same time, engaging in effective coping behaviours increases one's sense of control.

Locus of control and related constructs

One conceptualization which has received a great deal of attention in the perceived control literature is 'locus of control' (Rotter, 1966). 'Locus' refers to the place (or origin) of the control. When using this conceptualization, the target of control (Wallston *et al.*, 1987) is one's outcomes (or reinforcements). An internal locus of control orientation is where one believes one's outcomes (or reinforcements) are controlled by one's own actions or one's enduring characteristics, such as one's personality. When people believe their outcomes (or reinforcements) are determined by the actions of other people, they have an external locus of control orientation. The belief that outcomes/reinforcements are determined by fate, luck, chance or other random events has also been classified as an external locus of control orientation.

A related, but different, perceived control construct is 'self-efficacy' (Bandura, 1977, 1997). As originally set forth by Bandura,

self-efficacy is the belief that one 'can do' a particular behaviour in a particular situation. It is possible to believe that one's actions are responsible for one's outcomes – an internal locus of control – without believing that one can act in such a manner as to optimize one's outcomes. Bandura originally intended self-efficacy to be both behaviour-specific and situation-specific, but others have broadened the construct to make it generalizable to many behaviours in many situations. This broadened construct has been termed generalized self-efficacy (Schwarzer, 1992), mastery (Pearlin & Schooler, 1978) or perceived competence (Wallston, 2001*a*; *b*). The lack of perceived control has been termed helplessness (Seligman, 1975). By whatever name it is called, the belief that one is capable of taking effective action increases the likelihood that the action will occur (see also 'Self-efficacy and health behaviour').

Perceived control of one's health

When the outcome in question is health or health status, perceptions of control are either referred to as perceived health competence (Smith *et al.*, 1995) or health locus of control (see Wallston, 2001*a*; *b*; 2004). Perceived health competence is positively related to internal health locus of control (Smith *et al.*, 1995), but the correlation is only moderately positive indicating that the two constructs are differentiated. Perceived health competence is unidimensional: the more competent one feels, the greater the perceived control of one's health and the more positive the health outcomes (Smith *et al.*, 1995). Health locus of control, on the other hand, is multidimensional (Wallston *et al.*, 1978): an internal health locus of control orientation is usually orthogonal to (i.e. independent of) an external health locus of control orientation, especially powerful others' externality. It is possible to believe that control of one's health is simultaneously due to one's own actions as well as to the actions of other people, such as family members, friends or healthcare providers. It is even possible to hold those beliefs alongside the belief that one's health is due to fate, luck or chance. Thus, the relationship of health locus of control beliefs to perceived control of one's health is complex, as is the relationship of health locus of control beliefs to outcomes.

Measurement of control beliefs relevant to health

Forms A and B of the Multidimensional Health Locus of Control (MHLC) scales (Wallston *et al.*, 1978) consist of three, 6-item, Likert scales assessing one internal and two external HLC belief dimensions (powerful others and chance). These original MHLC scales were designed to assess locus of control beliefs about one's health in general. The two forms, A and B, were meant to be 'equivalent', although, over the years, Form A was more likely to be used with 'healthy' respondents, while Form B was more likely to be administered to patients. Form C of the MHLC (Wallston *et al.*, 1994) also consists of 18 items, but was designed to be made condition-specific. Thus, by substituting for the word 'condition' in each item, Form C can be turned into a measure of one's locus of control beliefs regarding any given medical condition (such as diabetes, arthritis, cancer, HIV infection, etc.). With Form C, the powerful others external dimension is split

into two independent dimensions: doctors and other people. More recently, Wallston and his colleagues (Wallston *et al.*, 1999) developed the God Locus of Health Control (GLHC) subscale to assess a different external dimension – the belief that one's health is controlled by God or a higher power. The 6-item GLHC subscale can either be administered by itself or can be integrated into the existing MHLC scales.

Derived from the generalization of Bandura's construct of self-efficacy, the Perceived Health Competence Scale (PHCS; Smith *et al.*, 1995) is an 8-item assessment of an individual's belief that he or she can do whatever is necessary to bring about good health. There are many other measures of control-related beliefs other than the MHLC and PHC scales including a number of disease-specific locus of control and behaviour-specific self-efficacy measures (see Wallston, 1989; 2001*a*; *b*; 2004; Walker, 2001). There are even disease-specific self-efficacy measures such as the arthritis self-efficacy scales (Lorig *et al.*, 1989).

A unifying theory of control

Jan Walker (2001) has recently developed a theory of control, based on her research and clinical experience with chronic pain patients, which unifies a number of control-related constructs and findings. Among the propositions in Walker's theory are the following:

- control (i.e. the attainment of desired outcomes in a given situation) may be achieved through the actions of self or other
- perceived control is influenced by past history of control and lack of control
- perceived control is associated with confidence and optimism
- external control (by others) is a type of instrumental social support
- instrumental support is maladaptive if it usurps personal control and leads to dependence
- emotional and informational support enhance a sense of control
- perceived personal control and perceived social support should be viewed as complementary variables in relation to control, but personal control is preferable to social support because it is more reliable and sustainable
- perceived certainty and perceived predictability are sufficient but not necessary conditions for perceived controllability
- perceived uncontrollability is associated with fear, anxiety and/or depression
- sense of control may be bolstered by spiritual beliefs (represented by belief in an external source of support)
- positive and negative emotions associated with confidence, optimism, fear, anxiety and depression reflect the degree of perceived control available from any source (self, others or spiritual) at a particular point in time.

Altering perceived control

Most forms of health care, disease prevention and patient education are designed to give patients a greater sense of control over their health (Wallston, 2004). The effectiveness of all forms of coaching and teaching is probably mediated by an increase in

control-related beliefs. In helping individuals hone their skills, coaches (and/or teachers and/or healthcare providers) help alter both actual and perceived control which, at least theoretically, leads to better performance and outcomes. Providing patients with greater control over some aspect of their healthcare delivery by giving them increased information about what will happen to them and why (thereby decreasing uncertainty), or giving them

choices over some aspects of their care (thereby increasing decisional control), has been shown to lead to lower distress and faster recovery (Wallston, 1989). Shapiro & Austin (1998) developed an integrated approach to psychotherapy, health and healing which they termed 'control therapy'. One outcome of this type of therapy, as well as with a number of cognitive-behavioural therapies, is to increase individuals' sense of control.

Personality and health

Stephanie V. Stone¹ and Robert R. McCrae²

¹Johns Hopkins University

²National Institute of Aging

The ways in which personality and health interact are myriad and complex. Does personality predispose us to certain diseases? Does disease lead to changes in personality? The original formulation of psychosomatic medicine sought a direct link between personality and health – anxiety and hypertension, depression and cancer – and was largely unfruitful. Current research seeks to clarify how personality is associated with health-related behaviours like smoking and exercise, which put people at risk for disease. By elucidating the link between personality and health behaviours, the field makes substantive contributions to both patient treatment and public health prevention and intervention programmes aimed at reducing the incidence and prevalence of disease.

Personality as traits

For most of history, scholars and laypersons alike viewed human beings as rational creatures with propensities, abilities and beliefs that guided their conduct. Early in the twentieth century, this view was supplanted by psychoanalysis and behaviourism which characterized personality in radically different ways: for psychoanalysts, the essence of the person was in unconscious and often irrational processes; for behaviourists, the person was no more than a collection of learned responses to environmental reinforcements. Contemporary research has in turn rejected these two extreme views of personality and returned to a more commonsense approach, in which familiar traits such as persistence and sociability are seen as important determinants of behaviour.

It does not follow, however, that personality psychology is nothing but common sense. It is only common sense to believe that old age leads to depression and social withdrawal, that raising the standard of living will make everyone happier, that parental discipline is the most important determinant of character. But none of these beliefs happens to be true (McCrae & Costa, 2003). In considering the ‘commonsense’ effects of personality on physical health, a healthy skepticism is sensible.

The remainder of this chapter focuses on current conceptions of individual differences in traits and some of their broad implications for health and medicine. For a discussion of alternative approaches to personality, consult Pervin & John (1999).

The nature of traits

Personality traits can be defined as ‘dimensions of individual differences in tendencies to show consistent patterns of thoughts,

feelings, and actions’ (McCrae & Costa, 2003, p. 25). One patient, for example, may be friendly and talkative and eager to communicate with the physician, whereas another may be reserved and volunteer little information. These behavioural differences may be due in part to past experience with physicians who encouraged or discouraged a personal relationship. But they are also likely in part to reflect pervasive characteristics of the patient, individual differences in the personality dimension of ‘Extraversion’. Extraverts tend to be sociable, energetic and enthusiastic whether they are at home, at work, at a party or in the hospital.

The definition of traits calls attention to several of their important characteristics. First, the word ‘dimension’ implies a continuous distribution of traits in the population. Although it is convenient to talk about ‘introverts’ and ‘extraverts’, in fact most people have an intermediate level of extraversion. All personality traits approximate a normal, bell-shaped distribution. Second, the word ‘tendencies’ highlights the fact that the influence of traits is probabilistic; even the most well-adjusted person is occasionally anxious or depressed; even the most conscientious person occasionally fails to complete a task. As a consequence, personality traits usually cannot be inferred from a single behaviour or a single interaction: instead, personality assessment requires the search for consistent patterns across many times and situations. Third, personality traits cut across the academic distinctions between cognitive, affective and behavioural domains: they are inferred not merely from overt behaviour, as habits would be, but also from patterns of thoughts and feelings.

The structure of traits

The English language has well over 4000 adjectives to describe personality traits and personality psychologists have developed hundreds of scales to measure traits they consider to be important. For decades, the sheer number of traits made systematic research difficult. If a researcher wished to discover the traits associated with, say, hypertension or arthritis, which should be measured? Short of assessing all 4000, research was bound to be hit-or-miss. When different researchers chose to measure different traits, how could their results be compared?

If all 4000 words referred to completely different traits, there would be no easy solution to those problems. But in fact there is great redundancy among trait terms and formal psychological constructs. The terms ‘assertive’, ‘bossy’, ‘controlling’, ‘dominant’ and ‘exacting’ all refer to similar, if not identical, attributes. These similarities can be used to organize a trait taxonomy that reflects the structure of personality.

Table 1. Examples of adjectives and questionnaire scales defining the five factors^a

Factor name	Definer Adjective	NEO-PI-R scale ^b
Neuroticism (or Negative Affectivity vs. emotional Stability)	Anxious	Anxiety
	Self-pitying	Angry hostility
	Tense	Depression
	Touchy	Self-consciousness
	Unstable	Impulsiveness
	Worrying	Vulnerability
Extraversion (or Surgency, dominance vs. introversion)	Active	Warmth
	Assertive	Gregariousness
	Energetic	Assertiveness
	Enthusiastic	Activity
	Outgoing	Excitement-seeking
	Talkative	Positive emotions
Openness to Experience (or Intellect, culture vs. conventionality)	Artistic	Fantasy
	Curious	Aesthetics
	Imaginative	Feelings
	Insightful	Actions
	Original	Ideas
	Wide interests	Values
Agreeableness (or Love, friendly compliance vs. Antagonism)	Appreciative	Trust
	Forgiving	Straightforwardness
	Generous	Altruism
	Kind	Compliance
	Sympathetic	Modesty
	Trusting	Tender-mindedness
Conscientiousness (or Dependability, will to achieve vs. Undirectedness)	Efficient	Competence
	Organized	Order
	Planful	Dutifulness
	Reliable	Achievement striving
	Responsible	Self-discipline
	Thorough	Deliberation

^aAdapted from McCrae & John, 1992.

^bScales are facet scales from the Revised NEO Personality Inventory.

In the past decade it has become clear that personality traits can be described in terms of five very broad dimensions of personality. Table 1 lists some of the adjectives and personality questionnaire scales that define each dimension of the Five-Factor Model. These dimensions constitute the highest level of a hierarchy; within each of the five it is possible and sometimes important to make distinctions. Anxiety and depression, for example, are both definers of Neuroticism, and people who are anxious are frequently depressed as well. But the two traits are also distinguishable both conceptually and empirically, and psychotherapists often find that distinction very important.

Development and life course of personality

One of the most surprising findings of recent years has come from studies of the behaviour genetics of personality. Monozygotic twins, whether raised together or apart, strongly resemble each other in personality. Children who are raised in the same family but who are biologically unrelated show little or no resemblance in personality. The conclusion seems to be that personality traits are more influenced by heredity than by child-rearing practices (Plomin & Daniels, 1987) – a finding that both psychoanalysts and behaviourists would

have difficulty explaining. Developmentalists have known for years that certain temperamental traits, like activity level and distress-proneness, appear to be biologically based, and these temperaments are clearly linked to the two dimensions of ‘extraversion’ and ‘neuroticism’. But ‘openness’, ‘agreeableness’ and ‘conscientiousness’ seem to be equally influenced by genetics.

This does not mean that the individual’s personality is fixed at infancy, and that adult character can be read from infant behaviour. There are many changes from infancy through adolescence and personality changes continue throughout the twenties. From college to middle-age, both men and women tend to become less emotional and excitable, and more altruistic and organized. These declines in neuroticism and extraversion and increases in agreeableness and conscientiousness seem to summarize much of what is meant by maturity. After age 30, personality changes little. In particular, old age is not marked by increasing depression, social withdrawal, conservatism or crankiness.

Personality is also stable in another sense: individual differences are preserved. That is, those individuals who score highest on a personality trait at one time also tend to score highest at a later time – even over intervals of 30 years (Costa & McCrae, 1992). People who are well-adjusted, imaginative and persistent at age 30 are likely to be well-adjusted, imaginative and persistent at age 80. This fact is crucial to an understanding of adult development: it means that people’s basic tendencies are highly predictable over long periods of time. One implication is that people can plan rationally for their own future by taking into account their current values, motivations and interests. Another implication is that once adequately assessed, personality trait information will retain its utility for behavioural medicine. Like sex, race and education, personality traits might be considered basic background information which could be included in an individual’s medical record.

The five factors and their relevance to medical practice

Historically, personality traits were of interest to physicians chiefly because they were thought to predispose individuals to particular diseases. Different personality patterns were believed to be contributing causes to hypertension, ulcer, asthma and other so-called psychosomatic disorders. Today there are continuing research efforts in psychophysiology (Stough *et al.*, 2001) and psychoneuroimmunology (Miller *et al.*, 1999) that try to establish a biological link between personality and health (see ‘Psychosomatics’ and ‘Psychoneuroimmunology’). However, most of the classical psychosomatic theories have not been supported by empirical research, and many others are the subject of ongoing controversy. But there is no doubt that traits influence health-related behaviours (Carmody *et al.*, 1999), including risky behaviours (Vollrath & Torgersen, 2002); the ways patients perceive (Goodwin & Engstrom, 2002) and cope with illness (Bosma *et al.*, 2004); and how they interact with health care providers (Eaton & Tinsley, 1999), and comply with medical advice (Courneya *et al.*, 2002) (see ‘Adherence to Treatment’, ‘Coping with Chronic Illness’, ‘Health-related Behaviours’ and ‘Symptom Perception’).

In this section we discuss the five major personality factors in greater detail and suggest ways in which knowledge of personality traits might help health care providers.

Neuroticism

Modern psychiatric nomenclature no longer recognizes a category of neuroses, but personality psychologists still use the term 'Neuroticism' to describe a basic dimension of personality (see Table 1 for some alternative labels). Individuals who score high on this dimension are prone to experience a wide variety of negative emotions, such as fear, shame and guilt. External stressors and internal drives often overwhelm them, leading them to feel helpless and act impulsively. They are prone to unrealistic thinking and have a poor self-image. Low scorers on this dimension are calm and hardy, resilient in the face of stress.

Although neuroticism – even at very high levels – is a dimension of normal personality rather than a psychiatric disorder, it is associated with increased risk for a wide variety of psychiatric disorders (Zonderman *et al.*, 1993). Neuroticism is also related to somatic distress. Individuals who are chronically anxious and depressed make more somatic complaints (De Gucht *et al.*, 2004). They may be more sensitive to their internal states, or more prone to interpret physiological sensations as signs of illness, or more likely to remember and report symptoms. At an extreme level, this is recognizable as hypochondriasis, but even moderate levels of neuroticism are associated with moderate increases in somatic complaints. This phenomenon complicates medical diagnosis, which depends heavily on patient reports of medical history and symptoms. Patients who are very high in neuroticism may over-report symptoms, but their self-reports cannot be ignored – after all, even hypochondriacs get sick. Conversely, patients who are very low in neuroticism may minimize symptoms and fail to seek appropriate care.

Does neuroticism actually cause disease? Certainly, acute emotional reactions have physiological consequences, and individuals high in neuroticism have more frequent distressing emotional reactions. Although it is reasonable to hypothesize that the long-term effect of these physiological disturbances would include organic disease, a number of large-scale studies have failed to show any direct link between neuroticism and mortality or morbidity from cancer or coronary disease. There is evidence, however, that neuroticism affects health behaviours which are in turn risk factors for disease. In a five-year observational study, covert hostility, an aspect of neuroticism, predicted both being overweight and weight cycling (Carmody *et al.*, 1999). In a large-scale community sample, beer consumption was positively related to neuroticism (McGregor *et al.*, 2003).

Extraversion

Extraversion includes both interpersonal and temperamental aspects. Interpersonally, extraverts are warm and friendly, enjoying conversation and having close personal relationships; they also enjoy the sheer social stimulation of crowds of strangers. Extraverts are assertive and easily take on leadership roles. Temperamentally, extraverts are characterized by a need for excitement, high levels of energy and activity and cheerful optimism; they laugh easily. Introverts, although they may have perfectly adequate

social skills, prefer to avoid crowds and tend to be serious in mood and measured in their pace of activity. Contrary to popular belief, introverts are not necessarily introspective or deep thinkers, nor are extraverts necessarily well-adjusted.

The characteristics that define extraversion are readily observed, and this dimension is the one which is most easily noticed by the health care provider. Most obviously, extraverts are talkative. This fact is of particular significance in view of the fact that 'talk is the main ingredient in medical care' (Roter & Hall, 1992, p. 3). How much and what is said in a medical interview depends upon many factors (Beisecker & Beisecker, 1990), including the physician's own level of extraversion. For example, Mechanic (1978) has suggested that family practitioners are more sociable than hospital doctors, and their interactions with patients are correspondingly more warm and personal. While interpersonal warmth may be appreciated by extraverted patients, introverts may prefer to maintain their distance and focus attention on the medical problem. Physicians may need to make extra effort to elicit information from these patients who are less likely to volunteer it.

While the interpersonal aspects of extraversion may be the most apparent to clinicians, there is growing interest in its relation to health via health-related behaviours. Courneya *et al.* (2002) reported that extraversion predicted exercise adherence in cancer survivors. In a longitudinal study by Kressin *et al.* (1999), extraversion predicted oral self-care behaviour.

Openness to experience

Individuals who are open to experience prefer novelty, variety and ambiguity in a variety of areas. They are imaginative and creative, with an active fantasy life, and they are responsive to beauty in art and nature. They are keenly aware of their own inner states, including emotional ambivalence. Open men and women are innovative and willing to try new approaches and they have a high degree of intellectual curiosity. They are liberal and unconventional in their political and social views. Closed individuals, by contrast, are conservative, conventional and down-to-earth; they prefer symmetry and simplicity and tend toward black-and-white thinking. They are reluctant to change either their behaviours or their views. Open individuals tend to be somewhat better educated than closed individuals, but openness should not be confused with intelligence.

Although openness is not strictly speaking an interpersonal domain of personality, it affects social interaction and is therefore relevant to clinical practice. Openness is an important predictor of how mothers communicate with paediatricians about their babies (Eaton & Tinsley, 1999). In the mental health setting, clinicians find that differences in openness are important determinants of the patient's view of therapy (Miller, 1991). Closed patients are likely to prefer conventional medical treatment; they tend to assume that doctors are the authorities and believe what they are told. Open patients may be less compliant: they may want more information than is normally provided, ask for second opinions and perhaps even research the topic themselves. They are more willing to consider innovative and non-traditional therapies and it seems likely that they make disproportionate use of alternative medicine. Acupuncture, aromatherapy and hypnosis are more appealing to open than to closed patients.

Agreeableness

Like extraversion, agreeableness is primarily an interpersonal dimension. Agreeable people are prosocial: they trust others and are themselves candid and straightforward; they try to help others and are sympathetic in attitudes. Antagonistic people are more self-centred, suspicious and devious. They may be arrogant and quarrelsome. Although agreeableness is socially desirable and agreeable people are more popular with their peers, there are also advantages to being disagreeable. Antagonistic individuals are competitive and proud of their tough-mindedness.

Early studies that sought to identify the so-called toxic component of the Type A behaviour pattern found that individuals who were rude, condescending and willing to express their anger directly to others – that is, who were low in agreeableness – were at higher risk of developing coronary heart disease (Dembroski *et al.*, 1989). More recent research indicates that health behaviours may mediate this association: antagonism, especially when coupled with low conscientiousness, predicts poor health behaviours (Martin *et al.*, 1999).

Antagonistic patients present other problems for healthcare providers: they are mistrustful, demanding and manipulative and often non-compliant (Auerbach *et al.*, 2002). Physicians not surprisingly find such patients unlikeable and such patients are frequently dissatisfied with their medical treatment (Roter & Hall, 1992). Extremely agreeable patients are well liked and generally satisfied, but may be too compliant for their own good – they are unlikely to adopt the consumerist perspective which some patient advocates recommend.

Conscientiousness

The final dimension of the Five-Factor Model is conscientiousness, a cluster of traits that encompass both self-restraint (order, dutifulness and deliberation) and active pursuit of goals. High scorers on measures of this dimension are hardworking, persistent and highly motivated; low scorers are easy-going and somewhat disorganized, and lack a clear direction in their life. At best, highly conscientious people are purposeful and effective; at worst, they are driven to perfectionism and neglect their personal life for the sake of their work.

In a recent meta-analysis of 194 cross-sectional studies, conscientiousness significantly (negatively) predicted a wide array of health risk behaviours including excessive alcohol use, unhealthy eating, risky driving, risky sex, suicide, tobacco use and violence (Bogg & Roberts, 2004). In another study, conscientiousness predicted not only wellness behaviours (e.g. exercise, taking vitamins), but also

accident control (e.g. learning first aid), and low traffic risk-taking (Booth-Kewley & Vickers, 1994). Conscientiousness is a prospective predictor of exercise behaviour (Conner & Abraham, 2001), and conscientious people are also the most likely to adhere faithfully to prescribed medical regimens (Christensen & Smith, 1995). They have the self-discipline and prudence to follow the advice that public service announcements offer. Not surprisingly, conscientious individuals live longer (Martin & Friedman, 2000).

Patients who are very low in conscientiousness present a problem to the healthcare system. Regimens that are distasteful or that require organization or effort are likely to be abandoned. Ideally, treatments would be designed to take into account the patient's level of conscientiousness. For example, a rigorous exercise programme might be best for a high scorer, whereas a more passive drug therapy might be more realistic for a low scorer. Where patient efforts are essential, health care providers should make special efforts to motivate and monitor patients low in conscientiousness. External support, e.g. reminder calls, may help these patients comply with treatment.

Behaviour and health: practical considerations

Understanding personality is vital for health care providers. For clarity, we have discussed each of the five domains of personality separately, but in reality they all operate concurrently in the patient. While this adds to the complexity of assessment, it also has positive implications for treatment, because it allows clinicians to focus on patients' strengths to design treatments that are maximally effective. For example, if a patient is both antagonistic and conscientious, he probably would not exercise to please his doctor, but might if medical advice were framed as a challenge.

The stability of personality is a double-edged sword for practitioners. To the extent that personality predisposes patients to engage in health-injurious behaviours, personality may be viewed as a lifelong risk factor for disease. But stability of personality also gives the physician a reliable basis for interacting with the patient and formulating treatment strategy.

Personality traits are not easily changed, but fortunately, it is not the traits themselves but the behaviours they predispose toward that are problematic for health. Although it is helpful to understand the patient at the level of broad dispositions, the goals of treatment are best framed in terms of modifications to specific behaviours.

Physical activity and health

Neville Owen, Kym Spathonis and Eva Leslie

The University of Queensland

Introduction

Participation in physical activity is associated with significant benefits to health, most importantly in the prevention of Type 2 diabetes, cardiovascular disease and some cancers (Bauman *et al.*, 2002; United States Department of Health and Human Services [USDHHS], 1996). In this chapter, we provide an overview of research on health-enhancing physical activity in adults. We provide brief examples of epidemiological studies on the relationships of physical activity to health outcomes: we also consider descriptive

studies of adult populations on levels of participation. Our focus is on physical activity as a set of behaviours: we describe research findings on the 'determinants' of physical activity and describe the theories of health behaviour that are now widely used in understanding and influencing physical activity.

Physical activity exercise and fitness

The terms, 'physical activity', 'exercise' and 'fitness' are sometimes used interchangeably and at times incorrectly (Sallis & Owen, 1999).

'Physical activity' refers to any bodily movement, but generally to the movements of groups of large muscles (particularly of the legs and arms) that result in significant increases in metabolic energy expenditure, above the resting level. Regularly taking part in such activities is associated with better health outcomes. Physical activity can be performed at a wide range of intensities: walking or other moderate-intensity activities such as swimming at a low, moderate or brisk pace; vigorous endurance activities (for example, jogging or running, walking fast uphill, riding a bicycle fast or in hilly terrain); and activities that increase strength and/or flexibility (for example, weight training, calisthenics or strenuous occupational or domestic tasks such as heavy lifting or carrying). 'Exercise' is physical activity done with the explicit purpose of improving or maintaining physical fitness or health. Exercise can be performed at a variety of intensities, although it usually involves more vigorous activities. Nevertheless, walking at a moderate intensity can be exercise, if it is done for the purpose of improving fitness or health.

Physical fitness is a physiological state, not a behaviour. It is thus not interchangeable with the terms 'physical activity' or 'exercise', which refer to sets of behaviours and to their contexts or purposes. Psychological fitness (personal resiliency or 'hardiness') can be associated with physical fitness. While psychological fitness is distinct from physical activity or fitness, for some individuals or groups (for example, athletes or those who are living with a chronic illness), the relationship between these two domains of health and well-being will be strong.

A behavioural epidemiology framework for physical activity and health

Sallis & Owen (1999) propose five main phases of 'behavioural epidemiology' research, as they may be applied to physical activity and health:

1. *Establish the links between physical activity and health:* This phase is complex, because different types and amounts of physical activity are related to different health benefits and risks. Once epidemiological and other studies document the associations between the relevant behaviour and health outcomes, research in the subsequent phases has strong foundations.
2. *Accurately measure physical activity:* The measurement of physical activity, particularly in large population studies and in the evaluation of interventions, is an ongoing challenge, but high quality measures are essential for all types of research. Many studies rely on self-report data, but more objective measurement tools are being developed and validated.
3. *Identify factors that influence physical activity:* Describing the characteristics of those who are most and least active can be helpful in deciding which groups are most in need of interventions. The potentially modifiable factors that are identified can then be targeted for change in exercise counselling, programmes or public campaigns.
4. *Develop and evaluate interventions to promote physical activity:* The majority of adults in the populations of industrialized nations are not sufficiently physically active for health benefits. Effective, evidence-based intervention programmes need to be developed and tested systematically.

5. *Translate research into policy and practice:* Each phase of the behavioural epidemiology framework is intended to build upon the previous phase or phases, so that evidence-based approaches may be adopted more widely and with confidence.

Understanding and influencing physical activity for individuals, groups, communities and whole populations is a new and important interdisciplinary area. Health psychology experts in the physical activity field work closely with exercise physiologists, physical educators, epidemiologists and other social and biomedical scientists (Sallis *et al.*, 2000).

Health psychology has much to offer. Psychological theories and methods are used in clinical and community settings to guide health practitioners in assisting individuals to become more physically active. They are used to inform the development of large-scale interventions for communities and populations (Marcus *et al.*, 1998). Psychological theories underpin ecological models of health behaviour (Owen *et al.*, 2004; Sallis & Owen, 1997, 2002). These provide a conceptual basis for the environmental and policy initiatives which will be needed to bring about population-wide increases in physical activity (Sallis *et al.*, 1998).

Phases 3 and 4 of the behavioural epidemiology framework (identifying factors that influence physical activity; developing and evaluating interventions to promote physical activity) are where health psychology has made particularly strong contributions. These have been in the development of conceptual models, in measurement and other research methods and in developing a plethora of practical programmes. These two phases of research and application form the main focus of our chapter.

Physical activity and population health outcomes

There is a substantial body of evidence suggesting that regularly taking part in physical activities of moderate intensity (for example, recreational walking or cycling) can have significant health-protective benefits (Bauman *et al.*, 2002; USDHHS, 1996). In the 1980s and early 1990s, the strongest evidence for physical activity and health benefits was in the area of heart-disease prevention. More recent reviews support the earlier recommendations on physical activity and health and continue to emphasize participation in moderate-intensity activities (particularly walking) on most days of the week for 30 minutes or more: this criterion is intended to be realistic and optimal for achieving health benefits in sedentary adult populations (Bauman, 2004). Higher volumes and intensities of activity and specific types of activity such as strength training have additional health benefits (Bauman *et al.*, 2002; USDHHS, 1996).

Epidemiological studies and controlled trials conducted in recent years reinforce the broader preventive benefits and the range of specific disease outcomes that may be postponed or amended, by being physically active on a regular basis. This is seen clearly in the case of Type 2 diabetes. There is recent compelling evidence from controlled trials that regular physical activity has a key role in the prevention of Type 2 diabetes in high-risk groups. For example, in a study conducted in Finland, intensive nutritional counselling and endurance exercise advice given to people with impaired glucose tolerance resulted in a significantly lower rate of progression to diabetes, compared with a control group.

The decrease in risk was related to the degree of lifestyle change (Tuomilehto *et al.*, 2001) (see 'Diabetes').

Physical activity also contributes to a reduced risk of developing some cancers, particularly colon and breast cancer (International Agency for Research on Cancer [IARC], 2002). There is a reduction in risk of colon cancer with increasing levels of activity, particularly more intense activities. Recent reviews highlight the potential for physical activity to reduce the risk of breast cancer, with indications of a 20–40% risk reduction in both pre- and post-menopausal women (Thune & Furberg, 2001). Physical activity has an independent effect on colon and breast cancer risk in addition to its role in preventing unhealthy weight gain (IARC, 2002).

The increasing population prevalence of inactivity is an important contributor to what is now being characterized as an 'obesity epidemic' (Erllichman *et al.*, 2002). Physically active persons are less likely to gain weight over the course of their adult lives. Findings from a range of cross-sectional studies have shown lower weight, body mass index or skin-fold measures among people with higher measured fitness and higher levels of habitual physical activity; however, prospective studies have shown less consistent relationships (Erllichman *et al.*, 2002) (see 'Obesity').

Over half of the adult population in most industrialized countries is, however, insufficiently physically active for health benefits (USDHHS, 1996). For example, recent data on trends in physical activity participation in Australia in the late 1990s (Bauman *et al.*, 2002; Bauman *et al.*, 2003) suggest that the rate of participation in physical activity by adults had declined by 6% between 1997 and 1999. Less than 50% of adult Australians achieved the recommended 150 minutes (30 minutes on at least five days of the week) of at least moderate-intensity activity. Similar findings have emerged in population surveys in the UK (Hillsdon *et al.*, 2001).

Public policies and programmes to encourage physical activity are being pursued seriously in many developed countries and elsewhere (Bauman *et al.*, 2002; USDHHS, 1996). Yet, the majority of the adult population of many industrialized countries is not engaging in the level of activity needed to accrue worthwhile health benefits. Thus, there is much that needs to be done, in research and in practice, to increase participation in physical activity. Effective interventions which can change the personal, social and environmental factors related to physical inactivity are needed.

Identifying factors that influence physical activity

The published research on physical activity is replete with findings from cross-sectional investigations of the associations between physical activity and a range of personal, social and environmental factors.

The term 'determinant', as it has typically been used in the physical activity research literature, is often used incorrectly to characterize studies (most typically cross-sectional surveys) that demonstrate reproducible associations ('correlates'), rather than cause-and-effect relationships (Bauman, Sallis *et al.*, 2002). While such correlations do not identify cause-and-effect relationships, they do help to generate hypotheses for further study and can illuminate the relevance (or otherwise) of particular theoretical constructs.

Table 1. Summary overview of the new evidence from studies of the correlates of physical activity, published since 1998 (based on the review by Trost *et al.*, 2002)

<i>Demographic and biological factors</i>	
• Marital status (married; –)	
• Overweight or obesity (–)	
<i>Psychological, cognitive and emotional factors</i>	
• Self-efficacy for physical activity (+)	
• Barriers to physical activity (lack of time; –)	
<i>Behavioural attributes and skills</i>	
• Past physical activity behaviour or 'habit' (+)	
• Healthy diet (+)	
• Smoking (–)	
<i>Socio-cultural factors</i>	
• Social support (++)	
<i>Physical environment factors</i>	
• Exercise equipment at home (+)	
• Perceived access to facilities (+)	
• Satisfaction with recreational facilities (+)	
• Neighbourhood safety (+)	
• Hilly terrain (+)	
• Frequently observe others exercising (+)	
• Enjoyable scenery (+)	
• Urban location (–)	
– mixed or weak evidence of negative association; -- strong negative association; + mixed or weak evidence of positive association; ++ strong positive association.	

Sallis & Owen (1999, Chapter 7) examined the personal, social and environmental factors associated with adults' participation in physical activity. Six classes of correlates of activity were identified: demographic and biological factors; psychological, cognitive and emotional factors; behavioural attributes and skills; socio-cultural factors; physical environment factors; and physical activity characteristics.

The overall pattern of findings suggests that individual-level attributes such as socioeconomic status and perceived self-efficacy demonstrate the strongest and most consistent associations with physical activity. Fewer consistent positive or negative associations were found in relation to behavioural attributes and personal skills, sociocultural influences and physical environmental influences.

In a more recent review, Trost *et al.* (2002) reported further evidence on associations between these six classes of attributes and being physically active, engaging in particular activities or conducting higher volumes of activity (see Table 1).

Several of the correlates of physical activity listed in Table 1 are associated with constructs from theoretical models of health behaviour. These correlates, for example, include self-efficacy, perceived barriers, past exercise habits and environmental attributes. The relevant theoretical models from health psychology, as we will illustrate below, have been particularly influential in the development of physical activity interventions.

Theories of physical activity behaviour and their applications

Theoretical models of health behaviour (see Glanz *et al.*, 2002) have been applied to research on the factors which can influence physical

activity and to the development and evaluation of interventions (see Godin, 1994; Marcus *et al.*, 1998; Owen *et al.*, 2004; Sallis & Owen, 1997, 2002; Spence & Lee, 2003).

Social-cognitive theory

Social-Cognitive Theory (SCT) has been widely used in developing interventions to influence physical activity, often in combination with constructs such as stages of change and the Transtheoretical Model (TTM; Marcus, Owen *et al.*, 1998). SCT has been particularly helpful in expanding the understanding of factors that influence physical activity participation, beyond individual-level factors. Theories focusing more on intra-personal processes (for example, attitudes, intention, beliefs) such as the Theory of Planned Behaviour and the Theory of Reasoned Action, have been applied to understanding the determinants of physical activity behaviour, with modest but, in many cases, significant predictive power (Godin, 1994).

Social-cognitive Theory proposes that personal, behavioural and environmental factors operate as reciprocal interacting determinants (Bandura, 1986). Studies of the correlates of physical activity and intervention trials based on SCT have focused on the individual's ability to control her or his own behaviour (or 'self-efficacy') and on how changes in the individual, the environment, or in both can produce changes in behaviour.

Bandura (1986) identifies four main sources of influences on self-efficacy: mastery of accomplishments (learning new skills and building confidence through successful new experiences); social modelling (learning new skills by observing others); social persuasion (being convinced by others of the desirability of new activities and their outcomes); and the interpretation of physiological states (in the case of physical activity, this might include, for example, interpreting the physical signs of exertion generally, or learning to feel comfortable with increased heart rate and respiration changes) (see 'Self-efficacy and health').

The transtheoretical model

The TTM (also known as the 'Stages of Change' model; Prochaska & DiClemente, 1983) has formed the theoretical basis for a number of cross-sectional studies and intervention trials on physical activity. According to the TTM, five stages of motivational readiness for physical activity may be identified (Marcus & Simpkin, 1994).

In the initial stage (precontemplation), individuals do not intend to take action to become more physically active in the foreseeable future. However, as the individual becomes more aware of the costs and benefits of engaging more regularly in physical activity, he/she progresses to the second stage (contemplation). As the individual takes steps to engage in physical activity (preparation), the development of behavioural plans and skills may assist him/her to become active. The fourth stage (action) occurs when an individual starts to become active, and the fifth stage (maintenance) is when the individual is able to continue activity on a regular basis for six months and beyond. Both the fourth and the fifth stages of behavioural change often require individuals to employ both cognitive and behavioural strategies to assist in avoiding relapse (dropping out of regular physical activity), or in re-engaging in activity

following relapse (see 'Transtheoretical model of behaviour change').

Interventions derived from SCT and the TTM

Interventions targeting self-efficacy and decision-making (key constructs from SCT and the TTM) have accumulated significant support from research trials (Sallis & Owen, 1999). These interventions emphasize building confidence about being physically active (enhancing self-efficacy). They also use specific techniques such as goal setting, completing 'decisional balance' protocols (explicitly listing and considering both the advantages and disadvantages of trying to be more active), relapse prevention training (skills in resuming being more active after time out), stimulus control (how to identify environmental factors that can prompt and remind one to be more active) and social support (help and encouragement from others).

Methods based on such behavioural techniques have a long history of being used in combined ways in physical activity interventions. For example, Martin *et al.* (1984) conducted a series of cognitive-behavioural intervention trials with sedentary adults. They found that attendance at exercise sessions was significantly improved by frequent personalised praise and feedback from instructors, and flexible goal setting. Overall, the interventions based on SCT produced attendance rates of 80% or greater, while a control group with the most basic programme had attendance of around 50%. In another intervention study, McAuley *et al.* (1993) randomly assigned middle-aged, sedentary adults to a self-efficacy enhancing programme or to a standard walking programme. Following the intervention, those in the efficacy-enhancement group were walking almost 50% more than were those in the control group. These two examples provide an example of how specific and combined SCT-based components can contribute to at least short-term successes of physical activity interventions which are delivered face-to-face in structured settings.

Other evidence however, suggests that most people prefer to be active on their own – either at home or in their local neighbourhood (Booth *et al.*, 1997). This is in contrast to using structured facilities such as gyms or fitness centres. Attending a clinic, a fitness facility or leisure centre, a class or group is inconvenient for many people: it may be more difficult for some to actually get to the site of the class than it is to engage in the physical activity elsewhere. There is a modest but consistent body of research to suggest that mass media campaigns targeting those in early stages of motivational readiness for physical activity can result in significant increases in slogan and message content recall, and have significant, but small and short-term impacts on behaviour (Bauman *et al.*, 2001; Marcus *et al.*, 1998).

Trials of 'mediated' interventions based on the TTM have used print and Internet delivery methods (Bock *et al.*, 2001; Marcus *et al.*, 1998). These interventions aim to match the main elements of the programme to the individual's stage of motivational readiness for change. However, the task of matching interventions to a person's level of motivational readiness for change must take into account that some people are not yet ready to change their behaviour but may be ready to make changes in their thinking about behaviour (Marcus & Forsyth, 2003). For example, programmes for precontemplators may focus on enhancing particular aspects of knowledge;

programmes for those in the action stage may, for example, focus on social support and injury prevention.

There is promising new evidence for the potential of physical activity programs that can be delivered via telephone and the Internet (Napolitano *et al.*, 2003). However, the trials of Internet-delivered programmes conducted thus far have dealt with small numbers of self-selected participants. A recent Australian trial compared print versus Internet delivery of a stage-targeted programme (Marshall *et al.*, 2003). It identified major challenges in the recruitment and retention of participants. For website-delivered programmes, there remains limited evidence to support their efficacy in changing behaviour, except in trials with small numbers of motivated participants.

While the new mediated approaches do show considerable promise, it is not realistically possible to engage all sedentary or insufficiently active adults in structured, formal physical activity programmes (whether face-to-face or mediated). It may also be unreasonable to expect large proportions of the population to make motivationally driven personal behaviour changes, if these efforts are not fully supported by the relevant environmental circumstances (see also 'Physical activity interventions').

Understanding environmental influences on physical activity: ecological models of health behaviour

Sallis & Hovell (1990) proposed a model of physical activity behaviour based on Social Learning Theory (an earlier version of SCT), which used a combination of personal, cognitive, social and environmental factors to explain patterns of physical activity. A key element of the Sallis and Hovell (1990) model was its emphasis on the role of environmental settings and supports. Specifically, environments that lack resources, or impose barriers may act to reduce the probability that the choice to be active will be made. As we will illustrate below, Sallis and Hovell's focus on the role of the physical environment has been developed within 'ecological' models of physical activity behaviour.

Sallis & Owen (1997, 1999, 2002) and Spence & Lee (2003) have proposed an ecological approach to understanding the determinants of physical activity behaviour, and have highlighted the distinction between social and physical environmental influences. Within the physical environment, natural environment factors such as the weather or climate; and built environment factors, such as urban design or availability of facilities can influence physical activity behaviour (Saelens *et al.*, 2003).

Ecological models can provide frameworks for considering the multiple levels (personal, social, environmental) on which physical activity determinants exert their influences (Sallis & Owen, 1997, 2002; Spence & Lee, 2003). The explicit emphasis on attributes of the physical environment in a complex, multi-level network of causality is a key feature of ecological models of physical activity (Owen *et al.*, 2000; Sallis & Owen, 1997, 2002). In public health advocacy and community initiatives, Sallis and Owen's (1997, 2002) ecological model has been used to highlight the interactions of social and organizational factors with environmental attributes and the communication media initiatives that can prompt personal choices to be active (Matsudo *et al.*, 2004).

The 'behaviour settings' construct, drawn from ecological psychology (Barker, 1968) is a key to understanding the role of

environmental determinants of physical activity (Owen *et al.*, 2000). Behaviour settings are the physical and social contexts in which behaviours occur, some being supportive of activity and others being discouraging or prohibiting of activity (Wicker, 1979).

Because cognitive-social theories (particularly SCT and the TTM) have been the predominant influences in behavioural studies of physical activity (Godin, 1994), the field has been shaped by assumptions that choices to be active or inactive are conscious, deliberate choices – consequent upon attitudes, intentions, self-efficacy and other cognitive mediators of behavioural change (Owen *et al.*, 2004). However, social-cognitive models do identify a strong role for environmental influences under some circumstances. For example, Bandura (1986) has argued that when behaviour is strongly facilitated or constrained by attributes of the environment in which it takes place (and plausibly this often is likely to be so for physical activity), direct environmental influences would be the predominant class of determinants.

Differences in physical activity between communities that have different environmental attributes have been observed – residents of 'traditional' communities, characterized by higher population density, higher street connectivity and mixed land use ('high walkable'), report significantly more walking and cycling for transport, than do residents of low population density, poorly-connected and single land use ('low walkable') neighbourhoods (Saelens *et al.*, 2003). Overall, there was an average difference between high- and low-walkable communities of approximately 15–30 minutes more walking per week for residents of high-walkable neighbourhoods.

The evidence from behavioural and public health research has recently been reviewed (Humpel *et al.*, 2002; Owen *et al.*, 2004) and a number of environmental attributes associated with being physically active have been identified (see Table 1). Even if relatively small amounts of the variation in physical activity are ultimately explained by the influence of environmental variables, it is the case that whole communities can be impacted by any change to make the environment more supportive of physical activity (Giles-Corti & Donovan, 2002). The effects of many small effects across communities could accumulate, to result in substantial support for individual behaviour change, which should lead to broader changes across whole populations.

Conclusions

Health psychology research and interventions to influence physical activity are rapidly developing areas, stimulated by a strong and growing body of evidence on the major health benefits of being habitually active. Health psychologists have contributed significantly to the knowledge base and to developing, refining and applying the theories that are now widely used in the physical activity field. We have used a behavioural epidemiology framework, to highlight those dimensions of research on physical activity and health (understanding determinants, developing theoretical models, designing interventions), within which health psychology has particularly important contributions to make.

It seems likely that future conceptual and practical advances will come from the blending together of the best of what is known about motivational approaches, with an ecological perspective.

Our understanding of the relevant determinants will become more definitive and theories of physical activity behaviour will be refined. It thus should be possible to design and implement interventions

that will strongly mobilize the personal, social and environmental factors which can help people to initiate and maintain the relevant behavioural changes.

Placebos

Irving Kirsch

University of Hull

Overview

A placebo is a sham treatment that may be used clinically to placate a patient or experimentally to establish the efficacy of a drug or other medical procedure. The placebo effect is the effect produced by administering a placebo. In addition, active medications may produce placebo effects as well as drug effects and these may be additive. In this case, the placebo effect is that portion of the treatment effect that was produced psychologically, rather than through physical means.

Typically, placebos are physically inert substances which are identical in appearance to an active drug. Occasionally, active substances are used as placebos. Active placebos have side-effects that mimic those of the drug being investigated, but do not possess the physical properties hypothesized to produce the beneficial treatment effect. Active placebos are used to prevent patients from using the sensory cues provided by side effects to deduce the condition to which they have been randomized.

Placebo effects are not limited to drug treatments. Any medical procedure can have effects due to the physical properties of the treatment and effects due to its psychological properties. Just as the effects of the physical properties of a medication can be tested by comparing its effects to those of a sham medication, so too the physically produced effects of other medical procedures can be established by comparison with sham procedures (e.g. sham surgery). For example, real and sham surgery have been compared in

the treatment of angina (Cobb *et al.*, 1959; Dimond *et al.*, 1960) and osteoporosis of the knee (Moseley *et al.*, 2002). In both cases, the effects appear to be due to the psychological properties of the treatment, rather than to the surgical procedures themselves.

Four notable and controversial issues currently occupy the attention of researchers investigating the placebo effect. The first is whether placebos are capable of producing psychological or physical effects. The second concerns the mechanisms by which these effects are produced. The third involves the search for a placebo responder. The fourth issue relates to attempts to extend the placebo construct beyond the bounds of physical medicine and into the arena of psychotherapy.

Research evidence

Are placebos effective?

The term placebo is Latin and means 'I shall please'. This reflects the historical use of placebos to placate patients whose complaints could not otherwise be treated. It also indicates a belief that while the placebos might please patients, they are not likely to produce real benefits.

During the 1950s, the possibility that placebo treatment might have genuine effects became more widely recognized, and the use of placebo controls in medical research became common. In case after case, medicines and treatment procedures that had been

'proven' effective in clinical trials were found to be no more effective than treatment by placebo. Though the mechanism of placebo-induced change was a mystery, medical researchers began to suspect that many effects previously attributed to specific treatments were in fact placebo effects. It was suggested that placebos could reduce the frequency of asthma attacks, relieve hay fever, suppress coughs, alleviate tension and anxiety, cure headaches, reduce pain, prevent colds and alleviate cold symptoms, cure ulcers, inhibit symptoms of withdrawal from narcotics, alter gastric function, control the blood sugar levels of diabetics, reduce enuresis, lessen the severity of arthritis, reduce the frequency and severity of angina attacks and reverse the growth of malignant tumours (Beecher, 1961; Honigfeld, 1964*a*, 1964*b*; Klopfer, 1957; Volgyesi, 1954). These data led to the concept of 'the powerful placebo' (Beecher, 1955).

The response to a medication is not the same thing as the effect of that medication. This is because there are many reasons by which a person might get better. One is the natural history of the disease. People get better from many conditions (e.g. the common cold) regardless of whether they are treated or not. Sometimes there is spontaneous remission in disorders that aren't always self-healing (e.g. depression or cancer). There is also the statistical problem of regression towards the mean, i.e. when you re-assess something, people who scored at the extremes will tend to display scores closer to the mean. Finally, the response to a medication includes the placebo effect. Placebos are intended to control for all these sources of improvement. Thus, the drug effect is assumed to be the difference between the response to medication and the response to placebo.

Analogously, a distinction can be drawn between the placebo response and the placebo effect. The placebo response is the change observed following placebo administration. In addition to the placebo effect, it includes the changes due to the natural history of the disorder, spontaneous remission and regression to the mean. For this reason, the placebo effect is best evaluated via comparisons with a no-treatment control condition. However, this is rarely done in medical research, where the interest is in evaluating treatment effects rather than placebo effects.

In an effort to evaluate placebo effects, Hróbjartsson and Gøtzsche (2001) reported a meta-analysis of treatments in which response to placebo was compared to changes observed in a no-treatment control condition. Finding a small but significant 'placebo effect', along with significant heterogeneity outcomes, the authors concluded that they had 'found little evidence in general that placebo had powerful clinical effects' (Hróbjartsson & Gøtzsche, 2001, pp. 1594–5). This widely cited meta-analysis has sparked an intense debate concerning the purported power of placebo.

Critics of the Hróbjartsson and Gøtzsche (2001) meta-analysis have noted a number of shortcomings. First, they included treatments for a wide variety of conditions, including the common cold, alcohol abuse, smoking, poor oral hygiene, herpes, infertility, mental retardation, marital discord, faecal soiling, Alzheimer's disease, carpal tunnel syndrome and other 'undiagnosed ailments'. It is likely that some of these conditions are responsive to placebo treatment and others not, hence the significant heterogeneity of outcomes reported by Hróbjartsson and Gøtzsche. As noted by Wampold *et al.* (in press), 'aggregating without regard to

consideration of heterogeneity of disorders and their amenability to placebo action does not allow for detection of a placebo effect should it exist'.

Wampold *et al.* (2005) reanalyzed the studies in the Hróbjartsson and Gøtzsche (2001) data set after classifying them by the degree to which the disorder was deemed by independent raters to be amenable to placebo treatment and by the adequacy of the experimental design. Disorders like insomnia, chronic pain and depression were deemed to be amenable to placebo treatment, whereas disorders like anemia and bacterial infection were deemed to be not amenable to placebo treatment. Design adequacy involved on such factors as random assignment and the placebo being indistinguishable from the active treatment. The results of this meta-analysis indicated a significant placebo effect in well-designed studies of conditions deemed amenable to placebo treatment, but no placebo effect in well-designed studies for conditions that had been deemed to not be amenable to placebo treatment. A particularly interesting finding in this meta-analysis was that there was no significant drug/placebo difference for conditions deemed amenable to placebo treatment.

These are not the only data indicating a powerful placebo effect. Although there are relatively few clinical trials of medications that include no-treatment control conditions, a number of experimental studies have been designed to investigate the effects of placebos. Numerous studies not included in Hróbjartsson and Gøtzsche's (2001) meta-analysis have shown that placebo analgesics, tranquilizers, stimulants and alcohol produce effects beyond those observed in untreated control conditions (see studies cited in Kirsch, 1997). In addition, a meta-analysis of published clinical trials of antidepressant medication indicated a change of 1.16 standard deviations on measures of depression following administration of placebo antidepressants, compared with a change of 0.37 standard deviations among untreated controls (Kirsch & Sapirstein, 1998). These data indicate a placebo effect size of 0.79 standard deviations. This is a powerful effect by any standard.

Just as inclusion of a placebo control is only one method of evaluating the effects of medical treatments, the inclusion of a no-treatment control group is only one method of evaluating the placebo effect. Medical treatment effects can be inferred when different doses of the same drug produce different effects or when a particular treatment is found to be significantly more effective than an alternative treatment. Similarly, placebo effects can be inferred when different placebos or apparent doses of the same placebo produce significantly different effects or when the effects of a placebo vary as a function of the information provided to the person to whom it is administered. Effects of this sort have been reported in a number of studies. For example:

- Asthmatic patients have been shown to exhibit bronchoconstriction after inhaling a placebo described as a bronchoconstrictor and bronchodilation after inhaling a placebo described as a bronchodilator (Luparello *et al.*, 1968; McFadden *et al.*, 1969; Neild & Cameron, 1985; Spector *et al.*, 1976).
- Placebo morphine is considerably more effective than placebo Darvon, which in turn is more effective than placebo aspirin (Evans, 1974). In each case, the placebo is about half as effective as the pharmacologically active drug. Similarly, placebos produce more pain relief when given after a more potent drug than they do

when given after a less potent drug (Kantor *et al.*, 1966). Thus, the effectiveness of a placebo pain reliever varies as a function of its believed effectiveness.

- Placebo and active analgesics are more effective when presented with a well-known brand name (Branthwaite & Cooper, 1981).
- Placebo injections are more effective than placebo pills (de Craen *et al.*, 2000).
- The colour of a placebo can influence its effects (reviewed in de Craen *et al.*, 1996). When administered without information about whether they are simulants or depressives, blue placebo pills produce depressant effects, whereas red placebos induce stimulant effects (Blackwell *et al.*, 1972). Patients report falling asleep significantly more quickly after taking a blue capsule than after taking an orange capsule (Luchelli *et al.*, 1978). Red placebos seem to be more effective pain relievers than white, blue or green placebos (Huskisson, 1974; Nagao *et al.*, 1968).
- The magnitude of the placebo response has been shown to vary as a function of the dose that the person is asked to consume (de Craen *et al.*, 1999; Kirsch & Weixel, 1988).
- Finally, Benedetti and colleagues (Benedetti *et al.*, 2003) developed a methodology for assessing the placebo effect without the use of placebos. Participants gave permission to receive a medication with or without foreknowledge of the onset of administration. Medication was subsequently administered intravenously, in some cases with the patient's knowledge and in other cases without any signal. Using this methodology, they found that substantial proportions of the effects of morphine on pain, stimulation of the subthalamic nucleus in Parkinsonian patients, and beta-blockers (propranolol) and muscarinic antagonists (atropine) on heart rate were due to the placebo effect. In addition, they reported that the effect of diazepam on postoperative anxiety was entirely a placebo effect, as hidden infusions of diazepam were totally ineffective in reducing postoperative anxiety.

Taken together, these data provide ample documentation of the presence of a placebo effect.

Psychological mechanisms underlying the placebo effect

Classical conditioning

How is it that an inert substance can produce psychological and physical changes? Currently, the two most popular explanations of the placebo effect are classical conditioning and response expectancy. Classical conditioning is a phenomena discovered by the Russian physiologist, Ivan Pavlov, at the beginning of the twentieth century. In classical conditioning, a stimulus (called an unconditional stimulus) that automatically elicits a response (called an unconditional response) is paired repeatedly with a neutral stimulus (called a conditional stimulus). After a number of such pairings, the conditional stimulus acquires the capacity to evoke a response (called a conditioned response). Generally, the conditional response is the same as the unconditional response, only weaker. In some cases, however, it appears to be the opposite of the unconditional response, in which case it may be referred to as a compensatory response.

As applied to placebo effects, conditioning theory posits the following sequence of events. Active medications are unconditional stimuli and the therapeutic responses they elicit are unconditional responses. The pills, capsules and injections by means of which the medications are delivered are conditional stimuli. Because these conditional stimuli are repeated paired with the active medications that produce the therapeutic benefits, they acquire the capacity to elicit these benefits as conditional responses.

Conditioning theory appears capable of explaining many placebo effects, but there are also some problems with this explanation. For one thing, the conditional response to morphine is an increase in sensitivity to pain (Siegel, 1983). However, the effect of placebo morphine is a reduction in pain sensitivity. Therefore, it cannot be due to classical conditioning. In fact, it seems to override the conditioning effect. Another problem with the conditioning model of placebo effects is that it does not account well for the existence of placebo effect throughout the history of medicine. Most of the substances that were used as medications before the twentieth century (e.g. turpentine, crushed glass, worms, spiders, furs, feathers, crocodile dung, lizard's blood, frog's sperm, pig's teeth, rotten meat, fly specs, powdered stone, iron filings and human sweat) are now recognized to have been placebos. Because they do not automatically produce therapeutic benefits, they cannot have functioned as unconditional stimuli for placebo effects.

Response expectancy

Response expectancies are anticipation of automatic subjective responses (e.g. changes in pain, anxiety, depression). According to Kirsch (1985), response expectancies tend to elicit the expected response. Thus, the anticipation of anxiety makes people anxious, the belief that one will stay depressed forever is very depressing, and the anticipation of changes in pain alters the perception of pain. More generally, subjective experience appears to be due to a mix of external and internal factors. It is shaped partially by external stimuli and partially by the person's beliefs, expectations and interpretations of those stimuli. As applied to the placebo effect, expectancy theory asserts that placebos produce their effects by changing people's expectations. A placebo antidepressant, for example, leads people to expect a change in their depression, and that expectation makes them feel less depressed. A shortcoming of expectancy theory is that it does not easily account for the physical effects of placebos (see also 'Expectations and health').

Research on conditioning and expectancy

Evidence in support of the classical conditioning model of placebo effects was reported by Voudouris *et al.* (1985; 1989; 1990). They reported an enhanced placebo effect following a series of conditioning trials during which the intensity of a pain stimulus was surreptitiously lowered when paired with placebo administration. They also showed that this conditioning effect was greater than that of a verbal expectancy manipulation. From a cognitive perspective, however, conditioning trials are themselves expectancy manipulations. So what was demonstrated in these studies can be interpreted as indicating that experiential manipulations (i.e. conditioning trials) are more effective than verbal manipulations in altering expectancies, a finding that had previously been reported by expectancy theorists (Wickless & Kirsch, 1989).

Montgomery and Kirsch (1997) conducted an empirical comparison of stimulus substitution and response expectancy interpretations of conditioned placebo effects. In addition to replicating the conditioning procedure used by Voudouris *et al.* (1985; 1989; 1990), Montgomery included an informed pairing conditioning group and an extinction control group. The informed pairing condition differed from the usual conditioning group in that subjects were told that the stimulus intensity was being lowered during conditioning trials. If the conditioning effect is a direct consequence of CS-US pairings, it should not be blocked by informing subjects of the manipulation. Conversely, if the conditioning effect is mediated by expectancy, nondeceptive pairings should fail to produce conditioning. Consistent with the expectancy interpretation, an increase in the placebo effect was obtained only when subjects were deceived into thinking that the intensity of the pain stimulus had been held constant. Furthermore, changes in pain reduction were accompanied by corresponding changes in expected pain reduction, indicating that the effect of the conditioning trials was mediated by expectancy.

It is important to note that conditioning theory and expectancy theory are not mutually exclusive. Specifically, classical conditioning may be one of the means by which expectancies are altered. Thus, if an active drug (the US) repeatedly elicits a particular therapeutic benefit (the UR), it will also lead people to expect that benefit when they think they are taking the drug, and that expectation might produce the placebo effect (the CR). Indeed, it is now widely accepted that classical conditioning works by producing representations (i.e. expectancies) about the consequences of conditional stimuli (Kirsch, Lynn, Vigorito & Miller, 2004).

Individual differences in placebo responding: the search for a placebo responder

There is considerable variation in response to placebo. Some participants may show a strong response, some a weak one and some no response at all. This has led researchers to search for the personality correlates of placebo responding. However, after more than a half century of research, 'the virtually unanimous conclusion among those reviewing the placebo literature is that there is no such thing as the placebo responder' (see review by Brody & Brody, 2000).

The conclusion that there is no such thing as a placebo responder is based on the failure to find reliable personality correlates of the placebo response. However, a failure to find correlates does not necessarily mean that placebo responding is not a personality trait. For example, the search for stable correlates of hypnotic suggestibility has been largely unsuccessful and the few correlates that have been found account for only a tiny proportion of the variance (Kirsch & Council, 1992). Nevertheless, hypnotic responding itself seems to be exceptionally stable, with test re-test correlations as high as 0.75 even with a 25-year interval between testing (Piccione *et al.*, 1989). Thus, hypnotic suggestibility appears to be a stable trait without many stable personality correlates. It is conceivable that this is the case for placebo responding as well, which is also, after all, a form of suggestibility.

Attempts to find correlates of the placebo response could succeed only if there is some reliability in the placebo response. However,

it is also possible that there is no such thing as a placebo responder and that placebo response is inherently unreliable. Data in support of this hypothesis were reported in an early but very influential study on the prevention of nausea (Wolf *et al.*, 1957). Participants were successively given placebo treatments for nausea, following which ipecac was administered. Response was defined as blocking the emetic effects of ipecac. This procedure was repeated seven times. Wolf *et al.* reported that response to earlier trials failed to predict response to subsequent trials. On the very last trial, for example, those who had been consistent placebo responders on the previous six trials were no more likely to respond to the placebo than those who had been consistent non-responders.

Although the Wolf *et al.* (1957) study supports the widespread conclusion that there is no such thing as a reliable placebo responder, there are a number of reasons for doubting this conclusion. First, it is not clear whether participants were informed that they might be receiving placebo on at least some trials. If so, they might have anticipated a crossover. In this case, success on a trial might lead them to think that they had received the active medication, rendering it more likely that a subsequent trial would be a placebo trial. This might counteract their tendency to respond to the subsequent trials. A second problem is that there were only 35 participants in the Wolf *et al.* (1957) study. Thus, the power was low for detecting a significant relationship. Third, because there was no no-treatment control condition and ipecac does not always produce nausea, it is possible that the non-occurrence of nausea on some trials was not always due to placebo administration.

Placebo psychotherapy

Given the importance of placebo effects in medical interventions, it was only natural that researchers began to question the degree to which the effects of psychological interventions might be placebo effects. To answer that question, studies were designed to include placebo psychotherapies, the effects of which can be compared to the genuine treatment (e.g. Paul, 1966). At first glance, this strategy seems reasonable, but, in fact, it is very problematic (Kirsch, 1978). There are both practical and conceptual problems with attempts to extend the placebo concept from the medical setting to the psychotherapeutic setting. Practically, it cannot be done; conceptually, it makes no sense to try.

The practical problem

In medical research, the purpose of using a placebo is to control for the psychologically produced effects of a particular treatment. To do this, it is important that the placebo have the same psychological properties as the treatment it is replacing. With pills and injections, this is easy. All that is needed is to omit the active ingredient. Thus, the placebo is the same size, shape, colour, taste and smell as the active medication. It is also provided with the same label and information.

With psychological treatments, constructing a matching placebo is impossible. By definition, a psychological treatment has no active physical properties. All of its ingredients are psychological. If a psychological treatment contained the same psychological properties as the real treatment (i.e. if the therapist used the

same words and procedures), it would no longer be a placebo or a control condition of any other kind. Instead, it would be the treatment.

As a result, procedures used as placebos in psychotherapy research are usually very different than the psychotherapies to which they are being compared. Among the procedures used as 'placebos' in psychotherapy research are the following: listening to stories, reading books, attending language classes, viewing films, participating in 'bull' sessions, playing with puzzles, sitting quietly with a silent therapist and discussing current events (see Prioleau *et al.*, 1983). Indeed, simply being placed on a waiting list has been labelled a placebo (e.g. Sloane *et al.*, 1975).

The conceptual problem

Following the medical model, it has become common to partition the response to psychotherapy as due to specific and non-specific factors, the latter being thought of as placebo effects. In medical research, that partition is unproblematic. Specific effects are those due to the chemical properties of the medication (or physical properties of a surgical intervention), whereas non-specific effects are those due to the psychological properties of the intervention. In psychotherapy research, the situation is altogether different. We do not need placebo controls to determine whether the physical properties of the treatment have an effect. We know the answer to that question without doing any studies at all, and that answer is no. Most psychotherapies do not have physically active properties. Their substance is words, and it is clearly not the sound of the words that are having an effect. Rather, it is their meaning. Moerman and Jonas (Moerman & Jonas, 2002) have defined the placebo effect as a patient's response to the meaning of a treatment. In this sense, most psychotherapy is a placebo by definition. That is, it is a treatment that is effective because of its psychological properties rather than its physical properties.

There are some treatment characteristics which are common to most psychotherapies and these are often referred to as placebo factors. Common factors include the establishment of a therapeutic relationship, discussion of the presenting problem; cognitive restructuring; and the provision of warmth, empathy, positive regard and response-contingent reinforcement, all of which might thus be labelled 'placebo factors'. Conversely, the specific rationale provided to clients about how the treatment works varies from treatment to treatment. So this would not be a placebo factor. It is worthwhile to examine the degree to which the effects of various psychotherapies are due to common factors, and comparative effect sizes suggest that this may account for a substantial proportion of treatment effects (Smith *et al.*, 1980; Wampold, 2001). However, this does not mean that psychotherapy is a placebo. Rather, it indicates the conceptual problem of applying the placebo concept to psychotherapy.

Clinical implications

Clinical use of placebos is relatively common. A survey of physicians and nurses, 60% acknowledged giving patients placebos (Nitzan & Lichtenberg, 2004). Given clinical benefits that are sometimes substantial and coupled with low rates of side-effects, it is not surprising that health providers would want to use them. Galvanizing the placebo effect may be especially useful in disorders like depression, in which placebos are almost effective as active medications (Kirsch *et al.*, 2002; Kirsch, Scoboria & Moore, 2002) and in which the medications pose serious side effect risks (Healy, 2003; Healy & Whitaker, 2003). The problem, however, is to find a way to capitalize on the placebo effect without deception. One way of doing this is to look for alternative treatments (e.g. physical exercise as a treatment for depression) which have been shown to provide benefit without incurring significant risk. The effects of these alternative treatments may also be largely due to the placebo effect, but this has not yet been demonstrated, and the side-effect profile may render these alternatives preferable. A second way to elicit the placebo effect without deception is to prescribe psychotherapy for disorders amenable to psychological treatment. In the case of depression, for example, meta-analyses indicate that psychotherapy is as effective as medication, possibly with the added benefit of a lower relapse rate (Hollon *et al.*, 1991).

The placebo effect may also enhance the benefits of an effective active treatment (Benedetti *et al.*, 2003). For that reason, clinicians should be careful about how they present the treatments they are administering or prescribing. Two different quantitative dimensions along which placebos can vary are the subjective probability or confidence that a change will occur and the magnitude of the expected change (Kirsch & Weixel, 1988). If too large a change is expected, a negative placebo effect may occur. For that reason, inculcation of high levels of confidence for initially subtle improvement may be optimal.

Conclusions

Placebos can affect a wide variety of conditions, and their effects can be substantial, in some cases coming close to duplicating the effects of active medications. These effects are specific to the type of placebo administered. Thus, placebo stimulants produce arousal, placebo sedatives produce sedation and so on. In addition, placebo effects can be observed in healthy volunteers. Thus, placebo effects cannot be fully explained by such factors as hope, faith or the therapeutic relationship. The effects of placebos seem to be mediated by response expectancies, and these can be produced or modified by classical conditioning. There is some evidence that placebo effects and drug effects are additive. This suggests the advisability of maximizing the placebo component of treatment, by inculcating realistically positive outcome expectations.

Introduction

Stressful life events have been linked to a range of immune-related disorders, including autoimmune diseases, infectious diseases and cancer. Some of the most compelling evidence for stress and disease associations stems from viral challenge studies, in which volunteers are exposed to a cold or influenza virus and then monitored in quarantine for the development of infection and illness. These studies find that individuals with more life stress, as measured by a higher number of recent stressful life events, higher perceived stress and more negative affect are more likely to develop colds than individuals with lower levels of stress (Cohen *et al.*, 1991), and that stressful events lasting a month or more are better predictors of developing colds than those of a briefer duration (Cohen *et al.*, 1998). In addition, individuals who are more sociable and have a diverse social network are less likely to develop a cold (Cohen *et al.*, 2003; Cohen *et al.*, 1997), possibly because such factors may be able to decrease the frequency of stressful life events or buffer deleterious effects of stress.

In addition to disease outcomes, stressful life events may also delay the healing of wounds. Recent studies have shown that long-term care givers who were caring for a severely ill family member experienced greater emotional distress and took nine days longer to

heal a dermal punch biopsy wound than age- and income-matched controls (Kiecolt-Glaser *et al.*, 1995). Similar findings were observed in dental students, whose punch biopsy wounds healed 40% more slowly during an examination period than during vacation (Marucha *et al.*, 1998). Such decrements in wound repair may have important implications with regard to surgical recovery and clinical wound repair. Broadbent *et al.* (2003) found that in patients undergoing a hernia operation, those with greater perceptions of stress and worry prior to operation had a more painful, poorer and slower recovery. Among patients at a wound clinic, Cole-King & Harding (2001) found that the healing of leg ulcers was delayed in individuals with higher levels of anxiety and depression (see also 'Life events and health' and 'Stress and health').

Potential mechanisms linking stress and immune disease

One means by which stress may lead to increased susceptibility to disease is by altering the function of the immune system. This hypothesis is one of the central concerns of the field of psychoneuroimmunology (PNI) which attempts to elucidate the relations between psychosocial factors, nervous, endocrine and immune

Table 1. Cells of the immune system

Cell type	Function
White blood cells (WBCs)/Leukocytes	Respond to antigens such as bacteria or viruses and altered host cells such as tumour or infected cells; include lymphocytes and phagocytes
Lymphocytes	Subset of WBCs that include T- and B-lymphocytes and NK cells; functions described below
T-helper lymphocytes	Enhance immune responses by stimulating T-cell replication and activating antibody production by B-lymphocytes
T-suppressor lymphocytes	Inhibit immune responses
T-cytotoxic lymphocytes	Destroy virus-, parasite- and tumour-infected cells; reject transplanted tissue
B-lymphocytes	Produce antibodies
NK cells	Destroy virally infected and tumour cells
Phagocytes	Subset of WBCs that include basophils, eosinophils, neutrophils, monocytes and macrophages; ingest and destroy antigens

systems and health. How stress may influence the immune system is not entirely clear. Stress may alter immune responses through the adoption of coping behaviours, such as smoking or drinking alcohol, that are known to compromise immunity (Kiecolt-Glaser & Glaser, 1988). Alternatively, stress may directly influence immune function through the activation of neuroendocrine pathways that lead to the release of various hormones and neurotransmitters, such as cortisol and catecholamines. Sympathetic nerve fibres innervate lymphoid organs, and immune cells, which migrate between lymphoid organs and the peripheral bloodstream, contain receptors for numerous hormones and neurotransmitters that are produced during stress (Plaut, 1987).

In PNI research, the most commonly measured component of the immune system is the immune cells, which are collectively known as white blood cells (WBCs) or leukocytes. While there are many types of leukocytes, each with distinct functions, such cells are interdependent and perform their functions in an orchestrated fashion to achieve immunocompetence. Table 1 lists the different types of immune cells and their primary functions.

Leukocytes also produce substances called cytokines. Cytokines which are produced by a subset of T-helper cells, called Th1 cells, include IL-2, TNF β and INF γ . These cytokines selectively activate T-cytotoxic cells and NK cells and thus promote cellular immunity. Cytokines produced by Th2 helper-cells include IL-4, IL-5, IL-6 and IL-13; they selectively activate B-cells and induce antibody production, thus promoting humoral immunity. For a description of measurements of immunocompetence in PNI research see the chapter on 'Psychoneuroimmunology assessments'.

Psychological stress and immunity

A substantial literature in both humans and animals supports associations between immunologic changes and psychological

and physical forms of stress (for a recent review, see Segerstrom & Miller, 2004). While the most frequently reported consequence of stressful events is the suppression of immune responses, other research suggests that some forms of stress may be able to both enhance and suppress aspects of the immune response by altering patterns of cytokine secretion (Marshall *et al.*, 1998). Because the cytokines of Th1 and Th2 cells antagonize each other, a suppression of one response may result in enhanced production of the other.

Naturalistic stressors and immunity

Academic stressors

Some of the most commonly examined stressors in relation to immunologic status have been examinations and other forms of academic stress. Indeed, several indices of immunosuppression have been observed among medical students during final exams. Compared to test-free periods, students undergoing exams have shown decrements in lymphocyte response to mitogenic stimulation, reduced NK cell activity, alterations in T-cell populations, increased plasma levels of circulating antibodies and changes in cytokine production (Kennedy *et al.*, 1988; Marshall *et al.*, 1998). Increased levels of circulating antibodies to Epstein-Barr and other herpes viruses have also been observed during examination periods, indicating, perhaps, the reactivation of latent virus by either direct neuroendocrine influences or weakened immunocompetence.

Several studies have found that some individuals are more susceptible to immune alterations during exams than others. For example, the largest immunologic changes were found to occur in students with the highest levels of overall life stress, anxiety, loneliness or tendency to ruminate about stressful events (Glaser *et al.*, 1992; Kiecolt-Glaser *et al.*, 1984; Marshall *et al.*, 1998; Workman & La Via, 1987). Personality styles associated with greater positive affect and adaptive coping strategies may attenuate stress-related immune alterations. Segerstrom *et al.* (1998) observed that optimistic first-year law students had higher levels of T-helper cells and NK cell cytotoxicity during their first semester of law school than did pessimistic students (see 'Personality and health').

While most studies support an effect of immune suppression from examination stress, other recent findings suggest that exams and other brief naturalistic stressors may increase Th2 cell-mediated humoral immunity and macrophage activity, and concurrently decrease Th1 cell-mediated cellular immunity. In a recent meta-analytic review of the PNI field, Segerstrom and Miller (2004) found that examinations are often associated with increases in IL-6 and IL-10, and decreases in IFN- γ . The decreased Th1 cytokine production is consistent with observed decreases in T-cell proliferative responses and NK cell activity, and increased antibody production to latent viruses. It is also possible that an increase in humoral activity during stress might contribute to an increased incidence of type-2-mediated conditions, such as allergic/asthmatic reactions and heightened autoimmune activity (Marshall *et al.*, 1998).

Bereavement

The loss of an intimate relationship from either death or divorce has also been associated with altered immunity, including suppression of lymphocyte responses to mitogenic stimulation, reduced NK cell activity and changes in T-cell sub-populations. Early investigations found lowered mitogenic lymphocyte proliferation in bereaved subjects following the loss of a spouse (Bartrop *et al.*, 1977) and that the degree of immune change was related to the severity of depressive response before and after the loss (Irwin *et al.*, 1987). In men infected with the human immunodeficiency virus (HIV), the death of an intimate partner or close friend has been found to result in lowered NK cell activity and proliferative responses to PHA compared with nonbereaved, HIV-infected men (Goodkin *et al.*, 1996; Kemeny *et al.*, 1995). Findings relating bereavement to numbers of T-helper (CD4) cells in HIV-positive men have been mixed, with some studies showing no relationship (Goodkin *et al.*, 1996; Kemeny *et al.*, 1995), and others linking bereavement to an enhanced CD4 decline (Kemeny & Dean, 1995) (see 'Coping with bereavement').

Separation, divorce and marital conflict

Separation, divorce and marital conflict have similarly been associated with immune alterations. Kiecolt-Glaser, Glaser, and colleagues found that recently separated or divorced women demonstrated lower percentages of circulating NK and T-helper cells, decreased proliferative responses to PHA and Con A, and higher antibodies to Epstein-Barr virus than a comparison group of married persons (see Kennedy *et al.*, 1988). Higher antibody levels to latent viruses were also found in separated or divorced men and couples reporting poorer marital quality (Kennedy *et al.*, 1988). Finally, studies from this research group have found that marital conflict that includes hostile interactions may evoke fairly persistent immune changes, even when couples report being happily married (Kiecolt-Glaser *et al.*, 1993; Kiecolt-Glaser *et al.*, 1997). In a study of newly-wed couples, those who exhibited more hostile or negative behaviours during a brief conflict resolution task were found to exhibit greater declines in functional immune measures 24 hours later (Kiecolt-Glaser *et al.*, 1993). Similar results were found in couples who had been married an average of 42 years (Kiecolt-Glaser *et al.*, 1997).

Other prolonged stressful events

Immunologic changes accompany other prolonged stressors, as well, such as long-term unemployment, occupational stress and care giving for a terminally ill patient. In an examination of the immune-related effects of care giving for a family member with Alzheimer's Disease, Kiecolt-Glaser and colleagues found that caregivers exhibited lower percentages of total lymphocytes and T-helper cell subsets, and higher antibody titers to Epstein Barr virus (Kiecolt-Glaser *et al.*, 1987). In addition, care givers demonstrated lower antibody responses to both influenza virus and pneumococcal pneumonia vaccines compared with age-matched controls (Glaser *et al.*, 2000; Kiecolt-Glaser *et al.*, 1996; Vedhara *et al.*, 1999). In two of these studies, fewer care givers achieved the

four-fold increase in antibody titre (used as a marker of vaccination success) than did controls (Kiecolt-Glaser *et al.*, 1996; Vedhara *et al.*, 1999). Given the increased morbidity and mortality among the elderly after exposure to influenza viruses, such findings may be of clinical importance. Finally, there is evidence that chronic stress and depression may contribute to the greater production of cytokines (Anisman & Merali, 2002) or a dysregulated cytokine response to vaccination (Glaser *et al.*, 2003). Higher levels of plasma IL-6 were observed in a group of care givers compared to individuals who were anticipating a housing relocation or community controls (Lutgendorf *et al.*, 1999). In older adults receiving an annual influenza vaccination, those with more depressive symptoms showed an increase in plasma IL-6 by two weeks after vaccination, whereas there was little change in adults reporting few or no symptoms of depression. Such findings suggest that depressed mood may be related to an amplified and prolonged inflammatory response after vaccination (Glaser *et al.*, 2003).

Both job stress and long-term unemployment have been linked to lowered lymphocyte reactivity to PHA (Arnetz *et al.*, 1987). In contrast to stress and burnout at work, a high sense of personal accomplishment at work may be associated with higher numbers of peripheral lymphocytes, particularly T-cell subsets (Bargellini *et al.*, 2000).

Traumatic events

Fewer studies have examined immunologic changes associated with exposure to extreme traumatic stressors, such as natural disasters, and accidental and deliberate man-made traumatic events. Such studies, however suggest that immune alterations may persist for long periods of time, particularly if symptoms of rumination, anxiety or post-traumatic stress disorder (PTSD) result. In an early study, persistent distress over the nuclear accident at Three Mile Island was associated with higher latent antibody levels and enumerative immune alterations in community residents more than six years after the accident (McKinnon *et al.*, 1989). Symptoms of PTSD were also related to lower NK cell cytotoxicity in residents of neighbourhoods that were damaged by Hurricane Andrew and this effect appeared to be mediated by the development of sleep disturbances associated with the trauma (Ironson *et al.*, 1997).

Two studies have investigated immune alterations in released male prisoners of war and women living in a refugee camp during the Bosnian and Croatian wars (Dekaris *et al.*, 1993; Sabioncello *et al.*, 2000). Both studies found higher numbers of activated lymphocytes in these individuals, compared with laboratory staff controls, along with an increase in proliferating lymphocytes in the female refugees (Sabioncello *et al.*, 2000). Although neither study included assessments for PTSD, other research suggests that the development of PTSD following war and other catastrophic events may be associated with elevated serum IL-6 and IL-1 β concentrations (Maes *et al.*, 1999; Spivak *et al.*, 1997), and NK cell activity (Laudenslager *et al.*, 1998). In addition, there is preliminary evidence that veterans with current PTSD or anxiety mount greater cutaneous delayed hypersensitivity test reactions than do veterans without PTSD, suggesting that exposure to disasters and the development of PTSD may be associated with enhanced cell-mediated immunity (Boscarino & Chang, 1999). Despite the methodological

difficulties in this area, these findings remain interesting because they counter evidence that chronic stress suppresses immune functions. These disparate results may be due, in part, to a dysregulation of the HPA axis in PTSD, whereby persistent activation of the HPA axis and enhanced negative feedback of this system lead to lower plasma and urinary cortisol concentrations (Yehuda *et al.*, 1990).

Taken together, most studies involving stress and immunity indicate that psychological stressors are associated with changes in immune functions. The most consistent alterations include reduced NK cell activity and lymphocyte proliferation to PHA and Con A, and increased antibody levels to latent herpes viruses. Changes in percentages or absolute numbers of lymphocyte populations are also frequently reported stress-related immune responses, although these changes are weaker and not as reliable across studies (Segerstrom & Miller, 2004). Preliminary studies also suggest that brief forms of stress may lead to cytokine changes that promote a shift from cellular (Th1) immunity to humoral (Th2) immunity and that traumatic events such as disasters might be linked to enhanced immune function, perhaps in the context of post-traumatic stress disorder and diminished cortisol levels.

Short-term laboratory stressors and immunity

During the last decade, many laboratory studies have been conducted to examine stress-immune interactions. Such investigations are advantageous because they approximate the effects of transient daily life stressors and provide a means to investigate potential endocrine mechanisms underlying associated immunological changes. A number of standardized laboratory stressors have been used in these experiments, including challenging computer tasks, mental arithmetic, electrical shocks, loud noise, unsolvable puzzles, graphic films depicting combat surgery, marital discussions involving conflict and mood manipulation tasks. Exposure to these stressors has been shown to evoke a variety of enumerative immune changes, the most consistent of which are increases in the numbers of circulating NK cells and T-suppressor/cytotoxic lymphocytes, and a decrease in the ratio of T-helper to T-suppressor cells. Decreases in lymphocyte mitogenesis and increased NK cell activity are also commonly reported (for a review, see Kiecolt-Glaser *et al.*, 1992). Less is known about cytokine responses to acute psychological stressors, but preliminary reports indicate that such tasks can evoke increases in serum levels and mitogen-induced production of certain cytokines, such as IL-6 and TNF- α (Kunz-Ebrecht *et al.*, 2003; Steptoe *et al.*, 2001), although negative findings have also been reported (Heesen *et al.*, 2002).

The data suggest that most of the immunologic changes following acute stress are rapid and transient, occurring as early as 5 minutes from stressor onset (Herbert *et al.*, 1994). One exception to this rapid response may be stress-induced alterations in serum cytokine levels, which, in some cases, may not be detectable until 45 minutes post-stress (Kunz-Ebrecht *et al.*, 2003; Steptoe *et al.*, 2001). The duration of immunological reactions to acute mental stress may also depend on the parameter in question. Changes in cell redistribution return to baseline within 15 minutes of stressor termination (Brosschot *et al.*, 1992), whereas changes in immune function may persist for at least 90 minutes after challenge (Zakowski *et al.*, 1992).

There is now a great deal of evidence that acute immune responses to psychological stress are largely mediated by activation of the sympathetic nervous system. The most direct evidence for sympathetic mediation is derived from the observation that changes in cellular immune function under stress are ameliorated by the prior administration of an adrenoceptor antagonist (Bachen *et al.*, 1995). Consistent with these findings, studies have also shown that individuals who demonstrate the greatest sympathetic reactions to brief mental stress (as indicated by heightened cardiovascular and catecholamine responses) also produce the greatest immunologic changes (Manuck *et al.*, 1991).

The extent to which individuals differ in their sympathetic, endocrine and immunological responses to stress may have implications for their susceptibility to stress-related illnesses. Recently, investigations have demonstrated that sympathetic and immunologic reactions to brief psychological stress may predict antibody responses to vaccines. Marsland *et al.* (2001) found that medical students who demonstrated the greatest decline in lymphocyte proliferation to PHA following laboratory stress also had the poorest antibody response to a hepatitis B vaccination programme. Cacioppo (1994) also found that sympathetic activation predicted response to an influenza vaccination, with a measured T-cell response declining more quickly in individuals who showed greater cardiac sympathetic activation following a mental task. Similarly, Burns *et al.* (2002) found that individuals who responded to acute stress with a larger cardiac output (reflecting heightened cardiac activation mediated by beta-adrenergic processes), exhibited lower antibody titres to hepatitis B vaccination, compared with those demonstrating a smaller cardiac output. How concomitant changes in other stress-related substances, such as cortisol may influence antibody responses to vaccines is currently unclear, but it is noteworthy that positive relationships between the magnitude of sympathetic and cortisol responses to acute stress have been reported (Cacioppo *et al.*, 1994).

Implications and future directions

Stressors of various types do induce a wide range of immunologic alterations in humans. It is through such changes in immune system functioning that stressors may ultimately be linked to subsequent disease. Before these firm conclusions can be reached, however, several gaps in our knowledge of stress-immune-disease relationships must be empirically addressed. Apart from the experimental studies on susceptibility to colds and wound healing in the PNI field, few studies have measured health outcomes. For example, no studies examining the effects of stress on antibody responses to vaccines have included an assessment of vaccine efficacy in terms of disease incidence and severity (Burns *et al.*, 2003). The importance of measuring health outcomes is highlighted by the fact that immune responses of stressed persons generally fall within normal ranges and thus it remains unclear if the nature and magnitude of immunologic change found in PNI research bears relevance to increased disease susceptibility.

Additional research that focuses on populations that may be most susceptible to the influence of stress is also needed. Older people are known to have greatly increased morbidity and mortality from infectious illness and immune alterations

associated with ageing include decreases in proliferative responses to mitogens, natural killer cell activity, antibody production and phagocytic activity (Scapagnini, 1992) as well as increases in IL-6 production (Cohen, 2000). Stress-related immune alterations may have more important consequences for individuals with already compromised immune systems, such as the elderly or those with autoimmune disorders or HIV-infection (Kiecolt-Glaser & Glaser, 1987).

There is little empirical evidence defining the roles of health behaviours and other mechanisms in evoking immunologic changes to stress. Preliminary evidence indicates that sleep disturbances following stress may play an important mechanistic role (Ironson *et al.*, 1997). Interactive effects between health practices and other variables may also be important to consider, especially for behavioural changes that are moderate. For example, Jung *et al.* (1999) found that mild to moderate levels of cigarette smoking were associated with lower NK cell activity, but only in individuals who were

also depressed. Further research on neuroendocrine influences on immune alterations during naturalistic stress is also needed, but is complicated by regulatory processes that accompany prolonged stress, such as negative feedback systems, receptor down-regulation and shifts in circadian rhythms. Despite these complexities, naturalistic studies do suggest that both the sympathetic nervous system and HPA axis play important roles in modulating immune function during stress (Burns *et al.*, 2002; Goodkin *et al.*, 1996; Mckinnon *et al.*, 1989; Vedhara *et al.*, 1999).

In conclusion, during the last 30 years, PNI research has made great strides in identifying relationships between psychological stressors and altered functioning in the immune system. This remains one of the most promising pathways through which stress may alter host resistance to disease onset or exacerbation. Carefully designed prospective studies, measuring all three aspects of the stress-immune-disease model are needed to more fully understand these associations.

Psychosomatics

Christopher Bass

John Radcliffe Hospital

Introduction and historical overview

The term 'psychosomatic' was first used in the early nineteenth century by Heinroth to mean 'belonging to the body and the mind' (Bynum, 1983). Psychosomatic conceptions were much older than this however. Plato observed that the ability of the 'physicians of Hellas' to cure disease was limited because they disregarded 'the Whole, which ought to be studied also, for the part can never be well unless the whole is well' (Plato (transl) See Padis, 1952). The term 'psychosomatic' is a modern designation for that holistic view of man and medicine which has its roots in ancient Greece. Throughout the nineteenth century it was widely accepted that psychological factors could play a part in the aetiology of physical illness.

The term has been used in a number of different ways in the last hundred years however. In the first half of the twentieth century three psychosomatic schools emerged and competed for prominence: the psychoanalytic, the psychophysiological and the psychobiological (holistic, biopsychosocial). The development of these three schools, which proved difficult to integrate, will be briefly described.

The psychoanalytical school, led by Alexander, focused on the postulated psychogenesis of a handful of somatic disorders of unknown cause such as bronchial asthma, rheumatoid arthritis, ulcerative colitis, essential hypertension, neuro-dermatitis, thyrotoxicosis and peptic ulceration. Alexander (1950) proposed that emotional changes in human beings were accompanied by physiological changes which led in turn to pathological physical changes: once physical pathology was established, psychological factors could help to maintain or aggravate it or to trigger relapse. For Alexander, a specific 'emotional constellation', one consisting of an unconscious conflict, defences against it, and emotions engendered by it, would elicit specific vegetative responses, which could lead to a specific bodily disorder. This led to the belief that a physical condition produced in this way would improve if the psychological disturbance improved, either spontaneously or as a result of psychological treatment.

Alexander's theories came to connote for many people nothing but the psychological causation of bodily disorders, and this psychological reductionism fell into disfavour after the 1950s. The other psychosomatic schools, the psychophysiological and the psychobiological, have gained prominence over the last 50 years, as the psychoanalytical school's influence has faded away. The psychophysiological school, derived from the work of Pavlov on the conditioned reflex and of Canon on the physiological concomitants of emotions, such as fear and rage, was prominently represented by Wolff, who postulated the contributory role of psychological stress on in the occurrence, course and outcome of a wide range of

diseases. Wolff and his colleagues examined the mediating physiological mechanisms that occur following one's exposure to personally meaningful information. That whole area of research has flourished subsequently under the label of psychophysiology.

The psychobiological school was derived from the work of Adolf Meyer. Led by Flanders Dunbar, this school was most explicitly holistic in its orientation. Dunbar, who founded the American Psychosomatic Society, published a substantial survey of her own and other clinicians' observations in the book 'Emotions and Bodily Changes' (Dunbar, 1954). She emphasized the need for a comprehensive, biopsychosocial approach to the study and management of all patients and not just those called 'psychosomatic'. She was one of the pioneers of liaison psychiatry, and also emphasized the need for preventive medicine and stressed the important role played by psychosocial factors in disease development and prevention.

In its modern usage the term 'psychosomatic' has come to connote holistic. This refers to a set of assumptions about mind and body, the role of psychosocial factors in health and disease and the place of these factors in medical management.

Recent definitions of the term psychosomatic emphasize the mind-body relationship as follows:

1. *Involving or concerned with the interdependence of mind and body*
2. *(Medicine) designating, pertaining or relating to illnesses having both physical and mental components, usually involving a physical condition caused or aggravated by mental or emotional disorder (Shorter Oxford English Dictionary, 2001).*

Psychosocial factors are believed to be involved, to a greater or lesser extent, in every disease and episode of illness. All disease is assumed to be multicausal, which is to say it is the result of a complex interplay of biological, psychological and social variables.

Recent developments

Since the 1970s theories have been less dogmatic. A key publication by Engel in 1977 proposed the biopsychosocial approach to illness. Subsequent research has focused on a number of broad areas that are not mutually exclusive. They include psychophysiological mechanisms; the impact of life events and difficulties on illness; the physical manifestations of psychological illness; the psychological consequences of physical illnesses; and the effect of psychological treatments. These five areas will be discussed below. The word 'psychosomatic' now appears in five leading journals, and both general hospital (liaison) psychiatry and health psychology have developed as major areas of clinical practice and research over the last two decades. A recent updated database of key references in this field has been published by Strain *et al.* (2003).

Psychophysiological research

A major purpose psychological physiological research has been to detect the physiological mechanisms and pathways between the perception of personally meaningful stimuli or information by the individual and the consequent changes in the functions of his or her various organs or tissues. Every sick person is exposed to personally meaningful information, such as remarks from doctors, which have the potential to affect mood or behaviour and in turn elicit changes in physiological functions. These may be therapeutic or deleterious. The most commonly researched psychosocial variable has been emotional stress.

The two main biological systems involved in the stress response are the sympathetic nervous system and hypothalamic–pituitary–adrenal system (HPA axis). The normal role of the sympathetic nervous system is to mediate the unconscious regulation of basic bodily functions. In a stressful situation it is also the chief mediator of the bodies' immediate alarm reaction – the so-called fight-or-flight response.

Disturbed regulation of the HPA axis can also occur in response to long lasting arousal. Regulatory disturbances in the HPA axis have been suggested to play a role in certain illnesses. For example, the lack of response to stimulation of the HPA axis results in low plasma cortisol levels: as a consequence normal activation does not take place when the HPA axis activated artificially. A subgroup of patients with chronic fatigue syndrome and fibromyalgia show these characteristic patterns (Parker *et al.*, 2001).

Other studies have shown that a person's psychological state may induce, presumably through neuroendocrine mechanisms, changes in the immune system that would facilitate the development of neoplasia. The field of psychoneuroimmunology has recently been the subject of a major review (Reiche *et al.*, 2004) (see 'Stress and health' and 'Psychoneuroimmunology').

Arising from the work of Dunbar in the 1950s a number of investigators examined the links between certain personality and behavioural characteristics and the development of coronary heart disease (CHD). Despite two decades of research effort the 'Type A' behaviour pattern turned out not to be aetiologically relevant, and a meta-analysis of the body of research on the physical health consequences of hostility concluded that the psychological trait of hostility – cynical mistrust, anger and aggression – is a risk factor for not only CHD but also for virtually physical illness (Miller *et al.*, 1996) (see 'Hostility, Type A behaviour and coronary heart disease' and 'Personality and health').

One of the most potent (and most frequently investigated) stressors in contemporary life is work. Occupational stress has become very topical, and is also a legitimate field of research (Wainwright & Calnan, 2002). It has been demonstrated that certain occupational characteristics are more likely to lead to adverse outcomes than others. For example, many jobs involving high degrees of effort but providing lower levels of reward – in terms of remuneration, job security and prospects for promotion – are at higher risk of developing several of the biological precursors of heart attack, such as raised cholesterol level and blood pressure. Job strain and effort – reward imbalance have also been found to be associated with high health risk behaviours and psychological illness (Marmot and Bartley, 2002).

This research in occupational stress has emphasized that being unsure of your ability to control a stressor appears to make matters

worse. Uncontrollable stressors carry a higher risk of provoking psychological depression than equally severe but controllable stressors. For example, when animals are subjected to severe and uncontrollable stressors they can develop a mental state called learned helplessness, which bears many of the hallmarks of clinical depression in humans (Seligman, 1986). Marmot has extended this work and recently argued that low social standing is seen not only as a condition of material deprivation but also an indicator of people's capability to control life and fully participate in society (psychosocial disadvantage). As a person's position in the social hierarchy decreases, the less likely he or she is to have full control over life and opportunities for full participation in society. Marmot (2004) has made a forceful case showing that low control over life and social disengagement are the most powerful explanatory factors for the social gradient of health: people who are lower in the hierarchy tend to have worse health and shorter life expectancy.

Control has multiple ramifications for mental and physical wellbeing (Breier *et al.*, 1987). For instance, it helps people to deal with chronic pain. A person who feels he/she is in control of pain and of their life will be consistently better able to cope with prolonged high levels of pain than one who feels helpless. Research has confirmed that boosting patients' sense of control helps in the management of pain. This is an important practical issue for cancer patients and others suffering from chronic pain (Morley *et al.*, 1999) (see 'Coping with chronic pain' and 'Self-efficacy and health').

Life events and difficulties

The notion that we are at increased risk of falling ill when exposed to a lot of disruptive change or emotional turmoil is not a new one. Early studies of absenteeism indicated that employees with unsettled personal lives tended to suffer frequent bouts of illness and take more sick leave from work.

The formulation of the concept of stressful 'life events' has led to thousands of research projects which have investigated the relationships between life events and health. Methodological problems bedevilled this work, which is essentially retrospective in nature and influenced by the perception and interpretation of the significance and meaning of events by individuals.

George Brown and his colleagues in London have been pioneers in this research endeavour and have developed a methodology that attempts to circumvent these difficulties (Brown & Harris, 1989). In a key early study they demonstrated that the link between severe life events and the onset of organic illness was likely to be mediated by the occurrence of a psychiatric (affective) disturbance (Murphy & Brown, 1980). Subsequent research, using the Life Events and Difficulties Schedule (LEDs) has shown that life events can have a very important role not only as precipitants but also as formative causes of a wide range of illnesses. For example, important links have been established between life events and the onset of a number of physical disorders such as multiple sclerosis and stroke. In the recent INTERHEART study, in which patients were recruited from 52 countries, the presence of a range of psychosocial stressors was associated with increased risk of myocardial infarction (Rosengren *et al.*, 2004). A range of functional somatic syndromes such as functional dysphonia, chronic fatigue syndrome and functional gastrointestinal disorders have also been shown to

be related to stressful life events (see Hatcher & House, 2003, for a recent account of this field) (see also 'Life events and health').

In addition to major life events, such as bereavement and unemployment, more mundane 'hassles of everyday life' and 'chronic ongoing difficulties' have also been shown to have an impact on health. Indeed, because these mundane problems are such a frequent occurrence, their cumulative influence on health may be more pervasive than the effects of rarer, but more traumatic life events (Bennett *et al.*, 1998).

Physical manifestations of psychological disorder

Patients who report physical symptoms with no identifiable cause have attracted considerable interest and controversy; not least because there is no consensus on how these disorders should be described. For many years patients with unexplained symptoms were said to have a 'psychosomatic' illness. However, this term is now considered to be potentially misleading when used to describe these patients, as it implies that the symptoms necessarily have a purely psychogenic origin, which is not always the case. An alternative term, 'somatisation', has been coined to describe a putative process by which some people experience and communicate psychological distress as physical symptoms, but this description presumes that psychological problems are being avoided and that the physical symptoms are 'all in the mind'. To avoid the artificial separation of the mind and body, terms such as 'medically unexplained symptom' and 'functional somatic symptoms' have been used. None of these terms is satisfactory, but it has been shown recently that patients with these disorders prefer the term 'functional' to other descriptions (Stone *et al.*, 2002).

Clusters of chronic medically unexplained symptoms can appear to form symptom syndromes, and so are sometimes given diagnostic labels such as irritable bowel syndrome, chronic fatigue syndrome or fibromyalgia, depending on the symptoms and the medical specialty to which the patient is referred. The results of a recent observational study suggest that substantial overlap exists across diverse symptom syndromes. Indeed, the overlap between such syndromes is so great that they are better seen as a single underlying disorder (Nimnuan *et al.*, 2001).

In adults, medically unexplained symptoms prompt almost half of all primary care consultations, but are shown to have an organic origin in only about 10–15% of patients who were followed for one year. In general hospitals these patients are responsible for 30–50% of presentations in outpatient departments: these patients are difficult to manage, costly and often the victims of iatrogenic illness if they are not identified and treated promptly. These disorders have attracted considerable attention (Mayou *et al.*, 1995) and have been the subject of numerous treatment studies in the general hospital. Cognitive behaviour therapy (CBT) is widely advocated for these patients, and in a systematic review of 31 controlled studies (29 randomized) physical symptoms improved in 71% of studies, psychological distress decreased in 38% and functional status improved in 47% (Kroenke & Swindle, 2000). Group CBT also helps patients with medically unexplained symptoms, and hypnosis has also shown benefits (see 'Cognitive behaviour therapy'). Regrettably, there are insufficient clinical psychologists in general hospitals available to provide appropriate treatment for these patients, who are an enormous burden on healthcare resources.

Table 1. Determinants of the occurrence of psychiatric disorder among physically ill patients

The physical disease as a cause of:
Symptomatic psychiatric disorder
Threat to normal life
Disability
Pain
Nature of the treatment
Side-effects
Mutiliation
Demands for self-care
Factors in the patient
Psychological vulnerability
Social circumstances
Other life stresses
Reactions of others
Family

Doctors

Psychological consequences of physical illness

Organic mental disorder may occur in the course of many serious physical illnesses or surgical procedures, especially among the elderly. Delirium, dementia and other organic disorders associated with specific medical conditions have been described by Lishman (1998). This section is concerned with emotional disorders consequent upon physical illness.

Certain factors increase the risk of serious psychiatric disorders developing in the physically ill. Patients are more vulnerable if they have had a previous psychiatric disorder or a life-long inability to deal with adversity, or if they have a disturbed home life or an otherwise unsatisfactory social background. Furthermore, certain kinds of physical illness are more likely to provoke serious psychiatric consequences. These include life-threatening illnesses, and illnesses requiring lengthy and unpleasant treatment such as radiotherapy or renal dialysis or mutilating treatment such as mastectomy (see 'Coping with chronic illness').

In the physically ill, the commonest psychiatric disorders are emotional disorders, which occur in 10–30% of patients with severe physical illnesses. Most of these emotional disorders can be diagnosed as adjustment disorders, whilst specific anxiety and affective disorders are also common. Other conditions that are less frequent are somatoform disorders and paranoid disorders. The many psychological symptoms that can be caused directly by physical illness are shown in Table 1.

Depressive and anxiety disorders precipitated by physical illness or injury may be regarded as being mediated by the meaning of the illness for the patient, rather than as a direct manifestation of cerebral dysfunction. Significant depression has been found in approximately 20–25% of unselected medical inpatients, but its prevalence has been reported as much higher immediately following myocardial infarction, and in patients suffering from rheumatoid arthritis, Parkinsonism or carcinoma of the pancreas. It is important to diagnose mood disorder in patients with physical illnesses because the psychiatric complications may adversely effect patients' prognosis and interfere with rehabilitation and timely return to work.

Furthermore, depression is associated with an approximately 50% increase in medical costs of chronic medical illness, even after controlling for severity for physical illness. Increasing evidence suggest that both the depressive symptoms and a major depression may be associated with increased morbidity and mortality from such illnesses as diabetes and heart disease. The adverse effect of major depression on health habits, such as smoking, diet, over-eating and sedentary lifestyle, its maladaptive effect on adherence to medical regimens, as well as direct adverse physiological effects (i.e. decreased heart rate variability, increase adhesiveness of platelets) may explain this association within morbidity and mortality (Katon, W.J. 2003).

In the last two decades there has been considerable interest in the psychosocial and psychopathological effects on modern medical and surgical technology, for example, transplantation surgery, chronic dialysis, intensive care units and long-term parenteral nutrition. More recent surgery for obesity has become a safer and more 'evidence based' procedure (Buchwald *et al.*, 2004) with improved outcomes. The recent clamour for cosmetic and plastic surgical procedures in patients with body image disorders has resulted in psychiatric casualties. As a consequence a need for pre-operative psychological assessment has increased, placing extra demands on psychological resources that often cannot be met (Grossbart & Sarwer, 2003).

Therapeutic research

Interventions in this field are usually directed towards modifying selected psychological variables; behavioural, cognitive or emotional. Therapeutic studies can be divided into two groups, which are not mutually exclusive: (a) those that employ psychotropic medication and (b) those that employ psychological methods.

- a. **Drug therapy.** Hypnotic and anxiolytic drugs are valuable for short periods when distress is severe, for example, during treatment in hospital. The indications for antidepressants are probably the same as those for patients who are not physically ill, although the older tricyclic antidepressants have drawbacks because of their side-effects. In a recent randomized, double-blind, placebo-controlled trial, Sertraline was found to be a safe and effective treatment in patients with recent myocardial infarction or unstable angina and without other threatening medical conditions (Glassman *et al.*, 2002).
- b. **Psychological treatments.** Behaviour medication and biofeedback have been used for many years for the relief of a wide range of symptoms such as urinary incontinence, tension headache, various other painful disorders and, more recently, chronic constipation (Bassotti *et al.*, 2004). This field of behavioural medicine demonstrates that physiological and pathophysiological functions can be modified by manipulation of psychological variables, a demonstration predictable from psychosomatic assumptions discussed earlier (see 'Behaviour therapy' and 'Biofeedback').

Psychological interventions have also been used in the rehabilitation of a wide variety of physical disorders such as stroke and myocardial infarction. Although there is no evidence to support the routine use of pharmaco- or psychotherapeutic treatment for

depression after stroke, the evidence for behavioural treatment after myocardial infarction is more positive (Mayou *et al.*, 2002).

Weinman and his colleagues showed that patients' initial perceptions of illness are important determinants of different aspects of recovery after myocardial infarction. Furthermore, they predict overall functioning and number of visits to the outpatient clinic in patients with chronic obstructive pulmonary disease. More recently Petrie *et al.* (2002) showed that an in-hospital intervention designed to alter patients' illness beliefs and perceptions about their heart attack resulted in improved functional outcome. This is clearly a key area for future research in cardiac rehabilitation (see 'Coronary heart disease: rehabilitation').

The usefulness of Cognitive behaviour therapy in medically unexplained symptoms – the so-called 'functional' disorders – has already been mentioned. Similar approaches have been used to treat patients with chronic pain, especially in the setting of multidisciplinary pain clinics (Morley *et al.*, 1999) (see 'Cognitive behaviour therapy' and 'Pain management').

Developments since 2001

In March 2003 the American Board of Medical Specialties unanimously approved the creation of a seventh psychiatric sub-specialty, 'psychosomatic medicine', which defines all those working in consultation liaison psychiatry and general hospital psychiatry.

This title should not seem surprising, given the appearance of the word 'psychosomatic' in four of the five leading journals that serve the sub-specialty and the names of professional associations. This followed two decades of lobbying among US psychiatrists (and similar informal discussions among UK psychiatrists) and has been reviewed by McIntyre (2002).

A word of caution is in place however. In a recent article Stone *et al.* (2004) explored the ways in which the word 'psychosomatic' was used in US and UK newspaper articles. They carried out a survey of all articles published in 14 US and UK newspapers between 1996 and 2002. The survey was limited to broadsheet newspapers. The authors found that 'psychosomatic' had a pejorative meaning, such as 'imaginary' or 'made up', in 34% of the articles in which the meaning could be judged. Most commonly, 'psychosomatic' was used to describe a problem that was psychological or in which the mind affects the body (56%) rather than a reciprocal interaction (5%). The authors concluded that although the term 'psychosomatic medicine' is the new name for the seventh sub-specialty of psychiatry, more needed to be done to educate the media about its actual meaning to make it attractive to patients.

Conclusion

Like hysteria, the word 'psychosomatics' continues to be widely used and has outlived its obituaries. The concept of psychosomatic medicine has become more widely accepted and is recognized as not only a reaction against mind-body dualism, but also as an organized field of scientific enquiry. In a clinical sense it represents an approach to the patient that recognizes the important relationship between psychological factors and bodily function, both in health and disease.

Quality of life

Lena Ring

Uppsala University

Human beings continually strive to create meaning in their lives and they struggle to achieve happiness by pursuing the things that they value (Diener *et al.*, 2003). Speculation about how to achieve 'the good life' or 'good quality of life' (QoL) is probably as old as humankind. According to Socrates: 'You should put the highest value, not on living, but on living well'. However, it is only in recent decades that there has been a growing interest in assessing QoL in healthcare (SAC, 2002) and conceptualizations of QoL in healthcare have been heavily influenced by earlier developments in the measurement of functional health status in medicine and the evolution of social indicators in the social sciences (Prutkin & Feinstein, 2002).

The concept of QoL began to appear in the social science literature in the 1920s (Wood-Dauphinee, 1999). The development of population indices was influenced by the social indicators movement, which emphasized the need to focus on social factors that influence satisfaction (Erickson, 1974; Andrews & Withey, 1976; Campbell, 1976). Most of these early measures were based on experts' ratings of objective phenomena such as the distribution of income. Later studies assessed subjective indicators such as satisfaction with income and satisfaction with life, using measures such as Cantril's self-anchoring scale, Bradburn's Scale of Affect Balance and Campbell and Converse's Human Meaning of Social Change Scale (Cantril, 1965; Bradburn, 1969; Campbell and Converse, 1972). Traditionally, medicine had focused on objective outcomes, such as mortality and morbidity assessed by clinical and laboratory indicators. In order to provide a comprehensive assessment of the benefits and costs of a treatment, a broader range of measures, such as QoL instruments, was proposed (Wood-Dauphinee, 1999). However, early measures such as the Karnofsky scale (Karnofsky & Burchenal, 1948) were based on 'experts' assessments of patients' functional status. It is now generally accepted that the patient is in the best position to assess his/her own QoL as proxies generally underestimate patients' QoL. Agreements between patient and proxy assessments are highest for physical aspects and lowest for psychological aspects of QoL, but proxies' ratings are consistently higher when the proxy is a relative compared to a member of the healthcare team (Wilson *et al.*, 2000) (see 'Health status assessment' and 'Quality of life assessment').

Patient QoL is increasingly measured as an adjunct to more traditional clinical outcomes and 'quality of life' has been a key term in MEDLINE since 1977. This reflects an increasing acceptance of a holistic approach to health that is more in keeping with a biopsychosocial model than the traditional biomedical model of disease (Engel, 1977). This change is due, in part, to the ageing of populations with a resulting increase in the prevalence of chronic

and degenerative diseases. Since there are few curative treatments available, maintaining or improving QoL may be the most realistic goals. Kozma *et al.* (Kozma, Reeder *et al.*, 1993) have proposed what they call the Economic, clinical, and humanistic outcomes (ECHO) model of health outcomes, that involves assessing interventions in terms of economic, clinical and humanistic (QoL) outcomes. By measuring such a range of such outcomes, a comprehensive picture, known as the 'balloon effect', of the impact of interventions on the healthcare system can be formulated. If only one outcome is assessed, we do not know how the rest of the balloon will react following an intervention or treatment. For example, a particular treatment regimen might save on drug costs but lead ultimately to an increase in hospitalization (Gunter, 1999).

Impressive developments in medical technology and knowledge, combined with budgetary restrictions, have increased the demand for evidence-based healthcare and have highlighted the need to enumerate outcomes for all medical decisions both at the policy level and at the level of individual treatment planning (Zou *et al.*, 2004). The development of more broadly based assessments is relevant here since such measures can contribute to the assessment of treatment efficacy and side effects resulting in more informed treatment planning (Claridge & Fabian, 2005).

The health goals of many governments and international organizations are to improve QoL. For example, the World Health Organization's goal for 'The Healthy Cities Project' is to improve all citizens' health and QoL. The European Commission's 'Quality of Life and Management of Living Resources Programme' is targeted at enhancing the QoL of all European citizens. In the US, the primary goal of 'Healthy People 2010' is to increase life expectancy and improve QoL. Several professional associations also focus increasingly on QoL as an important outcome. In pharmacy, for example, the definition of pharmaceutical care is 'the responsible provision of drug therapy for the purpose of achieving definite outcomes that improve the patient's quality of life' (Hepler & Strand, 1990). A number of scientific organizations, such as The International Society for Quality of Life Research (ISOQoL; <http://www.isoqol.org>) and the Cochrane Collaboration Health Related QoL Methods Group (<http://www.cochrane-hrqol-mg.org>) focus on the scientific measurement of QoL.

QoL assessment

The past two decades have seen a dramatic increase in the development of measures of QoL and hundreds of measures now exist (Bowling, 2001); The QOLID database; www.qolid.org). Many current QoL measures are based on population indices of happiness and wellbeing or on functional capacity and performance indices

(Prutkin & Feinstein, 2002). Only about 20% of measures are generic, 10% utility based and 1% individualized (Garratt *et al.*, 2002). Most are disease-, population- or domain-specific and many have been developed originally for use in oncology, cardiology and rheumatology. Most measures consist of multi-item scales but single-item, visual analogue scales might provide a valid and reliable alternative (de Boer *et al.*, 2004). Some authors have introduced shorter versions of their instruments (Coste *et al.*, 1997). Many of these measures are now widely used in clinical trials and some are also used in clinical practice and in population-based studies (see 'Quality of life assessment').

Clinical trials

QoL is now widely used as either a primary or a secondary endpoint in clinical trials and the range of applications of QoL measurements in clinical trials continues to expand. Even if the primary purpose of a treatment regimen is to increase survival, QoL outcomes are relevant. For example, Gridelli *et al.* (Gridelli *et al.*, 2004) found that Docetaxel administered weekly was more satisfactory for lung cancer patients than when administered every third week. Comparable increases in survival were found with both regimens, but the weekly treatment was associated with increased QoL and with fewer adverse events. QoL assessments are also relevant when comparing treatments regarding dose, administration form etc. Diel *et al.* (Diel, Body *et al.*, 2004) found that a higher dose of ibandronate increased QoL (physical, emotional, social and global) and decreased pain for patients with breast cancer and bone metastases. Weiss *et al.* (Weiss, Nguyen *et al.*, 2005) found a novel betamethasone valerate foam for treating stasis dermatitis, not only to be clinically superior to placebo, but also to be associated with improved QoL. QoL measures are particularly important for evaluating long-term preventive therapies such as blood pressure and cholesterol lowering drugs. In a now classic study, Croog *et al.* (Croog *et al.*, 1986) demonstrated that, whereas captopril, propranolol and methyl-dopa all showed satisfactory and comparable efficacy and safety profiles in patients with hypertension, QoL was significantly enhanced by captopril only.

The application of QoL outcomes in clinical trials is a complex and developing field. The outcomes of such studies have begun to be considered by regulatory authorities such as the FDA but it is generally agreed that significant further development is required before the weight accorded to such outcomes is similar to that accorded to the more traditional indicators of efficacy and safety (Willke *et al.*, 2004).

Clinical practice

QoL assessments have primarily been used for research purposes in clinical trials but have had relatively little impact on clinical practice, even though monitoring patients' QoL in clinical practice is likely to achieve better treatment outcomes. Patients are often unsatisfied with the quality of communication with, and the amount of information they receive from, their healthcare providers (Glimelius *et al.*, 1995) (see '*Patient satisfaction*'). Acute, medical problems are often attended to, while chronic problems and psychosocial aspects of care and treatment receive

less attention (Fallowfield *et al.*, 2001). Both patients and physicians often wish that these aspects of treatment could be given more attention (Detmar *et al.*, 2000). Even though patients and physicians are willing to discuss physical aspects of the condition, each expects the other to initiate discussion of psychosocial issues (Detmar *et al.*, 2000). Systematically monitoring patients' QoL might help to individualize care, enhance patient-physician communication, inform clinical decision-making and improve patient outcomes especially QoL itself. QoL information could enhance the clinical interview which tends to focus primarily on physical symptoms and it could serve as the basis for joint doctor patient decision-making about treatment options. Some studies have explored the possibility of improving the care of patients by using systematic and continuing QoL assessments in clinical practice (Greenhalgh & Meadows, 1999; Espallargues *et al.*, 2000). Improvements in patient-physician communication were found, but the impact on patient satisfaction was limited. Intervention studies in cancer patients have shown that providing patient-specific QoL information to the physician and the patient before an appointment is an effective means of improving patient-provider communication (Detmar *et al.*, 2002) (see '*Healthcare professional-patient communication*').

If QoL measures are to become a routine feature of clinical practice, they must be easy to use, highly reliable, valid and sensitive to change. Many current measures fail to meet these criteria (McHorney & Tarlow, 1995). Previous studies in clinical practice have used standardized QoL instruments, although it has been suggested that more individualized instruments might be preferable (Greenhalgh & Meadows, 1999). One approach might be to use individualized quality of life (IQoL) instruments (O'Boyle *et al.*, 2005). Developments in information technology mean that computer-administrated instruments can now be used to overcome some of the difficulties of administration and scoring in clinical practice (Velikova *et al.*, 2002).

Population studies

As early as the 1920s, QoL issues were included in political debate when discussing the potential impact on people's lives of policy decisions (Pigou, 1920). However, it was only after the Second World War that attention was focused on evaluating the QoL of whole populations. Around this time, the World Health Organization introduced a new definition of health which included physical, emotional and social wellbeing (World Health Organization, 1948). Subsequently, the social indicators movement emphasized the need to examine the distribution of health and wellbeing in different populations and to monitor change in relation to national goals (Michalos, 1980). For example, studies of QoL in general populations examined the influence of education, health, family and personal life, work, environment and finances on wellbeing (Andrews & Withey, 1976; Campbell, 1976).

Today, national health interview surveys (HIS) are common in Europe, the USA, Canada and Australia (Aromaa *et al.*, 2003). Most studies include self-assessed health, general mental health and physical disability as measures of wellbeing. Other initiatives such the International Quality of Life Assessment (IQOLA) project collect QoL data to obtain national reference norms for the SF-36

(Ware & Gandek, 1998). The IQOLA project has found a significant impact of chronic conditions on physical health and a moderate impact on mental health across the countries studied (Alonso *et al.*, 2004). The World Health Organization Quality of Life Assessment (WHOQoL) has been designed to assess QoL cross-culturally and to reflect the WHO's commitment to a holistic view of health (Skevington *et al.*, 2004). Diener and colleagues (Diener *et al.*, 2003) have focused on assessing subjective wellbeing in many different countries and have demonstrated substantial differences between cultures. It is proposed that these differences might be due to individual factors such as personality, genetic make-up, attitude and expectations as well as more global factors such as cultural norms, GNP and political systems.

Research in health economics that incorporates measures of both quantity and quality of life might help in realizing better population health. Governments must often make policy decisions about the allocation of limited resources and reliable data on the impact of such decisions on QoL may lead to more informed choices. Some health economists have argued for the use of combined economic and QoL measures such as the QALY as an aid to decision making in resource allocation (Drummond, O'Brien *et al.*, 1999).

Some future challenges for QoL research

Interpretability

The results of QoL assessments require interpretation since the meaning of QoL scores is neither intuitive nor exclusively causally related to biological factors. Interpretation of scale scores requires more than just a consideration of statistical significance. It requires demonstration of clinical relevance. Different concepts of clinical significance have been proposed (Marquis *et al.*, 2004). 'Distribution-based interpretations' are based on the statistical distribution of the results and the effect size is the most commonly used measure here. This refers to the magnitude of change compared to the variability in stable subjects. It is also possible to compare or 'anchor' scores to clinical status or other meaningful criteria such as life events or global ratings. Content-, construct- or criterion-based interpretations involve examining the content of the measure using qualitative and quantitative methods, examining the relationship between or among scales or examining how the scale relates to external variables such as job loss or utilization of healthcare. Norm-based interpretations compare scores for a particular group with large population-based samples.

Cultural issues

Although the meaning of QoL can differ across cultures, it may be possible to develop measures that can capture at least some elements of QoL across all cultures (WHO, 1998). The cross-cultural adaptation of an instrument involves both assessment of conceptual and linguistic equivalence and evaluation of measurement properties (Bowden & Fox-Rushby, 2003). However, cultures also differ markedly in their cognitive systems and beliefs about the world. Social differences affect not only beliefs about specific aspects of the world but also beliefs about the nature of cognitive processes themselves. For example, happiness, as opposed to perceived norms

about whether one should be satisfied or not, correlates significantly more strongly with life satisfaction in more individualistic nations such as North America and Western Europe than in more collectivist cultures such as China and India (Suh *et al.*, 1998). Latin Americans are among the happiest and East Asians are among the least happy based on this characterization of happiness (Diener *et al.*, 2003). It appears that East Asians weigh the worst areas of their lives when computing their life satisfaction while Latin Americans may be rooted in cultural norms supporting a belief that life in general is good (see also 'Cultural and ethnic factors in health').

Computerized adaptive testing (CAT)

Computerized Adaptive Testing (CAT) is a new method designed to make surveys much shorter, more precise and less expensive. In contrast to traditional surveys where the same questions are asked of everyone regardless of their answers, CAT surveys make it possible to individualize each assessment so that only the most relevant and informative questions are asked of each person at their particular level of health. Associated with CAT is the emerging statistical approach of item response theory (IRT), which is used instead of the 'classical' psychometric approach for constructing and calibrating generic and disease-specific HRQoL measures (Ware, 2003).

Cognitive aspects of survey methodology (CASM)

QoL assessments, although apparently simple, require sophisticated cognitive processing. Respondents are typically required to understand complex, abstract questions, retrieve information from long-term memory, aggregate that information and apply frequency judgements, magnitude estimation and decision heuristics in selecting which response category to endorse. There is growing interest in applying Cognitive Aspects of Survey Methodology (CASM) techniques to existing instruments to investigate whether the cognitive processes employed by respondents, in reading, comprehending and interpreting questions and in formulating and providing answers vary across cultures or with respect to other respondent characteristics. CASM provides techniques such as cognitive interviewing and linguistic analysis that help to elucidate the cognitive mechanisms underlying responses (McColl *et al.*, 2003).

Response shift

People with severe diseases often report QoL equal or superior to less severely ill people or healthy people and consistent disparities arise between clinical measures and patients' own evaluations. These findings reflect the dynamic nature of QoL, increasingly known as response shift (Schwartz & Sprangers, 2000). Response shift refers to a change in the meaning of one's evaluation of a construct as a result of a change in one's internal standards of measurement, a change in one's values or a redefinition of the construct. In repeated measures studies, a response shift may mask or exaggerate a treatment effect where the measures are patient reported outcomes (PROs) such as QoL. It can also be argued that achieving a response shift may be a reasonable therapeutic aim in helping patients adapt to health-related challenges.

This is in line with current suggestions in the positive psychology literature for using well-being therapy (Fava & Ruini, 2003).

Conclusion

The application of QoL assessment in healthcare has grown rapidly over the past decade. The concept and measurement of QoL entered medical research from two different sources, i.e. medical assessment of functional health status and developments in social indicators research. QoL assessments in healthcare are used mainly in clinical trials, clinical practice and in population-based studies. Exciting new developments in QoL research include, *inter alia*, the application of computer adaptive testing technology (CAT), item

response theory (IRT), cognitive aspects of survey methodology (CASM) and response shift analysis. The major challenge to the field is to develop a level of sophistication, interpretation and cross-cultural validity that allows QoL information to become an important part of routine clinical practice making possible an evidence-based approach to holistic patient care.

Religion and health

Karen Hye-cheon Kim¹ and Harold G. Koenig²

¹University of Arkansas for Medical Sciences

²Duke University Medical Center and Geriatric Research, Education and Clinical Center, VA Medical Center

Religion is an influential force in today's society. Over 4 billion worldwide identify themselves with a religious group (Bedell, 1997). In the USA alone, recent polls report that 93% believe in God, 30–42% of adults (72 million) attend religious services weekly and 85% report that religion is at least fairly important in their own lives (DDB Needham Worldwide, 2000; Gallup Poll, 2001). Religion is not only an influential force but a growing force as well. In the late twentieth century came the rise of religious fundamentalism (Sherket & Ellison, 1999), the awakening of new religious movements and the expansion of other older movements such as

Mormonism and Pentecostalism (Chaves, 1994). Religious beliefs about political issues and the family also continue to influence the cultural milieu. Since religion is deeply interwoven in social life, could not religion also influence health?

Research on the religion–health relationship has not only arisen from recognizing religion's continuing influence on private and public life, but also from the changing nature of medical institutions. The impersonal nature of medical treatment, burgeoning healthcare costs and the realization of science's limitations through medical mistakes have moved medical professionals and

researchers to consider and examine other avenues for health promotion and treatment (Koenig *et al.*, 2001).

Religion and medicine were virtually one and the same entity before the fourteenth century, but the divide between them grew after the 1500s, resulting after the Enlightenment in the clash between the two disciplines seen today (Koenig *et al.*, 2001). However, recent research on religion's connection to health has prompted a renegotiation of this relationship.

In this chapter, we will examine religion's relationship with physical health and with mental health. We will then discuss potential mechanisms through which religion may be connected to health. Finally, we will discuss the implications this research field has on medical practice and public health. Given that most research on religion and health has been conducted in the United States (Koenig *et al.*, 2001), the content of this chapter will be based largely on conceptualizations and studies of religion and health from a Judaeo-Christian framework.

Religion and physical health

Mortality

Over 100 studies have examined religion's relationship with mortality, including longitudinal investigations (Koenig, 2001a). Several aspects of religiosity have been consistently related to lower mortality, including self-reported religious attendance and mortality. In a 28-year longitudinal study of 5286 adults, frequent religious service attenders had a 23–36% lower mortality rate than infrequent attenders (Strawbridge *et al.*, 1997). In another study, those who never attended religious services exhibited 1.87 times the risk of death during a nine-year period compared with those who attended religious services more than once a week (Hummer *et al.*, 1999). Longitudinal studies examining religion's relationship with mortality have reported an average 30% reduction in mortality in healthy subjects after controlling for important confounders (Powell *et al.*, 2003). Regarding religious denomination, Seventh-Day Adventists, Mormons, the Amish, and to a lesser extent, Jews, have lower mortality rates than the general population (Koenig, 2001a).

Although the evidence suggests that religion (particularly religious attendance) is related to lower mortality, a few studies have reported the opposite (Koenig, 2001a). Patients experiencing religious struggles (i.e. believing that God does not love them, has abandoned them, is punishing them or does not have the power to help them) had a 19–28% higher mortality during a 2-year follow-up period (Pargament *et al.*, 2001). Thus, religion's relationship with mortality may depend on what aspect of religion is assessed in relation to health.

Cardiovascular disease

Studies examining religion's relationship with cardiovascular disease have reported less heart disease and lower cardiovascular mortality among the more religiously involved (Koenig, 2001a; Mueller *et al.*, 2001; Powell *et al.*, 2003). In two longitudinal studies following large American adult samples, religious attendance was related to lower rates of death from cardiovascular disease, even after adjusting for age, gender, education, ethnicity, health status

and social contacts (Hummer *et al.*, 1999; Oman *et al.*, 2002). The relationship of religious denomination membership with cardiovascular disease is more mixed, with some studies reporting higher rates of cardiovascular disease in some religious groups and lower rates in others (Friedlander *et al.*, 1986; Medalie *et al.*, 1973; Goldbourt *et al.*, 1993).

Regarding religion's relationship with stroke, few studies have been conducted. One six-year longitudinal study reported a positive relationship between religious attendance and lower stroke incidence (Colantonio *et al.*, 1992). Those who attended religious services once or twice per year or more were 14% less likely to have a stroke during the follow-up period. Controlling for mediating factors such as blood pressure helped to explain this effect.

Cancer

Numerous studies have compared the risk of cancer and mortality rates from cancer by religious denomination (Koenig, 2001a). Most consistently, Mormons and Seventh-Day Adventists have a lower risk of mortality from cancer than the general population (Phillips *et al.*, 1980; Berkel & deWaard, 1983; Enstrom, 1989). A handful of studies, however, have examined the relationship of general religious activity with cancer. National representative samples of American adults followed from one to three decades have reported a positive relationship between religious attendance and lower cancer mortality (Hummer *et al.*, 1999; Oman *et al.*, 2002). These relationships between religion and cancer mortality, however, became insignificant when demographics, health behaviours and prior health status were controlled. Studies examining religion's relationship with cancer progression have reported few significant relationships (Powell *et al.*, 2003).

Hypertension

Different aspects of religion have been positively related to lower blood pressure and less hypertension, particularly lower diastolic blood pressure (Koenig, 2001a; Mueller *et al.*, 2001). Most of these studies are cross-sectional, but two are prospective in design (Koenig *et al.*, 1998a; Timio *et al.*, 1997). In one of the largest of these studies, cross-sectional results at baseline indicated that participants who attended religious services and engaged in private religious practices (e.g. prayer and frequent Bible studying) had a 40% lower likelihood of having high diastolic blood pressure (90mm Hg or higher), even after adjusting for known risk factors for hypertension (Koenig *et al.*, 1998a).

Other studies of physical health

The literature on religion's relationship with disability is less clear. Two well-controlled longitudinal studies in the elderly have reported no relationship between religion (religious attendance, depth of religiousness) and disability development (Colantonio *et al.*, 1992; Goldman *et al.*, 1995). However, a well-controlled prospective study from Yale University reported a significant association of religious attendance and lowered risk for disability over 6 to 12 years of follow-up (Idler & Kasl, 1997). On the other hand, a few studies have reported religion's relationship with greater body weight

(Ferraro, 1998; Kim *et al.*, 2003), which may influence health (see 'Obesity').

Religion and mental health

Although the relationship between religion and physical health remains controversial, associations with mental health are more consistent.

Psychological well-being

A review of religion's relationship with psychological well-being reported that 79 of 100 studies found significant positive correlations (Koenig, 2001*b*). These positive associations between religion and well-being have been reported in a variety of samples, including groups of varying ages and religions (i.e. Christian, Jewish and Muslim) (Koenig *et al.*, 2001). Some longitudinal studies examining religion's relationship with well-being have reported significant relationships cross-sectionally (Graney, 1975; Willits & Crider, 1988), but not over time. However, at least half a dozen longitudinal studies have found significant positive relationships between religious involvement and well-being when studied over time (Koenig *et al.*, 2001).

Depression

Numerous studies have documented a lower rate of depression and faster recovery from depression among the more religious (Koenig, 2001*b*; McCullough & Larson, 1999; Mueller *et al.*, 2001). This relationship between religion and depression has been documented in several methodologically sophisticated studies. In a one-year longitudinal study of medically ill older patients, those reporting higher intrinsic religiosity experienced faster remission from depression (Koenig *et al.*, 1998*b*). This relationship remained significant after controlling for confounders. Of eight clinical trials, five reported that depressed subjects receiving a religious intervention recovered faster than subjects in control groups or those receiving secular interventions (Koenig, 2001*b*).

Anxiety

A majority of prospective cohort studies and clinical trials have reported religion's association with less anxiety (Koenig, 2001*b*; Mueller *et al.*, 2001). In one clinical trial, Muslim subjects randomly assigned to religious psychotherapy experienced lower anxiety than those receiving medications and supportive psychotherapy alone (Razali *et al.*, 1998). Cross-sectional studies examining religion's relationship with anxiety have reported mixed results; thus religion may not only influence anxiety but those who are anxious may turn to religion as well.

Other studies of mental health

Studies examining religion's relationship with psychotic symptoms and disorders are sparse and mixed, with some reporting religion's relationship with fewer psychotic symptoms or disorders (Koenig, 2001*b*; Verghese *et al.*, 1989), greater psychotic symptoms (Neeleman & Lewis, 1994) or no relationship (Cothran & Harvey, 1986; Lindgren & Coursey, 1995).

The literature on religion's relationship with suicide is clearer. A majority of studies, including those with prospective designs, have reported relationships between different aspects of religion (attendance, self-reported importance, belief in God, religious upbringing) and less suicide or more negative attitudes towards suicide (Koenig, 2001*b*; Mueller *et al.*, 2001).

A majority of studies examining religion's relationship with delinquency or crime have also reported inverse relationships, particularly among younger persons (Koenig, 2001*b*). Studies utilizing national samples have reported a positive relationship between different aspects of religion (attendance, importance) and lower delinquency among high school students (Stark, 1996; Wallace & Forman, 1998).

A small number of studies have also examined religion's relationship with body image and dieting, reporting mixed results (Kim, 2006; Kim, 2007; Wechsler *et al.*, 1981).

How is religion related to health?

Health behaviours

Religion's social sanctions against smoking, drinking and high-risk behaviours are possible mechanisms for its relationship with positive physical outcomes (Ellison & Levin, 1998; Sherkat & Ellison, 1999). A substantial number of studies confirm that more religious persons are less likely to abuse and use alcohol, drugs and cigarettes. These have included longitudinal studies and randomized trials, with different conceptualizations of religion (denomination, attendance, salience, upbringing) (Koenig *et al.*, 2001; Mueller *et al.*, 2001). Religion is also associated with lower high-risk sexual practices, extra-marital affairs and numbers of sexual partners among young adults (Koenig, 2001*b*) (see 'Sexual risk behaviour').

Theological teachings about the body and certain dietary restrictions may also serve to promote positive health behaviours, such as healthier nutrition and increased physical activity (Shatenstein & Ghadirian, 1998; Kim *et al.*, 2004). In contrast, religious teachings may also discourage adherents from obtaining appropriate medical care, which may serve to hinder health (Chatters, 2000).

Social support and networks

Religion provides adherents with social resources by increasing opportunities to enlarge and enhance social networks through religious services and other events (Chatters, 2000). Meaningful relationships may also be encouraged through religious doctrine's emphases on the virtue of caring and supporting others in need. Social support and network mechanisms through religion may also negatively affect health. Social relationships could be sources of distress and deterring from group norms could lead to negative emotions such as guilt and shame, which may hinder health (Chatters, 2000) (see 'Social support and health').

Stress and coping

Religious teachings, beliefs and behaviours (e.g. prayer) may enable adherents to counter and cope with stress (Mickley *et al.*, 1995). The similar ideologies, world-views and values which congregants share may also promote the formation of meaningful relationships,

which enables stress to be interpreted and tackled from a base of shared values and world outlooks (Ellison and Levin, 1998). This support in times of chronic and acute stress may help to buffer the negative relationship of stress with health (Sherkat & Ellison, 1999). However, religious coping may also be maladaptive. Utilizing negative religious coping, where one is struggling with one's faith, may contribute to poorer health outcomes (Pargament *et al.*, 2001) (see 'Stress and health').

Other psychosocial mechanisms

Religion provides meaning and understanding with regard to meta-physical questions and those questions related to why things happen (Musick *et al.*, 2000). Having this framework of understanding may serve to positively effect health. Embedded in religion's role of providing metaphysical meaning are theological teachings about worth which may also serve to promote health. Believing that one has a relationship with a divine being who loves personally and unconditionally may serve as a source of meaning and self-esteem (Ellison & Levin, 1998; Sherkat & Ellison, 1999).

Religion may also increase self-efficacy and perceived control. 'Doing' religion through supporting others could give participants a sense of achievement. Further, communicating with a deity through prayer, meditation and song offers a means through which the believer can petition for changes in circumstances that would otherwise seem beyond their control (Ellison & Levin, 1998; Sherkat & Ellison, 1999) (see 'Perceived control' and 'Self-efficacy and health').

However, some religious beliefs may engender feelings of shame and guilt, leading to negative self-esteem (Chatters, 2000). Religious struggle, including feeling punished by God, may also serve to decrease self-esteem (Pargament *et al.*, 2001). Thus negative aspects of religion may work concomitantly with other forms of religiousness to affect health.

Immune and neuroendocrine function and biological pathways

Religion may be related to health in part through influencing immune and neuroendocrine function. Several recent studies have reported religion's significant correlation with several immune function parameters, including higher T helper/inducer cell (CD4) counts (Woods *et al.*, 1999), greater numbers of white blood cells, greater total lymphocyte counts (Sephton *et al.*, 2001) and lower levels of an inflammatory marker (Interleukin-6) (Sephton *et al.*, 2000). Religion has also been linked with lower levels of cortisol, a biological measure of stress (Ironson *et al.*, 2002; Sephton *et al.*, 2000) (see 'Psychoneuroimmunology').

Implications

Physicians have struggled over the role religion should play in their work. Religion can be a sensitive topic that elicits a range of highly charged beliefs, attitudes and emotions from both doctor and patient. Unlike the traditional practice of medicine, religion is also seen as highly subjective and personal, which brings ethical concerns. Given these apprehensions, however, physicians see religion's role in the lives of many of their patients, and consequently realize that for some, health is beyond physical and mental and may in fact involve the spiritual as well. Taking a brief spiritual history of a patient would inform the physician as to whether faith is playing a role in their patient's health. If faith is playing a role, understanding the relationship between religion and health would enable the physician to encourage better health through a patient-centred approach, which can include referrals to chaplains or other pastoral counsellors as needed (Koenig, 2002).

Understanding the relationship between religion and health would not only enable medical professionals to be more knowledgeable in interacting with some patients, but would also enable public health professionals to more sensitively collaborate with religious communities. Religious communities have been the sites for several successful public health interventions (Lewis & Green, 2000; Resnicow *et al.*, 2001). Thus better understanding religion's relationship with various health outcomes may lead to the creation of more effective faith-based interventions. Being aware of how different aspects of religion can promote both positive and negative health outcomes could also inform programme makers in the creation of health promotion materials.

The study of religion and health is an ancient discipline that has been re-awakened in its present form. This new form has materialized itself in the empirical study of religion's relationship with health: Is there a connection? If so, how is religion connected to health? Future studies utilizing sophisticated methodological designs will be needed to elucidate direction of causality. Future work will also need to more accurately capture the complex, multi-dimensional nature of religion by including measures of religion other than religious attendance. Examining religion's relationship with health in a framework other than a predominately U.S. Judaeo-Christian one will also be needed to fully understand the religion-health connection. Thus in its current form, the work of religion and health is only beginning. However, in other ways the study of religion and health has been an ongoing one in that it asks questions that we have all asked ourselves at one point or another: Is there an unseen that affects what is seen? What is the exact nature of the world that we live in? Is there something bigger than the self that has an influence on life? Thus in this sense, the study of religion and health is nothing new, but rather an ancient question that has not only intrigued many generations past but will continue to intrigue many generations to come.

Risk perception and health behaviour

Baruch Fischhoff

Carnegie Mellon University

Introduction

Health depends, in part, on deliberate decisions. Some are private, such as deciding whether to wear bicycle helmets and seat belts, follow safety warnings, use condoms and fry (or broil) food. Other decisions involve societal issues, such as whether to protest about the siting of an incinerator or halfway house, vote for fluoridation and 'green' candidates or support sex education.

Sometimes, single choices have large effects on health risks (e.g. buying a car with airbags, taking a dangerous job, getting pregnant). At other times, the effects of individual choices are small, but accumulate over multiple decisions (e.g. repeatedly ordering broccoli, wearing a seat belt or using the escort service in parking garages). Yet other times, choices intended to reduce health risks achieve nothing or the opposite (e.g. responding to baseless cancer scares, subscribing to quack treatments).

In order to make health decisions wisely, individuals must understand the risks and benefits associated with alternative courses of action. They also need to understand the limits to their own knowledge and to the advice proffered by various experts. This chapter considers how to describe people's beliefs about health risk issues, as a step toward designing (and evaluating) interventions designed to improve their choice. A fuller account would also consider the roles of emotion, personality, culture and social processes (Lerner & Keltner, 2000).

Framing health-risk decisions

Any study of decision-making faces four strategic choices (Fischhoff, 2005):

a. *Does it begin with a formal analysis of the decision?* With cancer, for example, those decisions could include whether to rely on breast self-examination, get a genetic test, take an experimental

treatment or reduce sunbathing. The focal outcomes might include health effects, as well as changes in psychological wellbeing, personal relationships, insurability and family finances. The probabilities of these outcomes might be assessed with meta-analyses or expert judgement. The outcomes might be evaluated by conversion to a common unit (e.g. dollars, Quality Adjusted Life Years (QALYs)) or by the decision makers' preferences. Researchers who skip the formal analysis implicitly assume that they know both how people's choices will affect their lives and how people feel about those effects. Some decisions pose very familiar choices, hence need little formal analysis; others are novel, complex and uncertain – challenging any researchers' intuitions (Hastie & Dawes, 2002).

b. *Does the research adopt a persuasive stance?* Health researchers often hope to identify choices needing improvement. Those choices could be evaluated in terms of either 'rationality' or 'optimality'. The former criterion asks whether people have followed the internal logic of their beliefs and values. The latter asks whether people have done the best thing. The two standards could differ if people's beliefs or values are deemed wrong. If people have the wrong facts, then the remedy might be communicating the risks of current behaviours and the risk-reduction benefits of alternative ones. Having the wrong values might mean enjoying short-term pleasures (food, sex, thrills) too much and carrying about negative long-term consequences too little – even after knowing just what they entail. Trying to change what matters to people means presuming to know what is good for them. Adopting a persuasive stance means determining that people cannot be trusted to understand the facts and reach a rational conclusion. Its legitimacy depends on whether its targets acknowledge these limits (as might happen with complex, time-constrained choices or ones not worth thinking about).

- c. *Do interventions seek to improve specific choices or confer general mastery of the decision-making domain?* Any (non-fatal) choice is but one in a sequence. It may be revisited (e.g. 'should I stay the course [with a lifestyle change or drug treatment]?'). It may create new choices (e.g. 'should I reveal my test result?'). It may change the person involved (e.g. facing future choices with regret or pain). Broadening the context can make choices clearer – or overwhelm decision makers with detail. Efficiently manipulating behaviour, time after time, may undermine the chances for sustained, informed change. People may think in terms of individual choices, not realizing how risks and benefits mount up through repeated exposure.
- d. *Which individual differences should be considered?* People's circumstances (e.g. health, social support, financial resources, sensitivity to medication) and values (e.g. time horizon, tolerance for ambiguity, concern for others) may vary, so that people in ostensibly the same situation may face very different choices. A full account would also consider differences in the decision-making processes that they favour (e.g. reflecting their need for technical mastery, desire for autonomy, emotional resilience) and their social context (e.g. cultural expectations, shared decision making, safety net). People may also vary in their health literacy or in their decision-making competence (Parker & Fischhoff, 2005). The importance of all these factors varies. An effect can be robust and theoretically informative without having practical impact.

Quantitative assessment

Estimating the size of risks

A common presenting symptom in experts' complaints about lay decision making is that 'they do not realize how small (or large) the risk is'. Where that is the case, the mission of health communication is conceptually simple (if technically challenging): transmit credible risk estimates. Research suggests that lay risk estimates are, indeed, subject to bias (Kahneman *et al.*, 1982; Slovic, 1987).

In one early study (Lichtenstein *et al.*, 1978), subjects judged the annual number of deaths in the US from each of 30 causes (e.g. botulism, tornados, motor vehicle accidents), using one of two response modes. One task presented pairs of causes; subjects chose the more frequent, then estimated the ratio of the frequencies. The second task had subjects directly estimate the death tolls, after being told the answer for one cause (an anchor), in order to give an order-of-magnitude feeling for what numbers were appropriate. The study reached several seemingly robust conclusions.

- a. *Estimates of relative frequency were quite consistent across response mode.* Thus, subjects seemed to have a moderately well-articulated internal risk scale, which they could express even with these unfamiliar tasks.
- b. *Direct estimates were influenced by the anchor.* Subjects told that 50 000 people die annually from car accidents produced estimates that were two to five times higher than those produced by subjects told that 1000 die from electrocution.

Thus, they had a weak feel for absolute frequency, leaving them sensitive to the implicit cues in how questions are posed.

- c. *Subjects' mean estimates varied less than the statistical estimates.* The overall trend was over-estimating small frequencies and underestimating large ones. However, the anchoring effect means that absolute estimates are method dependent, making the compression of lay estimates the more fundamental result.
- d. *Some causes of death consistently received higher estimates than others of equal statistical frequency.* They tended to involve disproportionately visible risks (e.g. homicide vs. asthma), consistent with estimating frequency by events' availability, while failing to realize how fallible that index is (Gilovich *et al.*, 2002).
- e. *Subjects also assessed the probability of having chosen the more frequent of the paired causes of death.* They tended to be overconfident (e.g. choosing correctly only 75% of the time when 90% confident of having done so) – a special case of the general tendency to be inadequately sensitive to the extent of one's knowledge (Yates, 1989).

One recurrent obstacle to assessing or improving risk estimates is using verbal quantifiers such as 'very likely' or 'rare'. Such terms can mean different things to different people in one situation and to the same person in different contexts (e.g. likely to be fatal vs. likely to rain) (Wallsten *et al.*, 1986). The patterns in the 'causes of death' study could only be observed because it elicited quantitative estimates. As mentioned, though, with unfamiliar tasks, responses reflect the cues that people infer from task details, like anchors (Poulton, 1994; Schwarz, 1999). For example, Woloshin *et al.* (2000) evaluated a response mode using a linear scale for probabilities from 1–100% and a four-order log scale for probabilities from 0–1%. The responses that it elicited were at least as reliable and trustworthy as judgements evoked by other methods. However, it also elicited lower probabilities than a linear 0–100% scale. Presumably, the log-linear scale both made it easier to express small values *and* suggested that they might be appropriate. The opposite was true for the linear scale. If people knew just what they wanted to say, then the response mode would not matter. However, that need not be the case with the novel, often obscure tasks generated by researchers – or presented by life.

Evaluating the accuracy of lay estimates requires credible statistical estimates, for comparison purposes. Performance might be different (poorer?) for risks whose magnitude is less certain than those in public health statistics. Furthermore, laypeople may not see population risks as personally relevant, when assessing their own risk. Many studies have found that people see themselves as facing less risk than average others (which could be true for only half the population) (Weinstein, 1987). Such an optimism bias could prompt unwitting risk-taking (e.g. because warnings seem more relevant to other people). It could reflect both cognitive processes (e.g. the greater availability of ones' own precautions) and motivational ones (e.g. wishful thinking). The bias appears similarly in adults and adolescents, despite the common belief that teens' risk-taking is fuelled by a unique perception of invulnerability (Quadrel *et al.*, 1993).

These studies measure health risk perceptions under the assumption that people define 'risk' as 'probability of death'. However, in scientific practice, the meaning of 'risk' can vary by analysis. It might be expected loss of life expectancy or the expected

probability of death. The former definition places a premium on deaths of young people, who lose more life when they die prematurely. Thus, disagreements about the size of risks can reflect both different views of the facts and different definitions of 'risk'. Without a shared definition of 'risk', researchers and respondents may be talking about different things (see 'Communicating risk').

Investigators have examined the correlations between quantitative judgements of 'risk' and various subjective features (e.g. voluntariness, scientific uncertainty, controllability). Looking at correlations among ratings of the features (Slovic, 1987), they have found a recurrent picture, with two or three dimensions of risk, emerging similarly across elicitation method, subject population (e.g. experts vs. laypeople), and risk domain. Core concepts underlying these dimensions include how well a risk seems to be understood and how much of a feeling of dread it evokes. The locations of individual hazards in this 'risk space' may vary by person, in ways related to their preferred risk management policies (e.g. how tightly a risk should be regulated). Characterizing risks in multi-attribute terms allow individuals to decide what matters to them (Florig *et al.*, 2001). The British government has recently proposed characterizing risks in terms of these risk dimensions, complementing economic measures (HM Treasury, 2005).

Qualitative assessment

Event definitions

Scientific estimates of a risk's magnitude require detailed specification of the conditions under which it is to be observed. When researchers ask about risks without providing these needed details, they make it very hard to provide sensible answers. In order to respond correctly, subjects must first guess the question, and then know the answer to it. Consider, for example, a survey asking, 'How likely do you think it is that a person will get the AIDS virus from sharing plates, forks or glasses with someone who has AIDS?' Any simple aggregation of responses assumes that all subjects have spontaneously assigned the same value to each missing detail – and that the investigator knows what subjects have decided. For example, what did they infer about the kind of sharing (e.g. eating from the same bowl, using utensils that have been through a dishwasher) and about how frequently it occurs?

The inferences that subjects make, when reading between the lines, in order to complete the event definition, reveal their beliefs about the processes involved. For example, we asked teens to think aloud as they judged the probabilities of deliberately ambiguous events (e.g. getting into an accident after drinking and driving, getting AIDS through sex) (Fischhoff, 1996). These teens wanted to know the 'dose' involved with most risks (e.g. how much drinking, how much driving), when it was not stated. However, they seldom asked about the amount of sex, when asked about the risks of pregnancy and the risks of HIV transmission. They seemed to believe that a person either is or is not sensitive to the risk, regardless of the amount of the exposure. Morrison (1985) concluded that many sexually active adolescents explain not using contraceptives with variants of, 'I thought I (or my partner) couldn't get pregnant'.

Mental models of risk processes

These intuitive theories of how risks accumulate were a byproduct of research intended to improve the elicitation and communication of quantitative probabilities. Often, however, people are not poised to decide anything, hence need no estimates. Rather, they just want to know how a risk works, for the sake of warranted self-efficacy or to give quantitative estimates intuitive credibility ('How could the experts say that the risk is so small [or big]?' 'How could they be so sure about their predictions?'). The term 'mental model' is often applied to lay theories that are well enough elaborated to generate predictions.

If these mental models contain critical bugs, then they can lead to erroneous conclusions, even when people are otherwise well informed. For example, not knowing that repeated sex increases the associated risks could undermine much other knowledge. Morgan *et al.* (2001) found that many people know that radon is a colourless, odourless, radioactive gas posing some health risk. Unfortunately, people also associate radioactivity with permanent contamination, a widely publicized property of high-level radioactive waste that is not shared by radon. Not realizing that the major radon byproducts have short half-lives, homeowners might not even bother to test (believing that there was nothing that they could do, should a problem be detected). Leventhal and Cameron (1987) demonstrated how misunderstanding the physiology and phenomenology of maladies (e.g. hypertension) can reduce compliance with treatment regimes.

Creating communications

The design process

The first step in designing communication is to select the information that they should contain (Fischhoff, 1992). Poorly chosen information can both waste recipients' time and be seen as wasting it. Recipients may be judged unduly harshly if they are uninterested in information that seems (and perhaps is) only vaguely relevant to their choices.

In health decisions, like any others, not all facts are equally important. Even with well-formulated questions, it is easy enough to create a test of knowledge that any person will pass – or fail. A necessary precursor to assessing, or improving, health risk knowledge is explicitly identifying the critical factors creating and controlling a risk. Identifying people's existing beliefs must use procedures sufficiently open-ended to allow naïve mental models and formulations to emerge, beyond those presumed by researchers. The research should, for example, allow detecting the 'false fluency' of people using terms, without a functional understanding of their meaning (e.g. 'safe sex'; McIntyre & West, 1992).

Interventions can then focus on the most critical gaps. That could mean adding missing concepts, correcting mistakes, strengthening correct beliefs and de-emphasizing peripheral ones. It should concentrate on critical 'bugs' in recipients' beliefs, cases where they confidently hold incorrect beliefs that could lead to inappropriate actions (or, where they lack enough confidence in correct beliefs to act on them). The identification of those facts can be formalized by value-of-information analysis, determining the sensitivity of decisions to various facts. In one application, we considered the facts

critical to patients considering carotid endarterectomy (scraping out an artery leading to the brain, in order to reduce stroke risk) (Fischhoff, 1999). Although many things might go wrong, we found that only a few would change many patients' optimal choice. Focusing on those few facts best fulfils the duty of informed consent. It also frames the analysis of whether people understand enough to avoid paternalistic interventions.

Once information has been selected, it must be presented comprehensibly. That means considering both the terms that people use for understanding individual concepts and the mental models they use for integrating them. It means exploiting research into text comprehension, showing that (a) comprehension improves when text has a clear structure, (b) critical information is best remembered when it appears at the highest level of a clear hierarchy and (c) readers benefit from 'adjunct aids', such as highlighting, advanced organizers (showing what to expect), and summaries (Kintsch, 1986) (see 'Written communication').

Misdirected communications can prompt wrong decisions, create confusion, provoke conflict and cause undue alarm or complacency. Indeed, poor communications can have greater public health impact than the risks that they attempt to describe. When that is true, it should be no more acceptable to release an untested communication than an untested drug. Because communicators' intuitions about recipients' risk perceptions cannot be trusted, there is no substitute for empirical validation.

A case study, using a behavioural decision research approach

Young people hear a lot about how to reduce risks from sexually transmitted infections (STIs), especially HIV/AIDS. Nonetheless, the rates of STIs (and unplanned pregnancies) remain high. As a result, some adults despair of informational approaches, favouring manipulative ones. However, the 'failed' messages have seldom been based on normative analyses of teenagers' choices and informational needs. Rather, educators decided what teenagers needed to know, then tried to present it engagingly. A common criticism of campaigns, like 'Just Say 'No'', is that they oversimplify the normative analysis, by ignoring the full set of concerns held by teenagers.

In a normative analysis of the 'facts of life' needed for effective decision making, we identified the intertwined cognitive, affective,

social and physiological processes shaping STI risks (Fischhoff *et al.*, 1998). We found that most current messages focus on a subset of these factors. That focus has been rewarded: teenagers know many of those details. However, the repetition of familiar facts may create an unwarranted feeling of 'knowing it all'.

Moreover, teenagers, mastery of some facts is shaky, while other critical facts are missing from their mental models. Some of these omissions are deliberate. For example, although it is not hard to explain why oral and anal sex are risky, few US schools allow such 'explicit' explanations. Social constraints on discussion with adults may contribute to the confusion of many teenagers about how to use condoms or terms like 'safe sex'. Other omissions reflect topics outside health educators' usual concerns. For example, few are familiar with the research showing that teenagers (like adults) tend to think about the outcomes of single actions, rather than the results of repeating those actions (e.g. having sex, driving fast) (Downs *et al.*, 2006; Fischhoff, 1996).

Our prescriptive work has focused on filling such gaps in teens' mental models, as well as giving them a more realistic feeling for how much they know. It has also recognized that information means little unless teens feel empowered to use it. As a result, we created an interactive DVD for young women, conveying critical facts (about diseases, condoms, etc.), while also showing how to make and implement choices about sexual relations. Although the DVD's goals were determined from a behavioural decision research perspective, it draws broadly on behavioural research (e.g. self-efficacy theory). In a randomized control trial, the DVD increased STI knowledge and self-reported condom use, while decreasing condom problems and chlamydia reinfection rates (Downs *et al.*, 2004).

Conclusion

Communicating risks can be as complicated as assessing them. Research in this area is fortunate in being able to draw on well-developed literatures in such areas as cognitive, health and social psychology, survey research, psycholinguistics, psychophysics and behavioural decision theory. It needs those resources for dealing with unfamiliar topics, surrounded by uncertainty, without stable vocabularies, and difficult, threatening tradeoffs.

Self-efficacy in health functioning

Albert Bandura

Stanford University

We are witnessing a divergent trend in the field of health. On the one hand, we are pouring massive resources into medicalizing the ravages of detrimental health habits. On the other hand, the conception of health is shifting from a disease model to a health model. It emphasizes health promotion rather than disease management.

Health promotion should begin with goals not means. If health is the goal, biomedical interventions are not the only means to it. The quality of health is heavily influenced by lifestyle habits. This enables people to exercise some control over their health. To stay healthy, people should exercise, reduce dietary fat, refrain from smoking, keep blood pressure down and develop effective ways of managing stressors. By managing their health habits, people can live longer, healthier and retard the process of ageing. Self-management is good medicine. If the huge benefits of these few habits were put into a pill it would be declared a scientific milestone in the field of medicine.

Current health practices focus heavily on the medical supply side. The growing pressure on health systems is to reduce, ration and curtail health services to contain escalating health costs. The days for the supply side health system are limited. People are living longer. This creates more time for minor dysfunctions to develop into chronic diseases requiring costly treatments.

Social cognitive approaches focus on the demand side. They promote effective self-management of health habits that will keep

people healthy through their life span. The mounting demand for health care will force societies to change the balance of efforts from disease care to health promotion.

Effective self-management of health behaviour is not a matter of will. It requires development of self-regulatory skills on how to influence one's own motivation and behaviour (see 'Self-management'). Among the mechanisms of self-regulation, none is more central or pervasive than beliefs of personal efficacy. This core belief is the foundation of human motivation, wellbeing and accomplishments. Unless people believe they can produce desired effects by their actions they have little incentive to act or to persevere in the face of difficulties. Whatever other factors serve as guides and motivators, they are rooted in the core belief that one has the power to effect changes by one's actions.

Efficacy beliefs affect every phase of personal change: whether people even consider changing their health habits; whether they enlist the motivation and perseverance needed to succeed should they choose to do so; their vulnerability to relapse; success in recovering control after a setback; how well they maintain the habit changes they have achieved (Bandura, 1997). Perceived efficacy is the common pathway through which diverse psychosocial influences affect health functioning.

There are two major ways in which people's belief in their personal efficacy affects their health. At the more basic level, such beliefs act on biological systems that mediate health and illness.

At the second level, they operate by direct control over habits that affect health and the rate of biological ageing.

Biological effects of perceived coping efficacy

Many of the biological effects of beliefs of personal efficacy arise in the context of coping with stressors. Stress has been implicated as an important contributor to many physical dysfunctions (Krantz, Grunberg & Baum, 1985; O'Leary, 1990) (see 'Stress and health'). Controllability is a key organizing principle regarding the nature of stress effects. It is not stressful life conditions per se, but the perceived inability to manage them which produces the detrimental biological effects (Bandura, 1991; Maier, Laudenslager & Ryan, 1985; Shavit & Martin, 1987).

In social cognitive theory, stress arises from perceived inefficacy to exercise control over aversive threats and taxing environmental demands (Bandura, 1986). If people believe that they can deal effectively with potential environmental stressors, they are not perturbed by them. But, if they believe that they cannot control aversive events, they distress themselves and impair their level of functioning. The causal impact of beliefs of controlling efficacy on biological stress reactions is clearly verified in experimental studies in which people are exposed to stressors under perceived inefficacy and after their beliefs of coping efficacy are raised to high levels through guided mastery experiences (Bandura, 1997). Exposure to stressors without perceived efficacy to control them activates autonomic, catecholamine and endogenous opioid systems. After people's perceived coping efficacy is strengthened, they manage the same stressors without experiencing any distress, autonomic agitation or activation of stress-related hormones.

The types of biochemical reactions that accompany a weak sense of coping efficacy are involved in the regulation of the immune system. Hence, exposure to uncontrollable stressors tends to impair the function of the immune system in ways that can increase susceptibility to illness (Kiecolt-Glaser & Glaser, 1987; Maier *et al.*, 1985; Shavit & Martin, 1987). Lack of behavioural or perceived control over perturbing conditions increases susceptibility to bacterial and viral infections, contributes to the development of physical disorders, and accelerates the rate of progression of disease (Schneiderman *et al.*, 1992) (see 'Psychosomatics').

Most human stress is activated in the course of developing competencies. Stress activated in the process of acquiring coping efficacy may have different physiological effects from stress experienced in aversive situations with no prospect of ever achieving any self-protective efficacy. Indeed, stress aroused while gaining coping mastery over threatening situations can enhance different components of the immune system (Bandura, 1991). Providing people with the means for managing acute and chronic stressors increases immunological functioning. This has substantial evolutionary benefits given the prevalence of stressors in everyday life. If stressors only impaired immune function, people would be bedridden much of the time if not deceased.

The field of health has been heavily preoccupied with the physiologically debilitating effects of stressors. Self-efficacy theory also acknowledges the physiologically strengthening effects of mastery over stressors. A growing body of research verifies the physiological toughening by successful coping (Dienstbier, 1989).

Self-efficacy in self-management of health behaviour

As previously noted, people can exercise some measure of control over their health by managing their lifestyle habits. This requires development of motivational and self-regulatory skills (Bandura, 2004). Effective self-management operates through a set of psychological subfunctions that provide the motivators, guides and supports for personal change. People have to monitor their health behaviour and the circumstances under which it occurs, set proximal goals to motivate themselves and guide their behaviour, create incentives for themselves and enlist social supports to sustain their efforts.

Habit changes are of little consequence unless they endure. Maintenance of habit change requires instilling a resilient sense of efficacy as well as imparting skills. Experience in exercising control over troublesome situations and setbacks serve as efficacy builders (Marlatt *et al.*, 1995). This is an important aspect of self-management. If people are not fully convinced of their personal efficacy, they rapidly abandon the skills they have been taught when they fail to get quick results or suffer reverses. Once equipped with self-regulatory skills and a resilient sense of efficacy, people are better able to adopt behaviours that promote health and to eliminate those that impair it.

To improve the quality of health of a nation requires intensifying health promotion efforts and restructuring health delivery systems to make them more productive. Efficacy-based models have been devised combining knowledge of self-regulation of health habits with computer-assisted implementation. This self-management model provides effective health-promoting services in ways that are individualized, intensive, highly convenient and cost effective (Bandura, 2004). By linking the interactive aspects of the self-management model to the Internet, one can vastly expand its availability to people wherever they may live, at whatever time they may choose to use it.

The weight of disease is shifting from acute to chronic maladies. Biomedical approaches are ill-suited for chronic diseases because they are devised mainly for acute illness. The self-management of chronic diseases is another example where self-regulatory and self-efficacy theories provided guides for the development of cost-effective models with high social utility.

The treatment of chronic disease must focus on self-management of physical conditions over time. Holman and Lorig (1992) devised a generic self-management program in which patients are taught pain control techniques and proximal goal setting combined with self-incentives as motivators to increase level of activity. They are also taught problem-solving and self-diagnostic skills, and how to take greater initiative for their health care in dealing with health systems. This approach retards the biological progression of diseases, raises perceived efficacy, reduces pain, decreases the use of medical services and improves the quality of life.

Impact of prognostic judgements on efficacy beliefs and health outcomes

Much of the work in the health field is concerned with diagnosing maladies, forecasting the likely course of physical disorders and prescribing remedies. Medical prognostic judgements involve

probabilistic inferences from knowledge of varying quality and inclusiveness about the multiple factors governing the course of a given disorder. One important issue regarding medical prognosis concerns the range of determinants included in the prognostic models. Because psychosocial factors account for some of the variability in the course of health functioning, inclusion of self-efficacy determinants in prognostic models enhances their predictive power (Bandura, 2000).

Prognostic judgments are not simply inert forecasters of a natural course of a disease. Prognostic expectations can affect patients' beliefs in their self-efficacy. Therefore, diagnosticians not only foretell, but may partly influence, the course of recovery from disease. Prognostic expectations are conveyed to patients by attitude, word and the type and level of care provided them. People are more likely to be treated in enabling ways under positive expectations than under negative ones. Differential care that promotes in patients different levels of personal efficacy and skill in managing health-related behaviour can exert stronger impact on the trajectories of health functioning than simply conveying prognostic information. Prognostic expectations can alter patients' sense of efficacy and behaviour in ways that confirm the original expectations. The self-efficacy mechanism operates as one important mediator of such self-confirming effects.

Socially-oriented approaches to health

The quality of health of a nation is a social matter not just a personal one. It requires changing the practices of social systems that impair health rather than just changing the habits of individuals. Vast sums of money are spent annually in advertising and marketing products and promoting lifestyles detrimental to health. With regard to injurious environmental conditions, some industrial and agricultural practices inject carcinogens and harmful pollutants into the air we breathe, the food we eat and the water we drink, all of which take a heavy toll on health. Vigorous economic and political battles are fought over environmental health and where to set the limits of acceptable risk.

We do not lack sound policy prescriptions in the field of health. What is lacking is the collective efficacy to realize them. People's beliefs in their collective efficacy to accomplish social change by perseverant group action play a key role in the policy and public health approach to health promotion and disease prevention (Bandura 1997; Wallack *et al.*, 1993). Such social efforts take a variety of forms. They raise public awareness of health hazards, educate and influence policymakers, devise effective strategies for improving health conditions, and mobilize public support to enact policy initiatives (see 'Health promotion').

Sexual risk behaviour

Lorraine Sherr

Royal Free and University College Medical School

Sex and risk – strange bedfellows

It is strange that the concept of sexual behaviour – the most normal and human of behaviours – should be considered in the same context as ‘risk’, which relates to extreme, out of the norm and potentially danger invoking behaviours. Yet the concept of sexual risk behaviour has been well established. Sexual risk and the underlying related issues are of great importance in the pursuance and sustaining of health.

What is meant by risk?

There are a number of theories which try to encapsulate the concept of risk and risk behaviour (see ‘Risk perception’). Generally, risk behaviour can be divided into two forms, namely (1) risk exposure and (2) risk seeking. Risk exposure concerns the situational variables associated with risk, often, but not always, not under the direct control of the individual. Risk seeking encompasses all behaviours where there is some active planning or behaviour to seek out risk. However, it may also include an absence of behaviour, which may result in risk. So for example the non-use of contraception may be seen as a risky behaviour, where inactivity or the failure to behave is the core risk determinant. Whilst seeking unprotected sex with a casual partner may be a more active risk-seeking behaviour, where the action (rather than the inaction) is at the core of the risk exposure.

There is also a difference between risk seeking and risk exposure. Many acts may be potentially risky, but the actual risk is unknown. For example unprotected sex may result in a pregnancy, but it may not.

When is sexual behaviour risky?

It is difficult to gather a precise definition of when sexual behaviour is risky. If it is related to consequence, the same consequences may be risky for some individuals and not for others. Pregnancy as an outcome may be desired and then considered as not risky. On the other hand it may not be desired, and then sexual behaviour resulting in a pregnancy is risky – despite the same outcome. So it is clear that outcomes in themselves cannot be the only definition of risk. Exposure to sexually transmitted diseases and infections is an area where the concepts of risk and sex are clearly associated. Much research in relation to HIV infection, HIV prevention and the promotion of ‘safer sex’ has emerged since the beginning of the HIV epidemic in the late 1980s. Such literature explores individual, couple and social levels of behaviour, safety and risk (see ‘HIV and AIDS’).

A working hypothesis for risky sexual behaviour is associated with undesirable outcome. Although this provides a helpful working definition, it also depends on whose desires are to be considered. Given that sexual behaviour affects couples, groups, families and societies, the desires of one element may not necessarily coincide with the desires of another. Sexual behaviour, risk reporting and coding is complex (Cleland *et al.*, 2004) and there is a wide debate on the efficacy of research, the reliability of measurement and the difficulties in recording and verifying sexual behaviour as well as risk (Ankrah, 1989; Catania *et al.*, 1990; Frank, 1994; Sheeran and Abraham, 1994; Huygens *et al.*, 1996; Weinhardt *et al.*, 1998; Fenton *et al.*, 2001).

A number of areas of research will be briefly outlined where issues of sex and risk are studied. Sexual risk is associated with pregnancy, contraception, sexual behaviour, sexual health and sexually transmitted infections (STIs). HIV infection and AIDS is one of the most studied areas of risk associated with sexual behaviour.

Sexual debut

The recent National Survey of Sexual Attitudes and Lifestyles (Natsal) studies in the UK have provided detailed evidence of sexual behaviour patterns (Wellings *et al.*, 2001). In this national survey (1990 $n=18\,867$; 2000 $n=11\,161$), it was found that by the age of 25, 95% of men and 98% of women had experienced heterosexual intercourse. Birth cohort data from the two successive studies show a downward turn of age at first intercourse over time, with recordings of 20 years for men and 21 for women for those born in 1930s, 17 for both men and women for those born in the 1970s and 16 for both men and women for those born in the 1980s. These figures vary in different countries and cultures.

Early age of sexual debut is seen as a marker for risk, or potential risk, in a number of studies. Early age of sexual debut was associated with increased risk of pregnancy in the under 18-year age group. Age itself may not be the only risk associated with early sexual debut, but contraceptive use may be a clearer indication of potential risk exposure.

Pregnancy-related risk

Pregnancy is both a desired and undesired outcome of sex. The risk in this context relates to the biological risk as well as the psychosocial risk associated with conception. Thus failure to conceive (infertility) has a set of psychological risks associated with it, while on the other hand, unplanned conception or conception in association with a set of correlates is often categorized (rightly or wrongly) as risky. Age (too young or too old) has been seen as a risk, but this may

often mask public attitude rather than outcome. For example young age is often measured in terms of the maternal age, rather than couple age. Youth may be a surrogate marker for unplanned pregnancy or economic hardship. These other factors may be the drivers of risky outcomes rather than simple age. Similarly, older age and risk is studied. Biological risk (such as higher prevalence of genetic conditions) may be associated with older age – but again maternal rather than paternal age is usually measured. Possible confounders also exist in this literature where people with difficulties in conceiving may be disproportionately represented in older age groups. Furthermore studies have shown that if one focuses on negative outcomes then biased views are enhanced. Positive outcomes have been well established with both younger and older parenthood (Sherr, 1995).

In a systematic review of sexual risk and teenage pregnancy, Mead and Ickovics (2005) have shown that behaviours which lead to teenage pregnancy also place young women at risk for STDs and repeat pregnancy.

Sexual behaviour risk

There are a number of components of sexual behaviour risk which have been described, studied and the target of intervention studies. Caution is needed to ensure that the indicators of risk actually match true risk behaviour (Slaymaker, 2004).

• *Sexual health*

There has been an increased focus of attention in the area of sexual health. The rates of sexually transmitted infections have driven health services to enhance provision and broaden interventions. In the British National Survey of Sexual Attitudes and Lifestyles (Natsal) Fenton *et al.* (2005) noted that numbers and type of partners remained the dominant risk factors associated with STIs in the UK. Mercer *et al.* (2003) noted a high degree of sexual problems (34.8% men and 53.8% women reported some form of problem in the NATSAL survey). Johnson *et al.* (2001) examined changes in sexual behaviour over time in two consecutive national surveys and found an increase in partner numbers, new partners, paying for sex and generally pointed out that gains from increased condom use were offset by increased partner change. Sangani *et al.* (2004) have shown in an overview that there is a clear link between STI and HIV infections. They further noted that there is some evidence that STI interventions can affect HIV and vice versa (see 'Sexually transmitted infections').

• *HIV and AIDS*

The HIV epidemic runs unabated (see 'HIV and AIDS'). Some countries have managed to exhibit a downturn of new infections. The advent of new treatments, antiretroviral drugs, enhanced adherence to these treatments, HIV prevention initiatives and global strategies have all contributed to the efforts to contain the spread of HIV. Yet new infections occur rapidly, illness and death rates are still dramatic and emerging problems of drug resistance virus, orphaned children and an AIDS weariness in the public eye are all current challenges. Sexual risk in the presence of HIV remains the major factor for exposure. Risk behaviours are described as unprotected sex with a partner of unknown or discordant serostatus. A steady increase in such behaviours has been reported over time in a large

number of population based studies (Elford *et al.*, 2004; Dodds *et al.*, 2004).

• *Contraceptive risk*

The availability and uptake of contraception is a major factor in behavioural management of sexual risk. However, there has been some tension in the literature given concerns that the provision of contraception may increase risk by promoting sexual behaviours and that abstinence policies may be preferable. In a recent review (Bennett and Assefi, 2005), there was clear evidence that abstinence only programmes were not as effective as contraceptive promotion for avoidance of teenage pregnancies.

Holmes *et al.* (2004) showed in a systematic review that condoms were effective in both HIV and STI prevention (see 'Contraception').

• *Unprotected sex risk*

In HIV, Creese *et al.* (2002) showed the cost efficacy of interventions in Africa. Bollinger *et al.* (2004) provide a clear matrix on the complexity of interventions and their potential efficacy. The advent of HIV, the upsurge of incidence of sexually transmitted infections as well as avoidance of unwanted pregnancies has resulted in a mass of studies looking at condom use. In general there have been a multitude of condom prevention programmes with varying degrees of success. Barriers to condom use are associated with individual factors (such as motivation, personal appraisal, willingness, experience, knowledge), couple factors (such as negotiation, trust, sustained condom use) and community factors (such as availability, social norms, endorsement, social meaning and the conflict between condoms and the desire for reproduction). The data is more complex, given that it is not simply condom use that is important, but sustained condom use. Partial or sporadic condom use may provide some protection, but is not complete. Social power and normative support can influence condom use (Albarracin *et al.*, 2004).

• *Sexual partner risk*

Choice of sexual partners has been studied as potential risk. Furthermore, a number of studies have explored risk for groups where choice is not active and coercion, relationship imperatives or social need have limited such choice. Clearly sexual networking raises the potential for risk exposure. A number of studies have examined strategies used to limit such risk, such as

- Negotiated safety where partners enter into negotiated agreements regarding sexual partners and risk,
- Age selection where some partners preferentially choose sexual partners from certain age groups in an attempt to ameliorate risk. This has a two-sided effect where it may decrease risk for one partner, but enhance risk for the other.
- Couple interventions. These have particularly examined discordant couples in relation to HIV infection where one member is negative and the other positive. A number of psychological interventions in the form of behavioural counselling have been effective. Additional biomedical resources, such as sperm washing techniques for those wanting to conceive have been shown to be protective for the negative partner.
- Social level factors must not be overlooked. HIV widowhood or orphanhood is associated with a period of increased risk.

Mobility, migration and economic hardship are also well established contributors to elevated risk exposure.

- Forced sex and rape have immediate as well as long-term consequences. Rape survivors are at elevated risks of infection, unwanted pregnancies and mental health problems.
- **Sexual behaviour and emotional relationships**

Sexual behaviour is intricately bound up with emotional relationships. Thus risk cannot be confined to physical or biological risk, but must also examine emotional risk and the social environment in which sexual behaviour as well as sexual risk is conducted. Studies have provided insight into a range of sexual behaviours, with an understanding of a number of concepts. The literature on sexual deviance explores the normative and non-normative practices and consequences for individuals. The literature on sexual abuse provides complex understanding of the experience, triggers and ramifications of sexual abuse. Responses to sexual abuse and subsequent risks have been well documented. There is a broad literature which studies the relationship between sex, drugs and alcohol. Some studies show how risk and risk behaviours cluster, while others look at causative links between drug use, alcohol use and sexual risk.

The advent of impotence treating drugs such as sildenafil (Viagra) may have implications for safe sexual behaviour and HIV prevention (Sherr *et al.*, 2000). Studies have shown that the use of such compounds is not necessarily associated with increased risk behaviour, but have also highlighted the use of the internet for access to such compounds for reasons of stigma and shame. This opens up the whole area of health education and prescription associated counselling and the ways in which new technologies need to be adapted to accommodate such need.

- **Sexual risk mediators**

There are a number of factors which mediate sexual risk, such as gender, culture, age, economics and social environment. Sexual risk is not equivalent between the genders.

- **Theoretical explanations and sexual risk**

It is complicated to understand what constitutes a sexual risk, how this is measured and operationalized in studies. This is compounded by the subsequent need to understand associations and links between individual and situational factors and such risk. Psychological understanding of sexual risk in HIV has concentrated on social and or cognitive models (see for example *Theory of Planned Behaviour*, Ajzen, 1991), with applications that have looked at relationships, negotiations and normative influences (see, for e.g. van der Ven *et al.*, 2002; Crawford *et al.*, 2001; Davidovich *et al.*, 2000). Personality theory provides a line of understanding (see for example studies looking at personality clusters and risk) or risk judgements (see, for example, Weinstein, 1980, 1984, 1989; Weinstein & Lachendro, 1982; McKenna, 1993). Integrated concepts have also been explored, such as the notion that risk evaluation affects planned behaviour or personality (Elford, Bolding & Sherr, 2002; Elford, Bolding, Maguire & Sherr, 1999; International Collaboration on HIV Optimism, 2002).

Risk reduction has been addressed in some theories. Three major approaches include Social Learning theory, Social Influence Theory

and Cognitive Behavioural Theory. These theories indicate that risk reduction requires a number of stages such as:-

- Information handling
- Identification of social pressure and peer influence
- Prepare for and anticipate risk situations
- Create positive behavioural norms
- Skill acquisition for coping and acting under pressure
- Testing

There are many tests available to monitor and measure outcome. The process of such testing may play a role in risk identification, reduction and management. For example a test for HIV has long been available. The process of HIV testing has been expanded to include a basic minimum of counselling in preparation for testing and on receipt of test results. Such counselling has a role to play not only in risk identification and emotional preparation, but also in future risk reduction.

In pregnancy, routine antenatal care may include elements of risk identification and management. High levels of abuse in pregnant women have been monitored in studies in the US, Canada and the UK. Antenatal discussion has a role to play in disclosure and management. Sexual and physical abuse in pregnancy is associated with negative mental health as well as physical outcomes.

- **Myths and Sexual risk**

As well as an extensive literature understanding sexual risk, there are also a number of myths and misunderstandings surrounding the concept. Some of these will be briefly set out.

Optimism and HIV risk

It was generally believed that optimism over the new HIV treatments would be associated with enhanced sexual risk. This could be understood in two ways – optimism around treatment which reduced the ‘seriousness’ of HIV infection or optimism around infectivity which reduced the likelihood of infection after risk exposure. Clearly this raised a worrying concept. However, studies have shown that the absolute levels of optimism are actually low, and realism is the better descriptor of the post antiretroviral treatment mood. Amongst the optimistic, cross-sectional studies have shown associations with risk. However, more thorough longitudinal studies have shown increases in risk behaviour among both the optimistic and non-optimistic, thus cautioning against blanket presumptions.

The inherent appeal of risk

Another problem in the literature is the presumption that risk is aversive. There is good evidence to show that there is an inherent appeal of risk. This may vary by factors such as personality, situation or age. Thus health promotion that labels risk may have a ‘boomerang’ effect whereby it enhances the appeal rather than decreases the appeal of certain behaviours.

Gender and power

Some studies make presumptions about power. This is often seen in relation to women who are construed in many studies as lacking in power. However, a careful examination of female behaviour, especially in the HIV context, shows that a power analysis is a very gender-biased analysis and that concepts such as compassion, commitment and reliability may better explain such female behaviour.

Cognitive factors

A clear understanding of cognitions, how they work and how they affect behaviour may provide some insight into decision-making, information appraisal and risk behaviour. Information is selectively recalled. Memory plays a key role in decision-making. Information and understanding are necessary but not sufficient factors in behaviour change.

Psychological interventions

Any understanding of sexual risk requires some insight into whether such risks can be understood, predicted, avoided, modified or are open to change (Abraham *et al.*, 1998). A number of theories have provided insight into risk behaviour (Albarracin *et al.*, 2001) and have formed the basis for intervention studies (Fishbein, 2000).

Kamb *et al.* (1998) carried out a definitive randomized controlled trial intervention in STD clinics across the USA showing how various counselling interventions were related to significant risk behaviour

decreases at multiple follow-up. Elwy *et al.* (2002) carried out a systematic review of effectiveness of interventions to prevent STIs and HIV in heterosexual men. Successful interventions were invariably comprised of multiple component interventions. Bennett and Assefi (2005) provided a systematic review of interventions to prevent teenage pregnancy and showed that much of the decrease was associated with increased contraceptive use rather than sexual abstinence.

Conclusion

Sexual risk is a complex phenomenon. Yet there is a high burden of ill health, emotional challenge and social consequence associated with the outcomes of sexual risk behaviours. Sexually transmitted infections, unwanted pregnancies, HIV infection and AIDS are all consequences of sexual risk that require urgent attention. Psychological understanding can aid in formulating the problems, measuring the behavioural components, providing interventions and ameliorating the effects of such risk.

Sleep and health

Jason Ellis

University of Surrey

Introduction

Where much has been written about sleep from a clinically disordered perspective, only relatively recently, with the direct and indirect costs of an increasingly demanding 24-hour society being realized, has the concept of sleep entered the arenas of health psychology and behavioural medicine. Moreover, the reported neglect of discussions regarding sleep, beyond the use of hypnotics within doctor–patient interactions, coupled with an increasing understanding of sleep as a modifiable health behaviour has led to calls for sleep being placed high on the health psychologists' agenda. To this end, researchers have uncovered reciprocal links between the quality, quantity and timing of sleep, as both a subjective and objective

phenomenon, and numerous health and social outcomes. This chapter explores those links, focusing on the relationship between sleep need, sleep regulation and circadian rhythmicity, whilst examining the influence of human behaviour on these relationships.

What is sleep?

Sleep is an active process consisting of two stages, rapid eye movement sleep (REM) and non rapid eye movement sleep (NREM) (of which there are four sub-stages). Although not discrete, each stage of sleep can be characterized physiologically by different frequencies and amplitudes in brain-wave activity and together they

make up what is known as sleep architecture. In Stage 1 the body enters a transitional period between sleep and wakefulness from which awakening is easy. Electroencephalographic (EEG) activity changes from a rhythmic pattern of alpha waves (8–13 cycles per second and below 50 microvolts) to mixed frequency, lower voltage brainwave activity, eventually leading to the official onset of sleep or Stage 2 sleep. Stage 2 is characterized by the presence of ‘sleep spindles’ (bursts in EEG activity above 11.5 cycles per second for more than 0.5 seconds) and ‘K-complexes’ (high voltage, short duration waveforms) as well as reduced muscle tension and slow rolling eye movements. Stages 3 and 4, also known as Slow Wave Sleep (SWS), are deeper, involving progressively higher voltage (an amplitude of 75 microvolts is usual) and slower brainwave activity (i.e. delta activity of less than 4 cycles per second), limited eye movements and muscle tension. During this time it is usual to have sleep spindles accompanying delta waves. The final stage of sleep, REM, is similar to Stage 1 sleep, being characterized by low voltage, mixed frequency electroencephalographic activity without sleep spindles and K-complexes. However, REM differs from Stage 1 sleep in that muscle tension is nonexistent, indicating that the body is in a state of paralysis and only the eyes and respiratory system are active. It is during REM that dream activity is believed to take place, although recent research suggests people can also dream in NREM. There are many theories as to the purpose of REM and consequently dreams. Traditional explanations for REM, such as the voiding of unwanted thoughts or reversed learning, have shown little empirical validity, whereas the suggestion that REM sleep is a period whereby information obtained throughout the day is assimilated into existing neural templates appears most credible and fits well within the existing literature (Jouvet, 1998).

An important feature of the K-complex (also known as an ‘arousal’), found predominately in NREM sleep, is that it can create nocturnal awakening. Normally, an arousal is approximately 10–15 seconds in duration and the sleeper is briefly awoken but unable to remember the event in the morning. However, arousals may increase in quantity and duration in response to internal (e.g. upper airway obstruction) or external (e.g. noise) stimuli.

Sleep throughout the lifespan

Marked changes in sleep architecture occur throughout the lifespan, with newborn infants requiring approximately 15 hours of sleep each day and entering sleep through REM then cycling between REM and NREM on a 50–60 minute cycle. After infancy, children enter sleep through NREM and this pattern continues throughout the lifespan. The time spent in SWS is at a peak in young children then begins to decrease during late adolescence. A young adult’s sleep comprises 75% NREM sleep and 25% REM on a 90-minute cycle, although most deep sleep occurs during the first third of the night. The typical progression of sleep throughout the lifespan (excluding neonates) is a movement through NREM stages 2–4 (only the first cycle includes full Stage 1 sleep) then a reversal through stages 4–2 before the onset of REM sleep, then the cycle begins again. Over the course of a night there will be approximately 4–6 complete sleep cycles with the later sleep cycles comprising longer REM periods and shorter NREM periods.

The ageing process has marked effects on specific aspects of sleep architecture, pertinent to sleep-onset-latency (initiating sleep) and

sleep maintenance (staying asleep) (Dijk *et al.*, 2001). Compared with the sleep of a young adult, researchers suggest an overall sleep efficiency of between 70–75% in older adults (Bliwise, 2000). However, when sleep disorders such as periodic limb movements (PLMs) and sleep disordered breathing are controlled for, this difference is approximately 80–85% (McCall *et al.*, 1992). Additionally, whereas arousal rates during sleep are calculated at approximately 10 per hour in young adults (Anderson & Waters, 1998), this increases to approximately 23–27 arousals per hour in the older adult population (Boselli *et al.*, 1998). SWS also changes with ageing, reducing from 18% of total sleep time at age 20 to between 5–10% for those between 60 and 80 years old (Hume *et al.*, 1998) (see ‘Ageing and health behaviour’).

Sleep need and sleep regulation

Although inter- and intra-individual differences in quantity of sleep need exist (e.g. short sleep durations are associated with extraversion), as do significant discrepancies between sleep need and actual sleep durations achieved, there appears a consensus that approximately 7–7.5 hours a night is typical, with larger deviations being associated with an increasing risk of mortality. Additionally, sleeping less than 4 hours a night has been associated with a 2.8 times higher mortality from cancer in men and 1.5 in women (Kripke *et al.*, 1979). More recently, associations between shorter sleep durations and obesity have been found in young adults (Hasler *et al.*, 2004) even after controlling for other obesity-related factors such as family history of obesity and levels of physical exercise. In this instance Spiegel *et al.* (2005) suggest that reduced leptin levels (leptin is a hormone which is receptive to caloric intake and communicates energy needs to the brain), as a result of reduced sleep, may be responsible through alterations in appetite regulation.

Overall, sleep durations are considered in alignment with sleep needs if the individual reports feeling refreshed and alert throughout the day. However, perceived sleep needs are also prone to change due to affective state. During stressful periods, such as exam periods, and in depression-related disorders, longer sleep durations are preferred and as such a greater discrepancy between actual sleep need and sleep durations can develop and become problematic (Ellis & Fox, 2004; McCann & Stewin, 1988). Moreover, studies have shown sleep architecture is disrupted by anxiety, resulting in less SWS and an increase in Stage 1 sleep (Fuller *et al.*, 1997). It is argued however that regularity in sleep scheduling, especially waking time, is a major determinant of sleep satisfaction and sleep regulation in itself is maintained through a continual interplay between the ANS, the homeostatic drive for sleep and the circadian rhythm.

Autonomic nervous system balance

Sleep regulation is largely tied to the balance between the sympathetic and parasympathetic branches of the ANS and it is during the transition through the NREM stages that parasympathetic dominance increases until full dominance is reached within REM. Conversely, during the latter phases of sleep, the sympathetic branch of the ANS begins to dominate as evidenced by the increase in HPA secretory activity. Both exogenous (e.g. excessive heat or

noise) and endogenous factors (e.g. pain or anxiety), through activation of the sympathetic branch of the ANS, can inhibit sleep initiation or evoke an arousal during sleep. Additionally, it has been shown that individual differences in refractory periods, following ANS activation, can also affect sleep regulation and ANS activation is also prone to conditioning.

Homeostatic drive for sleep

Just as homeostatic mechanisms govern the relationship between hunger and food intake, sleep and the specific ultradian stages of sleep (i.e. NREM stages), are regulated by a homeostatic drive. The homeostatic drive increases the need for sleep based upon the timing and duration of the last sleep episode and declines once sleep has been initiated. In these instances the hypothalamic system creates the motivation to sleep and attempts to balance any discrepancies between sleep need and sleep durations accrued, by mobilizing sleep promoting behaviours (e.g. feelings of tiredness).

Daytime napping for longer than 20 minutes has been related to adverse changes in the sleep–wake cycle through reducing the homeostatic drive for sleep, whereas physical activity relates to an increase in the homeostatic drive. This is particularly relevant when considering as many as 80% of older healthy adults nap during the day (Wauquier *et al.*, 1992) and levels of physical activity are also low in this population.

Sleep deprivation

It is important to note that although a third of the population report sleepiness as a result of chronic sleep deprivation, sleep deprivation studies (both partial sleep and total sleep deprivation) as models of sleep deprivation should be examined cautiously. Experimental manipulations of sleep are prone to both experimenter and participant motivation, as blinded studies are difficult to perform. Additionally, most sleep deprivation studies tend to involve a strict regulation of waking activities, therefore creating an unnatural environment. With these points in mind, researchers concur that sleep deprivation reduces psychomotor performance, cognitive functioning and memory, resulting in deteriorations in mood, although the effects of sleep loss on mood have been shown to be moderated by personality characteristics such as neuroticism (Blagrove & Akehurst, 2001) (see ‘Personality and health’). Other studies have shown the adverse effects of sleep deprivation on medical decision-making and levels of witness suggestibility.

Another feature of sleep deprivation is intrusive NREM sleep episodes during periods of wakefulness, the most common of which are known as microsleeps. Microsleeps manifest for between 15–30 seconds and attention to the environment and motor functioning reactivity are significantly reduced, making them potentially dangerous (e.g. whilst driving). Similarly, REM sleep may also intrude on the waking experience during a prolonged sleep deprivation, manifesting in the form of hallucinations.

Sleep loss also has consequences on the immune system, with even a minor sleep deprivation leading to acute reductions in natural killer cell, T-Cell and monocyte functioning, impairing the host defence mechanism and increasing susceptibility to pathogens. For example, Bergmann and colleagues (1994) found that natural

carcinoma cells were attacked with only 40–50% efficiency after a period of sleep deprivation in rats. Additionally, Spiegel *et al.* (1999) suggest that the increases in sympathetic nervous system activity and higher evening cortisol concentrations, following sleep deprivation, are comparable to those of older adults, thus increasing susceptibility to premature age-related chronic conditions such as hypertension. Furthermore, Van Cauter investigated the relationship between sleep deprivation and glucose tolerance. She found that a relatively short period of sleep deprivation (i.e. 96 hours) led to glucose metabolisms resembling those seen in the primary stages of diabetes (Scheen & Van Cauter, 1998; Van Cauter *et al.*, 1998).

The effects of sleep loss can be quickly reversed. A recovery period between one and three days, irrespective of the amount of sleep debt accrued is usual with the recovery sleep comprising largely of REM and SWS. Additionally, levels of arousal on awakening can have a great impact on subjective measures of sleepiness, so having to attend to the environment quickly may ameliorate the immediate effects of sleep loss.

Circadian rhythms

The circadian pacemaker is the 24-hour body clock that influences chronobiological changes, endocrine changes and Body Core Temperature (BCT) through the suprachiasmatic nuclei (SCN), with BCT being one of the best markers of circadian rhythmicity. Located in the anterior of the hypothalamus, the two SCN, containing approximately 10 000 neurons each help regulate the circadian rhythm through an interplay between the optic nerves and the pineal gland. Signals from the optic nerves pass through the SCN and on to the pineal gland, regulating the production or inhibition of melatonin (melatonin is a hormone which reduces body temperature, aiding sleep onset). Darkness signals the pineal gland to release melatonin into the bloodstream whereas light inhibits its proliferation. Studies with blind people demonstrate that melatonin is still regulated to a 24-hour cycle by the pineal gland in the absence of light signals; however, the timing of the circadian rhythm is usually disrupted. Melatonin release is increased by selective serotonin reuptake inhibitors and antipsychotic drugs but significantly reduced by benzodiazepines and caffeine.

During a normal 24-hour sleep–wake schedule, several hormones, tied to the circadian rhythm, are also secreted. Growth hormone and prolactin are released during SWS and testosterone blood levels peak during REM sleep. Similarly, although sleep-independent, several hormone secretions are aligned to the circadian rhythm. Cortisol secretion, in response to adrenocorticotrophic hormone (ACTH), rises toward the end of the sleep and is at its peak upon waking.

Studies in time-free environments (e.g. caves) suggest a slightly longer natural circadian rhythm than 24 hours and without environmental cues such as food intake, bright light exposure and physical activity (zeitgebers), the circadian rhythm can desynchronize. If the circadian rhythm becomes desynchronized (arrhythmicity), dysfunctional chronobiological changes such as lowered melatonin release occur and a significant discrepancy between the BCT and circadian rhythm develops. BCT increases at night are associated with nocturnal wakefulness and physiological activation, particularly in older adults (Lushington *et al.*, 2000). As the body ages,

the SCN, begins to deteriorate, leaving the body clock to rely increasingly upon zeitgebers to monitor the sleep-wake cycle (Duffy *et al.*, 1996). Two additional factors which can disrupt the endogenous harmony of the circadian rhythm are shift work and transmeridian flight.

Rotating shift work has been widely associated with gastrointestinal dysfunction and cardiovascular disease, although poor eating habits and the timing of food intake (i.e. the timing of gastric juice secretion) may moderate these relationships. Another possible explanation for the ill effects experienced through rotating shift work is the gradual adaptation in cortisol secretion timing, which may take weeks to adjust to a change in routine. The least disruptive shift rotation is one that occurs slowly and follows a natural circadian cycle (i.e. earlies . . . lates . . . nights . . . off). However, the adverse effects of shift work can be further exacerbated by an existing illness (diabetes or epilepsy particularly) and coping with shift work is in itself affected by the timing and types of work undertaken. Shifts of 12 hours or more that involve handling harmful substances, heavy physical activity or critical monitoring are more deleterious. Similarly, shift work with few breaks or with breaks of a short duration are more harmful.

The daytime sleep after a night shift tends to be shorter and contain reduced Stage 2 and REM sleep and increased Stage 1 sleep. Additionally, being 'on-call' during the night, even if not awoken, tends to create an expectancy fragmentation in normal sleep architecture. Overall, the circadian pacemaker of the night shift worker is in continual opposition to environmental zeitgebers and therefore the circadian rhythm remains arrhythmic. Another important factor to consider is the socio-domestic consequences of shift work. Although evening shift work results in little circadian dysregulation, complexities within family role functioning, social isolation and marital disharmony are commonly reported and are reflected in the high rates of divorce amongst evening shift workers (see 'Shift work and health').

In terms of transmeridian flight, desynchronization between the circadian pacemaker and cues from the external environment create phase-delay (westward travel) or phase-advance (eastward travel) in the circadian rhythm. Both phase-delay and phase-advance result in 'jet lag', the physical manifestations of which include lethargy, disorientation, loss of appetite and sleep disturbances the following night. Several factors, such as number of time zones crossed and age (50+) mediate the level of 'jet-lag' experienced and eastward travel has been shown to be more deleterious, requiring a longer recovery period. However, individual differences in experiences of jet lag do exist with approximately one third of people unaffected by transmeridian flight and another third highly susceptible.

In cases of circadian arrhythmicity, due to transmeridian flight, deterioration in the SCN or shift-work, controlled release of melatonin has been shown to reinitialize the circadian rhythm (Garfinkle *et al.*, 1995) although the long-term consequences of self-administered melatonin remain undetermined.

Other sleep disrupting factors

Where it appears that variation in sleep and circadian routines adversely affects sleep architecture, several drugs can also have a significant impact on sleep through the Central Nervous System (CNS), the most common of which are caffeine, nicotine and alcohol.

Caffeine has a plasma half-life of approximately three to four hours (although significant individual differences exist) and is an antagonist to adenosine receptors within the CNS. Doses of caffeine, between 100mg–500mg, significantly delay sleep onset, resulting in less total sleep time and reduced SWS and REM sleep. Caffeine is found in many foods and drinks (one cup of tea contains 25–50 mg; instant coffee 60–80 mg) and most OTC analgesics contain high levels of occult (non-identified) caffeine. Similarly, with a half-life of approximately one to two hours, in large doses, nicotine inhibits nicotinic synapses within the CNS, resulting in CNS stimulation and reductions in total sleep time and REM as well as delays in the onset of sleep. Further compounding the relationship between nicotine and sleep is the finding that one of the main symptoms reported during smoking cessation is sleep disturbance (see 'Tobacco use').

Although alcohol promotes the initiation of sleep and has been shown to increase total sleep time, through depression of the central nervous system, the sleep obtained changes quite dramatically. REM sleep is suppressed whilst blood alcohol levels are high but a rebound in REM sleep occurs (to the cost of SWS) when blood alcohol levels reduce. The diuretic effect of alcohol as well as the increased time spent in REM creates frequent nocturnal awakenings. An additional problem exists in that frequent use of alcohol to sleep creates a tolerance and more alcohol is needed to obtain its sedative effects, creating dependence (see 'Alcohol abuse').

Conclusions

Although research has begun to draw associations between the quantity, quality and timing of sleep episodes and health and social outcomes, the full extent of the relationship between sleep and health still remains largely uncovered. With causal studies of the relationships between sleep functioning and psychological and physical health outcomes in their infancy many more studies are needed to progress our understanding of sleep and its correlates in the real world. What is known is that complex interrelationships exist between the homeostatic drive for sleep, the circadian rhythm and the autonomic nervous system in order to maintain sleep homeostasis and it is our behaviour and the conditions within our society which challenge these systems, increasingly beyond tolerable levels.

Albert Einstein College of Medicine

Social support and health

This chapter discusses the relation of social support to health outcomes. We consider approaches to the conceptualization of social support and discuss findings on the relation of social support to onset, progression or recovery from chronic illnesses which are major sources of mortality. An emphasis is on understanding physiological and behavioural mechanisms through which social support is related to health status. In a final section we summarize developments in this area, note current debates and suggest directions for clinical research.

Conceptualization and measurement of social support

There are two major approaches to conceptualizing social variables related to health. The structural approach focuses on assessing the structure of a person's network of social connections. In a typical network assessment the respondent is asked to name persons with whom he/she has a connection, typically including questions about spouse, family, friends, neighbours and workmates. Network assessments may also include questions about membership of community organizations (e.g. churches, professional or service organizations, fraternal organizations) and participation in sports, cultural

activities and leisure/recreational activities. A score for network size is based on the total number of connections a person has; a score for social integration is based on the total number of different roles a person has in the community; and a score termed 'social participation' is based on the total amount of participation in activities that involve other people. These indices are taken to represent the extent of a person's integration in the community (Cohen, Underwood & Gottlieb, 2000).

The functional approach to support measurement focuses on asking questions about the extent to which a person would have supportive functions available if needed. The supportive functions typically assessed include emotional support, the availability of persons with whom one can talk about problems and receive sympathy, understanding and reassurance. Instrumental support is the availability of persons who can provide relevant goods and services, for example assistance with household tasks, child care or transportation and loaning money or tools when needed. Informational support is having people available who can provide useful advice and guidance and information about community resources or contacts. Assessments of social companionship ask whether there are persons available to do things with for a range of leisure activities. These indices represent the extent to which a person has available social resources that would be useful for coping with problems (see 'Social support assessment').

Models of support effects

A conceptual theme in social support research is whether having good support serves to reduce the impact of stressors. If a support index shows comparable effects for persons with a low stress level and a high stress level, this is termed a main-effect process and suggests that the operation of support does not depend on the person's stress level. An alternative model suggests that support will be particularly beneficial for persons experiencing a high level of stress. This is termed the 'buffering model' because having high support serves to reduce (buffer) the impact of stress and this process implies that support helps people to cope better with stressors. Prior studies of health outcomes indicated that main effects were typically observed for structural measures of support (e.g. network size), whereas buffering effects were observed for functional measures, particularly emotional support (Cohen & Wills, 1985).

Social support and health: findings

Support and mortality

In prospective studies with mortality as the criterion variable, the researchers assess a sample of participants at a baseline point, obtaining structural and/or functional support measures and indexing demographic or behavioural variables that could be correlated with support. The sample is then followed over time and mortality status is determined some years later. At present over 80 such studies have been conducted; almost all show significant beneficial effects of support on mortality from diseases including cardiovascular disease and cancer. On average, persons with low support have two to three times greater risk of mortality compared to those with high support (Uchino, 2004). Studies have been conducted with large population-based samples in various areas of the USA and

Europe, and effects of social support are found to be independent of variables such as age and gender. Protective effects have been found for all structural indices (network size, social integration and social participation) and recent studies have found effects on mortality for functional measures including emotional and instrumental support (Wills & Filer, 2001). The prospective studies have typically found effects of support on mortality with control for indices of substance use (e.g. cigarette smoking) and preventive health behaviours (e.g. diet and exercise), but also have noted that persons with higher support tend to have a more health-promoting lifestyle. This suggests that the effect of social support on health status may be at least partly attributable to these other factors, but possible mechanisms of support effects have not generally been tested in studies of mortality.

In recent years, studies have shown similar effects of social support in other national populations; for example, studies conducted in Hong Kong and Japan showed that higher social participation predicted lower rates of mortality. Differences in support effects as a function of social/cultural variables such as socio-economic status, ethnicity and individualistic vs. collectivist cultures have been investigated to some extent, but the amount of research is limited and there remains a need for further exploration of this question (Uchino, 2004). Research has also extended the concept of individual social support to supportiveness at the community level, defined as feelings of mutual trust, cohesion and responsibility among community residents and termed 'social capital'. For example, Kawachi *et al.* (1997) analyzed state-level indices of social trust and civic engagement from survey data collected in 39 states in the USA, and results showed that states with higher social capital had lower age-adjusted mortality rates.

Support and disease progression

Longitudinal studies have linked social support to disease progression for several conditions including cardiovascular disease and cancer (Helgeson *et al.*, 1998). For example, Angerer *et al.* (2000) found emotional support was related to less progression of coronary artery disease over a 2-year period, as assessed by angiography. A 9-year study of patients with HIV examined effects of life events and social support and found that persons with higher functional support showed slower disease progression as indexed by both CD4 cell counts and clinical diagnoses (Leserman *et al.*, 2002).

Support and recovery from illness

Research has also shown measures of social support related to recovery from illness. In these studies, participants who have a major health problem (e.g. myocardial infarction) are identified through clinic or hospital settings: an interview including a support assessment is conducted and the participants are then followed over time to determine their outcomes. Results have shown that persons with larger social networks or more functional support are more likely to recover from an episode of serious illness. For example, a study by Williams *et al.* (1992) examined a large sample of patients identified by an angiography clinic as having advanced coronary artery disease and followed them over a 10-year period; results showed that a compound support index was related to longer survival time, controlling for household income and for a

comprehensive index of medical risk at baseline. Effects for recovery from illness were also found by Berkman *et al.* (1992) in a community sample of older persons for whom data on support were available from several time points before and after the illness. Among persons who had been hospitalized for a myocardial infarction, emotional support predicted lower likelihood of mortality over a 6-month period, controlling for demographics and prior medical status. Recent studies of medical patients have been consistent with prior findings, showing measures of social participation and confidant availability related to lower likelihood of new disease episodes or mortality (e.g. Brummett *et al.*, 2001; Dickens *et al.*, 2004).

Buffering effects

Many studies have shown buffering effects of social support for psychological outcomes: negative life events have less effect on depression/anxiety among persons with high support, compared with those with low support (Cohen & Wills, 1985). Buffering effects have also been demonstrated in several studies with mortality as the outcome. For example, Rosengren *et al.* (1993) found that life stress had a strong effect on mortality among men with low emotional support, but stress had little effect for men with high emotional support. Falk *et al.* (1992) found that men with high job stress and low emotional support had a disproportionate risk of all-cause mortality, compared with those with high stress and high support. This study also found a buffering effect for a structural measure, social participation.

Relations to physiological indices

Several studies have tested relations of social support to physiological indices which are relevant for cardiac disease and other illnesses. Studies using ambulatory monitoring have shown social support related to blood pressure in daily situations; for example, Linden *et al.* (1993) conducted a day of ambulatory blood pressure monitoring with college students and found that women higher in available support showed lower aggregated systolic blood pressure in daily life. In a 9-year longitudinal study of a middle-aged female cohort, Raikonen *et al.* (2001) found that decreases in functional support over time were related to development of hypertension. A study of women in Sweden investigated several risk factors and

found higher functional support related to lower levels on all four elements of the metabolic syndrome (central obesity, hypertension, dislipidemia and elevated blood glucose), which presents a substantial risk for heart disease (Horsten *et al.*, 1999). With regard to cancer, a study of participants from a screening program found a composite social support measure related to lower levels of prostate-specific antigen, which has been linked to prostate cancer (Stone, Mezzacappa, Donatone & Gonder, 1999).

Mechanisms of support effects

Because of accumulated findings on health effects of social support, research has shifted in recent years towards studying how these effects occur (Berkman *et al.*, 2000). While social networks or social support could be related to health status without involving any other processes, it is plausible that social variables have effects on intermediate processes that then influence a person's health status, a process termed 'mediation' (Wills & Cleary, 1996). The mediator could be a psychological process (e.g. perceived control), a behavioural process (e.g. smoking) or a physiological process (e.g. stress reactivity). Figure 1 illustrates a direct effect from a social variable to a physical effect (path a or path d), and an indirect effect from a social variable to a physical effect through a mediator (paths b or c). For example, low support could be related to cigarette smoking, which would then have effects on lung and arterial cells so as to increase risk for disease. We discuss three plausible mechanisms for mediated effects as follows:

Reactivity and inflammatory processes

Support could be related to risk for cardiovascular disease through a stress-reactivity mechanism. Several studies have tested whether having support reduces autonomic reactivity (i.e. increase in heart rate and blood pressure) under stressful conditions and whether social support has relations to other cardiovascular parameters (Rozanski *et al.*, 1999). Studies in laboratory settings show that having support available is related to less reactivity under stress, whereas negative social interactions predict greater reactivity under stress (Uchino, 2004). Such studies suggest a mechanism for why social support is related to blood pressure in various settings, because persons with higher autonomic reactivity are posited

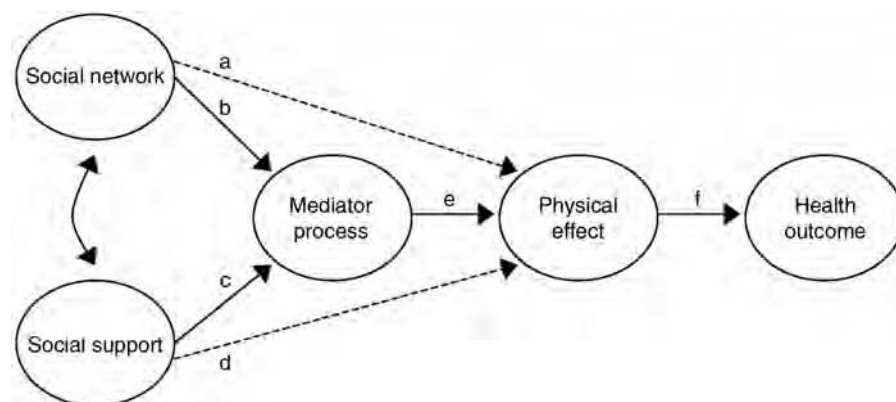

Fig 1 Theoretical model of relation of social network structure and social support functions to health outcome, with indirect relation through mediator process or direct pathway to physical effect.

to be more likely to develop hypertension (cf. Horsten *et al.*, 1999; Raikonen *et al.*, 2001). Studies in field settings have also shown measures of loneliness or social support related to levels of C-reactive protein (Schnorpfeil *et al.*, 2003) and fibrinogen (e.g. Steptoe *et al.*, 2004), which reflect inflammatory processes in risk for heart disease (see 'Stress and health').

Immune system functioning

A mechanism has been outlined in which social support may influence susceptibility to infectious diseases and cancer through effects on immune system functioning. Studies with animal models and human subjects have previously linked social affiliation and perceived support to immune-function indices such as greater T-cell proliferation and higher levels of natural killer (NK) cells (Kiecolt-Glaser *et al.*, 2002). Current research has continued these trends. For example, a study of a workplace sample found, controlling for a number of potential confounders, that persons with more supportive social networks had higher levels of NK cells (Steptoe *et al.*, 2004). Support measures have also been linked to levels of cytokines such as interleukin-2 and -6, and to tumour angiogenesis factors such as Vascular Endothelial Growth Factor (VEGF). For example, a study of patients with malignant tumours found that persons with greater social wellbeing had lower levels of VEGF (Lutgendorf *et al.*, 2002). It has been suggested that support operates through enhancing emotional status, because several studies have found larger networks and higher functional support related to lower levels of cortisol, a marker for negative affect (Steptoe *et al.*, 2004; Turner-Cobb *et al.*, 2000) (see 'Psychoneuroimmunology').

Behavioural mechanisms

Social support could also influence health status through relations to behavioural processes. One plausible process is substance use, as a number of studies have shown that persons with higher support are less likely to smoke cigarettes and engage in heavy drinking (Wills & Filler 2001). It has also been suggested that social control processes linked to social support could encourage persons to maintain a healthier diet, to exercise regularly and to get adequate sleep, all of which are protective factors against several diseases (Berkman *et al.*, 2000; Steptoe *et al.*, 2004). In addition, a substantial body of research has found that persons with more support from friends and family show better adherence to medical treatment regimens, a process that could reduce disease recurrence and enhance recovery from illness (DiMatteo, 2004).

Developments, debates and clinical implications

In summary, research has shown that persons with larger social networks or higher levels of functional support enjoy better health status. This protective effect has been demonstrated across a variety of national populations and has been found for persons of different age, gender and social standing. The field has expanded conceptually to include community-level measures of social capital. In addition to main effects for support, stress-buffering effects have been demonstrated in a number of studies. Prior distinctions between

structural and functional aspects of support have become less clear, as measures of network size and social participation have shown buffering effects for mortality as an outcome, while studies of emotional support and relationship satisfaction have shown these related to lower mortality rates. Thus a prior emphasis on social networks as a health-protective factor has expanded to include consideration of how structural and functional approaches can be merged so as to better understand the role of social factors in health status (Berkman *et al.*, 2000; Cohen, 2004).

Recent developments

A recent development in the area is research designed to investigate mechanisms of how support is related to health, through studying physiological and behavioural processes that may mediate the protective effect of social support. Though mechanisms have not typically been tested in studies of mortality (Uchino, 2004), recent studies have examined relevant intermediate processes. This research has shown support measures related to autonomic reactivity and immune-system functioning and has also shown social support to be related to several behavioural processes. These findings are suggestive in helping explain the linkage of social variables to individuals' health status.

While the field has advanced in this regard, the role of positive or negative affect in support effects is not well studied; the relative importance of stress-dampening mechanisms and effects on immune system function is not known; mediation through behavioural mechanisms has not been studied in detail and it is possible that part of the protective effect of social networks does not involve any of these processes (i.e. a direct effect). We lack comparative studies to clarify which of the intermediate processes are most relevant in accounting for the health effects of social support, using analyses that test directly for mediation. Though many pieces of evidence are available, achieving this larger aim will require studies that link social and physiological assessments and examine intermediate processes over longitudinal periods sufficient to show whether support has direct effects or mediated effects on outcomes. Analytic approaches such as structural equation modelling can help to clarify such questions (Wills & Cleary, 1996).

Debates

Although many findings on the role of social support for disease onset and recovery from illness are well established, there is ongoing discussion about interventions designed to improve health through increasing social support. In recent years, studies have been conducted to investigate whether support can be increased through working directly with indigenous supporters (e.g. family and relatives), or through adding what is termed grafted support: formal psychotherapy or professionally-led support groups. While studies typically show that social support interventions enhance mental health and quality-of-life indices (Hogan, Linden & Najarian, 2002), effects on health outcomes have been mixed; there have been null effects for psychotherapy interventions with heart disease patients, and for cancer patients some possible negative effects of peer support groups have been noted (Helgeson *et al.*, 2001). It is now recognized that the technical issues for conducting

support interventions are not well understood, and explicating these issues is a focus of current research (see 'Social support interventions').

A specific debate concerns the role of support interventions for increasing survival time among cancer patients. Earlier studies had shown that patients who participated in support-group interventions had longer survival times, but some recent studies have reported that support improved quality of life but had no effect on survival. The promise of the positive findings has been balanced against the null results, and the reasons for the differing results are debated at present (see Palmer, Coyne, Spiegel & Giese-Davis, 2004).

Clinical implications

A large body of research has shown that social ties can be a protective factor, making individuals less vulnerable to disease and more resilient in the face of negative life events. An implication for health professionals is that social relationships existing in the community can be important for assisting the treatment effort, or in the case of negative interactions, making it more difficult for individuals to benefit from treatment.

Though the technology of conducting support interventions is still developing, researchers agree that health professionals can adopt an expanded view of physician-patient relationships through thinking about the patient's social network as well as the patient him- or herself. Health professionals can make systematic efforts to reach out to social network members so as to inform them (as well as the patient) about treatment procedures and educate them about how to help maintain treatments, using home visits, telephone calls or more recently, Internet communications. Learning how to enlist the beneficial effects of social networks in the treatment process is a question for both psychology and medicine and interdisciplinary research should be productive for discovering the best ways to accomplish this goal.

Socioeconomic status and health

Lion Shahab

University College London

Background

Although the influence of wealth, status and power on health has been documented across different cultures for centuries (Liberatos, Link & Kelsey, 1988), it was not until the nineteenth century that more systematic scientific evidence emerged showing that those who were more affluent lived longer and healthier (e.g. by Villermé (1840) in France, Chadwick (1842) in Britain and Virchow (1848) in Germany). However, with the advance of bacteriology in the late nineteenth century and the ensuing dominance of the biomedical paradigm of health and illness, considerations of socioeconomic status (SES) in relation to health were largely put aside and confined to its role as a control variable (House, 2002).

With the realization of the limits of modern medicine, interest in social epidemiology and medical sociology grew again during the second half of the twentieth century (Bloom, 2002) and so did the output of research looking at SES, in particular poverty, and health. These early studies assumed a threshold effect of SES on health (Adler & Ostrove, 1999, see Figure 1); increases in income were thought to improve health only beneath, not above, a given ‘poverty line’. As discussed below, however, emerging evidence showed the picture to be far more complex than this.

Main observations

Socioeconomic status as used in research is a conglomeration of various concepts which centre around indicators of desirable social and material attributes. How it is operationalized depends both on theoretical orientations as well as practical limitations

and most studies tend to estimate SES either by educational attainment, income, occupation or a combination of these (Kaplan & Keil, 1993). Irrespective of the actual SES measure used, the last 50 years have produced a number of consistent ‘big’ findings about the association between SES and health (Young, 2004).

The most ubiquitous feature of this association is its shape. What has been found in virtually all studies is a ‘gradient’ effect (Adler *et al.*, 1994) rather than a threshold effect (Figure 1), which holds across various countries (Braveman & Tarimo, 2002), different ethnic groups within countries (e.g. Davey-Smith *et al.*, 1996) and gender (e.g. Bosma *et al.*, 1997). Stepwise increase in SES is accompanied by:

- Stepwise improvement of standardized mortality rates (e.g. Marmot, Shipley & Rose, 1984), disease progression (Lynch *et al.*, 1998) and life expectancy (e.g. Guralnik *et al.*, 1993)
- Stepwise reduction of infant mortality (e.g. Maher & Macfarlane, 2004), chronic disease (e.g. Townsend, 1974) and psychiatric disorder morbidity (e.g. Dohrenwend & Schwartz, 1995)
- Stepwise increase in self-reported good physical (Figure 2) and mental (Figure 3) health (e.g. Hemingway *et al.*, 1997).

The only notable exception to this rule is the differential incidence of neoplastic diseases, some of which follow the social gradient (e.g. lung cancer, Mao *et al.*, 2001) whereas others do not (e.g. breast cancer, Devesa & Diamond, 1980).

Additional features of the SES–health relationship include the existence of ethnic differences that hold within each different social class; non-white populations tend to have worse health indices than white populations along the social spectrum (Pamuk *et al.*, 1998).

Adapted from: Pamuk *et al.*, 1998.

Fig 3 General mental health by family income and sex, England, 2003.

Source: Health Survey for England, 2003.

There is considerable evidence for the influence of SES on health at all stages of the life cycle; the social gradient is found from childhood (e.g. Case, Lubotsky & Paxon, 2002) through to old age (e.g. House *et al.*, 1994). Of particular importance for health across the lifespan is childhood SES. Although health is modified by changes in SES throughout life (Blane, 1999), the social class of origin influences health risks independent of risks associated with the class of destination (e.g. Bartley & Plewis, 1997).

It is worth noting that the health gap between the rich and poor is widening. Both in the UK (Macintyre, 1997) and in the USA (Pappas, Queen, Hadden & Fisher, 1993), there is ample evidence for an increase in health disparities between different socioeconomic groups despite overall improvement in general health. A similar widening of health inequalities has also been observed between countries. For instance, over the last 30 years life expectancy rose in Western Europe whereas it declined in Eastern Europe (Bobak & Marmot, 1996).

Cross-cultural research into population health has unearthed another aspect of the social gradient. Although it is clear that a nation's health depends on its wealth, what may be equally important is how this wealth is distributed within socio-economic hierarchies. More egalitarian countries such as Sweden tend to have better overall health indices than other wealthy countries with greater social inequalities such as the USA (Daniels, Kennedy & Kawachi, 2000 but see Mackenbach *et al.*, 1997) (see 'Cultural and ethnic factors in health').

Lastly, the association between SES and health seems to persist even after controlling for a wide range of possible determinants (Lantz *et al.*, 1998). This implies that there may be direct causal pathways from SES to health. How then, can one explain the link between socio-economic status and health?

Causal explanations

The reasons offered for socioeconomic inequalities in health are diverse and multifaceted. The seminal Black Report, produced by the UK Department of Health's Working Group on Health Inequalities in 1980, suggested three possible explanations for the observed association.

Artefact

First of all, the association may be an artefact of the way that both SES and health are assessed. In fact, despite the suggestion that findings may be affected by the methods used to estimate SES (e.g. Oakes & Rossi, 2003), the consensus is that the consistency of findings across different measures strongly implies that the relationship cannot be artefactual (e.g. Blane, 1997).

Social selection

Secondly, the report proposed that social selection may explain differentials in health by SES. This view implies that health determines SES and not vice versa (see next section). Whether people change their socio-economic position with reference to their parents (inter-generational) or to themselves at an earlier point in life (intra-generational) depends on their health status. While there is evidence for the effect of ill health on downward and good health on upward inter- and intragenerational social mobility, this effect is estimated to be only very moderate in size and therefore not sufficient to explain the SES-health associations (van de Mheen *et al.*, 1999).

Yet it is also possible that a less direct selection pathway could account for socioeconomically determined health differences. One could argue that some individual qualities, such as cognitive ability, coping styles, physical and mental fitness etc. influence success in

life and health simultaneously, thereby making social mobility dependent on determinants of health rather than health itself (Goldman, 2001). This approach may indeed have more explanatory scope than the direct selection hypothesis, especially with regards to the possible contribution of genetic factors to the SES–health relationship through personal attributes (Mackenbach, 2005) (see ‘Personality and health’).

Social causation

It is, however, the third explanation provided by the Black Report, which accounts for most (40–70%, Marmot *et al.*, 1991) of the observed social gradient – the impact of socioeconomically conditioned determinants on health. In particular, material, behavioural,

psychosocial and biological factors have been identified as providing distal and more proximate causal pathways from SES to health (e.g. see Figure 4 for a comprehensive theoretical model of the various determinants of health).

Material factors

The main thrust of health inequalities is likely to derive from material and economic inequalities. People in lower socioeconomic positions have to put up with worse living conditions; they are more often exposed to toxic waste, air and water pollution, crowding, ambient noise and generally poor housing quality, all of which are linked to ill health (Evans & Kantrowitz, 2002). Furthermore, these living environments are more conducive to unhealthy lifestyles, featuring a higher concentration of alcohol outlets and a lack of stores selling healthy foods (e.g. Macintyre, Maciver & Sooman, 1993). People with lower income also experience more risky and physically demanding working environments (Lucas, 1974).

In addition, there is evidence of restricted access to, and less effective utilization of, medical care by patients from lower SES (e.g. Field & Briggs, 2001), in part due to the physical environment (e.g. lack of transportation, Takano & Nakamura, 2001).

The influence of economically determined access to health care alone, however, cannot explain the social gradient (Adler *et al.*, 1993), as material differences do not explain the subtle graduation of health indices detected even at the higher end of SES.

Behavioural factors

Behavioural factors related to medical care provide additional insights into this association. Differential health outcomes across different socioeconomic groups may be a result of both differences in doctor–patient communication (Willems *et al.*, 2005) and varying compliance with medical advice. For instance, unsatisfactory adherence to a prescribed medication regime predicts health deterioration and is more common in less well educated people likely to be lower down the socioeconomic scale (Goldman & Smith, 2002)

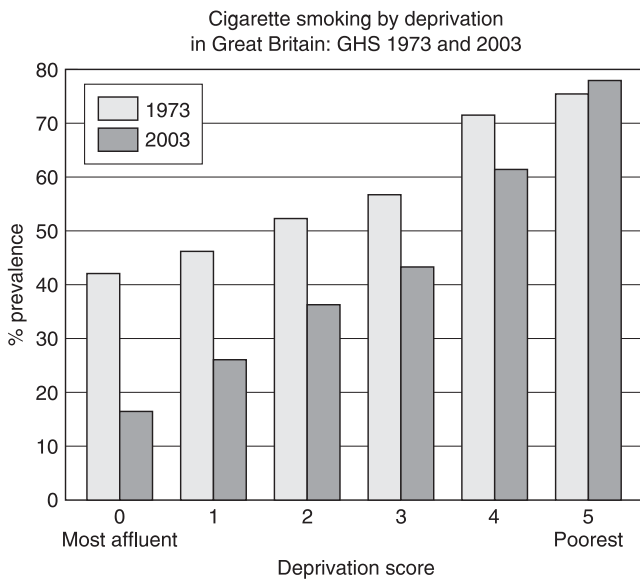

Fig 4 Smoking prevalence in the UK by SES. Source: Jarvis & Wardle, 2005.

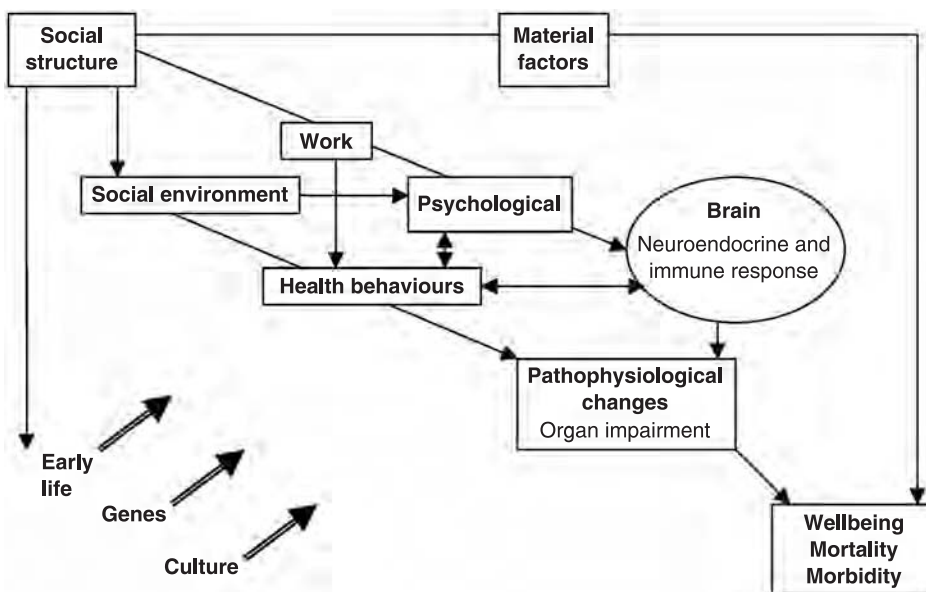

Fig 5 Model of pathways that mediate and moderate the relationship between socioeconomic status and health. Source: Brunner & Marmot, 1999.

(see 'Adherence to treatment'). However, although possibly explaining some of the SES–health relationship, this is unlikely to be the whole story since the social gradient is evident even before the need to seek medical treatment.

A more obvious explanation relates to behaviours which determine health status directly. For instance, cigarette smoking is strongly linked to socio-economic status and exhibits a gradient very similar to that of health and SES (see Figure 5). What is more, the gap in smoking prevalence between social groups has substantially increased over the last 30 years. Thus health behaviours such as smoking may account not only for health differentials across the whole social spectrum but also explain the observed widening of health differences between socio-economic groups (Jarvis & Wardle, 2005). This proposition is corroborated by evidence of comparable gradient relationships with SES in a variety of other health behaviours. People in lower SES are less likely to be physically active (e.g. Helmer *et al.*, 1989), are more likely to overeat and be obese (e.g. Helmer, Mielck & Classen, 1992), as well as to consume alcohol to excess (e.g. Davey-Smith *et al.*, 1996).

However, even when these various behavioural factors are controlled for in analysis, the social gradient is reduced not eliminated (e.g. Marmot *et al.*, 1984). Perhaps psychosocial factors can further elucidate causal pathways from SES to health.

Individual psychosocial factors

One of the most prevalent psychosocial determinants of health is stress. Empirical studies show that people of lower SES are more consistently exposed to chronic stress (Turner *et al.*, 1995), which in turn is associated with poorer physical and mental health (e.g. Avison & Turner, 1988). Variation in chronic stress may also explain some of the ethnic differences in health that are found along the social gradient. For instance, discrimination as a stressor has been related to hypertension, a precursor of cardiovascular disease (Krieger & Sidney, 1996). There is additional evidence that being higher up in the socio-economic hierarchy reduces the risk of exposure to negative life events (McLeod & Kessler, 1990), which may induce acute (Theorell, 2005) and chronic illnesses (Cohen & Williamson, 1991).

Social support is a psychosocial factor proposed to moderate the relationship between SES and health. Social support appears to buffer the impact of stress on health, and is associated with socio-economic status both in terms of social network size and participation (Thoits, 1995). Other coping resources important to the social gradient include 'sense of control'. Higher perceived control over life circumstances is more prevalent in people of higher SES and this is related to improved health outcomes (Lachman & Weaver, 1998) (see 'Perceived control'). In accordance with the demand-control model (Karasek, 1979), low perceived job control has been associated with both lower SES and increased cardiovascular disease risk in the UK Whitehall II study and, furthermore predicted sickness absence when it was accompanied by high work demands (North *et al.*, 1993). Psychosocial work characteristics may also partially explain the inverse association of depression, itself a risk factor for coronary heart disease (Booth-Kewley & Friedman, 1987), with SES (Stansfeld, Head & Marmot, 1998).

It appears that those exposed to most hardship are also those who have the least resources (both in economic and psychosocial terms) to cope with it. But it is not only at the individual level of

explanation that it is possible to discern reasons for the reported observations on health and SES.

Population psychosocial factors

Research shows that residents of low-income neighbourhoods show lower collective efficacy; that is they perceive less social cohesion and social control, which may not only affect physical wellbeing (e.g. reduction in physical activity outside the home) but also mental health (Cohen *et al.*, 2003). These population effects are not only restricted to low-income neighbourhoods; rather they appear to be related to income inequalities in the social environment. Greater inequality is associated with lower collective efficacy but also greater hostility (a risk factor for coronary heart disease, see Dembroski *et al.*, 1989) (see 'Hostility, Type A behaviour and coronary heart disease') and violence (Wilkinson, 1999). Indeed, neighbourhood effects account for a large proportion of health outcomes (Pickett & Pearl, 2001).

Wilkinson has argued that social ordering may have a direct effect on health through the effects of social anxiety, which arises from fear of rejection and negative evaluations by others. Shame and social anxiety are intimately linked to social comparison, a process at least partly based on socio-economic position (Sennett & Cobb, 1973). Social anxiety is an innate mechanism that fosters social inclusion by diverting conflict in social relationships (Leary & Kowalski, 1995). However, increased social inequalities lead to intolerable and chronic anxiety which may result in frustration and aggression. Thus in societies with narrower income differences and therefore lower social anxiety, the quality of social interaction is postulated to be better and overall health superior.

Of course all the factors cited so far, be they material, behavioural or psychosocial, at the individual or population level, are themselves interrelated. For example, adopting a healthier lifestyle like giving up smoking – usually a difficult process – may be particularly difficult for people whose lives are already more prone to stressful episodes due to work strain and neighbourhood effects, which deplete their coping resources. In addition, people of lower SES, as a result of economic constraints, would find themselves in an environment that promotes smoking both physically (access to more stores selling cigarettes) and socially (greater acceptance of smoking habit, e.g. Curry *et al.*, 1993) (see 'Tobacco use').

Biological factors

All of the above determinants, at least within a biomedical model (for a more sociological explanation see Young, *ibid.* for instance), are thought to influence health through proximal biological factors. For example, as a result of damage to arterial walls and a decrease in HDL cholesterol, smoking leads to atherosclerosis, which is linked to cardiovascular disease morbidity (e.g. Brischetto *et al.*, 1983).

More generally, Seeman and McEwan (1999) suggest that stress (in the broadest sense of the word), which is caused by various material, behavioural and psychosocial health determinants, elevates the activity of physiological systems and over time leads to 'wear and tear' of these. Life experiences but also genetic predisposition contribute to 'allostatic load', i.e. stress-induced damage. In the short run, the human body is well equipped to deal with stressors through the action of hormonal stress mediators in the hypothalamic–pituitary–adrenal axis and sympathetic adrenal medullary response system. However, constant insults delivered to

this system decrease the efficiency with which it is turned on and off (as captured by the concept of 'reactivity') and the resultant bodily changes lead to poor health and illness (see 'Stress and health'). The assessment of allostatic load by secondary outcome measures such as fibrinogen has produced gradients equal to those for disease morbidity and mortality (Markowe *et al.*, 1985) and their inclusion as control variables has even been shown to reduce SES risk differences to non-significance (e.g. Lynch *et al.*, 1996).

Current and future directions

This biological perspective lends support to the emerging field of life course epidemiology (Kuh *et al.*, 2003), which proposes the study of long-term effects across the life span. It is evident that no single pathway is responsible for the observed health differentials and this approach is able to integrate different causal descriptions into a coherent whole, forming a conceptual framework for the multitude of explanatory levels (see Figure 5) that bear upon individual and population health. It allows for a better understanding of the temporal influence on health, such as the impact of childhood SES on adult health. As mentioned earlier, numerous studies have found that both the social and physical environment in childhood partly determines a child's mental and physical ability as well as biological and behavioural patterns later in life (e.g. Rahkonen *et al.*, 1997).

The life course approach can thus account for cumulative risk (as implied by 'allostatic load') but also for the independent and interactive influence on health exerted by biological and social factors (Kuh *et al.*, 2003). Lastly, it allows for an exploration of the reciprocal nature of the relation between environmental and genetic determinants on health (Mackenbach, *ibid.*).

Others, however, argue for a paradigm shift to a sociological (critical realist) perspective as offering a better approach for explaining socioeconomic health differentials (e.g. Scambler & Higgs, 2001).

Either way, with the development of novel frameworks comes the demand for appropriate methodology to do justice to the investigation of issues as complex as those involved in social epidemiology. More sophisticated multilevel analytical approaches rather than simple regression analyses are required in order to disentangle the various dynamic forces that affect health outcomes (Merlo, 2003). This also highlights the need for better measures of social status in order to preclude the possibility of producing spurious relationships in increasingly intricate analyses (Oakes & Rossi, 2003).

Whatever the outcome of future research, health inequalities are not immutable (Whitehead, 1990). Rather they represent a social injustice that is unlikely to be alleviated by anything other than wide-ranging public policies, which promote a more egalitarian society and aim directly at reducing socioeconomic inequalities (Link & Phelan, 1995).

Stigma

Robert West¹ and Ainsley Hardy²

¹University College London

²Loughborough University

Stigma involves a negative evaluation of and associated lowering of respect for individuals because of some personal characteristic, which may be physical or behavioural. For a review see Major & O'Brien (2005). It may arise from violation of moral precepts, fear

of contamination, pity, perception of reduced competence, disgust or any of a number of different evaluations. It can be 'enacted' in the sense that non-sufferers treat the stigmatized individual differently or 'felt' in the sense that the individual feels embarrassed or shamed

regardless of what others do or feel (see Scambler, 1998). It can vary in intensity and clearly has no fixed boundaries. Thus people can feel and be stigmatized even by virtue of their age.

Stigma as a phenomenon is important in medical practice partly because of medical conditions that arouse it and partly because of other characteristics that influence the way that medical conditions are addressed. Thus, mental illness carries a degree of stigma and that affects the degree to which patients seek help and the kind of help that is provided. However, poverty, age or lack of education can also be stigmatized and that can affect the treatment people receive for conditions such as heart disease.

Stigma can arise from a variety of aspects of medical conditions. Stigma is associated with disfigurement arising from the condition itself (Papathanasiou *et al.*, 2001) or its treatment (Devins *et al.*, 1994), a reduction in perceived competence such as intellectual impairment (Rasaratnam *et al.*, 2004) or even hearing loss (Hetu, 1996), behaviours that appear bizarre such as 'tics' (Davis, Davis *et al.*, 2004), frightening such as epileptic fits (Chaplin *et al.*, 1998) or dangerous such as delusional behaviours (Brady & McCain, 2004), conditions that are considered to have been brought about in part as a result of actions that are considered immoral as in AIDS (Duffy, 2005), conditions that reflect adversely on a person's social position as can occur in the case of tuberculosis and poverty (Jaramillo, 1998), conditions that affect body parts that are considered 'private' or 'dirty' such as urological conditions and faecal incontinence (Go *et al.*, 2002; Norton, 2004) or conditions that reflect adversely on a patient's strength of character such as obesity (Seidell, 1998) and drug dependence (Joseph *et al.*, 2000) or conditions that are judged to be at least partly self-inflicted (Ritson, 1999).

There are clear differences in stigmatization of medical conditions across countries and cultures. For example one study found differences in stigmatization of epilepsy across different European countries (Baker *et al.*, 2000). Another reported that 'supernatural' explanations of epilepsy can protect individuals from stigmatization (Peng, 1983). Male infertility appears to be particularly stigmatized in countries where ability to produce children is highly prized (Inhorn, 2004).

The effects of stigmatization are obvious, both in terms of self-esteem and psychological wellbeing of sufferers of stigmatized conditions and in terms of how they are treated by the clinical community and society at large (e.g. Fabrega, 1991; MacLeod & Austin, 2003; Puhl & Brownell, 2003). These effects have been well

documented in terms of delay in treatment-seeking, resources devoted to care, the individual clinician's approach to care and the systems in place for managing the care process. What is less obvious is the effect on the diagnosis or cause of death that is recorded (King, 1989). Neither is it so well appreciated that stigma can attach to the relatives of afflicted individuals. For example, the stigma attached to suicide in Taiwan has been found to have important effects on the surviving relatives (Tzeng & Lipson, 2004). Stigma can also lead to reluctance to disclose diagnoses to patients. It has been reported that clinicians are often reluctant to disclose a diagnosis of 'borderline personality disorder' to patients for fear of the affect this may have on the patient (Lequesne & Hersh, 2004).

In terms of reducing the adverse effects of stigmatization of medical conditions, clearly legislation has some role to play in reducing overt discrimination but this need not influence attitudes. It is important for all clinicians to be aware of the potential felt or enacted stigma associated with a wide range of conditions, to recognize their own feelings about particular conditions and in multicultural societies to be acutely aware of cultural differences that may influence presentation of and response to different conditions. Disclosure can be enhanced by use of written forms or even computer-administered interviews, possibly because of the greater sense of anonymity (Newman *et al.*, 2002). It is generally believed that stigma can, in many cases be combated at both an individual and population level by improved education and it appears that increased media exposure to stigmatized conditions such as disfigurement or epilepsy can lessen the adverse emotional reactions through a process of 'normalization' (e.g. Joachim & Acorn, 2000). Counselling is one obvious approach to helping patients to overcome felt or enacted stigma (e.g. Galletti & Sturniolo, 2004) but there has been little research into its effectiveness. An innovative approach is the use of websites to change the way that people view conditions such as depression (Griffiths *et al.*, 2004).

One aspect of stigma that is not widely considered is the intentional or unintentional effects that public health campaigns can have (Guttman & Salmon, 2004). At least part of the reduction in smoking prevalence in some countries can be attributed to a decrease in its social acceptability. It may be argued that this kind of social pressure can be extended in the cause of public health though the cost would obviously be high for individuals who cannot or do not want to conform to the new social values.

Stress and health

Susan Ayers¹ and Andrew Steptoe²

¹University of Sussex

²University College London

The concept of stress is used in a variety of disciplines such as physiology, engineering and sociology. The concept originated in physics where stress is defined as external force applied to a system, and strain is the change in the system that is due to the applied force. In psychology and behavioural medicine the study of stress has moved beyond simple definitions towards identifying the processes of stress and mediating factors. Thus in psychology and medicine the term ‘stress’ covers a wide range of research that concentrates on different aspects of the stress process. For example, much medical stress research does not consider psychological factors and concentrates on physical stress responses, such as the impact of physical exercise on blood volume depletion. There are therefore conflicting views on how useful the concept of stress is. On the one hand some believe the concept is so widely misused and poorly defined that it is no longer useful and should be abandoned (e.g. Kasl, 1983). On the other hand, stress can be seen as an

important construct that has the potential to unify different disciplines and help us understand the relationship between mind and body.

Stress is therefore a complex and multifaceted construct with many component parts. At a basic level, it is useful to distinguish between stressors, which are internal or external factors that cause ‘stress responses’, which can be physical, behavioural, cognitive or affective; and chronic strain, which is the negative impact of the stress process on the person. Current psychological models of stress emphasize the role of appraisal as central in determining a stress response.

When considering the link between stress and health it is important to acknowledge the breadth of the concept of health also. Physical health outcomes vary widely and psychosocial stress is likely to play a different role in different health outcomes – both in terms of varying clinical impact and the processes or mechanisms

underlying this. Add to this the role of stress in psychological health and it is apparent that we need to acknowledge many different possible pathways between stress and health, such as physiological, psychological and behavioural. For example, the mechanisms by which stress may exacerbate an asthma attack are likely to be very different to the mechanisms by which stress may affect symptoms of depression or disability.

In this chapter we will look briefly at some of the conceptual issues and problems that arise in stress research, then examine current transactional theories of stress, before considering the link between stress and health and the possible pathways between stress and health. This chapter is an abbreviated version of a more detailed chapter we have written elsewhere (see Steptoe & Ayers, 2004).

Conceptual problems

As the concept of stress is amorphous and widely used in different disciplines, it is a challenge to try to unify conceptual understanding and research findings from different areas. In order to do this we need to rely on more complex models of stress and its components. However, this often results in somewhat artificial distinctions. For example, psychosocial stressors are numerous and can be classified in a number of different ways. It is possible, for instance, to distinguish between external objective events such as natural disasters, and internal subjective experiences like role conflict or not achieving one's goals. Then there are inter-personal stressors such as conflict at work, and macrosocial stressors like high unemployment, socio-economic inequality and war. Stressors vary on many dimensions, including duration and severity and these dimensions have also been used to define various categorical systems.

A common distinction is made between acute life events such as the death of a relative or job loss, chronic stressors such as family conflict or looking after a disabled relative and less severe daily hassles such as problems travelling to work. Further stressor categories such as role strain and traumatic stress are also sometimes used. One of the advantages of identifying acute life events is that they can be pinpointed in time and are relatively easy to define. This makes it possible to analyse the temporal sequence between life experiences and illness onset and life event methods have proved especially useful in psychiatric research. As far as physical illness is concerned, chronic stressors are frequently more important, since they elicit long-term disturbances in behavioural and biological processes which contribute to the development of disease.

These categorizations have a number of conceptual and measurement problems. First, the distinction between different categories of stressor is not always clear. For example, an apparently acute event, such as divorce, is usually preceded by the chronic stress of a difficult relationship and can lead to further chronic stressors, such as financial difficulties. Secondly, there are conceptual limitations to many of the categories. For example, whether a stressor is perceived as traumatic varies between individuals, therefore classifying an event as a 'traumatic stressor' confuses subjective response with the event. Related to this is a third problem, which is that it is difficult to measure stressors without some reference to stress responses (see 'Stress assessment'). Measures of daily hassles include items such as 'trouble relaxing' and 'not enough personal energy', which are arguably symptoms of strain rather than stressors. Finally, there are instances where non-events, such as a lack of stimulation, are stressful.

Theories of stress

Psychological theories of stress have arisen from two different sources – those that try to account for normal stress processes and those that look specifically at psychological stress disorders, such as post-traumatic stress disorder. These theories of normal and abnormal stress processes have developed largely independently of each other. In this chapter we concentrate on theories of normal stress responses.

The study of normal stress processes initially led to theories that concentrated on aspects of the stress process, such as the stressor (e.g. life events approach) or the physical stress response (e.g. Selye, 1956) (see 'Life events and health' and 'Psychosomatics'). Current interactional or transactional theories of stress emphasize individual differences in perceived stress and the importance of psychological processes – particularly cognitive appraisal. The interactional approach to stress proposes that the interplay between environmental stimuli and the person is critical in determining stress responses. An example of an interactional approach is the person–environment fit model in occupational psychology, in which stress arises when people are exposed to environments with which they are unfamiliar, or which do not suit their skills and capacity (French *et al.*, 1982).

The transactional approach goes beyond the interactional approach by positing that the various factors involved in stress influence each other and act as both independent and dependent variables. The dominant transactional model was developed by Richard Lazarus and his colleagues, who defined stress as 'a particular relationship between the person and the environment that is appraised by the person as taxing or exceeding his or her resources' (Lazarus & Folkman, 1984, p. 19). Cognitive appraisal is central to this model. Lazarus suggests that when an event occurs individuals go through three stages of appraisal. The first stage is primary appraisal, where the demands of the event on the individual are evaluated. The second stage is secondary appraisal, where people evaluate the resources they have available to cope with the demands. Available resources can be environmental (such as economic factors, social factors, the presence of others) or personal (such as previous experience with this type of event, self-efficacy, self-esteem, repertoire of coping strategies). It should be apparent that these resources also influence primary appraisal. For example, an academic examination will be appraised as less demanding by a student with a thorough knowledge of the subject and plenty of time to revise (good resources to cope). On the other hand, the examination will be appraised as more demanding by a student with little knowledge of the subject and little time to revise (poor resources to cope). Thus primary and secondary appraisal do not necessarily occur in a linear and sequential fashion, but influence each other and may occur in parallel. Recent research suggests that this may vary according to level of demands, and that perceived personal resources are more likely to influence appraisals of stress under low levels of demand (Guillet *et al.*, 2002).

As a result of this process, an event can be evaluated as irrelevant, i.e. not relevant to the individual's wellbeing; benign-positive, i.e. positive and/or non-threatening; or stressful. According to this model, stressful appraisals can be further broken down into those that involve harm or loss, challenge or threat, although these categories are not mutually exclusive. For example, physical assault can involve appraisals of both immediate harm and future threat of

recurrence. These ideas have been incorporated into theories of abnormal stress responses, such as anxiety disorders, where appraisal of continued threat is thought to be important in the development of the disorder (e.g. Ehlers & Clark, 2000). According to the transactional approach, when demands are appraised as exceeding resources coping strategies are applied in an effort to change the situation, or the response to that situation. The process is iterative, with the situation being reappraised after coping attempts have been made, often leading to further coping efforts.

This model has stimulated a substantial amount of research, much of which supports the role of appraisal in modulating subjective and physiological stress responses. For instance, Lazarus and others have carried out a series of experiments in which people are shown gruesome films, having been randomized to different types of appraisal or cognitive orientation, such as reminding them that the film is acted (denial of reality), that film is real but shown for educational purposes (intellectualization). People assigned to denial or intellectualization appraisals have smaller physiological and subjective responses to the film compared with controls (e.g. Steptoe & Vögele, 1986). Non-experimental research also supports a role for appraisal in adaptation to stressors. Pakenham & Rinaldis (2001) found that strong appraisals of challenge, controllability and weak appraisals of threat were predictive of better psychological adjustment to HIV/AIDS, as measured by depression, global distress, social adjustment and subjective health status.

However, the model has been criticized on a number of points, many of which question the central role allocated to cognitive appraisal processes (Zajonc, 1984). The difficulty of measuring appraisal as part of a dynamic process means it is hard to distinguish appraisal from cognitive processes that are part of the stress response itself. There are undoubtedly situations where conscious appraisal does not take place and people react quickly to hazards, such as when avoiding accidents. The model has also been criticized for being limited to the psychological level of analysis, without consideration of physical, social and cultural influences. It has little to say about the nature of stress responses themselves and how they interact. Nevertheless, transactional models have greatly increased understanding of individual differences in the stress process, and the role of cognitive factors in integrating experience of the environment with the social and psychological responses which the person brings to bear on the situation.

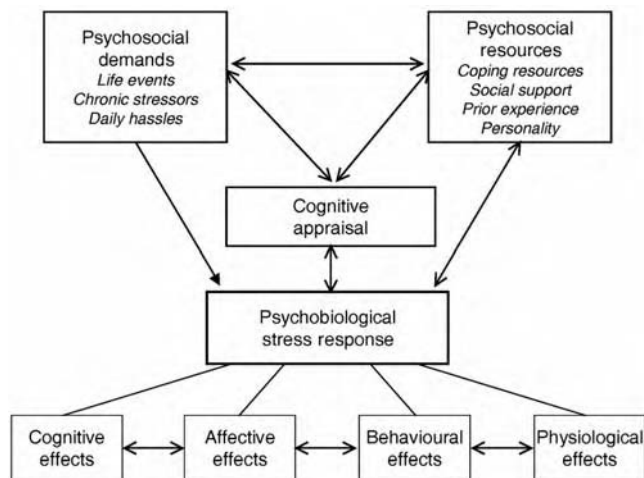

Fig 1 An outline of the transactional model of stress.

Figure 1 is a simple schematic of a transactional framework that attempts to bring together the factors that are relevant to the stress process. This framework begins with the assumption that stress responses are stimulated by potential or actual threats or challenges to the integrity or survival of the person (Weiner, 1992). Psychosocial stressors may be anticipated, may be real or imaginary and may involve understimulation as well as overstimulation. The appraisal of these aversive experiences depends in part on the psychosocial resources that the individual brings to bear on the situation. These resources include coping responses, prior experience of similar situations in the past and social supports. Appraisal is also influenced by personality and temperament. The multidimensional stress response arises when adaptive capacity is exceeded. The pattern of stress response varies over time, depending on whether exposure to the threat is acute or chronic, and whether there is habituation or sensitization to the situation. There is also a close interplay between the components of the stress response and the coping process. For example, an increase in cigarette smoking has been frequently observed as part of the stress response (Jarvis, 2002). At the same time, a large proportion of smokers state that smoking helps relieve tension, so smoking is partly a coping response. Smoking may alter the cognitive response to stress by increasing alertness and aiding mental concentration, so it can be viewed as partly adaptive. However, smoking also augments physiological stress responses and health risks, so it has maladaptive consequences as well.

It is evident from this framework that stress is a process and not a state and that it involves a fully interactive rather than a linear system. A major challenge in health research is teasing out the interplay between these elements.

Links between stress and health

The influence of stress processes on health and risk of disease is studied from a variety of perspectives using animal models, epidemiological survey techniques, clinical investigations and laboratory experiments. There are two broad approaches to studying these effects in humans. The first is to assess the impact of particular categories of potentially stressful conditions and the second is to investigate the aetiology of specific diseases. Many studies have shown that stress and morbidity are associated, but this does not necessarily mean that stress plays a causal role. There are a number of difficulties in establishing a definitive link. Firstly, the diseases in which stress is implicated are typically multifactorial, with a range of genetic, biological and environmental determinants. It is not a case of a disease being due either to stress or to other factors, but of stress processes contributing to aetiology to a variable extent in different people and different conditions. This can make it difficult to identify an independent role of stress. Much clinical research on stress and health is cross-sectional, so inferences about causality cannot be drawn. Indeed, no single type of scientific investigation is sufficient. Rather, it is necessary to integrate evidence from several sources – animal experiments, prospective epidemiological surveys, clinical investigations and laboratory experiments.

Secondly, there are a number of moderators of the stress response that need to be taken into account. Stressor characteristics, such as duration and severity are important determinants of the psychobiological response. In addition to this, characteristics such as controllability, predictability and novelty have been shown elicit greater

emotional, behavioural and physiological responses. For example, a wide range of animal and human studies has shown that uncontrollable stressors elicit greater corticosteroid and catecholamine responses, increase tendencies to gastric lesions and reduce immune defences (Steptoe & Appels, 1989). Coping responses and social support are also important moderators of the stress response (see 'Psychoneuroimmunology' and 'Social support and health'), as are individual differences. For example, Taylor *et al.* (2000) put forward an argument, largely based on animal models, that females have different physiological and behavioural responses to stress. They posit that the well documented fight-flight response is more likely in males whereas females are more likely to show a tend-befriend response.

Thirdly, the impact of stress processes on health is not all mediated through direct biological responses. As noted earlier, behavioural responses also contribute. An elegant example of behavioural mediation comes from studies of the development of high blood pressure in air traffic controllers. Air traffic control is a stressful occupation, with persistent high demands and need for rapid decision-making, which carries great responsibility. It was established 30 years ago that air traffic controllers have increased risk of hypertension compared with workers in similar environments doing other jobs (Cobb & Rose, 1973). It was supposed that this was due to persistent activation of the sympathetic nervous system. But DeFrank *et al.* (1987) showed that the occurrence of high blood pressure was preceded by marked increases in alcohol consumption, and that this mediated the link between work stress and morbidity. Research has since established that stress is associated with a range of risky health behaviours, such as poor diet, less exercise and increased smoking (e.g. Ng & Jeffery, 2003), which suggests that behavioural responses to stress are likely to contribute to the relationship between stress and health.

A fourth problem in establishing causal links between stress and disease is the wide variation in individual responsivity. How is it that two people have similar life experiences, yet one becomes ill while the other remains healthy? Why do some people contract infectious illness while others experience increased risk of coronary heart diseases when faced with chronic stressors? Some of this variation is due to the interplay of demands and resources outlined in Figure 1. But in addition, it is necessary to consider individual vulnerability factors. This has led to the diathesis-stress model, a version of which is summarized in Figure 2. The outcome of the stress process

depends on constitutional and biological risk factors that determine whether the individual remains healthy or develops coronary heart disease, musculoskeletal pain, shows exacerbation of autoimmune diseases or other adverse effects. For example, a recent longitudinal study found that the association between stressors and depression is moderated by a polymorphism in the serotonin transporter gene (Caspi *et al.*, 2003).

The diathesis-stress model enables us to account for individual vulnerability and therefore differences in health outcome. In addition, it is important to recognize that stress can act in a number of different ways to influence the onset or progression of disease. For example, Steptoe (1998) outlines four ways in which psychosocial stress may act on disease. In the first instance, stress may be causal in disease, such as chronic stress resulting in damage to arterial walls and hence aiding the development of atherosclerosis. Secondly, stress may trigger an episode of disease, such as a sudden stressor triggering a heart attack, although this is unlikely unless there is some underlying pathology in the first instance. Thirdly, stress may disrupt or exacerbate existing pathology or symptoms, hence affecting the course or prognosis of the disease. Fourthly, stress may inhibit physical defence systems. For example, chronic stress may deplete the immune system, which increases vulnerability to infection.

Conclusion

Psychosocial stress and its link with health is a complex and multifactorial process. Transactional models of stress account for individual differences in perceived stress and in stress responses. The diathesis-stress model explains how individual vulnerability interacts with stress to result in a range of different health outcomes. The complexity of psychosocial stressors and individual variability in both stress responses and health outcomes makes it difficult to establish a definitive link between stress and health. The processes through which stress may affect health can be psychobiological or behavioural, and stress may act in various ways to influence the onset and progression of illness. However, there is a wealth of evidence demonstrating an association between stress and health and research in the areas of psychophysiology and psychoneuroimmunology is critical in understanding the physiological processes which may mediate between perceived stress and physical health (see 'Psychoneuroimmunology').

Symptom perception

Elizabeth Broadbent and Keith J. Petrie

The University of Auckland

Introduction

Experiencing physical symptoms is very common. General population surveys show most people experience some form of symptom like headaches, aching joints and muscles or upper respiratory complaints two to three times a week (Dunnell & Cartwright, 1972; Hannay, 1978; Kroenke & Spitzer, 1998). Studies also show that rates of symptom reporting differ across various demographic groups. For instance, females generally report more symptoms than males, unemployed people more than employed, people living alone more than people living with a few others (Pennebaker & Epstein,

1983). These findings suggest that there is more to the reporting of symptoms than just underlying changes in physiology.

Understanding the factors that influence the perception of symptoms is important because symptom reporting forms such a central part of most medical encounters and diagnosis. The (mis)perception of symptoms typically forms the basis of delay in seeking treatment, the overuse of medical services and the inappropriate use of medication. Symptom perception is also important in determining responses in chronic illnesses. People with diabetes or asthma, for example, must regularly manage their illness by monitoring their symptoms and responding with self-medication and

behavioural responses. This chapter explores the psychological processes involved in the perception and reporting of physical symptoms.

How accurately do people perceive symptoms?

People are generally accurate when perceiving extreme symptoms or bodily states that need attention immediately. For example, individuals can almost always tell when they need sleep, need to eat or to urinate. More ambiguous symptoms such as heart rate or blood pressure have not evolved in such a way that they dictate behaviours. Peoples' reports of such symptoms have generally been shown to be poorly related to objective markers of their physiology in laboratory studies (Pennebaker, 1984). For example, although some individuals are more accurate than others, on average participants are unable to accurately report their heart rate during several differing tasks (Pennebaker, 1984). There is some evidence that accuracy improves in naturalistic settings, with one study showing that diabetics are better at estimating their blood glucose levels at home than when blood glucose is artificially manipulated in a hospital setting (Cox *et al.*, 1985). Asthmatics rely on symptom perceptions to self-medicate, yet 60% of asthma patients have been shown to be unreliable in detecting changes in their lung function under normal daily conditions (Kendrick *et al.*, 1993). Other studies show that while 90% of hypertensive patients believe they are able to tell when their blood pressure is up by monitoring their symptoms, such as heart beat and face-warming (Meyer *et al.*, 1985), the bulk of evidence suggests the contrary (Baumann & Leventhal, 1985; Brondolo *et al.*, 1999; Meyer *et al.*, 1985). Part of the reason why symptom reports are poorly related to objective measures of physiology may simply be that we are more hard-wired to notice large or abnormal changes in physiological functioning rather than more subtle or graduated changes. Other reasons for the disparity involve the psychological process concerned with noticing and interpreting symptoms.

Noticing symptoms

The extent to which we notice symptoms depends on how much attention we pay to our bodily states. Studies have demonstrated that people report more symptoms in boring rather than in interesting environments. This finding can be explained by the competition of cues theory which proposes individuals have a limited capacity to process stimuli and internal (bodily) and external (environmental) cues compete for attention (Pennebaker, 2000). When we are engaged in a cognitively engaging and demanding activity, such as playing sport, our attention is focused on external cues and we are less likely to attend to our bodies. When we are in less interesting situations, such as sitting in a boring lecture or movie, we become more aware of our bodies and notice more symptoms. In fact, higher teaching evaluations of lecturers has been related to lower frequency of students coughing during class (Pennebaker, 1980). Thus the extent to which we notice symptoms depends on how stimulating we find the environment. Two interesting experiments have shown that the provision of external cues can improve jogging speed and reduce symptom reports (Pennebaker & Lightner, 1980). Participants were found to run faster on a cross-country

course than on an oval running track, and joggers on a treadmill who listened to distracting sounds reported less fatigue and fewer symptoms than joggers who listened to an amplification of their own breathing. As this study shows, the more we focus internally, the more we notice symptoms. This characteristic has been exploited by most parents to distract young children when they fall over and injure themselves. Ironically in clinical conditions, the social isolation and disability that often accompanies chronic illnesses and pain conditions intensify the noticing of patients' symptoms and pain (see 'Coping with chronic illness' and 'Pain management').

In most situations individuals use a combination of both external and internal information to determine their current bodily state. However, it seems that high symptom reporters have a strong tendency to make use of external cues to determine internal body states. In a study where high and low symptom reporters were shown neutral and gruesome slides and asked to estimate their heart rate, high symptom reporters reported their heart beat increased markedly in response to the more grisly slides although their actual heartbeat showed little change (Pennebaker, 1981).

Studies also suggest that men and women may differ in the prominence they give to internal and external cues. Research shows men tend to rely more on internal physiological cues as sources of information, whereas women rely more on external contextual cues (Roberts & Pennebaker, 1995). In laboratory conditions, where external cues are not available, women tend to be less accurate than men, and correlations between symptoms and blood pressure readings are higher for men than for women (Pennebaker *et al.*, 1982). In the real world, accuracy does not tend to differ between men and women because internal and external cues are both available.

Individuals potentially have a large amount of somatic information available but we screen out all but the information that is most salient, relevant and potentially threatening. Our cognitive schema, can guide which information we attend to and cause us to interpret the information in a way that is consistent with the activated schema. Changing the cognitive schema can manipulate the type of somatic information attended to, causing individuals to selectively look for and encode information consistent with that particular schema. For example, when individuals have been labelled with a fictitious illness they are more likely to report symptoms consistent with their knowledge of that illness than individuals who are told they do not have the 'illness' (Croyle & Sande, 1988).

The process of attending to schema consistent information can happen very quickly. For example, the effect of someone vigorously scratching their back and arms when seated next to you, means you are much more aware of itchy areas on your skin and likely to also start scratching. Similarly, one person yawning at a dinner table can cause others to yawn almost instantaneously.

More dramatic examples of the effect of schemas on symptom perception are medical students' disease and mass psychogenic illness. As many as a third of medical students report an incident where they fear they may have the disease they have been recently studying. Mass psychogenic illness incidents represent the same process on a far grander scale. Typically, a dramatic or highly visible illness in one individual sets off a rapid escalation of similar cases. Usually the incident occurs in the context of a closed social setting such as a school or factory and sometimes following a triggering

event such as an unusual smell. The most common symptoms in such incidents are nausea, headache, tight chest, dizziness and fainting. Colourful examples of mass psychogenic illness appear throughout history (Bartholomew, 1994).

Expectations about experiencing symptoms are also an important determinant of symptom reporting, particularly after the administration of drugs. Placebo controlled trials have shown individuals tend to amplify symptoms they expect and minimize symptoms they do not anticipate (see 'Placebos'). A study of patients suffering from food allergies found a quarter of patients developed allergic symptoms following injection with saline when it was described as an allergen (Jewett *et al.*, 1990). Similarly, in a study of aspirin for treatment of unstable angina, the participant information form at two study centres listed gastrointestinal irritation as a possible side effect, but the third centre did not. Six times as many patients withdrew from the study because of gastrointestinal distress in the centres mentioning this symptom than the centre that did not (Myers *et al.*, 1987). Expectations of symptoms in response to medication seem to operate by priming individuals to notice any unusual symptoms and to interpret these sensations in the context of a reaction to treatment (see 'Expectations and health').

Interpreting symptoms

There is some evidence that people may hold symptom attribution styles, or a tendency to attribute symptoms along one of three dimensions: somatic (e.g. something wrong with the body), psychological (e.g. due to being upset) or normalizing (e.g. room too hot) (Robbins & Kirmayer, 1991). These styles are related to past experiences of illness and predict clinical symptom presentation, with somatic attributers more likely to present with somatic symptoms and psychological attributers more likely to present with psychosocial symptoms than the other groups. Past experience of illness may provide a schema for the interpretation and attribution of new symptoms.

Causal attributions for symptoms can have far-reaching consequences on health behaviours, including adherence, restriction of activities and presentation to the doctor. A recent study found that HIV patients who attributed their symptoms to medication side effects were more likely to be non-adherent to their medication regime than those who believed the symptoms were due to other factors such as disease progression (Siegel *et al.*, 1999). Those who did not experience a reduction in symptoms after starting their medication and believed that this indicated their medication was not working were also more likely to be non-adherent. In a community sample of people with fatigue, those who attributed their fatigue to myalgic encephalomyelitis were found to be more handicapped and to restrict their activities more at follow-up than those who attributed their fatigue to either psychological or social factors (Chalder *et al.*, 1996) (see 'Attributions and health').

Our responses to symptoms depend on how we interpret them. Most symptoms are transient and benign and the majority of individuals respond by waiting, doing nothing or self-medicating (Freer, 1980). One diary study showed that while symptoms were recorded on 38% of the days in the study medical care was only sought for 5% of those symptoms. So, how do we decide if our chest pain is a pulled muscle or a heart attack?

As symptoms are common and mostly benign, individuals often judge the seriousness of symptoms through the use of simple heuristics and how their symptoms match to the prototypes they hold for various common illnesses. If symptoms appear quickly and are accompanied by pain and restrict activities, symptoms are more likely to be judged as serious and requiring medical attention. People develop prototypes of illnesses based on their own previous experiences as well as knowledge gained from the media and other sources. When people experience a symptom they try to identify which illness they have by matching the symptom to their lay prototype of an illness. This match strongly influences coping strategies and help-seeking behaviour. For example, heart attack patients who experience symptoms consistent with their mental picture of a heart attack (most typically this includes chest pain and sudden collapse) present to hospital earlier than patients whose symptoms vary from their preconceived ideas of a heart attack and may be a closer match to their ideas about indigestion (e.g. upset stomach, nausea) (Perry *et al.*, 2001). Similarly, patients who experience a breast lump present to a doctor more quickly than those who experience other breast symptoms, because a lump is more consistent with their picture of breast cancer (Meechan *et al.*, 2003). Thus symptom interpretation can contribute to delay in seeking medical care in the areas of breast cancer and myocardial infarction and strongly influence prognosis (FTT Group, 1994; Richards *et al.*, 1999). A better understanding of this psychological process has the potential to improve interventions designed to reduce delay and significantly influence patterns of mortality (Petrie & Weinman, 2003) (see 'Delay in seeking help').

The influence of emotions

Emotions play a strong role in symptom reporting. Considerable research has been conducted on the role of negative mood, trait negative affectivity and anxiety on symptom reporting and help-seeking behaviour. Negative moods have been shown to consistently trigger symptoms and health care actions such as taking medicines, seeking medical advice and restricting activity (Verbrugge, 1985). Following induction of a negative mood, healthy participants report more aches and pains and greater perceived vulnerability to health events (Salovey & Birnbaum, 1989). Research has shown that high trait negative affect is closely linked to higher symptom reports without any consistent relationship to objective health status (Costa & McCrae, 1987). Individuals high in negative affect are characterized by a tendency to experience a range of distressing negative emotions such as anxiety and depression. Individuals scoring high on trait negative affect have been shown to report two to three times as many symptoms as individuals low on negative affect (Costa & McCrae, 1980).

Evidence suggests that negative affect influences both noticing and interpretive processes. In situations framed as non-threatening, the accuracy of symptom perception has been shown to be similar between individuals high and low in negative affect, but in situations framed as threatening accuracy decreases in individuals high in negative affect and increases in individuals low in negative affect (van den Bergh *et al.*, 2004). High negative affect has been associated with hypervigilance and increased scanning for impending trouble, which seems increase the extent to which people notice symptoms and attribute these symptoms to an illness.

Those high in negative affect are more schema-driven in determining their somatic states and tend to make more negative interpretations than other individuals regarding common symptoms (Affleck *et al.*, 1992). This is supported by a recent study examining symptoms following vaccination. A week following the vaccination participants high in negative affect attributed a far wider range of general symptoms to the effects of the vaccination than did low negative affect participants (Petrie *et al.*, 2004). Similarly, high trait negative affect was associated with higher rates of symptom complaints following exposure to a respiratory virus regardless of whether individuals had objective evidence of a cold (Feldman *et al.*, 1999).

A number of patients who generally do not have significant medical illness consistently seek medical care, consuming a large amount of health care resources in terms of primary care and specialist appointments, hospital admissions and laboratory and other investigations (Smith *et al.*, 1986). These frequent attenders of health services tend to be high in trait anxiety (Banks *et al.*, 1975). Those who use healthcare services extensively are also less likely to make normalizing attributions for common somatic symptoms than are other people (Sensky *et al.*, 1996).

Conclusions

Psychological processes strongly influence symptom perception and reporting. Future research in the psychology of physical symptoms is likely to improve our understanding of the links between symptoms and health care behaviour. Furthermore, psychological interventions offer a way to change individuals’ symptom perception to improve their functioning and alter their health behaviours. For example, a diabetes training programme on the recognition of symptoms, inaccurate symptom beliefs and external influences on blood glucose levels has been shown to improve patients’ recognition of hypoglycaemic and hyperglycaemic episodes, estimations of blood glucose levels and metabolic control (Cox *et al.*, 1988; Cox *et al.*, 1989; Cox *et al.*, 1991). Another intervention, which trained somatization syndrome patients in both biological and psychological aspects of somatoform symptoms, reduced their number of somatoform symptoms, general psychopathology, anxiety, depression, subjective health status, life satisfaction and visits to the doctor (Bleichhardt *et al.*, 2004) (see ‘Psychosomatics’).

Theory of planned behaviour

Stephen Sutton

University of Cambridge

The theory of planned behaviour (TPB; Ajzen, 1991, 2002*b*), an extension of the theory of reasoned action (TRA; Ajzen & Fishbein, 1980; Fishbein & Ajzen, 1975), is widely used to study the cognitive determinants of health behaviours (Conner & Sparks, 2005; Sutton, 2004). It has several advantages over other ‘social cognition models’: (1) it is a general theory, and it can be argued that general theories should be preferred to health- or behaviour-specific theories for reasons of parsimony (Stroebe, 2000); (2) the constructs are clearly defined and the causal relationships between the constructs clearly specified; (3) there exist clear recommendations for how the

constructs should be operationalized (Ajzen, 2002*a*); and (4) meta-analyses of observational studies show that the TPB accounts for a useful amount of variance in intentions and behaviour (but see the discussion of variance explained in Sutton, 2004).

According to the theory, behaviour is determined by the strength of the person’s intention to perform that behaviour and the amount of actual control that the person has over performing the behaviour (Figure 1). According to Ajzen (2002*b*), intention is ‘the cognitive representation of a person’s readiness to perform a given behaviour, and ... is considered to be the immediate antecedent of behaviour’,

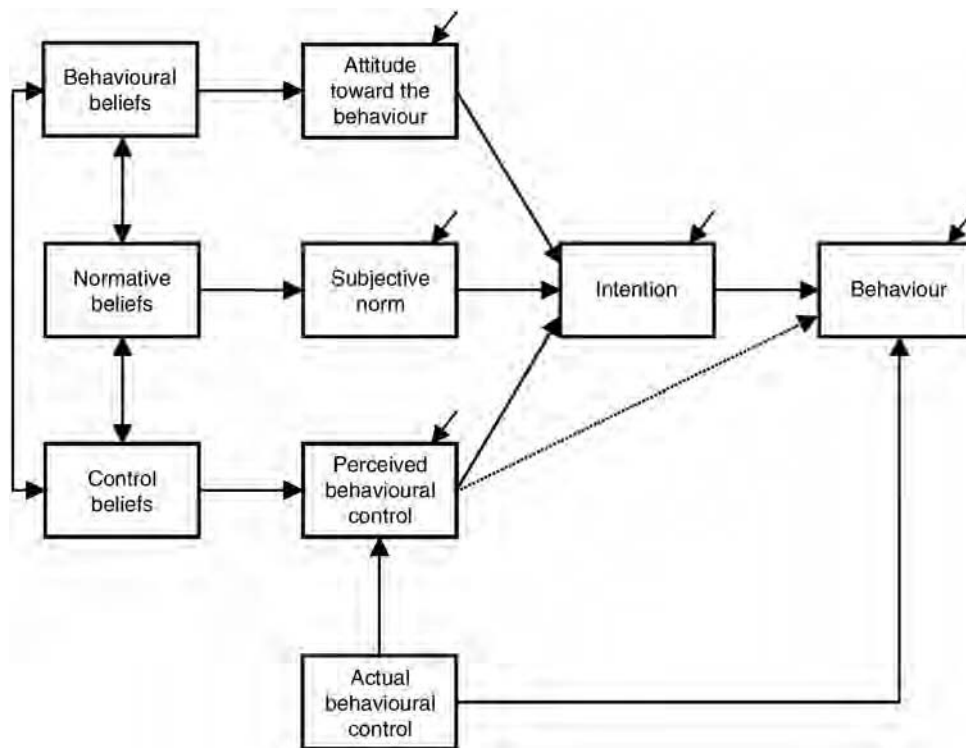

Fig 1 The Theory of Planned Behaviour. The small, unlabelled arrows represent other, unspecified causes of the endogenous variables.

and actual behavioural control ‘... refers to the extent to which a person has the skills, resources and other prerequisites needed to perform a given behaviour’. Figure 1 also shows an arrow from perceived behavioural control to behaviour. ‘Perceived behavioural control’ refers to the person’s perceptions of their ability to perform the behaviour. It is similar to Bandura’s (1986) construct of self-efficacy (see ‘Perceived control’ and ‘Self-efficacy and health’). Indeed Ajzen (1991) states that the two constructs are synonymous. Perceived behavioural control is assumed to reflect actual behavioural control more or less accurately, as indicated by the arrow from actual to perceived behavioural control in Figure 1. To the extent that perceived behavioural control is an accurate reflection of actual behavioural control, it can, together with intention, be used to predict behaviour.

The strength of a person’s intention is determined by three factors: (a) their attitude toward the behaviour, that is, their overall evaluation of performing the behaviour; (b) their subjective norm, that is, the extent to which they think that important others would want them to perform it; and (c) their perceived behavioural control.

Attitude toward the behaviour is determined by the total set of accessible (or salient) behavioural beliefs about the personal consequences of performing the behaviour. Specifically, attitude is determined by $\sum b_i e_i$, where b_i is belief strength and e_i is outcome evaluation. Similarly, subjective norm is determined by the total set of accessible normative beliefs, that is, beliefs about the views of important others. Specifically, subjective norm is determined by $\sum n_j m_j$, where n_j is belief strength and m_j is motivation to comply with the referent in question. Finally, perceived behavioural control is determined by accessible control beliefs, that is, beliefs about the presence of factors that may facilitate or impede performance of the behaviour. Specifically, perceived behavioural control is determined

by $\sum c_k p_k$, where c_k is belief strength (the perceived likelihood that a given control factor will be present) and p_k is the perceived power of the control factor (the extent to which the control factor will make it easier or more difficult to perform the behaviour).

The ‘principle of correspondence’ (Ajzen & Fishbein, 1977; Fishbein & Ajzen, 1975) or ‘compatibility’ (as it was renamed by Ajzen, 1988) states that, in order to maximize predictive power, all the variables in the theory should be measured at the same level of specificity or generality. This means that the measures should be matched with respect to the four components of action, target, time and context. The rationale given for the principle is a pragmatic one: it improves prediction. Presumably, however, there is also a theoretical rationale for the principle, namely that, by measuring the TPB variables at the same level of specificity, we are matching cause and effect (Sutton, 1998).

Although the TPB holds that all behaviours are determined by the same limited set of variables, each behaviour is also substantively unique, in two senses (Fishbein, 2000). First, for a given population or culture, the relative importance of attitude, subjective norm and perceived behavioural control may vary across different behaviours. For example, some behaviours may be influenced mainly by attitude, whereas other behaviours may be influenced mainly by subjective norm. Ogden (2003) points out that many studies using the TPB find no role for one or other of the three putative determinants of intention and therefore that the theory ‘cannot be tested’. However, this represents a misunderstanding of the TPB. If at least one of the components is found to predict intention in a given study, this is consistent with the TPB. Nevertheless, it is a weakness of the theory that it does not specify the conditions under which intention will be mainly influenced by attitude, subjective norm or perceived behavioural control.

The second sense in which each behaviour is substantively unique is that, for a given population or culture, the behavioural, normative and control beliefs that underlie attitude, subjective norm and perceived behavioural control respectively may also differ for different behaviours. In the same way, for a given behaviour, the relative importance of attitude, subjective norm and perceived behavioural control and the content of the underlying beliefs, may vary across different cultures or populations.

The TPB is a general theory. In principle, it can be applied to any target behaviour without needing to be modified. For example, in applying the theory to a health-related behaviour, there should be no need to add a variable representing risk perceptions. If beliefs about the health risks of the behaviour (or its effect on reducing risk) are salient to a substantial proportion of the target population, this should emerge in an elicitation study that uses open-ended questions to elicit accessible beliefs (Ajzen, 2002a; Ajzen & Fishbein, 1980; for an example of an elicitation study, see Sutton *et al.*, 2003).

Like other theories of health behaviour, the TPB is a causal model and should be treated as such (Sutton, 2002a, 2004). It says, for instance, that if you hold constant a person's subjective norm, perceived behavioural control and actual behavioural control and you change their attitude toward the behaviour, this will lead to a change in their intention (assuming that attitude is a determinant of intention for the behaviour in question in this target group), and this in turn will lead to a change in their probability of performing the behaviour (assuming that the person's intention is stable and that the behaviour is at least partly under their control).

The TPB is often depicted without actual control in the path diagram and, to date, has always been tested without measuring actual control. In this case, the direct path from perceived behavioural control to behaviour is causally ambiguous (Sutton, 2002a, 2002b). In particular, if we observe an independent predictive effect of perceived behavioural control on behaviour in an observational study in which actual control is not measured, this may be due partly to a causal effect of perceived behavioural control on behaviour and partly to a correlation induced by actual behavioural control influencing both perceived behavioural control and behaviour (Sutton, 2002a, 2002b). More generally, failing to measure and control for the effects of actual behavioural control will lead to biased estimates of the causal effects of perceived behavioural control and intention on behaviour, unless it can be assumed that perceived control is an accurate reflection of actual control (i.e. that perceived and actual control are perfectly correlated and this correlation arises from a direct causal effect of actual on perceived control).

Although Figure 1 shows an arrow going directly from actual control to perceived control, this is inconsistent with the theory's assumption that the effects of any variable on perceived control must be mediated by control beliefs. The absence of arrows, either one- or two-headed, between actual control and behavioural and normative beliefs respectively can be interpreted as indicating zero correlations and no direct causal influence in either direction. However, to date, Ajzen has not discussed these possible relationships. If actual control were related to one or both of these variables, again this would have implications for the interpretation of regression analyses from which actual control was omitted.

The theory predicts an interaction between perceived behavioural control and intention on behaviour. Ajzen (2002b) states it as

follows: 'Conceptually, perceived behavioural control is expected to moderate the effect of intention on behaviour, such that a favourable intention produces the behaviour only when perceived behavioural control is strong'. He also notes that 'In practice, intentions and perceptions of behavioural control are often found to have main effects on behaviour, but no significant interaction' (see also Conner & Armitage, 1998). This interaction derives from an interaction between intention and actual control (and so would be predicted to occur only in situations in which perceptions of control are accurate). In particular, intention is expected to have a stronger influence on behaviour the greater the degree of actual control the person has over the behaviour. For simplicity, this interaction is not shown in Figure 1.

The TPB is often described as a deliberative processing model. However, although some decisions may involve conscious deliberation and careful weighing up of pros and cons, in many cases the processes involved in the formation and modification of beliefs, attitudes and intentions may be largely automatic (Ajzen & Fishbein, 2000; Fishbein & Ajzen, 1975). A person's attitude toward a particular behaviour may be automatically updated when new information about the behaviour is received, and this attitude may be automatically elicited and guide behaviour in relevant situations. (However, although it seems plausible that automatic processes control the formation and change of beliefs, attitudes and intentions, for most health-related behaviours it seems less plausible to suggest that behaviour itself is automatically elicited.)

How well does the theory perform?

Table 1 summarizes the findings from meta-analyses of observational studies of the TPB in terms of the multiple correlation (R) and its square (which can be interpreted as the proportion of variance explained) for predicting intention and behaviour. With the exception of Ajzen (1991), all the meta-analyses explicitly or by implication restricted the analysis of prediction of behaviour to prospective studies in which intention and perceived behavioural control were measured at time 1 and behaviour was measured at time 2.

The findings for both intention and behaviour show reasonable consistency. For intention, the multiple correlations range from 0.59 to 0.71 (between 35% and 50% of variance explained). Prediction of behaviour was lower, as expected, with the multiple correlations ranging between 0.51 and 0.59 (between 26% and 35% of the variance explained). All the effect sizes in Table 1 are 'large' in terms of Cohen's (1992) guidelines.

Godin and Kok (1996) found differences between different kinds of behaviours with respect to how well the theory predicted intentions and behaviour. For example, for behaviour, the theory worked better in studies of HIV/AIDS-related behaviours than in studies of 'clinical and screening' behaviours. However, these results were based on small numbers of studies and possible confounds such as sample characteristics and differences in how the TPB variables were measured were not examined. Godin and Kok's review needs to be updated and extended.

Extensions of the TPB

There have been numerous attempts to extend the TPB by adding variables such as anticipated regret, moral norm and self-identity

Table 1. Summary of findings from meta-analyses of the theory of planned behaviour

Meta-analysis	Effect size ^a						
	<i>k</i> ^b	Predicting intention (BI) from AB, SN and PBC			Predicting behaviour from BI and PBC		
		<i>R</i>	<i>R</i> ²		<i>k</i>	<i>R</i>	<i>R</i> ²
Ajzen (1991)	19	.71	.50	17	.51	.26

^b*k* is the number of datasets.

^cRestricted to studies of health-related behaviours.

^dRestricted to studies of condom use.

^eRestricted to studies of physical activity.

^fRestricted to studies that included measures of both 'perceived difficulty' and 'perceived control'.

(Conner & Armitage, 1998). For the sake of parsimony and theoretical coherence, candidate variables should be provisionally accepted as official components of the theory only if a number of conditions are satisfied. First, there should be sound theoretical reasons for believing that a given candidate variable influences intention or behaviour independently of the existing variables, that is, that the variable has a direct causal effect on intention or behaviour. In some cases, it is possible that the proposed additional variable is already captured by one of the existing variables.

Second, in order to retain the existing structure of the TPB, the proposed new variable should have an expectancy-value basis like attitude, subjective norm and perceived behavioural control; in other words, the new variable should be determined by accessible beliefs that are specific to the target behaviour. This would seem to rule out some variables, for example self-identity. This also means that the expectancy-value basis of descriptive norm (the belief that significant others are or are not performing the target behaviour), which Ajzen (2002a) has proposed as a sub-component of subjective norm in the latest version of the theory, needs to be specified. This requirement, that any additional variable is homologous in structure to the existing variables, also implies that including too many additional variables in the theory would make it unwieldy to use in practice. Furthermore, additional open-ended questions for eliciting accessible beliefs would need to be devised for use in

pilot studies. This has not yet been done for descriptive norm (Ajzen, 2002a).

Third, measures of a proposed new variable should be shown to have discriminant validity with respect to measures of the existing components, in other words to be measuring something different from measures of the existing variables (see 'Health cognition assessment').

Finally, the new variable should be shown to predict intention and/or behaviour independently of the existing components in studies in which the latter are well measured in accordance with published recommendations. It is likely that there are many false positive findings in the literature because the existing components are not always optimally measured. Of course, if the aim is simply to improve the predictive power of the theory rather than to specify additional determinants of intention, only the last of the requirements set out above is relevant.

External variables

The TPB, like other social cognition models, does not rule out other causes of behaviour. Many other factors such as socio-demographic, cultural and personality factors may influence behaviour, but these are assumed to be distal factors, in other words to be farther removed from the behaviour than the proximal factors specified by the theory. Thus, the TPB divides the determinants of behaviour into two classes: a small number of proximal determinants, which are specified by the theory (i.e. are internal to the theory); and all other causes, which are left unspecified but which are assumed to be distal and to influence behaviour only via their effects on the proximal determinants. In this sense, the TPB is sometimes said to be 'sufficient'.

A strategy for guiding future research on the determinants of health behaviour is to continue to use the TPB as a model of the proximal determinants of a given behaviour and to specify external factors that are hypothesized to influence the components of the theory or to influence behaviour directly, that is to develop theories that relate external factors to the theory's components. In effect, this is extending the causal model representing the TPB to the left, specifying the more distal causes of a particular behaviour and the mechanisms by which they influence the components of the theory and behaviour (Sutton, 2004).

Intervention studies

The TPB has direct implications for behaviour change interventions. According to the theory, changing behaviour requires changing either (1) the accessible beliefs that underlie attitude, subjective norm and perceived behavioural control or (2) actual behavioural control or (3) both (Sutton, 2002b). As Hobbis and Sutton (2005) point out, with the possible exception of Project RESPECT (Fishbein *et al.*, 2001), there have so far been few successful examples of effective TRA- or TPB-based interventions. In their systematic review, Hardeman *et al.* (2002) identified seven studies in which the TPB was used to develop the intervention and the effectiveness of the intervention was evaluated in a randomized controlled trial with a behavioural outcome. Of these, four showed at least one positive change in the intervention group compared

with the control group and the other three showed mixed effects. Although these findings seem encouraging at first glance, Hardeman *et al.* note a number of problems with these studies. In particular, in most cases it was not possible to identify which components of the theory were being targeted in the intervention. Furthermore, only one study (Brubaker & Fowler, 1990) reported a mediation analysis to test the extent to which the intervention effect on behaviour was mediated by the components of the theory. This study deserves further discussion as Fishbein and Ajzen (2005) cite it as a 'success'. The study compared three conditions: a persuasive message based on the TPB that was designed to modify participants' beliefs about the consequences of performing testicular self-examination (TSE); a persuasive message that was not based on the TPB; and a no-message control condition. There were significant differences in self-reported behaviour at one week and four weeks after the intervention. The mediation analysis (which combined the two message conditions) suggested that the effect of exposure to a message on intention and behaviour was partly mediated by the TPB variables,

though the most important mediator was actually 'TSE knowledge', which is not a component of the theory.

Conclusions

The TPB provides fairly consistent prediction of intentions and, to a lesser extent, behaviour, across a range of different behaviours including health-related behaviours. However, the vast majority of studies have used observational designs; the causal predictions of the theory should be tested in randomized experiments (Sutton, 2002a). The theory has not so far fulfilled its promise as the basis for developing effective health behaviour interventions.

Transtheoretical model of behaviour change

Stephen Sutton

University of Cambridge

Stage theories of health behaviour assume that behaviour change involves movement through a set of discrete stages, that different factors influence the different stage transitions and that interventions should be matched to a person's stage (Sutton, 2005; Weinstein *et al.*, 1998).

The transtheoretical model (TTM; Prochaska & DiClemente, 1983; Prochaska *et al.*, 1992, 2002; Prochaska & Velicer, 1997) is the dominant stage model in health psychology and health promotion. It was developed in the 1980s by a group of researchers at the University of Rhode Island. The model has been used in a large number of studies of smoking cessation, but it has also been applied to a wide range of other health behaviours (Prochaska *et al.*, 1994). Although it is often referred to simply as the stages of change model, the TTM includes several different constructs: the 'stages of change', the 'pros and cons of changing' (together known as 'decisional balance'), 'confidence and temptation' and the 'processes of change'. The TTM was an attempt to integrate these different constructs drawn from different theories of behaviour change and systems of psychotherapy into a single coherent model; hence the name transtheoretical (for example, see 'Health belief model', 'Self-efficacy and health behaviour' and 'Theory of planned behaviour').

The stages of change provide the basic organizing principle. The most widely used version of the model specifies five stages: precontemplation, contemplation, preparation, action and maintenance. The first three stages are pre-action stages and the last two stages are post-action stages (although preparation is sometimes defined partly in terms of behaviour change). People are assumed to move through the stages in order, but they may relapse from action or maintenance to an earlier stage. People may cycle through the stages several times before achieving long-term behaviour change.

The pros and cons are the perceived advantages and disadvantages of changing one's behaviour. Confidence is similar to Bandura's (1986) construct of self-efficacy. It refers to the

confidence that one can carry out the recommended behaviour across a range of potentially difficult situations. The related construct of temptation refers to the temptation to engage in the unhealthy behaviour across a range of difficult situations. Finally, the processes of change are the covert and overt activities that people engage in to progress through the stages. The Rhode Island group has identified 10 such processes that appear to be common to a number of different behaviours: five experiential processes and five behavioural processes.

In stage theories, the transitions between adjacent stages are the dependent variables, and the other constructs are variables that are assumed to influence these transitions – the independent variables. The processes of change, the pros and cons of changing and confidence and temptation are all independent variables in this sense. Descriptions of the TTM to date have not specified the causal relationships among these variables.

Measures

The most commonly used method of measuring stages of change is the staging algorithm, in which a small number of questionnaire items is used to allocate participants to stages in such a way that no individual can be in more than one stage. Table 1 shows a staging algorithm for smoking that has been used in a large number of studies since it was first introduced by DiClemente *et al.* (1991). Precontemplation, contemplation and preparation are defined in terms of current behaviour, intentions and past behaviour (whether or not the person has made a 24-hour quit attempt in the past year), whereas action and maintenance are defined purely in terms of behaviour; ex-smokers' intentions are not taken into account.

This algorithm has a logical flaw: a smoker cannot be in the preparation stage unless he or she has made a recent quit attempt.

Table 1. TTM staging algorithm for adult smoking, from <http://www.uri.edu/research/cprc/measures.htm>

Are you currently a smoker?

- Yes, I currently smoke
- No, I quit within the last 6 months (Action Stage)
- No, I quit more than 6 months ago (Maintenance Stage)
- No, I have never smoked (Non-smoker)

(For smokers only) In the last year, how many times have you quit smoking for at least 24 hours?

(For smokers only) Are you seriously thinking of quitting smoking?

- Yes, within the next 30 days (Preparation Stage; if they have one 24-hour quit attempt in the past year – refer to previous question . . . if no quit attempt then Contemplation Stage)
- Yes, within the next 6 months (Contemplation Stage)
- No, not thinking of quitting (Precontemplation Stage)

Thus, a smoker can never be ‘prepared’ for his or her first quit attempt (Sutton, 2000a).

A problem with most staging algorithms is that the time periods are arbitrary. For instance, action and maintenance are usually distinguished by whether or not the duration of behaviour change exceeds six months. Changing the time periods would lead to different stage distributions. The use of arbitrary time periods casts doubt on the assumption that the stages are qualitatively distinct, that is, that they are true stages rather than pseudo-stages (Bandura, 1997; Sutton, 1996).

Staging algorithms and measures of the TTM independent variables for a number of different health behaviours are given on the Rhode Island group’s website (<http://www.uri.edu/research/cprc/measures.htm>).

Evidence

Weinstein *et al.* (1998) specified four research designs that can be used to test predictions from stage theories: cross-sectional studies comparing people in different stages; examination of stage sequences; longitudinal prediction of stage transitions; and experimental studies of matched and mismatched interventions. This section will focus on TTM studies that have used the last two of these designs because in principle they provide the strongest tests of the model. We also consider intervention studies that have compared TTM-based stage-matched interventions with generic, nonmatched interventions or no-intervention control conditions. See Sutton (2000b) for a discussion of the analysis and interpretation of cross-sectional data on stages of change, and Rosen (2000) and Marshall and Biddle (2001) for meta-analyses of cross-sectional studies on the TTM.

Longitudinal prediction of stage transitions

Longitudinal data can be used to test whether different theoretically relevant variables predict stage transitions among people in different baseline stages. To date, 11 prospective studies have used the TTM variables to predict stage transitions, all in the domain of smoking cessation. Two of these (DiClemente *et al.*, 1985; Prochaska *et al.*, 1985) used an old staging algorithm and an early

version of the TTM. They were reviewed by Sutton (2000a). Nine more recent studies were reviewed by Sutton (2006): De Vries and Mudde (1998); Dijkstra and De Vries (2001); Dijkstra *et al.* (2003); Hansen (1999); Herzog *et al.* (1999); Segan *et al.* (2002, 2006a, 2006b); Velicer *et al.* (1999).

These nine studies found some evidence that different predictors are associated with different stage transitions. However, there were few consistent findings, providing little support for the TTM. Most of the studies used relatively long follow-up periods (at least six months). Future studies should use shorter follow-up periods to minimize the likelihood of missing stage transitions (with the proviso that at least six months is required to detect the transition from action to maintenance).

Experimental match-mismatch studies

The strongest evidence for a stage theory would be to show consistently in randomized experimental studies that stage-matched interventions are more effective than stage-mismatched interventions in moving people to the next stage in the sequence. Only three studies to date have compared matched and mismatched interventions within the framework of the TTM or closely related models (Blissmer & McAuley, 2002; Dijkstra *et al.*, 1998; Quinlan & McCaul, 2000).

Dijkstra *et al.* (1998) compared the effectiveness of individually tailored letters designed either to increase the pros of quitting and reduce the cons of quitting (outcome information) or to enhance self-efficacy or both. Smokers were categorized into four stages of change: preparers (planning to quit within the next month); contemplators (planning to quit within the next six months); precontemplators (planning to quit within the next year or in the next five years); and immotives (planning to quit sometime in the future but not in the next five years, to smoke indefinitely but cut down or to smoke indefinitely without cutting down). The sample size for the main analyses was 1100.

Dijkstra *et al.* (1998) hypothesized that immotives would benefit most from outcome information only, preparers from self-efficacy enhancing information only and the other two groups from both types of information. Thus, counter-intuitively, precontemplators and contemplators were predicted to benefit from the same kind of information. However, the study showed only weak evidence for a beneficial effect of stage-matched information. In respect of the likelihood of making a forward stage transition, assessed at 10-week follow-up, there were no significant differences between the three types of information among smokers in any of the four stages. However, preparers who received the self-efficacy-enhancing information only were significantly more likely to have quit smoking for seven days at follow-up than preparers in the outcome information only condition. Combining immotives and precontemplators, the percentage of smokers who made a forward stage transition did not differ significantly between those who received stage-matched and stage-mismatched information. Among contemplators and preparers combined, the percentage who made a forward stage transition and the percentage who quit for seven days were higher among those who received the stage-matched information than among those who received the stage-mismatched information, but these comparisons were only marginally significant ($p < 0.10$). It is not clear why the researchers combined the stages in this way (immotives and

precontemplators; contemplators and preparers), given the hypothesis of the study.

Quinlan and McCaul (2000) compared a stage-matched intervention, a stage-mismatched intervention and an assessment-only condition in a sample of 92 college-age smokers in the precontemplation stage. The stage-matched intervention consisted of activities designed to encourage smokers to think more about quitting smoking. The stage-mismatched intervention consisted of action-oriented information and activities intended for smokers who are ready to quit smoking. At one month, 30 participants had progressed to contemplation, one participant had progressed to preparation and 5 participants had progressed to action. Contrary to the hypothesis, a greater percentage of participants in the stage-mismatched condition (54%) progressed than in the stage-matched (30%) or assessment-only (35%) conditions; however, this difference was not significant. Significantly more smokers in the stage-mismatched condition tried to quit smoking than in the stage-matched condition.

Finally, in a study of physical activity, Blissmer and McAuley (2002) randomly assigned 288 university staff to four conditions, including: (1) stage-matched materials (personalized, stage-appropriate covering letter plus stage-matched manuals) delivered via campus mail on a monthly basis; and (2) stage-mismatched materials delivered in the same way. After 16 weeks, 40.4% of the matched group had progressed one or more stages compared with 31.8% of the mismatched group. This difference was in the predicted direction but did not approach significance at the 0.05 level (Sutton, 2005). A limitation of the study, which the authors acknowledge, is that 57% of participants were in the action or maintenance stage at baseline, and the short follow-up period would have prevented those who had recently entered the action stage from progressing to maintenance.

Considered together, these three experimental studies of matched and mismatched interventions found little or no evidence for the stage model predictions.

Intervention studies

Three reviews have summarized the evidence on the effectiveness of TTM-based stage-matched interventions compared with generic, non-matched interventions or no-intervention control conditions (Bridle *et al.*, 2005; Riemsma *et al.*, 2003; Spencer *et al.*, 2002). The second and third of these reviews were restricted to smoking cessation interventions. Both Bridle *et al.* (2005) and Riemsma *et al.* (2003) concluded that there was limited evidence for the effectiveness of stage-based interventions, but Spencer *et al.* (2002) reached a more positive conclusion.

However, all these reviews included studies that were not proper applications of the TTM. For an intervention to be labelled as TTM-based, it should (1) stratify participants by stage and (2) target the theory's independent variables (pros and cons, confidence and

temptation, processes of change), focusing on different variables at different stages. Not surprisingly, the interventions that come closest to a strict application of the TTM are those developed by the Rhode Island group. The group's studies of TTM-based smoking cessation interventions have yielded mainly positive findings (e.g. Pallonen *et al.*, 1998; Prochaska *et al.*, 1993; Prochaska, Velicer, Fava, Rossi *et al.*, 2001; Prochaska, Velicer, Fava, Ruggiero *et al.*, 2001). By contrast, adaptations of these interventions evaluated by other research groups in the UK and Australia have yielded mainly negative results (Aveyard *et al.*, 1999, 2001, 2003; Borland *et al.*, 2003; Lawrence *et al.*, 2003).

None of these studies speaks directly to the validity or otherwise of the TTM. Process analyses demonstrating that TTM-based interventions do indeed influence the variables they target in particular stages and that forward stage movement can be explained by these variables have not been published to date.

Conclusions

The TTM has been very influential and has popularized the idea that behaviour change involves movement through a series of discrete stages. It has also stimulated the development of innovative interventions. However, the model cannot be recommended in its present form. Fundamental problems with the definition and measurement of the stages need to be resolved. Although a cursory glance at the huge literature on the TTM gives the impression of a large body of mainly positive findings, a closer examination reveals that there is remarkably little supportive evidence. It would be helpful if the Rhode Island group presented a fuller specification of the model that (1) stated which variables influence which stage transitions and (2) specified the causal relationships among the pros and cons, confidence and temptation and processes of change. It would also be helpful if the group addressed the detailed critiques of the TTM by, among others, Carey *et al.* (1999), Joseph *et al.* (1999), Littell & Girvin (2002), Rosen (2000) and Sutton (1996, 2000a, 2001), and responded to Weinstein and colleagues' (1998) exposition of the conceptual and methodological issues surrounding stage theories.

To date, research on stage theories has been dominated by the TTM. However, partly in response to the problems that have been identified with this model, alternative stage theories are beginning to attract attention and hold promise for future research and practice. These include the precaution adoption process model (Weinstein & Sandman, 1992, 2002) and the 'perspectives on change' model developed by Borland and colleagues (Borland, 2000; Borland *et al.*, 2004; Segan *et al.*, 2006a).

Unemployment and health

Stanislav V. Kasl and Beth A. Jones

Yale University School of Medicine

Introduction

In this chapter we intend to provide an assessment of the research literature on unemployment and health. We draw on our somewhat more recent and much more detailed review of this research (Kasl & Jones, 2000), as well as on some key or trendsetting studies that have been published in the last few years.

In orienting the reader to this topic, we begin with a few general observations on recent research trends and themes:

1. There continues to be a strong and sustained interest in the topic of unemployment and health, both in the USA and, even more so, in Western Europe.
2. The boundaries of the topic have enlarged, reflecting the impact of changes in the economies of many industrial countries. Specifically, there is a growing interest in the impact of job insecurity, downsizing and involuntary part-time employment (e.g. Ferrie, Shipley *et al.*, 2003; Friedland & Price, 2003; Kivimaki *et al.*, 2003). In fact, the old dichotomy of working vs. unemployed is being replaced by a continuum which includes in-between categories of sub-optimal employment (Grzywacz & Dooley, 2003). This newly complex domain of research has generated its own glossary to help readers understand the concepts being investigated (Bartley & Ferrie, 2000).

3. There is a commendable trend toward more sophisticated study designs. This includes, above all, longitudinal data analyzed with multivariate techniques which allow reasonable controls for potential confounders. Thus the concerns centering on the question of ‘causation or selection?’ (i.e. does the observation of poorer physical and/or mental health reflect the impact of unemployment or does it, instead, denote the influence of prior characteristics of the individuals who later become unemployed?), which were highlighted at the beginning of our chapter in the first edition of this handbook, no longer seem as salient. However, these concerns remain pertinent since the studies of the impact of unemployment on health are based on a variety of observational (non-experimental) designs.

Some conceptual and methodological issues

Unemployment studies are often conducted from the perspective of classical occupational epidemiology: the exposure variable is operationalized rather simply, such as working vs. unemployed, secure vs. insecure employment, downsized vs. not. Length of exposure may be sometimes incorporated as well. In contrast, conceptualizations that centre on the meaning of work and on the

impact work can have on individuals and their families tend to be rich and complex. For example, Jahoda (1992) suggests that a job, aside from meeting economic needs, has additional 'latent functions': a) imposes time structure on the day; b) implies regularly shared experiences and contacts with others; c) links an individual to goals and purposes which transcend his/her own; d) defines aspects of personal status and identity; e) enforces activity. Similarly, Warr (1987) discusses a number of environmental features of work which he postulates are responsible for psychological wellbeing: opportunity for control, skill use, interpersonal contact, external goal and task demands, variety, environmental clarity, availability of money, physical security and valued social position. In addition, for some individuals, job loss may represent the termination of exposures, such as work stress or specific work hazards, which themselves may be adverse influences on health. The implication of such formulations is that the experience of job loss and unemployment is likely to be multi-faceted and involve different intervening processes, moderating influences and outcomes. At minimum, one should try to separate the effects of economic hardships from the other effects of being without a job, a distinction which many studies do not address. The unemployment experience may also affect sub-groups of individuals differently. For example, age (and stage of the life cycle) is an important consideration: the unemployment experience is likely to be different for a) a young person completing his/her education and unable to find a job, versus b) a young worker with unclear career goals, and in his/her first job which s/he finds unsatisfying, versus c) a middle-aged head of household, with dependents at home, losing a long-held job made obsolete by new technology, versus d) an elderly worker, in poor health and close to retirement, in a job which is physically demanding.

Studies which are designed to capture the complexity of theoretical formulations about the meaning of the job loss experience are relatively rare and most often deal with mental health outcomes. For example, a Michigan study (Price, Choi & Vinokur, 2002) examined several steps in the mediating mechanisms leading from exposure to poor health and functioning, including financial strain and reduction in personal control.

With regard to study design methodologies, it is self-evident that except for controlled randomized intervention programmes (e.g. Price, 1992), all unemployment studies have been observational (non-experimental). However, important distinctions among study designs need to be recognized. The strong observational designs have included: a) studies of factory closures in which all employees lose their jobs and are then followed for health status changes (Morris & Cook, 1991); b) longitudinal follow-up studies of employed and unemployed individuals on whom baseline health status data allow for statistical adjustments of possible selection biases (e.g. Morris, Cook & Shaper, 1994); and c) follow-up studies of unemployed individuals in which the benefits of re-employment can be examined and adjusted for selection biases. Weak designs have included: a) longitudinal follow-ups of employed and unemployed persons on whom baseline data are too limited (e.g. age and education only) to adequately control for many possible selection factors; and b) cross-sectional comparisons in which selection factors can rarely be separated from causation. Retrospective accounts of reasons for job loss (i.e. whether or not it is health-related) allow for some control of selection biases, but their adequacy is difficult to assess.

We should also note the existence of a hybrid design in which data on individuals are supplemented with ecological information on economic indicators for the community or the region (e.g. Turner, 1995). This is a strong design, particularly when longitudinal data are collected. Specifically, it enables one to answer two additional questions: a) Do changes in community level of unemployment impact on the health and wellbeing of those who remain employed? b) Do the levels of community unemployment moderate the impact on the unemployed, e.g. is the impact on the individual unemployed person greater when the community level of unemployment is high than when it is low? A recent report (Beland, Birch & Stoddart, 2002) failed to show a contextual effect, either as a main effect or as a moderator and the authors emphasized the importance of the multi-level modelling approach as the proper strategy for examining ecological effects.

Finally, we wish to mention one additional approach which has a long history in unemployment research (see Kasl, 1982): the analysis of aggregate ('ecologic' or 'macroeconomic') data in which annual fluctuations in some economic indicator, often the nationwide percentage of the labor force that is unemployed, are related to annual changes in some outcome, such as total mortality, cause-specific mortality, alcohol consumption and acts of domestic violence (e.g. Brenner, 1987). At present, these business cycle analyses are seen as rather controversial, often involving data analyses which are difficult to follow and understand. For example, recent data from Germany (Neumayer, 2004) show that when one controls for state-specific effects, aggregate mortality rates are lower in recessions; opposite (i.e. expected) results are obtained if one fails to control for state-specific effects.

Impact of unemployment on mortality and morbidity

There are some eight to ten epidemiologic studies which have examined the relationship between unemployment and mortality during the last decade (see Kasl & Jones, 2000, for more detail). Studies using data for Great Britain, Sweden, Finland, Denmark and Italy are in agreement in demonstrating an excess mortality associated with unemployment. The excess may be as high as 50%–100%, but is reduced to about 20%–30% by adjustments for confounders which reflect pre-existing characteristics. When those who became unemployed for health reasons are excluded, aspects of social class are stronger confounders than baseline health (usually assessed with limited data) and lifestyle habits (see 'Socioeconomic status and health'). Men and women appear to show comparable impact, as do wives of unemployed men. Younger persons seem to be at risk for greater impact, while occupational groupings do not suggest much variation in impact. Cause-specific analyses suggest that suicides, accidents, violent deaths and alcohol-related deaths tend to be especially elevated, but do not explain all of the excess mortality.

It is noteworthy that the one study which used US data but otherwise similar methodology (Sorlie & Rogot, 1990), failed to detect any impact of unemployment on mortality. This discrepancy with the European data is not easily explained, particularly since it is believed that the 'social net' protecting the unemployed is stronger in these European countries than in the USA.

Overall, the conclusion that unemployment increases the risk of total mortality is prudent but not unassailable. Selection factors are

clearly present as contributory influences, and fully controlling for them has not yet been possible.

Studies of unemployment and morbidity introduce potentially a new concern not applicable to mortality studies: the procedure for measuring health status outcomes. There are at least two concerns: 1) The influence of psychological distress on some measures could be substantial: that is, measured physical symptoms and complaints could be due to the distress rather than some underlying physical condition, or psychological distress could lower the threshold for reporting existing physical symptoms. 2) Measures based on seeking and/or receiving care could indicate differences in illness behaviour rather than underlying illness. In addition, it may be occasionally simply too difficult to determine what is being measured. Thus in a nicely designed prospective study of closure of a sardine factory in Norway (Westin, 1990), the rates of disability pension observed over a 10-year follow-up period were higher, compared with rates at a nearby 'sister factory' which stayed open. While these pensions are 'granted for medical conditions only', it is still difficult to know what exactly is being assessed and what health status differences would have been observed with other types of measurements.

There is reasonable agreement from several longitudinal studies (see Kasl & Jones, 2000 for more detail) that the job loss experience has a negative impact on health, though the precise nature of this impact is difficult to pinpoint. For example, in a Canadian study of GE factory closure (Grayson, 1989) former employees reported on a survey a high number of ailments. However, the elevated rates were for such a wide range of conditions that the authors suggested that the results indicate higher levels of stress which produce 'a series of symptoms that people mistake for illness itself'. (see 'Stress and health' and 'Symptom perception'). A British study of factory closure examined the impact on general practice consultation rates (Beale & Nethercott, 1988). Comparisons of rates were made both before vs. after factory closure as well as changes over time among cases vs. controls. The factory closure was clearly associated with increased rates of consultation, referrals and visits to the hospital. More refined analyses revealed that illnesses which were indicative of relatively 'chronic' conditions (i.e. those with previous high rates of consulting) were the ones which showed the increase. Thus it is not clear if these conditions were exacerbated by the factory closure, or if there was simply an increased rate of consulting, without any underlying clinical changes.

A number of other reports, based both on longitudinal and cross-sectional data, have offered confirmatory evidence regarding an adverse impact of unemployment on morbidity. The range of outcome variables is quite wide - hospital admissions, medical consultations, use of prescribed drugs, reports of chronic conditions, disability days, activity limitations and somatic symptoms. The difficulty is that these studies typically show a selected impact rather than a uniform one across all indices examined and little consistency emerges across studies when one tries to identify those variables which are particularly sensitive to the job loss experience.

While most of the studies address the impact of unemployment in middle-aged workers, we are now beginning to see also studies of workers in their last decade of employment. For example, Gallo and colleagues (Gallo, Bradley, Siegel *et al.*, 2000; Gallo, Bradley, Falba *et al.*, 2004) have shown that older workers (50+) experiencing involuntary job loss may be at greater risk for depression, disability, stroke and (possibly) myocardial infarction, compared with those who

continued being employed. Those who chose to retire after losing their jobs were excluded from analysis. This suggests that being in the later stages of the life cycle does not protect older workers from the adverse effects of job loss seen among middle-aged workers.

Studies of unemployment among those in their late teens and early twenties have been mostly cross-sectional reports on various behavioural and physiological outcomes (Kasl & Jones, 2000). However, now we are beginning to see such studies being converted into longitudinal follow-ups; for example, a 14-year follow-up of a Swedish cohort (Hammarstrom & Janlert, 2002) shows that early unemployment among young men and women can contribute to adult health problems such as higher levels of symptoms and unhealthy lifestyles.

Impact of unemployment on biological and behavioural risk factors

The biological variables which have been examined in relation to unemployment include: a) indicators of 'stress' reactivity, such as serum cortisol, which do not have a well documented relationship to specific diseases; b) a very diverse set of indicators of immune functioning which are linked to possible disease outcomes theoretically rather than empirically; and c) risk factors for specific diseases, typically cardiovascular disease, where the presumption is that a chronic impact on these due to unemployment translates into higher risk for clinical disease (Kasl & Jones, 2000).

Studies using neuroendocrine variables or indicators of immune functioning find broad support for the conclusion that these biological parameters are sensitive to some aspect of the unemployment experience. Specifically, the findings strongly suggest the presence of anticipation effects (i.e. before job loss has taken place) and short-term elevations, but generally do not demonstrate the continually elevated levels with continued unemployment. It appears that in these unemployment studies these biological parameters exhibit acute reactivity, but chronic effects suggestive of increased risk of future disease are not usually demonstrated (see 'Psychoneuroimmunology').

Investigations of cardiovascular risk factors in relation to unemployment reveal that the threat of unemployment (i.e. holding a job with an insecure future) may be associated with higher levels of risk factors, particularly total serum cholesterol and low density lipoproteins. Otherwise, the results suggest a pattern somewhat similar to the neuroendocrine findings. For example, analyses of blood pressure and serum cholesterol changes from a Michigan study of plant closure (Kasl & Cobb, 1980) revealed a substantial sensitivity of these variables to the experience of anticipating the closing of the plant, losing the job and going through a period of unemployment and finding a new job. However, these were acute effects reflecting specific transitions. Men who continued to be unemployed did not stay at higher levels of risk factors but their risk factor level declined even in the absence of finding a new job.

There are also studies of very young adults which suggest the possibility that cardiovascular risk factors may not be sensitive to unemployment in this age group. It is not clear, however, if this is an age effect per se, or if the unemployment experience so close to the end of formal schooling is different from unemployment later in the life cycle.

There are several reports which are concerned with the impact of unemployment on health habits and behavioural risk factors. The typical variables examined include cigarette smoking, alcohol consumption, body weight and physical exercise (Kasl & Jones, 2000). Cigarette smoking tends to be relatively stable, while body weight shows an impact in some studies (i.e. an increase) but not in others. Alcohol consumption has been of great interest, but the picture is distinctly a mixed one (e.g. Hammarstrom, 1994). Many studies fails to show an increase, though one well designed longitudinal study showed an increase in the diagnosis of clinically significant alcohol abuse attributable to being laid off (Catalano *et al.*, 1993). That same study also showed that employed persons working in communities with high unemployment rates were at a reduced risk of becoming alcohol abusers. It is worth noting that some of the examined health habits are also likely to represent selection factors; that is, there is evidence that higher levels of smoking and heavy drinking predict a greater likelihood of subsequent unemployment.

Impact of unemployment on mental health and wellbeing

There is little doubt that unemployment has a negative impact on mental health and wellbeing (Kasl & Jones, 2000). This conclusion, however, does not preclude or pre-empt a second one, namely that selection dynamics often play a role as well. Still, moving beyond these broad generalizations, in order to formulate additional more specific conclusions, becomes difficult because the evidence is less consistent and/or less complete.

Longitudinal studies strongly support the expectation that unemployment will have an adverse impact on (sub-clinical) symptoms of poor mental health (e.g. Warr *et al.*, 1988); it is unlikely that the impact is also on overt diagnosable clinical disorder. Longitudinal studies also generally (but not always) demonstrate that becoming re-employed is associated with a reduction in symptoms (e.g. Kessler *et al.*, 1988; Warr *et al.*, 1988). In general, it would appear that depressive symptoms are the most sensitive indicator of impact of unemployment. However, because symptom checklists tend to be very inter-correlated, often similar finding are obtained with other scales such as anxiety or psycho-physiological symptoms. Other types of impact have been described, such as lower self-confidence and higher externality (one's life is beyond one's control); self-esteem may be impacted only on items which reflect self-criticism (Warr *et al.*, 1988).

The considerable literature on the psychological impact of unemployment permits some additional observations:

1. Findings on young adults generally show a similar negative impact but also point to the considerable importance of the nature of the first (or early job): symptoms of distress may be highest among dissatisfied workers, lowest among satisfied workers and the unemployed at intermediate levels.
2. Evidence for possible gender differences in impact is inconclusive, but there is some suggestion that women may be less likely to benefit (i.e. reduction of symptoms) from the unemployment-to-re-employment transition than men. Among wives of husbands who have been laid off, symptoms do go up, but with some delay. We have no studies of impact of wives' layoff on husbands.

3. Evidence for rural–urban differences is limited but fairly suggestive: the impact on symptoms of distress may be weaker in the rural setting, but rural workers are more likely to miss aspects of work and work-linked activities (Kasl & Cobb, 1982).
4. The magnitude, duration and time course of impact are not easily linked to duration of unemployment in the many studies, suggesting that adaptive processes may attenuate or alter the impact.
5. Financial difficulties and additional life events are two likely mediators of impact of unemployment on mental health.
6. Buffers which moderate the impact include high levels of social support, participation in social–leisure activities, absence of psychiatric history and high sense of mastery over life's important outcomes, and high self-esteem. High work commitment aggravates the negative impact of becoming unemployed, but among those going from unemployment or re-employment, high work commitment enhances the degree of recovery.

Impact of job insecurity, downsizing and under-employment

As we noted in the introduction, the old dichotomy of working vs. unemployed is being replaced by a continuum which includes in-between categories of sub-optimal employment (Grzywacz & Dooley, 2003), such as experiencing the threat of job loss, working in a downsized company, and being involuntarily underemployed. We conclude this chapter with some of the emerging evidence of the impact of these employment situations.

There are several recent prospective investigations of the effects of job insecurity (e.g. Ferrie *et al.*, 2002; Ferrie *et al.*, 2003; Lee *et al.*, 2004) which suggest that: a) the loss of job security negatively affects self-reported health and psychological symptoms, particularly as this becomes a chronic situation of insecurity; b) financial insecurity is the by-product of job insecurity which has the strongest negative impact; c) removal of the threat of insecurity does not fully re-establish pre-threat levels; d) impact on specific diseases, such as coronary heart disease, is only partially demonstrated. Temporary employment, which is another facet of job insecurity, appears to be associated with increased mortality while moving from temporary to permanent employment is protective (Kivimaki *et al.*, 2003).

Studies of downsizing (e.g. Kivimaki *et al.*, 2003; Kivimaki *et al.*, 2001; Kivimaki *et al.*, 2000) suggest that there are broad negative effects on health and wellbeing, including sickness absences and musculo-skeletal symptoms. These effects seem to be mediated by increases in job demands and job insecurity, reduction in job control and changes in social relations at work. In short, downsizing seems to lead to profound changes in the work setting which increase some of the familiar work stressors and reduce social buffers.

The concept of 'underemployment' has just recently begun to gather investigators' attention. The September 2003 issue of the *American Journal of Community Psychology* is devoted to this topic (Dooley & Catalano, 2003) and Friedland and Price (2003) present some of the evidence on health impact from a longitudinal study. Support is provided for the general conclusion that health and wellbeing of under-employed workers is poorer than for those who are adequately employed. However, types of underemployment – hours, income, skills and status – have somewhat different effects and effects also differ by the indicator of health that is used.

Clearly, the recent changes in the economies of most industrial countries have added to our old concerns – adverse health impact of physical exposures, of work stressors and of unemployment – some

new concerns that reflect the adverse impact of insecurity, downsizing, and under-employment.

Section II

Psychological assessment

Brain imaging and function

Erin D. Bigler

Brigham Young University

Brain imaging and function

Until the advent of computerized tomography (CT) in the 1970s, it was impossible to non-invasively image the brain (Eisenberg, 1992). However, once introduced, CT imaging rapidly advanced the technology of brain imaging and today remains one of the cornerstone technologies, especially for the assessment of acute neurologic symptom onset (i.e. a stroke) or injury.

Simultaneous with the development of CT imaging were tremendous improvements in computer technology, with faster processors and increased memory capacity. This provided the backdrop for essentially all other improvements that have occurred in brain imaging, once the breakthrough technology of CT imaging had been introduced. The physics and mathematics behind CT technology also became the inspiration for applying the principles of nuclear magnetic resonance (NMR) to human brain imaging. NMR principles had long been known and were, in fact, the basis for the Nobel Prize in Physics in 1952, but essentially had only been applied to physics and engineering (Eisenberg, 1992). In the 1970s researchers realized that radio frequency (RF) waves could reflect differences in biological tissues, such as the brain, since atoms within the molecules that form grey matter of the brain would 'resonate' differently in response to a pulsed magnetic field than those within white matter or cerebrospinal fluid. Detecting these differences in emitted RF waves – following the application of brief, pulsed, but very strong magnetic fields – could then be reconstructed to create an image of the brain (or any other biological tissue). We now refer to this as magnetic resonance imaging or MRI. As with CT imaging, the image resolution was initially limited but now image quality mimics gross anatomy.

Not only does MRI have the capability to approximate gross anatomy, it also has been shown to have many properties that permit multiple ways to analyze the brain image. For example, MRI-based diffusion tensor imaging (DTI) permits the detailing of brain pathways as well as indexes of the health of brain tissue. MRI spectroscopic analysis, referred to as magnetic resonance spectroscopy (MRS), provides a method to assess chemical composition of brain tissue. For example, certain levels of N-acetylaspartate (NAA), which can be readily determined with MRS techniques, are considered markers of neuronal injury. Such findings may be particularly important in anoxic and degenerative disorders (Gimenez *et al.*, 2004).

Taking from CT technology, another aspect of brain imaging developed out of what was originally nuclear medicine: these techniques provide methods of measuring functions of the brain. The early standards of 'functional neuroimaging' (Bigler, 1996*a,b*; Bigler & Orrison, 2003; Orrison *et al.*, 1995) consisted of single photon

emission computed tomography (SPECT) and positron emission tomography (PET). Both of these methods utilize radioactive compounds referred to as radiopharmaceuticals. These are injected into the blood stream and the imaging methods capitalize on detecting the uptake of the radiopharmaceutical as a measure of brain function.

Another method of functional imaging, however, utilizes MRI technology which in turn permits the preciseness of anatomical detail from MRI. This technology is referred to as functional magnetic resonance imaging or fMRI, actually localizing brain regions that activate to a particular stimulus or that may deviate from normal in a particular disease or disorder. The main principle in fMRI is the detection of subtle differences in what is referred to as the blood oxygen level dependent (BOLD) signal, which is an indirect reflection of haemodynamic flow and oxygen utilization (see Papanicolaou, 1998).

The oldest non-invasive way to record activity from the brain was electroencephalography (EEG), which dates back to developments early in the previous century, but not really put into widespread clinical application until the early 1950s. In the past, EEG methods would not have been considered a form of brain imaging, but in the last two decades EEG recordings have been integrated with various neuroimaging methods and are very much considered part of contemporary neuroimaging. While a distinctly separate technology from EEG, magnetoencephalography (MEG) is often discussed in the same context as EEG, in large part because the original recording montage was similar to EEG (see Papanicolaou, 1998). However, in MEG what is being recorded are minute changes in magnetic field potentials. Based on the superconducting quantum interference device (SQUID), ultrasensitive detection of subtle magnetic flux within the brain is possible without the spatial limitations that restrict how many brain regions can be monitored by EEG. As with EEG, MEG can be integrated with three-dimensional (3-D) MRI to assist in demonstrating where changes or differences in the MEG reside within the brain.

Some select examples of brain imaging techniques will be presented in the next section. There are numerous excellent texts that more comprehensively review the various brain imaging techniques described in this chapter, as well as others, and their application in the study of brain-behaviour relationships (Orrison, 2000; Osborn, 1994; Osborn *et al.*, 2004). The reader should keep in mind how rapidly this field has expanded, especially in the last decade, and the broad application of brain imaging techniques to the study of human behaviour has really just begun. Along these lines neuroimaging is now becoming a critical part of evaluation and treatment for neuropsychiatric disorders (Etkin *et al.*, 2005).

Examples of neuroimaging in normal and pathological states

CT Imaging

Figure 1(A) shows CT imaging in a case of traumatic brain injury. Currently, CT scanning is the imaging of choice for acute assessment of brain injury, because it is fast, detects most types of major pathological conditions and does not have the same restrictions of MRI with regards to use with life-saving devices (i.e. since MRI is based on applying a powerful magnetic field, any device that has magnetic properties, such as a heart pacemaker are not compatible with performing an MRI). CT imaging is particularly adept at detecting skull anatomy and pathology, but anatomic resolution is limited, and detailed neuroanatomical research is typically better served by MRI technology.

MRI

Contemporary MRI provides exquisite detail of brain anatomy, as shown in Figure 1(B). MRI capitalizes on a straightforward

biological fact of brain tissue: brain tissue can be compartmentalized into three main categories – white matter comprised of mainly myelinated axons; grey matter comprised of cell bodies; and Cerebral Spinal Fluid (CSF) filled spaces, which also house part of the cerebrovasculature. Particularly evident in MRI imaging, there are two basic premises in interpreting findings which are shown in Figure 1(B): (1) symmetry of bilateral brain structures and, (2) similarity of normal brain structures, in other words the ‘normalcy’ of how one brain compares to another. Because of the clarity of isolating brain tissue with MRI techniques, 3-D reconstruction of the brain can be routinely achieved, as shown in Figure 1(E), (F) and (G), which can depict normal brain anatomy and/or pathology.

Functional neuroimaging

Functional neuroimaging refers to a variety of imaging methods that provide some inference about underlying activity or function of a particular brain region. There are numerous functional neuroimaging methods, but the most common are functional MRI or fMRI (Rorden & Karnath, 2004), single photon emission tomography

Fig 1 (a) Computerized tomography (CT) scan demonstrating presence of haemorrhagic lesions in the frontal and temporal lobes. This patient sustained a significant brain injury in a fall down a flight of stairs. CT imaging is based on tissue density where the darker the image, the less dense the tissue and oppositely, the whiter the image the more dense the tissue. That is why the skull shows white since bone has the greatest density. The haemorrhagic lesions also show white (see arrows), because as blood coagulates, it becomes denser. Note the clarity that CT has in detecting the haemorrhage. (b) Coronal section of a healthy brain using contemporary magnetic resonance imaging (MRI) showing the clarity of anatomical detail that can be achieved. Such level of clarity permits precision in studying anatomical relationships with behaviour. (c) Magnetic resonance imaging (MRI) axial view of the brain with a section through the level of the lateral ventricles in a case of anoxic brain injury that shows no structural abnormalities; however, (d) Positron emission tomography (PET) imaging shows reduced activity in the mid-left hemisphere (see arrow). This illustration nicely shows that even when structural imaging using MRI may appear normal, the functional imaging can reveal various abnormalities. (e, f and g) Using thin section magnetic resonance imaging (MRI), as in (b), the human brain can be reconstructed in any plane and sectioned in any perspective. Note that all three models of this healthy brain are on the same level with the brain in the same location for all, only the section removed is different. (e) represents a left frontal oblique revealing part of the brain, with the posterior part still imbedded in the skull. (f) and (g) represent variations on left frontal oblique views of the brain in situ. Obviously, from such illustrations it is evident that three-dimensional (3-D) reconstruction of the brain can be achieved for any brain structure or region of interest.

(SPECT), positron emission tomography (PET), quantitative electroencephalography (qEEG) and magnetoencephalography (MEG); see also Orrison *et al.*, and Papanicolaou books on functional brain imaging (Orrison *et al.*, 1995; Papanicolaou, 1998). MRI is based on the 'signal' detection of radiofrequency waves from the head and how they react when a strong magnet field is pulsed. fMRI capitalizes on that technology where the detection of differences in the blood oxygen level detection (BOLD) MRI signal indicates level of activity or engagement of a particular brain region. Both PET and SPECT depend on the detection of some type of a radiopharmaceutical that has been introduced into the body. At rest, the brain should exhibit general uniform levels of activation and both PET and SPECT can detect changes from the baseline that reflect either areas of increased or decreased activity of a particular brain region. qEEG is essentially a computerized analysis of brain electrophysiology that can be presented in a holistic montage to view brain activity and MEG is somewhat similar, but is dependent on very small magnetic fields associated with neural cells and how they may change from baseline.

As an example of functional neuroimaging, the case shown in Figure 1(C) had an MRI of normal appearance, yet when PET imaging is integrated with the MRI as in Figure 1(D) it is clearly evident that a large area that looks 'normal' on MRI is not functioning normally. This case is a nice example that normal-appearing brain tissue does not necessarily mean normal function.

Future directions

Faster processing and higher field strength will undoubtedly improve the capability of MRI. For example, MRI techniques are being developed for what is referred to as in vivo microscopy (Bilgen, 2004). This technique provides exquisite detail that has the potential to show such things as cellular layering in the

cerebral cortex. Advances are also being made in the development of neurotransmitter ligands to study drug interactions and drug/brain/behaviour interactions using various MRI technologies (see Jenkins *et al.*, 2004). Similar statements can be made about the other imaging methods where developments in computer technology will undoubtedly improve all aspects of functional neuroimaging as well.

Conclusions

Contemporary neuroimaging techniques provide a breadth of methods for studying in vivo brain-behaviour relationships. MRI resolution is currently on par with gross anatomic inspection of the brain. Three-dimensional image analyses permit the study of structural brain regions from any perspective, as well as the framework for either directly studying activation patterns with fMRI techniques, or for integrating other functional neuroimaging methods such as MEG, EEG or PET. Functional neuroimaging techniques have been rapidly improving; these improvements permit the study of brain activation patterns in normal and abnormal conditions with the goal of better understanding the neurobiological basis of human behaviour. Such discoveries will have particular relevance not only for assessing but also for treating a broad spectrum of neurological and neuropsychiatric disorders.

Communication assessment

Linda Worrall

The University of Queensland

This chapter outlines how a speech and language therapist might assess communication disability. It firstly describes the different approaches to communication and communication disability, and then uses a biopsychosocial approach using the World Health Organization's International Classification of Functioning, Disability and Health (World Health Organization, 2001) as a conceptual framework for communication disability assessment. The different types and purposes of assessment for speech and language therapists are outlined and examples of communication assessments are provided throughout. The description of communication disabilities and assessments is by necessity brief and avoids the use of profession-specific terms. Readers are referred to texts by Haynes and Pindzola (1998) or Ruscello (2001) for more detailed information on communication disability assessment.

The study of communication and communication disabilities is often interdisciplinary involving audiologists, neuropsychologists, psycholinguists, sociolinguists, linguists, neurologists, physiologists, neurophysiologists, otolaryngologists and speech and language therapists, to name a few. In most countries of the world, however, it is the responsibility of speech and language therapists to provide services to people with communication disabilities. While hearing impairment is also a communication disability, audiologists have the expertise to assess this area. Speech and language therapists view communication holistically and may use a modality approach (verbal, nonverbal or written) to communication, a linguistic approach (phonetic, phonological, semantic, syntactical and pragmatic), or an information processing or psycholinguistic approach (e.g. input and output modular systems). When speech and language therapists wish to examine communication disability more broadly, they are often interested not only in the impairment, but also the effects that the impairment has on their client's life. The World Health Organization's International Classification of Functioning, Disability and Health (ICF; World Health Organization, 2001) is increasingly becoming the conceptual framework of the profession, with several countries adopting the framework in their scope of practice documents (Threats & Worrall, 2004). In simple ICF terms, speech and language therapists consider voice, speech, fluency, language and swallowing impairments. They then consider the effects of these impairments of the activities and participation in everyday life. They also consider how the environment and the client's own personal factors contribute to their communicative functioning. All of these constructs are considered in the assessment process.

Assessments are conducted by speech and language therapists for a number of reasons: diagnosis, determination of severity, prognosis and therapy planning (Rosenbek *et al.*, 1989) and outcome

measurement (Frattali, 1998). It is unusual that any one assessment will fulfil all these requirements. Speech and language therapists will therefore use different types of assessment (standardized testing, ecological observations, therapy as assessment, client self-report scales, goal attainment scaling and simple outcome ratings) to meet their needs. This paper will however focus on commercially available standardized communication assessments.

There has been considerable debate in the literature about whether speech and language therapists should assess (and treat) impairments only or whether functional or social model approaches should be a clinician's first option (e.g. Duchan, 2001; Worrall, 2001). Generalization and priorities in goal setting have also been issues in this debate with some authors challenging the assumption that the rehabilitation process must begin with efforts to lessen the impairment (with the assumption that this will generalise to everyday life) with compensatory efforts to minimize the activity limitations and participation restrictions attempted after that. The biopsychosocial approach to disability espoused in the ICF suggests that contextual factors are important components of human functioning and assessing or treating the impairment in isolation at any stage of the rehabilitation process ignores a vital part of disability – that the impairment is not the sole source of the disability. Emerging from this debate has been the discussion of the role of the client in goal-setting and ultimately assessment and intervention. Collaborative decision-making has become a professional value that is being embraced by speech and language therapists and is influencing many aspects of the why, when, where and how communication assessment occurs. Collaborative decision-making with communicatively disabled clients brings its own set of challenges. The emergence of client-centred healthcare in many parts of the world and legislation that protects the rights of people with disabilities is mandating collaboration with clients with communication disabilities, no matter how severe the communication disability may be (see 'Disability' and 'Disability assessment').

The following sections describe the primary components of communication from a speech and language therapist's perspective. Using the ICF terminology, the different impairments that contribute to a communication disability are outlined. Examples of health conditions that may cause the impairment are provided. A review of the impairment-based measures is made and, where available, measures of activity limitation or participation restriction, environmental and personal factors are described. Evidence-based practice is a mainstay of speech and language therapy practice. Evidence-based practice issues in communication assessment primarily relate to the psychometric properties of the assessments and therefore are contained within the technical manuals of individual assessments.

Voice

Impairments of the voice include structural or functioning problems of the vocal tract. Vocal nodules, spastic dysphonia, vocal fold paralysis and laryngectomy following laryngeal cancer are all examples of impairments of the voice (see 'Voice disorders'). Voice assessment at the impairment level is often a mixture of perceptual voice analysis which uses the clinician's ear to listen to the pitch, volume and quality of the voice (e.g. Laver, 1980; Oates & Russell, 1998, 2003; Pindzola, 1987) and acoustic or physiological measures which measure the performance of the vocal tract using instruments such as the Visipitch or the Computerized Speech Laboratory (www.kayelemetrics.com). Many modern hospitals have established voice clinics which have videolaryngoscopy and other imaging techniques that allow clinicians to view, record and measure the functioning of the vocal tract, particularly the all-important vocal folds.

Assessments such as the Voice Activity and Participation Profile (Ma & Yiu, 2001) and the Voice Handicap Index (Jacobson *et al.*, 1997) are being used to assess the impact of the voice impairment of the lives of the clients.

Speech

Speech impairments are a result of structural or functioning problems of the total speech production mechanism and while it includes the vocal tract (and hence includes impairments of the voice), the term speech impairment is predominantly focused on articulatory problems which occur in the oral region. Speech impairments in children include articulation disorders or sound production impairments which are an 'inability to produce a perceptually acceptable version of a phone in isolation or in any phonetic context' (Dodd, 1995; p. 54) and phonological disorders (impairment of rules of sound production, such as final-consonant deletion, which can cause speech to be unintelligible) and can be caused by health conditions such as cleft palate, developmental verbal dyspraxia or congenital hearing impairment. Dodd (1995) distinguishes between three types of phonological disorder; a delayed phonological disorder in which the phonological processes are normal but typical of younger child; consistent deviant phonological disorder which has one or a number of disordered rules; and an inconsistent phonological disorder whereby 10 or more words (of 25 given) are produced differently on two out of three occasions and this is associated with phonological planning deficit. There is some debate about whether phonological disorders in children are speech or language impairments since the phonological rules impaired in this type of disorder are a part of the language processing system (Crystal & Varley, 1993). In adults, speech impairments may result after surgery for cancer of the tongue or result from neurological conditions such as stroke, brain injury, Parkinson's disease or multiple sclerosis which affect the muscles of speech.

Assessment of speech impairment in children uses oromotor examinations (e.g. St Louis & Ruscello, 2000) and articulation tests which allow phonological analysis if required (e.g. Goldman & Fristoe, 1986) while in adults, speech impairments such as

dysarthria or verbal dyspraxia are assessed using tools specifically designed for that purpose such as the Frenchay Dysarthria Assessment (Enderby, 1983) and the Apraxia Battery for Adults (Dabul, 1979). Physiological measures such as electropalatography (e.g. Dent, 2001) are also becoming more widespread. Commercially available assessments of speech that examine the impact of the speech impairment on everyday life are not so common (Beukelman, Mathy & Yorkston, 1998; Enderby, 2000).

Fluency

An impairment of fluency includes both stuttering and cluttering. While stuttering is relatively well known, cluttering is not so identifiable, but consists of rapid unintelligible bursts of speech. Authors such as Gillam *et al.* (2000) and Crystal and Varley (1993) consider that fluency is as an aspect of speech, therefore stuttering is a type of speech impairment (see 'Stuttering').

Many children progress through a phase of normal dysfluency that does not result in chronic stuttering behaviour (Onslow & Packman, 1999). There are assessments for young children, school-aged children, adolescents and adults (see Haynes & Pindzola, 1998). Assessment at the impairment level typically includes counts of repetitions, prolongations, percentage of syllables stuttered and speaking rates. There are also assessments of avoidance behaviour and attitudes towards communication but as Yaruss (2002) and Blood and Conture (1998) note, there has been little development of stuttering measures at the activity limitation/participation restriction level.

Language

Language impairment is possibly the most complex part of communication to assess. Language is considered to be a central function, most commonly centred in the dominant hemisphere of the brain with receptive language being processed in the posterior region around Wernicke's area and expressive language being processed in the anterior region around Broca's area. Language impairments are acquired from brain damage in these areas through stroke (aphasia), traumatic brain injuries, or degenerative conditions such as dementia. In developing children, language impairment may be associated with developmental delay or may be seen in otherwise normal children who have a specific language impairment which can affect their communication from an early age and their education upon entering school. There may also be disruptions or disorders to the language system in conditions such as autism or Rett's syndrome. An impairment of literacy or written language use (reading and writing) has a lay term of 'dyslexia' but is viewed by speech and language therapists as a phonological awareness disorder.

There has been ongoing debate about the co-existing roles of cognition and language in many health conditions that result in a language impairment, but in general it has been recognized that some health conditions where there is generalized brain damage (e.g. traumatic brain injury, dementia), the term that should be used is cognitive-language or cognitive-communication disorder, rather than aphasia (a term used to describe focal lesions). However, even when there is localized damage in aphasia, there

has been debate about the coexistence of cognitive problems and their impact on language (see 'Aphasia'). Speech and language therapists seeking to separate cognition and language impairments in their clients typically use specially constructed assessments which assess cognition without a language load (e.g. Helm Estabrooks, 2001).

Assessment of language impairment in adults is mostly through aphasia tests such as the Western Aphasia Battery (Kertesz, 1982) and the Boston Diagnostic Aphasia Examination (Goodglass *et al.*, 2001). Tests that use a psycholinguistic model of processing include the Psycholinguistic Assessment of Language Processing in Aphasia (Kay *et al.*, 1997) and the Comprehensive Aphasia Test (Swinburn *et al.*, 2004). There are specific tests for single modalities such as reading (e.g. LaPointe & Horner, 1998) or specific linguistic constructs such as semantics (e.g. Kaplan *et al.*, 1983) syntax (e.g. Bishop, 2003) or pragmatics (e.g. Prutting & Kirschner, 1987). The effects on everyday life of the language impairment in adults may be measured by numerous assessments which include the American Speech Language Hearing Association Functional Assessment of Communication for Adults (Frattali *et al.*, 1995), the Communication Activities of Daily Living (Holland *et al.*, 1999), the Communicative Effectiveness Index (Lomas *et al.*, 1989) and the Stroke and Aphasia Quality of Life Scale-39 (Hilari *et al.*, 2003).

In children, language impairment is gauged through a myriad of assessments. Goldstein and Gierut (1998) list almost 100 language assessments for children and adolescents. One of the most popular assessments is the Clinical Evaluation of Language Fundamentals, 4th edition (Semel *et al.*, 2003). Goldstein and Gierut also note that there are few commercially available measures of activity limitation or participation restriction for children with language impairment. Clinicians mostly rely on observational coding and ecological inventories to report the

effect of language impairment on communicative activity limitations.

Conclusion

This chapter has described voice, speech, fluency and language impairments from a speech and language therapist's perspective. Standardized assessments of the impairments, activity limitations and participation restrictions that form part of the communication disability have also been described. It is clear that while assessment at the impairment level is well developed, there remains much to be done to assess the consequences of voice, speech, fluency and language impairments in everyday life. Whether standardized assessment is the most appropriate method of evaluating everyday communication is debatable. Further research into the viability and acceptability of alternative methods using more ecological methods is required.

The assessment of contextual factors, both environmental and personal, that impact on an individual with a communication disability is also not well researched. Some speech and language therapists have developed services that seek to dismantle barriers to participation for people with a communication disability. In London, Connect – Communication Disability Network (www.ukconnect.org) is an excellent example of such a service. While appropriate evidence about the effectiveness of this service is yet to emerge, this is one of the exciting service developments in speech and language therapy. In an effort to develop appropriate communication assessment methods for evaluating their service, this group has pioneered methods that fully value the client and their opinions in the assessment process (see http://www.ukconnect.org/research/index.html?rate_scale). This is the new direction for communication assessment.

Coping assessment

Ellen A. Skinner

Portland State University

Introduction

When adversity strikes, when mental and physical functioning and health are at risk, humans ‘fight back’. Humans come with and develop a set of adaptive processes that gives them the potential to fend off disaster, to reshape challenges and to transform stressful experiences into psychological growth. Coping describes some of these adaptive processes (Coelho *et al.*, 1974; White, 1974). Researchers agree that how people cope makes a material difference to the impact which stressful life events (including illnesses and chronic medical conditions) will have on them, both concurrently and long-term. However, the nature of these coping processes and how to assess them remain issues of hot contention.

Overview of the field

In early work, coping and defending were conceptualized as indicators of ego maturity; hence, coping was assessed by clinicians using extensive interviews (e.g. Haan, 1977; Valliant, 1986). As it became uncoupled from ego psychology, coping was seen as a manifestation of personality traits; hence, dispositional coping styles were assessed by questionnaires that tapped one or two dimensions of coping, such as sensitization versus repression. (For historical overviews, see Lazarus, 1993; Lazarus & Folkman, 1984; Murphy, 1974; Parker & Endler, 1996; Skinner, 2003; Snyder, 1999.)

Starting in the late 1970s, transactional, contextual and process-oriented views of coping appeared, which dominate the field today (Lazarus & Folkman, 1984; Moos & Billings, 1982;

Pearlin & Schooler, 1978). From this perspective, coping depicts the ways an individual deals with a specific stressor in a particular context, as the transaction unfolds over time. How people cope is shaped, not only by personal factors, but also by the stressors they are facing, the social resources available, and especially by their appraisals of the meaning of the stressful encounter (see 'Stress and health').

However, stressors (such as illnesses) are not single discrete traumatic events. Instead they represent a series of new, ongoing and cumulative demands (e.g. the disease's symptoms, course, treatment, side effects and prognosis, as well as social, emotional and physical consequences and reactions). Hence, when constructing patterns of coping, individuals are not only seeking effective actions, they must also defend high priority goals, manage emotions and maintain relationships. A repertoire of ways of coping is needed to deal with these sometimes contradictory demands. For example, in coping with a medical condition, it is important to acquire information in order to create an effective treatment plan. However, facing the facts can also be overwhelming. Strategies, such as minimization or focusing on the positive, are needed to keep distress within manageable levels (see 'Coping with chronic illness' and 'Coping with stressful medical procedures').

Moreover, coping is a dynamic process, consisting of episodes or bouts of dealing with these multiple different facets of stressors. Within a coping episode, ways of coping can change or cycle, depending on how the transaction unfolds. If a coping strategy proves to be ineffective, it may be replaced by an alternative strategy, or induce a fall into helplessness. Across episodes, coping itself evolves as new stressors are encountered, as appraisals are recalibrated and as resources are added or depleted. Coping depicts an active effortful struggle to continually (re)balance opposing demands, to recover from setbacks and to prepare for future challenges.

Overview of assessment

At present, it would be warranted to describe the state of assessment in the field of coping as chaotic and confusing. An enormous number of coping assessments, perhaps hundreds, are in use. Assessments have been created for adults, children, adolescents and the elderly. They measure ways of coping with stress in general, with stressful events in specific domains (such as work or health), with specific traumatic events (e.g. crime victimization or loss of a loved one), or they require participants to identify a single recent stressful event and describe how they actually coped with it. In a recent review, we identified over 100 assessments, tapping over 400 ways of coping (Skinner *et al.*, 2003). Researchers attempting to select an assessment of coping can justifiably feel bewildered, not only by the sheer number of measures available, but also by the wide range of strategies assessed and the heterogeneity of items used to assess them. Critiques of coping assessments abound (e.g. Beehr & McGrath, 1996; Cohen, 1987; Coyne & Gottlieb, 1996; Schwarzer & Schwarzer, 1996; Sommerfield, 1996; Stone *et al.*, 1992).

However, confusion in assessment is not based solely on operational issues. The solution is not as simple as comparing psychometrics and selecting the best questionnaire, checklist, interview,

or observational system. Confusion, to some extent, reflects a growing recognition of the complexity of the phenomena itself. The challenge to researchers is to capture coping in a way that does justice to its conceptual richness. Coping is not a simple construct. It does not reflect a single set of self-perceptions or a uni-dimensional group of behaviours. Coping is a complex higher-order organizational construct that reflects the functioning of a multi-level interactional system unfolding over time. That is why coping is so critical to human adaptation. That is also why it is so difficult to assess (see also 'Stress assessment').

Researchers creating (or selecting) a measurement scheme must grapple with three inter-related facets of coping: (1) coping encompasses a profile of changing ways of dealing with demands, current and future; (2) although coping describes an individual's actions, it emerges from a system and is diagnostic of the entire coping system, of which the individual is just a part; and (3) coping is a multi-level process that takes place across several time scales. Each of these facets is explained briefly and its implications for assessment considered. The presumption is that researchers and practitioners who understand the complex underlying nature of coping will be better prepared to capture and study it meaningfully in empirical investigations and to recognize and respond to it meaningfully in their clients and patients.

Coping as a profile

In order to be adaptive, a coping response must be suited to the demands it was created to deal with as well as the circumstances and resources available at the time. As a result, the number of potential coping responses is virtually unlimited. Researchers have dealt with this issue by grouping coping responses into 'ways' of coping; among the most common are problem-solving, avoidance, seeking social support, distraction, direct action, aggression, self-blame, escape, social withdrawal, religion, positive cognitive restructuring, emotional expression, information-seeking, acceptance, wishful thinking, rumination and worry, denial and focus on the positive.

Each of these ways of coping has a set of questionnaire items, a checklist entry and/or a set of coding criteria for open-ended interviews or observations. For example, problem-solving might be tapped by items like 'I made a plan of action and followed it', cognitive restructuring by items like 'I think about the good things I am learning from the situation', rumination by items like 'I can't stop thinking about how I am feeling', social withdrawal would include 'I avoided being with people' and catastrophizing would include 'I feel like I can't stand it any more'.

In terms of specific ways of coping, the best assessments in the field today have been constructed using confirmatory factor analysis. Researchers identify a set of items (usually five or six in number) tapping each target way of coping, and then examine the extent to which each set is unidimensional and can be distinguished from each other set. Using this strategy, researchers have created unidimensional, reliable (internally consistent) and distinct indicators of a wide variety of ways of coping. These represent state-of-the-art assessments.

However, no encounter with stress can be dealt with by a single way of coping. Also, although there is consensus on the best

strategies for measuring single ways of coping, there is no agreement about how many (and which) strategies should be included in comprehensive assessments of coping. In our review of systems for classifying ways of coping, we note that, of the 100 schemes identified, no two included the same set of ways of coping: some included as few as 2 or 3, others tapped 20 to 30 (Skinner *et al.*, 2003). The problem is widespread disagreement over what constitute core or central ways of coping.

Several distinctions have been suggested as higher-order categories to encompass multiple ways of coping (for a complete list see Rudolph *et al.*, 1995 or Skinner *et al.*, 2003). The most common are 'approach versus avoidance' and 'problem- versus emotion-focused' coping. Despite the contributions both of these distinctions have made to the field, neither is useful as a higher-order category of coping (Skinner *et al.*, 2003). Approach and avoidance are not good higher-order categories because both include potentially adaptive and maladaptive ways of coping. Emotion-focused and problem-focused coping are not good higher-order categories because all ways of coping have implications for both problem-solving and emotional reactions (Lazarus & Folkman, 1984).

Families of coping

In recent years, researchers have turned to the notion of higher-order families of ways of coping to organize the hundreds of ways of coping identified in previous research (Skinner *et al.*, 2003). A family includes a variety of ways of coping that all serve the same functions in dealing with stress. For example, if problem-solving is considered part of a family, it could include other ways of coping that serve the same functions, such as strategizing, planning, repair, direct attempts, instrumental action and decision-making.

We have identified a dozen core families of coping based on action types (see Table 1; Skinner *et al.*, 2003). Although there is not complete consensus that these are the core categories of coping, several are not particularly controversial, such as problem-solving, seeking support and escape/avoidance. Some represent the dominant ways of coping in specific domains, for example, information-seeking in the health domain, and negotiation in dealing with interpersonal stressors. Some reflect reactions to stress that have been studied extensively outside the field of coping, such as helplessness (Seligman, 1975) and dependency (M.M. Baltes, 1997).

Several reflect cutting edge ideas in the field of coping. For example, ways of coping have been identified that serve to direct attention away from the distressing features of a situation and toward more positive thoughts and activities. Referred to as accommodation (Brandtstädter & Renner, 1990) or secondary control coping, this family includes positive thinking, cognitive restructuring, focus on the positive and distraction. It is structurally distinct from escape (Ayers *et al.*, 1996) and, unlike denial, does not interfere with effective action.

Another family includes ways of coping that focus attention toward the negative features of a stressful situation. The best understood way of coping in this family is rumination (Nolen-Hoeksema, 1998), a risk factor for depression. Sometimes referred to as submission, surrender, or involuntary engagement, this family also includes

ways of coping such as perseveration and intrusive thoughts. Unlike constructive expression of emotions, however, these ways of coping exacerbate distress and interfere with problem-solving.

Families of coping as adaptive processes

In order to understand their functions in adapting to stress, these twelve families can be organized as three sets of four tightly connected pairs and their opposites, as depicted in Table 1. In one set, problem solving is closely connected with information-seeking and these are considered to be opposites of helplessness and escape. These four families help people coordinate their actions with the contingencies in the environment in order to produce desired or prevent undesired outcomes. Problem solving identifies effective actions and information seeking locates new contingencies.

A second set of four families is organised around support seeking, which is considered to be tightly connected to self-reliance, and the opposites of delegation and social isolation. These four families help people coordinate their reliance on others with the social resources that are available in order to stay connected to others. Support seeking allows the individual to access social resources whereas self-reliance preserves resources for later use and protects others from the burdens of stress.

The third set of four families is organized around negotiation, which is closely connected to accommodation, and the opposites of surrender and opposition. These families help people coordinate their preferences with available options in order to reach high priority goals. Accommodation allows an individual to adjust to the options that are currently available and negotiation may lead to the creation of more options.

Comprehensive coping profiles

The idea of twelve families of coping linked to higher-order adaptive processes provides a framework for assessment. It implies that any measure of coping, no matter the domain, developmental level, or time frame, should consider including ways of coping from each family. Although, as mentioned previously, some families may be more commonly studied in conjunction with particular stressors, this framework allows researchers to consider the use of less common strategies, such as information seeking for interpersonal problems (e.g. 'I asked my friend why she got so mad at me') or the use of negotiation with medical conditions (e.g. 'I decided that even if I couldn't walk, I could still get around in a wheelchair').

The specific ways of coping selected from each family will depend on their appropriateness for the target event and age group. For example, young children accommodate to unchangeable negative events using behavioural distraction whereas older children can use cognitive strategies, such as focus on the positive. Moreover, an indicator of 'stressfulness' can be drawn from the idea of the twelve families. An event would be more stressful to the extent that it eliminates an entire family of coping from use. So, for example, certain medical conditions are more stressful because little is known about their cause or treatment (eliminating information-seeking).

Most importantly, this framework makes clear the tenability of the notion of coping profiles, meaning that coping cannot be described by a single dimension, no matter how important, but instead should

Table 1. Families of coping organized according to their adaptive processes

Family of Coping	Family function in adaptive process	Adaptive process	Also implicated
Problem-solving Strategizing Instrumental action Planning	Adjust actions to be effective	Coordinate actions and contingencies in the environment	Watch and learn Mastery Efficacy
Information-Seeking Reading Observation Asking others	Find additional contingencies		Curiosity Interest
Helplessness Confusion Cognitive interference Cognitive exhaustion	Find limits of actions		Guilt Helplessness
Escape Cognitive avoidance Behavioural avoidance Denial Wishful thinking	Escape non-contingent environment		Drop and roll Flight Fear
Self-reliance Emotion regulation Behaviour regulation Emotional expression Emotion approach	Protect available social resources	Coordinate reliance and social resources available	Tend and befriend Pride
Support Seeking Contact seeking Comfort seeking Instrumental aid Spiritual support	Use available social resources		Proximity-seeking Yearning Other alliance
Delegation Maladaptive help-seeking Complaining Whining Self-pity	Find limits of resources		Self-pity Shame
Isolation Social withdrawal Concealment Avoiding others	Withdraw from unsupportive context		Duck and cover Freeze Sadness
Accommodation Distraction Cognitive restructuring* Minimization Acceptance	Flexibly adjust preferences to options	Coordinate preferences and available options	Pick and choose Secondary control
Negotiation Bargaining Persuasion Priority-setting	Find new options		Compromise
Submission Rumination Rigid perseverance Intrusive thoughts	Give up preferences		Disgust Rigid perseverance
Opposition Other-blame Projection Aggression	Remove constraints		Stand and fight Anger Defiance

be characterized by a range of ways of coping, which can best be organized according to these twelve families. The use of these twelve families allows researchers to select meaningfully from among the hundreds of ways of coping which they encompass, but also to consider how the families work together with each other (as synergistically positive or as antagonistic opposites) and how they function in service of higher-order adaptive processes.

Coping as a system

Researchers are slowly coming to grips with the notion that coping reflects the functioning of an entire system. The simplest implication of this view is that it is not possible to understand coping by looking only at coping itself. Coping actions emerge from a coping system, the elements of which have been pretty well identified. They include the coping individual as well as the stressor, the person's appraisals, the personal and social resources and liabilities in the situation and the history of outcomes of previous coping efforts.

Because ways of coping emerge from (and are diagnostic of) this entire system, there has been controversy about how to interpret their meaning. When coping was considered a manifestation of ego processes or of personality, maladaptive coping indicated an immature person or a neurotic personality. As coping came to be seen as situation-specific, no ways of coping could be considered 'maladaptive': they were all suited to their particular demands and contexts.

However, considering coping as a system reveals a third alternative. On the one hand, some ways of coping are maladaptive, as recognized by any parent, teacher, spouse, or friend. These are ways of coping, such as helplessness, rumination, or exploding, which are detrimental in the long run, or developmentally maladaptive, because they weaken the coping system, robbing it of social and personal resources and consolidating liabilities, such as low self-efficacy or exhausted friends. On the other hand, these are not 'wrong' ways of coping or individual flaws; instead they are the result of a coping system that is overwhelmed. This can happen when personal vulnerabilities are high, when social resources are low, or when the stressor is simply too great.

If formal or informal interventions are to be effective in improving coping, then information about the entire coping system must be assessed (Skinner & Edge, 1998). Parents or doctors who see individuals falling into helplessness or stuck in cycles of rumination, can recognize the problem, but without understanding the rest of the system (including the range of stressors, other demands, the individual's appraisals and his or her social and personal resources and liabilities), it is not possible to make changes to the system that will allow the person to cope more adaptively. Simply telling someone to 'pull themselves together' or to 'stop stewing about it' can place additional burdens (e.g. self-regulatory demands or self-blame) on an already overtaxed system.

Coping as a multi-level process

Coping takes place on many levels and over many time scales (Beehr & McGrath, 1996). When dealing with complex long-term demands

(such as a chronic illness or a child who is emotionally disturbed), people may eventually develop a network of coping that incorporates all these levels. At the highest level, they may work out an overall structure for handling the demands, a kind of proactive coping (Aspinwall & Taylor, 1997), such as a plan of diet, medication, exercise and relaxation for a chronic illness, or a plan of individualized education, homework and sleep schedules for an emotionally disturbed child. At the next level, they may develop and practice routines for dealing with reoccurring stressors (e.g. flare-ups or outbursts), allowing them to be handled with minimum effort and attention (Coyne & Gottlieb, 1996).

They may accrue a buffer of time, credit, or social support to aid them in dealing with crises (Taylor *et al.*, 2000). They may also discover ways of coping that help them recover from failures and setbacks (Heckhausen & Schulz, 1995). Finally, they can work toward a pattern of daily coping that allows them to monitor global conditions, but to focus awareness away from the negative features of the situation and onto its genuine positive aspects (Folkman & Moskowitz, 2000).

To capture these holistic multilevel processes of coping, cutting edge research has turned (back) to the use of detailed open-ended interviews (e.g. Folkman, 1997; Murphy & Moriarity, 1976). As stated by Moos, more than 30 years ago:

Full understanding can only come with detailed intensive study, either through interviews or through naturalistic observations of the actual day-to-day processes by which adaptation occurs. (Moos, 1974, p. 335)

Moreover, reflecting the idea that coping is a changing profile of responses to multiple varying stressors over time, new methods for assessment have been developed in which participants report their coping every day, or even multiple times a day, using a daily diary format (e.g. Stone & Neale, 1984; Tennen *et al.*, 2000). These methods, if they are expanded to tap the entire coping system, promise assessments that can capture the dynamics of coping.

When intervening into a coping system, practitioners should consider all these levels. For example, early in the course of treatment, it might be necessary to gather information about the condition (e.g. using daily diaries) in order to determine the factors that trigger a flare-up, even though focusing on the condition may increase distress. After structures have been set up, coping strategies can be promoted that direct attention away from the condition and toward positive experiences. It should be noted that the time frame for creating such an adaptive network of coping might be months or even years.

Conclusion

From their entry into the field of psychology, conceptualizations of coping as an adaptive process have held the promise of contributing to our understanding of how people are able to deal with adversity and why they sometimes succumb to its pressures. As assessments become more organized around families of coping which are connected to adaptive processes and begin to reflect coping as a profile of responses that emerge from an entire system of coping that itself unfolds on multiple levels and time scales, research on coping may better fulfil that promise.

Traditional assessments of mental disorders provide highly individualistic evaluations of the patients' presenting problems, recent stressors and salient symptoms. Such individualized assessments, while rich in detail, lack the necessary standardization for reliable diagnoses. As a result, traditional assessments are often marred by inaccuracies, most notably in missed diagnoses and misdiagnoses (Rogers, 2003). To improve diagnostic reliability, healthcare professionals should augment traditional evaluations with more standardized assessments that include structured interviews. Following a review of current diagnostic predicaments, the chapter examines the role of structured interviews in improving clinical practice.

Diagnostic predicaments

The assessment of mental disorders within the primary care system has not kept pace with diagnostic advances. As a result, diagnoses are often a hit-or-miss proposition. Consider for the moment the comparatively straightforward diagnosis of major depression. Tiemens *et al.* (1999) found the majority of patients with major depression went undiagnosed and untreated by primary care physicians. This finding is very consistent. Lowe *et al.* (2004) found that 60% of cases with major depression were missed diagnoses in primary health care. Even when the diagnosis was broadened to include any depressive disorder, the accuracy did not improve (i.e. 59% missed diagnoses). Misdiagnosis of major depression was also common. When these physicians did diagnose major depression, they were inaccurate in 62% of the cases. These worrisome results extend beyond major depression to a range of Axis I disorders (see Christensen *et al.*, 2003; Spitzer *et al.*, 1994).

Many healthcare professionals take comfort in the availability and expertise of mental health specialists. Research data suggest this may be a false comfort. When traditional psychiatric evaluations are compared with standardized assessments, several important findings are suggested. First and foremost, traditional evaluations typically are not comprehensive; they often miss co-morbidity, overlooking additional Axis I and Axis II disorders (see Zimmerman & Mattia, 1999). Probably because of comorbidity, Shear *et al.* (2000) found clinicians in outpatient practice overlooked most anxiety disorders (94.7%). Second, traditional evaluations tend to neglect uncommon diagnoses. In reviewing 500 traditional evaluations, Zimmerman and Mattia (1999) found that body dysmorphic and somatoform disorders were almost never

diagnosed; these results are markedly discrepant with 500 standardized assessments from the same setting.

The subjectivity of traditional evaluations makes them susceptible to biases. North *et al.* (1997) studied diagnoses in an outpatient care programme for homeless persons. We interpret their results as suggesting the possibility of diagnostic bias. Their traditional evaluations appeared to over-diagnose antisocial personality disorder by 100% and under-diagnose depression by 60%. Such biases may also extend to cultural issues. As carefully reviewed by Baker and Bell (1999), clinicians tend to overdiagnose schizophrenia and under-diagnose depression in African American patients. While not eliminating biases, systematic assessments ensure that standardized questions and clinical ratings are applied methodically, irrespective of circumstances or cultural background.

Overview of structured interviews

Healthcare professionals must grapple with diagnostic predicaments outlined above. Treatment of mental disorders cannot be optimally effective without accurate multiaxial diagnoses. Fortunately, structured interviews can provide the verifiable reliability and diagnostic accuracy required for modern healthcare practices. This section begins with a simple overview of terminology.

The term, 'structured interview', applies to all standardized interviews that provide verbatim clinical inquiries and quantify responses based on explicitly delineated criteria. Structured interviews are subdivided into 'fully-structured' and 'semi-structured' formats (Rogers, 2003). Fully-structured interviews standardize all inquiries and do not permit clinician-initiated probes. In contrast, most standardized interviews are semi-structured: clinicians are obliged to ask verbatim questions and probes. In occasional cases of ambiguity, they augment these verbatim inquiries with their own individualized (i.e. non-standard) questions. Semi-structured interviews sacrifice a small degree of standardization in order to achieve greater clarification of clinical data.

What can be accomplished with structured interviews? In an enumerated format, we outline their five chief advantages:

1. *Comprehensiveness.* Structured interviews ensure that clinical inquiries provide complete coverage of diagnoses or other clinical constructs. For example, Psychopathy Checklist-Revised

(PCL-R; Hare, 2003) guarantees that major elements of psychopathology are systematically evaluated.

2. *Standardization.* The hallmark of structured interviews is the systematization of clinical inquiries and concomitant ratings. In particular, variations in the recording of valuable clinical data are minimized. This uniformity of data allows practitioners to make direct comparisons needed in documenting the course of the disorder or response to specific treatments. For example, the Schedule of Affective Disorders and Schizophrenia (SADS; Spitzer & Endicott, 1978a) anchors gradations of symptom severity with specific criteria.
3. *Level of measurement.* Traditional interviews yield idiosyncratic information at the nominal (i.e. presence or absence) level of measurement. In contrast, the carefully constructed ratings of structured interviews typically provide an ordinal (i.e. greater or lesser severity) level of measurement that reliably distinguishes levels of impairment. For example, the Structured Interview for DSM-IV Personality Disorders (SIDP-IV; Pfohl *et al.*, 1995) provides four levels for Axis II symptoms: (1) not present, (2) sub-threshold (i.e. some but insufficient evidence of the trait), (3) present and (4) strongly present (i.e. causing impairment or subjective distress).
4. *Non-pejorative enquiries.* Clinicians must exercise considerable sensitivity and professional judgement when asking patients with mental disorders to disclose the nature of their symptoms and impairment. Structured interviews are tested clinically, if not empirically, to ensure that their inquiries do not offend patients but promote mutual respect and self-disclosure. For example, the SIDP-IV asks indirect questions about social relationships rather than intrusive probes into avoidant and borderline characteristics.
5. *Reliability.* Empirically validated assessment methods require a formal investigation of reliability (i.e. the consistency of observations across time and different clinicians). Structured interviews can be rigorously tested to ensure they have sufficient reliability for the assessment of diagnoses and salient symptoms. Rogers (2001) systematically reviewed reliability data for Axis I and Axis II structured interviews.

Seminal research by Ward and his colleagues offers insights into the advantages of structured interviews. In examining diagnostic disagreements, they found that most discrepancies (62.5%) occurred among experienced psychiatrists because they used different standards for evaluating symptoms of mental disorders. They found that most of the remaining disagreements (32.5%) resulted from differences in clinical inquiries used by individual psychiatrists. Structured interviews with standardized ratings seek to minimize differences based on both clinical inquiries and diagnostic criteria.

Despite these advantages, structured interviews can be misused in health care settings. The most common risk is a routinization of the assessment, whereby clinicians become bound to the protocol and insensitive to human elements of the interactive process. With proper training, this risk is easily avoidable. The goal of structured interviews is a natural and unforced flow of clinical inquiries. With practice, the formal structure should become unobtrusive. While faithful to the standardization, clinicians can remain empathetic and genuinely interested in the patient's responses.

Diagnostic models and healthcare practice

Modern healthcare faces formidable challenges as many public and private agencies struggle with cost containment and even the unspoken rationing of services. To succeed, diagnostic interviews must take into account these uninviting realities. Therefore, we propose two diagnostic approaches. First, the 'augmented clinical practice' essentially re-tools the clinical assessment but requires a minimum expenditure of professional resources. Second, the 'multiaxial-diagnostic model' provides a sophisticated assessment of Axis I and Axis II disorders. Each model is introduced and examined separately.

Augmented clinical practice

Many healthcare facilities have only limited access to highly trained psychologists and psychiatrists. Despite high patient loads, primary care settings want to avoid the current diagnostic predicaments. For mental disorders, current data suggest that missed diagnoses and misdiagnoses significantly outnumber accurate diagnoses in primary care practices. When faced with high demand and limited resources, we recommend the augmented clinical practice approach.

The overriding goal of augmented clinical practice is simply to maximize diagnostic accuracy for common Axis I disorders. Two structured interviews are clinically useful for this endeavour: the Mini International Neuropsychiatric Interview (MINI; Sheehan *et al.*, 1997) and the SADS-Change Version (SADS-C; Spitzer & Endicott, 1978b). Each interview has a separate goal: the MINI targets common Axis I disorders, while the SADS-C focuses on salient symptoms which often require clinical intervention.

The MINI

The MINI (Sheehan *et al.*, 1997) is a brief Axis I interview, approximately 15 minutes in length which is conducted by healthcare staff who need only modest training in mental disorders. Despite its brevity, the MINI provides surprisingly good coverage of common Axis I disorders. It addresses the following diagnostic categories: (a) mood disorders (i.e. major depression, dysthymia and mania), (b) anxiety disorders (i.e. panic disorder, agoraphobia, social phobia, simple phobia, generalized anxiety disorder, obsessive-compulsive disorder and post-traumatic stress disorder), (c) psychotic disorders (i.e. general screen but no specific diagnoses), (d) eating disorders (i.e. anorexia and bulimia nervosa) and (e) substance abuse disorders (i.e. alcohol abuse, alcohol dependence, drug abuse and drug dependence).

Validation research (see Sheehan *et al.*, 1998) has examined its results in relationship to both the DSM-IV and ICD-10 using the Structured Clinical Interview for DSM-IV Disorders (SCID) and the Composite International Diagnostic Interview (CIDI). Research demonstrates a moderately high agreement with more extensive structured interviews; median kappas were 0.67 with SCID-based diagnoses and 0.63 with CIDI-based diagnoses.

The MINI was fully intended to be an international measure, easily accessible to healthcare professionals. It was simultaneously

Table 1. An overview of commonly-used Axis I and Axis II interviews

Feature	Axis I structured interviews			Axis II structured interviews		
	SADS	SCID	CIDI	SIDP-IV	IPDE	SCID-II
DSM-IV	Partial	Yes	Yes	Yes	Yes	Yes
ICD-10	No	No	Yes	No	Yes	No
Diagnostic reliability	Excellent	Good	Good	Sufficient	Good	Sufficient
Gradations of symptoms	3 to 6	2 or 3	2	4	3	3
Level of training	High	Moderate	Moderate	Moderate	Moderate	Low
International research	Limited	Limited	Extensive	Limited	Extensive	Limited

validated in English and French. Further efforts are underway to provide translations in 30 different languages. As an important feature for cost containment, the MINI is available free of charge and can be downloaded from the internet at <http://www.medical-outcomes.com>.

The MINI appears to be an ideal measure for minimising missed diagnoses and misdiagnoses. When potential diagnoses are identified, either a mental health specialist or physician knowledgeable in mental disorders should confirm the diagnosis and recommend the treatment regimen.

The SADS-C

The SADS-C (Spitzer & Endicott, 1978*b*) addresses 36 key symptoms of mental disorders which are often the focus of clinical intervention. While evaluating cardinal symptoms of mood, anxiety and psychotic disorders, the SADS-C does not provide sufficient coverage for formal diagnoses. Instead, it targets these salient symptoms and alerts healthcare professionals to potential diagnoses.

The SADS-C has impressive reliability and validity (Rogers *et al.*, 2003). With a moderate level of training, healthcare staff can learn to administer this brief measure (10–20 minutes) and achieve high levels of reliability for individual symptoms and sub-scales. Importantly, research (see Rogers, 2001) has demonstrated the usefulness of the SADS-C to evaluate critical changes in clinical status. Therefore, the SADS-C can provide a vital role in primary health care in relapse prevention and identifying new episodes of mental disorders.

Multiaxial-diagnostic model

The sophisticated assessment of mental disorders requires a systematic evaluation of Axis I and Axis II diagnoses. Some healthcare settings have the professional resources to place a premium on accurate diagnoses, including complex differential diagnoses. Towards this goal, the multiaxial-diagnostic model systematically evaluates disorders, syndromes and salient symptoms affecting the patients' functioning.

Rogers (2001) provides a comprehensive examination of Axis I and Axis II interviews, including their clinical applications and validation. This chapter selects three Axis I and three Axis II interviews

that are widely used in clinical practice. It distills information on their development and updates data on their validation. The three Axis I interviews include the SADS (Spitzer & Endicott, 1978*a*), the Structured Clinical Interview for DSM-IV Disorders (SCID; First *et al.*, 1997, 2002), and the Composite International Diagnostic Interview (CIDI; World Health Organization, 1997). The three Axis II interviews are comprised of the SIDP-IV (Pfohl *et al.*, 1995), the International Personality Disorder Examination (IPDE; Loranger, 1999) and the Structured Clinical Interview for DSM-IV Axis II Personality Disorders (SCID-II; First *et al.*, 1994). These six structured interviews provide healthcare professionals with an array of well-validated diagnostic measures which are clinically applicable to a broad range of settings.

Axis I interviews vary substantially in their diagnostic coverage (see Table 1). For example, the SADS opted for an in-depth examination of mood and psychotic disorders addressing symptoms and associated features in considerable detail. In contrast, the SCID has chosen a much broader coverage of DSM-IV disorders but sacrificed symptom severity and associated features. Finally, the CIDI has the broadest coverage but focuses primarily on the presence and absence of Axis I symptoms.

Table 1 summarizes the salient features of Axis I and Axis II interviews. This table and the following discussion should assist health care professionals in identifying the appropriate structured interviews for their setting and populations. We begin with a review of the SADS, a classic measure with contemporary applications.

The SADS

The SADS is an extensive semi-structured Axis I interview that relies heavily on the training of interviewers in order to achieve impressive inter-rater and test-retest reliabilities. The SADS is distinguished from other Axis I interviews by the natural flow of its questions and its sophisticated rating of symptom severity. As a result, interviewers need advanced training in diagnostic interviews and supervised experience with the SADS.

The SADS focuses on depth rather than breadth. In addition to inclusion criteria, it evaluates clinical characteristics and associated features of mood and psychotic disorders. As a result, it provides rich description of the patient's functioning rather than a checklist format found with some Axis I interviews.

The SADS is especially suited for assessing Axis I symptomatology and measuring its severity. The SADS should be given strong consideration in clinical settings where it is hoped that hope to achieve the following objectives:

- *Clinical management of critical symptoms.* In conjunction with the SADS-C, the SADS can measure the severity of symptoms and their changes in severity across time.
- *Diagnoses for discrete episodes.* The SADS allow the experienced interviewer to focus on current and past episodes in reliably establishing the course of specific disorders.
- *Extensive use in medical settings.* Clinical research has demonstrated the usefulness of the SADS in assessing co-morbidity and mental disorders in medical populations (Rogers *et al.*, 2003).
- *Reliability on both diagnostic and symptom levels.* For specialized applications in healthcare settings, it is imperative to assess diagnoses and concomitant symptoms with a high level of reliability. The SADS has unprecedented reliability (Rogers, 2001). Even for individual symptoms, the median intra-class coefficients tend to exceed 0.70. For current diagnoses, most studies (see Rogers, 2001) produce exceptional inter-rater reliabilities (i.e. >0.85 for median kappas or ICCs).

The SADS does have several drawbacks. Internationally, few studies have formally investigated the effects of language and cultural issues on its validity. In addition, the SADS does not correspond perfectly with DSM-IV; SADS-based diagnoses will occasionally need to be augmented with several additional inquiries to match DSM-IV inclusion criteria.

The SCID

The SCID was developed expressly for the evaluation of DSM symptoms and disorders. With an emphasis on diagnostic simplicity, its questions often parallel the inclusion criteria for DSM-IV. With an emphasis on efficiency, many screening questions are used to reduce the administration time. As a result, the SCID provides comprehensive coverage of common Axis I diagnoses. By design, however, it de-emphasizes the assessment of individual symptoms and does not provide gradations of symptom severity.

The SCID should be selected in health care settings that place a premium on broad diagnostic coverage and reliability. The SCID requires comparatively less training than the SADS and conveniently addresses specific diagnoses in a sequential manner. Several versions of the SCID are available. A major limitation of the current SCID-Clinical Version (SCID-CV) is the absence of a subclinical level; interviewers are forced to rate symptoms as present or absent.

The classic reliability study by Williams, Gibbon *et al.* (1992) produced worrisome results for the SCID including highly variable agreement on such common disorders as depression and substance abuse. Fortunately, more recent research (e.g. Zimmerman & Mattia, 1999) has produced much more consistent and positive results. Because it de-emphasizes symptoms, the SCID should not be used to establish symptom reliability.

Researchers have an exceptional opportunity to utilize an expanded SCID, namely the SCID-I Research Version (SCID-RV; First *et al.*, 2002), which utilizes a sub-clinical gradation and offers

comprehensive diagnostic coverage. For example, the SCID-RV provides extensive coverage of somatoform disorders, including somatisation and body dysmorphic disorders. Importantly, the SCID-RV can be tailored to individual studies. For a reasonable charge, it is available on disk and can even be sent as an email attachment (website: <http://www.scid4.org/orderfrm.htm>). Naturally, researchers will need to establish diagnostic reliability for their tailored versions of the SCID-RV.

In summary, the SCID-CV is a well validated efficient interview that can be effectively used in both mental health and medical settings. It efficiently provides broad diagnostic coverage with good reliability. Its research counterpart, the SCID-RV, provides broader diagnostic coverage and more refined clinical ratings.

The CIDI

The CIDI is a composite Axis I interview that combines all the items from the Diagnostic Interview Schedule (DIS; Robins *et al.*, 1989) with selected items from the Present State Examination (PSE; Wing *et al.*, 1998). This exhaustive measure evaluates Axis I disorders for both DSM and ICD diagnoses. With its cross-cultural perspective, the CIDI was translated into more than a dozen languages.

Establishment of the CIDI reliability and validity is complicated by (a) its complex array of symptom questions and ratings, (b) use of distinct versions with different content, (c) use of two diagnostic systems (DSM and ICD) and (d) many different language translations. Nevertheless, studies of diagnostic reliability have produced mixed (Rogers, 2001) to very positive results (see Wittchen, 1994). For validity studies, the CIDI relies heavily on DIS research with moderately good convergence.

The CIDI appears to be a good choice as an Axis I interview in countries where both DSM and ICD systems are used. It provides a functional bridge across diagnostic systems. The CIDI offers rich clinical descriptions with generally reliable Axis I diagnoses.

Axis II interviews

Personality disorders are often overlooked by traditional interviews. Fortunately, three structured interviews (see Table 1) are readily available with strong psychometric properties. In the subsequent paragraphs, the comparative strengths of each Axis II interview are underscored.

The SIDP has been validated with a broad range of inpatient and outpatient populations. It is ideally suited for assessing comorbidity in patients with Axis I disorders. Its topical organization (e.g. activities, relationships and emotions) flows naturally and facilitates patients' participation. With moderately good reliability, the SIDP has been used extensively in treatment outcome studies. The hallmark of the SIDP is its clear diagnostic boundaries, producing 'pure' personality disorders (i.e. single diagnosis) in approximately half of the patients evaluated.

The IPDE is composed of separate versions to evaluate DSM and ICD personality disorders. Like the SIDP, it is topically organized to promote patient cooperation. Patients with Axis I disorders can be evaluated with the IPDE, although it has not been sufficiently tested with psychotic disorders or severe

depression. The IPDE has moderately good reliability for both symptoms and diagnoses. Given its extensive research with dimensional diagnoses, the IPDE produces very reliable results in measuring the level of personality traits. The hallmark of the IPDE is its international applications to different cultures, languages and diagnostic systems.

The SCID-II is an efficient Axis II interview organized by diagnosis rather than relevant topics. Used in conjunction with a written screen, interviewers can rapidly assess probable personality disorders. This emphasis on efficiency detracts from the natural flow of questions and can be experienced as repetitive because questions on the SCID-II parallel those on the screen. The hallmark of the

SCID-II is its efficiency in minimising the number of inquiries and facilitating rapid diagnoses.

Concluding remarks

Traditional evaluations are fraught with diagnostic errors, namely missed diagnoses and misdiagnoses. Recent advances in structured interviews have brought much-needed standardization to clinical inquiries and concomitant ratings. As a result, Axis I and Axis II interviews produce reliable and valid diagnoses widely applicable across healthcare settings.

Disability assessment

Raymond Fitzpatrick

University of Oxford

The concept of disability

Disability is a broad and sometimes contentious term. It provides an apparently neutral method of describing limitations and difficulties that individuals may have of functioning in their environment. However to individuals with disabilities, and to organizations that represent them, the term 'disability' appears unnecessarily negative with implications of deviance and abnormality. A plethora of approaches to disability span those that at one extreme define disability as inherent properties of individuals, through to the other extreme that considers disability a harmful social construction which labels and oppresses particular minorities.

Fundamental changes to how we view disability are revealed in the evolution of the World Health Organization's thinking about health and disease. In 1980 it produced what was at the time considered a progressive and enlightened International Classification of Impairments, Disabilities and Handicaps (ICIDH). The ICIDH schema defines impairment as any loss or abnormality of psychological, physiological or anatomical structure or function. Impairment therefore refers to failure at the level of organs or systems of the body, with impairment usually arising from disease. Disability refers to any restriction or lack of ability to perform an activity in the manner considered normal. The emphasis is therefore on things that individuals cannot do. Handicap is any disadvantage for an individual, resulting from impairment or disability that limits the fulfilment of a role for that individual. It refers to the social disadvantages that may follow from disease. A simple example might be that osteoarthritis (disease) results in poorly functioning hips or knees (impairment). This impairment results in reduced mobility (disability), in turn resulting in loss of work and social contact (handicap).

Two sets of criticisms were frequently expressed about ICIDH. Firstly it was viewed as too biomedical and reductionist, because it viewed all the problems of individuals with disabilities as stemming from inherent aspects of their disease, rather than, for example, societal approaches to disability. Secondly the emphasis upon 'disability' and 'handicap' was excessively negative reinforcing unhelpfully pessimistic views of disability. The WHO therefore introduced a new classification system: the International Classification of Functioning, Disease and Health, or ICF (WHO, 2001).

The ICF model is more interactive (rather than linear) with four key elements: (i) body functions and structures (e.g. memory function, structure of the nervous system), (ii) activities and participation (e.g. self care, social and community life), (iii) environmental factors (products and technology for communication, immediate family) and (iv) personal factors (age, gender). Health is another contextual factor similar to environment and personal factors but

not considered necessarily of primary causal importance. Overall the language is neutral, causes are not unilinear from disease and the emphasis is upon the scope for positive activities and participation. Another key shift is that the new WHO model is applicable to all individuals in a population (viewing activities and participation as a continuum), rather than focusing on a minority of 'disabled'. Overall disability is considered an umbrella term for all of the interactions between the four elements just described rather than a property of individuals. This new WHO schema offers potentially a more thorough and coherent approach to disability; however at present it is largely a theoretical formulation and sustained effort will be required to operationalise it in terms of the measurement systems described in the remainder of this chapter (see also 'Disability').

Population surveys in both the UK and the USA have reached rather similar estimates of the prevalence of disability amongst adults – approximately 14% being considered disabled due to ill health. Arthritis, blindness, stroke, coronary heart disease and bronchitis are the disorders most responsible for disability.

Principles of assessment

Until recently assessment of disability focused almost exclusively upon a core of issues; the extent to which the individual can operate independently in terms of a range of important functions. To some degree assessment has begun to include broader issues such as handicap. More recently, assessment has also incorporated issues raised by the WHO's paradigm shift towards participation. As assessment includes such broader domains, it inevitably becomes more multidimensional since, for example, disability in one dimension will not necessarily predict high levels of problem in another dimension.

Two levels of functioning are commonly distinguished; basic and instrumental activities of daily living (ADL). Basic ADL functions are those that are essential for self-care such as bathing, dressing and feeding. Instrumental ADL are those activities such as doing laundry, shopping, housekeeping, getting around in public, activities that are necessary for someone to maintain a level of independent living. Problems with instrumental ADL (IADL) are far more common than for basic ADL, so that estimates of the prevalence of disability are very much influenced by whether the broader range of IADLs are included.

Purposes of assessment

Assessment of disability may serve a number of different purposes. It is essential to be quite clear about the purpose to which any given

measure is to be put. A particular measure of disability may, for example, be very useful as a population survey instrument for estimating the prevalence of disability in a population, but not perform well as a measure of outcome in clinical trials.

The earliest applications of measures to assess disability were in the context of hospital decisions about how to allocate nursing care to patients of greatest dependency and need. They now have a broader range of application in helping health professionals' assessments of their patients. In a typical study of such applications, Wagner and colleagues (1997) set out to improve the care of patients with epilepsy by providing evidence about patients' disability to their doctors, with the data on disability provided by patients themselves by completing a health status measure. Doctors were unaware of the information so provided and in 13% of consultations the new information resulted in a change of therapy. Both patients and doctors generally find it helpful and appropriate that the doctor is aware of the broader impact of their health problems. However to date systematic reviews suggest that, although providing health professionals with evidence about their patients' disability and broader aspects of health is considered important, it does not change the management of their patients sufficiently to significantly impact upon ultimate health outcomes (Greenhalgh & Meadows, 1999).

Another use of measures of disability is to track trends in populations in order to assess progress in public health and identify barriers to progress at the level of the population as a whole rather than selected sub-groups receiving interventions. Thus, the US Department of Health and Human Services uses a simple set of core questions in population surveys, for example, respondents' self-ratings of health and judgements of number of days in month that health prevented the respondent from performing usual activities (Centers for Disease Control and Prevention, 2000). These simple measures identify differences in health between states, poorer health and higher disability levels in sections of the United States with less education and trends over time in population disability.

Prognosis

A related use of disability assessments is in the prediction of future problems, either in terms of increased risk of deterioration in health or indeed mortality, or in terms of increased demands on the healthcare system. There is substantial evidence that such assessments play that role. For example, Keysor and colleagues (2004) administered a simple, short measure of self-reported health status, the Health Assessment Questionnaire to over 1400 patients with rheumatoid arthritis recruited from clinics from 11 cities across the United States. Higher levels of disability reported in the questionnaire at baseline proved to be a significant predictor of mortality in a ten-year follow-up of mortality.

Measures of outcome

Disability measures may be used to assess the progress of patients over time, and by extension to assess outcomes of healthcare in quality assurance, evaluation studies or clinical trials. For example, Messier and colleagues (2004) carried out a randomized controlled trial to examine whether long-term exercise or dietary weight loss

would be effective in reducing pain and disability in obese individuals with osteoarthritis. The principle outcome measure was self-reported physical function as assessed by Western Ontario and McMaster Universities' Osteoarthritis Index (WOMAC). Modest weight loss combined with moderate exercise proved to have a significantly greater beneficial effect on disability than either intervention alone or a control group in standard care. The scope for finding real benefit from novel interventions, whether drugs or complex interventions is quite modest and self-reported disability measures offer an attractive way of identifying such small but worthwhile gains.

Measurement requirements

The measurement properties required for disability assessments are the same as for all other health status and psychometric instruments. Assessments need to be reliable, valid, sensitive to change, acceptable, relevant and practical to use. However a proliferation of disability instruments has occurred in which the majority of instruments have not been evaluated against such criteria. Test-retest reliability is one key component of measures, but for observer-based measures of disability, inter-rater reliability is also of importance. There are no 'gold-standard' criteria against which to measure validity. Instead, a battery of approaches should be used that includes the important stage of informal examination of whether the content of measures is appropriate to the intended use and encompasses all relevant dimensions. More formal assessment of validity involves construct validity by comparing results with other related measures or predictive validity in which scores are examined against subsequent health status or healthcare use.

Sensitivity to change requires particular attention. It cannot be assumed that, because an instrument has been shown to be valid in terms of distinguishing degrees of severity of disability between patients that it will also be sensitive to change over time in disability within patients. For example, the standard American Rheumatism Association (ARA) functional classification distinguishes just four levels of disability, ranging from 'complete functional capacity' to 'largely or wholly incapacitated'. There is a substantial amount of change that can occur to patients in degree of disability whilst remaining within a single grade of the ARA scale. Such broad categories can therefore understate the effects of healthcare interventions. Similarly in Parkinson's disease, the Hoehn and Yahr scale distinguishes between just five levels of severity. When patients are asked to judge disability themselves in measures repeated over time, changes are identified that are not detected by the more broad categories of Hoehn and Yahr (Fitzpatrick *et al.*, 1997). Increasing attention is now given to identifying the smallest change in a disability measure that would be meaningful to the patient or of statistical significance, in order to improve the clinical interpretability of change scores for instruments, either in terms of individual patient care or results from trials. The evidence with regard to disability assessment in Parkinson's disease is that similar change scores emerge as meaningful whether the criterion is based on patient judgement of what is meaningful or on statistical criteria (Fitzpatrick *et al.*, 2004).

A problem that can limit the sensitivity to change of disability measures derives from so-called 'ceiling' and 'floor' effects. Instruments may not leave scope for patients to express further improvement or deterioration beyond the items included in the instrument. A common way of identifying possible floor and ceiling effects is by the proportion of scores falling at the extremes of an instrument. Thus Mao and colleagues (2002) compared three measures of balance in patients who had a stroke. The instruments differed in the proportion of scores at the extremes, suggesting that they would differ in their capacity to measure the extent of true underlying change in the construct of balance.

Types of instruments

Direct clinical testing

Traditionally, clinicians have used a number of physical tests to assess aspects of function and disability, for example, by timing how long it took patients to complete tasks such as walking given distances, or by assessing the performance of particular tasks such as buttoning and unbuttoning. One problem with such assessments is that they may be unrepresentative of the challenges faced by the patient in the usual environment. A more fundamental problem is that such tests can be very unreliable, although by careful standardizing of instruction to patients and methods of recording observations, it is possible to obtain very good inter-rater reliability (Pincus *et al.*, 1991). Clinical tests such as walking time can be useful but are inevitably limited in scope because of inherent difficulties of directly observing many IADLs such as shopping and use of transport.

Observer-based assessments

One of the first, and still most commonly used, of such assessments is the Index of ADL developed by Katz and colleagues (1963). Individuals are rated by observers on a three-point scale of degree of independence for each of six activities: bathing, dressing, toileting, transfer (moving in and out of bed and chairs), continence and feeding. It clearly concentrates on more basic ADLs and uses rather broad categories of assessment so that it may not be appropriate as an outcome for the majority of interventions from which only modest benefits are expected.

Probably more widely used now is the Barthel Index which assesses patients on ten dimensions: feeding, grooming, bathing, dressing, bowel and bladder care, toilet use, ambulation, transfers and stair climbing. The Barthel Index exists in a variety of forms which differ in items and methods of scoring. Studies comparing different forms of the Barthel Index with each other and with comparable measures of disability are inconclusive but generally seem to indicate that shorter and simpler measures are often as reliable valid and responsive as longer forms (Hsueh *et al.*, 2002). Because no single measure of observer-assessed disability clearly dominates others in terms of measurement properties, there is now a growing proliferation of instruments, either modifying existing scales for generic use, or designed for specific use with particular conditions such as stroke or multiple sclerosis or particular functions such as mobility.

Standardized interviews and questionnaires

There is now increased emphasis upon instruments either in the form of standardized instruments or self completed questionnaires that focus on the individual's own perception and experience of disability. An example is the Sickness Impact Profile (SIP) (Bergner *et al.*, 1981). It comprises 136 statements with 'yes' or 'no' responses. Items contribute to one of 12 scales: walking, body care and movement, mobility, work, sleeping and rest, eating, housework, recreation, emotion, social interaction, alertness and communication. The first three scales can be combined to produce a 'physical scale' which most closely resembles a disability assessment. Scoring of items is weighted on the basis of extensive prior rating exercises of panels to assess severity. It has been shown to be valid in a wide range of disabling conditions. Nevertheless its relatively large number of items has resulted in efforts to shorten and simplify it. Thus, van de Port and colleagues (2004) devised a shorter version of SIP with items tailored to individuals with stroke; they demonstrated validity and concluded that measurement properties were not inferior to those of the longer original SIP.

Probably more extensively used now is the SF-36 which comprises 36 items each contributing to one of eight scales: limitations in physical activities because of health problems, limitations in social activities because of physical or emotional problems, limitations in usual role activities because of physical health problems, bodily pain, general mental health (psychological distress and wellbeing), limitations in usual role activities because of emotional problems, vitality (energy and fatigue) and general health perceptions (Brazier *et al.*, 1992). Items can also be summarized in terms of two broader scales to simplify reporting: physical and mental health summary scales. Unfortunately the success in terms of rate of uptake of the instrument has resulted in a number of varying forms of the basic instrument. As with clinician- and observer-based scales, there is also a tendency for investigators to develop disease-specific adaptations of the core instrument. For example the Multiple Sclerosis Quality of Life Health Survey is an instrument intended for use with individuals with multiple sclerosis; it comprises the SF-36 with 18 disease-specific items added on (Pittock *et al.*, 2004). One major advantage of SF-36 is that the relative ease of use and wide-ranging applicability of its content has resulted in frequent use in general population surveys so that scores for specific groups can be compared with normative evidence (see also 'Quality of life assessment').

A wide range of disease-specific instruments have also appeared that have relevance to assessment of disability in specific populations. For example the Health Assessment Questionnaire (HAQ) (Fries, Spitz & Young, 1982) is widely used for individuals with rheumatoid arthritis and related conditions. It contains 20 items across 8 areas of function: dressing and grooming, rising, eating, walking, hygiene, reach, grip and outside activity. The HAQ is very widely used: it is, for example, a powerful predictor of future health status and use of healthcare services by those with arthritis (Ethgen *et al.*, 2002).

Handicap and participation

Recently, efforts have been made explicitly to address broader aspects of disability emphasized by WHO models discussed earlier.

Amongst the earliest of instruments to address the WHO agenda for disability was the London Handicap Scale (Harwood *et al.*, 1994). The scale generates a profile of handicaps on six different dimensions (mobility, physical independence, occupation, social integration, orientation and economic self-sufficiency) by asking respondents to select between six levels on each item. It has been shown to be sensitive to change in an evaluation of a day hospital rehabilitation programme for stroke patients (Hershkovitz *et al.*, 2004).

Similarly Noreau and colleagues (2004) developed the LIFE-H instrument specifically to assess social participation in individuals with disability focusing on items to assess a person's performance in daily activities, social roles (life habits) leisure and community participation. It should be noted that many instruments such as SIP and SF-36 do contain items and dimensions addressing WHO-type concerns regarding handicap and social participation, but were not explicitly developed and tested against the WHO-based conceptualization of disability.

Individualized measures

An important approach to rehabilitation in disability is 'goal attainment scaling' in which patient and therapist jointly set priorities in terms of specific targets for particular functional problems. The idea of personalizing or individualizing has been adopted in the field of assessment, moving away from the idea of assessing a standard list of pre-selected items to assessing items identified by the patient. Tugwell and colleagues (1990) developed an instrument to assess disability in arthritis (the Patient Preference Disability Questionnaire) in which patients identify up to five functional problems of concern to them arising from their disease. The instrument proved sensitive to changes in a placebo controlled drug trial. A number of instruments have been developed based on the same principles of individuals selecting issues of concern to them. A systematic review assessed available evidence for such instruments (Patel and colleagues, 2003). The authors concluded that whilst some instruments had good evidence of measurement properties, they were all fairly impractical for the purposes of clinical trials and related evaluative research because of

practical difficulties arising from the need for in-depth interviews to collect data. By contrast, the principle of personalizing goals remains of fundamental importance in clinical aspects of disability.

Issues for the future

Two major developments are now needed in the field of disability assessment. The first development is that recent advances in statistical analysis of data such as scales and additive scores need to be fully applied and tested in the context of disability assessment. There are numerous scales now available to assess disability. However none is free of possible problems to do with redundancy of items, floor or ceiling effects, difficulties of assuming equivalence and additivity of items and other such statistical problems. It has been argued that recently developed statistical methods such as item response theory may overcome such problems, in particular by identifying items that address the full spectrum of phenomena such as disability with true interval or even ratio-level measurement (Lindeboom *et al.*, 2003).

The second development that is required is increased effort directly to compare the performance of measures of assessment of disability. A start has been made. A study made by Katz and colleagues (1992) found that shorter measures of disability were no less sensitive to change than were longer and more detailed instruments. Similarly Wiebe and colleagues (2003) carried out a systematic review of measures of outcome that had been used in randomized controlled trials. They concluded that generic or general-purpose measures of health status were less sensitive to important changes in patients than were more disease-specific measures. More such direct head-to-head comparison of instruments to assess disability is needed mainly to produce a stronger evidence base regarding the comparative performance of instruments, but also to reduce the volume of instruments available.

It is unlikely that major breakthroughs will now occur through development of new instruments. Instead existing methods need to be applied more clearly to identify the value and relevance of existing measures.

Health cognition assessment

Brian McMillan and Mark Conner

University of Leeds

Introduction

Health cognitions are items of knowledge or beliefs about health and illness. These include evaluations of health-relevant behaviours, expectations about the consequences of these behaviours, self-representations, perceptions of social approval or disapproval resulting from engaging in these behaviours, perceptions about the behaviour of others, perceptions regarding one's own abilities and thoughts about one's personal disposition towards engaging in particular behaviours. The assessment of health cognitions is more than merely the rule-based assignment of numerals to objects or events. Assessment must assign values to entities that are theoretically meaningful, and in this respect assessment and theory

go hand in hand. Theory provides us with guidance as to what we should measure, but it is good measurement that theory depends upon.

Self-report methods for assessing health cognitions

Health cognitions are commonly assessed by self-reports measured using Guttman, Thurstone, Likert, or semantic differential scales (Kline, 2000), although only the latter two continue to receive significant attention. Likert scales are less cumbersome than Thurstone's technique without compromising on reliability and validity. Semantic differential scales consist of bipolar adjective

scales where respondents are asked to rate an attitude object (e.g. 'Exercising for 30 minutes, 5 times a week would be ...' Good–Bad). Unlike other techniques, semantic differential scales do not require the development and scaling of specific belief items (see Eagly & Chaiken, 1993).

Important considerations for self-report measures

Since good theory depends upon dependable measurement, it is disappointing that much published work examining health cognitions pays scant attention to reliability and validity. Theory-based measures of health cognitions should be developed by paying the same attention to reliability and validity as we expect from other areas of psychology. Issues which should be considered include face validity (does the measure appear to measure what it purports to measure?), content validity (does it match the defined content domains?), concurrent validity (does it correlate highly with similar measures of this construct?), predictive validity (does it predict a particular criterion?) and construct validity (are the constructs confirmed by factor analyses?). We should also expect health cognition measures to be reliable, internally consistent (commonly measured using coefficient alpha) and ideally there should be additional checks for reliability such as parallel forms reliability (do different versions of the measure correlate highly?). Use of multi-item measures can improve the reliability of measures, yet there are abundant studies in the literature using single item measures of unknown reliability. Since many health cognitions such as attitudes may vary with time, test–retest reliability (do scores from the same measures taken at two separate time points correlate highly?) is less relevant to health cognition measures (cf. Kline, 2000).

Many factors may affect the validity of health cognition measures, such as social desirability and the ordering of items within a questionnaire. Randomization of items within a questionnaire is one defence against order effects, whereas concerns over social desirability can be addressed by ensuring participant confidentiality and anonymity where possible. Inclusion of a social desirability measure will also allow for analyses to ascertain if it has an impact on the relationships between measured variables.

Ajzen's (1988) principle of compatibility emphasizes the importance of matching the elements of action, target, context and time. If we are concerned with predicting behaviour, then it is essential that we are as specific as possible about the nature of this behaviour. For example we could ask; 'I intend to cycle to work every weekday for the next month, unless I am on holiday'. This question contains reference to the action (cycling), the target (place of work), the context (unless they are on holiday) and the time period (every weekday for the next month). This may seem overly pedantic, but were we simply to ask participants if they intended to cycle to work, we would have no idea how often they intended to cycle, or even if they intended to do it any time in the near future. These considerations apply not only to predicting behaviour but also predicting health cognitions. If we wish to examine how well attitudes predict intention, the measures should also be matched in terms of action, target, context and time.

Theories incorporating health cognitions

Social cognition models have become popular frameworks for research aimed at furthering our ability to understand, predict and change health behaviours. Such models include Attribution Theory (AT), the Health Belief Model (HBM), the Theory of Planned Behaviour (TPB), Social Cognitive Theory (SCT), Protection Motivation Theory (PMT) and Health Locus of Control (HLC). Stage models such as the Transtheoretical Model of Change (TTM), and the Precaution Adoption Process Model (PAPM) have become increasingly popular, as have models which incorporate constructs from both these approaches, such as the Health Action Process Approach (HAPA). An in-depth description of each of these models is beyond the scope of this chapter. See Conner and Norman (2005) and chapters on 'Attributions and health', 'The health belief model', 'Theory of planned behaviour' and 'Transtheoretical model of behaviour change'.

Figure 1 shows the core cognitive constructs which have been used to predict health behaviour in the literature. There is much overlap between these theories and constructs often differ on little more than name.

Abraham and Sheeran (2000) identified five core cognitive antecedents of health behaviours: attitude, self-representations, norms, self-efficacy and intention. In order to include attributions and locus of control we have labelled the self-efficacy construct 'control perceptions', and replaced intention with 'disposition to act' as this incorporates constructs from a wider range of theories.

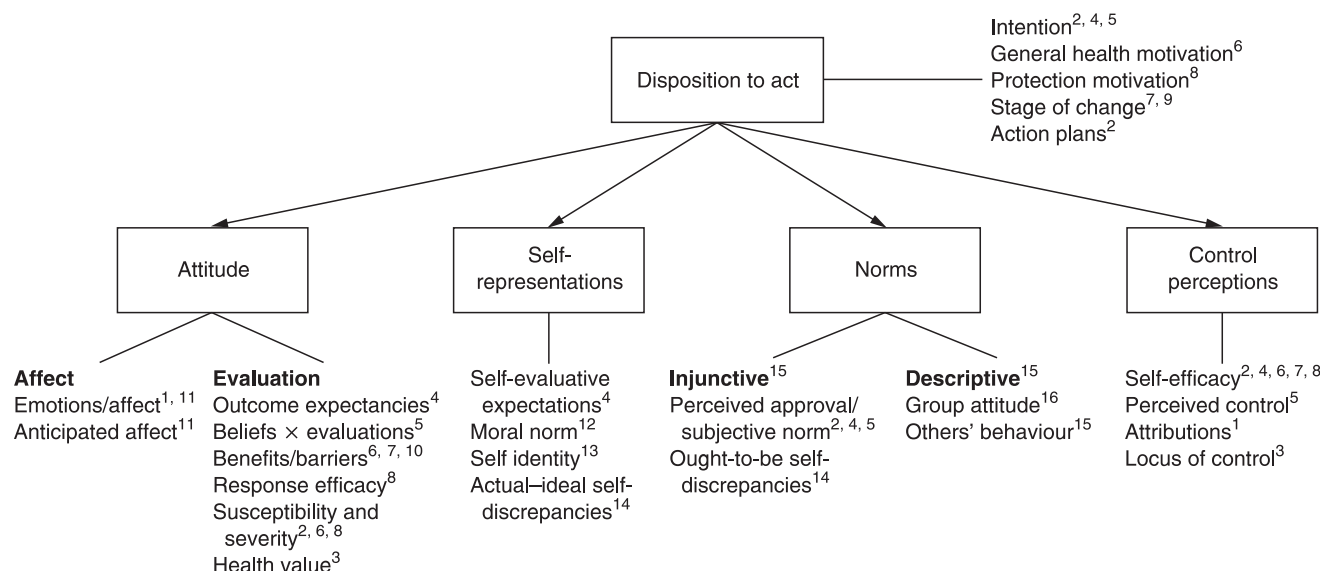

Measuring attitude

Attitudes are typically measured using semantic differential items such as;

My eating fruit as part of my	good	1	2	3	4	5	6	7	bad
midday meal tomorrow	harmful	1	2	3	4	5	6	7	beneficial
would be ...	pleasant	1	2	3	4	5	6	7	unpleasant

The semantic differentials used in such measures should result from careful pilot work, as concerns have been raised that measures of attitude are frequently biased towards their cognitive component (Conner & Sparks, 2005). Weiner's attributional model (1985) includes an 'emotion' construct, but within the context of different attributions leading to different emotions, such as guilt or shame. Work into anticipated affective reactions approaches this issue in a different tense, and considers how anticipated feelings relate to the performance of a behaviour. O'Connor and Armitage (2003) measured anticipated affect with the use of semantic differentials; 'If I deliberately harmed myself I would feel ...' – 'feeble–strong', 'tense–relaxed', 'sad–happy'. Others have focussed on more specific aspects of anticipated affect, such as anticipated regret (Conner & Sparks, 2005).

The evaluative component of attitude is typically measured in terms of 'Performing behaviour X would lead to outcome Y'.

Theories

1. Attribution Theory (e.g. Weiner, 1985, 1986)
2. Health Action Process Approach (Schwarzer et al., 2003)
3. Health Locus of Control (Wallston et al., 1978)
4. Social Cognitive Theory (Bandura, 1986, 1997)
5. Theory of Planned Behaviour (Ajzen, 1991)
6. Health Belief Model (Rosenstock et al., 1988)
7. Transtheoretical Model (Velicer et al., 1998)
8. Protection Motivation Theory (Maddux & Rogers, 1983)
9. Precaution Adoption Process Model (Weinstein, 1988)

Fig 1 Core health cognitions (adapted from Abraham & Sheeran, 2000).

Within the TPB, beliefs and evaluations are measured separately using items such as:

Eating fruit as part of my midday meal tomorrow would make me healthier	unlikely	1	2	3	4	5	6	7	likely
Being healthier would be	bad	1	2	3	4	5	6	7	good

respectively. The beliefs to be included should result from careful pilot work using open-ended questions such as 'what do you think would be the advantages/disadvantages for you of being more physically active in the next twelve months' and 'what would you like or enjoy/dislike or hate about being more physically active in the next twelve months?'

Within the HBM and TTM, the evaluative component of attitude is measured in terms of perceived benefits or barriers of performing a behaviour. For example, Champion (1984) used items such as 'Self breast exams can help me find lumps in my breast' and 'Self breast exams are time consuming' – 'Strongly disagree–Strongly agree' to measure the pros and cons of self breast examination. In PMT, attitudes towards particular behaviours are measured in terms of response efficacy, e.g. 'Regular exercise will reduce my chances of having a heart attack'. The TPB uniquely includes separate assessments of outcome likelihood and outcome evaluation, whereas other models, such as the HAPA, HBM and PMT measure perceived susceptibility to a particular condition and perceived severity of that condition. Champion (1984) measured the HBM components of susceptibility and severity with

items such as: 'There is a good possibility that I will get breast cancer' and 'If I got breast cancer, it would be more serious than other diseases' – 'Strongly disagree–Strongly agree'. Schwarzer *et al.* (2003) recommend similar measures for the HAPA, but suggest that susceptibility should be measured in terms of absolute susceptibility – 'How do you estimate the likelihood that you will ever suffer from ...' – 'very unlikely–very likely' and relative susceptibility 'If I compare myself to an average person of my age and sex, the risk of my suffering from ... is ...' – 'very unlikely–very likely' (see also 'Risk perception').

Measuring self-representations

Self-representations are an important group of health cognitions, although many popular theories fail to include them as a separate component. SCT includes self-evaluative expectations as a subset of outcome expectations. Operationalizations of SCT have measured self-evaluative expectations using items such as 'I would feel more responsible if I used a condom' (NIMH, 2001) and as such they appear very close to measures of anticipated affect. Moral norms also come under the umbrella of self-representations, and have been measured in studies applying the TPB using items such as 'It would be morally wrong for me to deliberately harm myself' and 'Deliberately harming myself goes against my principles' – 'Strongly disagree–Strongly agree' (O'Connor & Armitage, 2003). Self-identity is also an important cognitive antecedent of health behaviour and has been measured using items such as

'I like to think of myself as someone who always thinks carefully about how to cross the road' 'disagree strongly–agree strongly' (Evans & Norman, 2003). Higgins (1987) highlights the importance of perceived discrepancies between our ideal and actual self in terms of how we subsequently behave. Research into this area commonly employs the Selves Questionnaire (Higgins, 1987).

Measuring norms

Normative influences on behaviour form a part of many social cognition models, and are typically measured as perceptions of approval or disapproval of important others. In the TPB subjective norms are measured using items such as;

People who are important to me think I ...
Should 1 2 3 4 5 6 7 Should not ... eat
fruit as part of my
midday meal
tomorrow

and specific normative beliefs are measured using the wording of the item above but replacing 'people who are important to me' with specific referent groups identified from pilot work, such as 'my friends' or 'my partner'. In addition, the TPB includes a measure of motivation to comply for each specific referent group;

With regard to your diet, Not at all 1 2 3 4 5 6 7 Very much
how much do you want
to do what your friends
think you should?

Within the HAPA and SCT, normative beliefs are included in the outcome expectancies component and are measured in terms of social approval or disapproval being a pro or con of following a particular course of action, e.g. 'If I start exercising regularly, then I will receive a lot of praise from my partner'. SCT also incorporates normative beliefs as a form of outcome expectancy, e.g. 'My sex partner would get mad if I said we had to use condoms' (NIMH, 2001).

Cialdini, Reno and Kallgren (1990) noted that normative influences on behaviour should be split into two types; injunctive norms (perceived approval or disapproval) and descriptive norms (perceptions of what others think and do). Descriptive norms are typically measured in terms of perceived behaviour of others, for example 'Most of my friends/family/co-workers exercise regularly' – 'Strongly disagree–Strongly agree'. Group attitudes have been measured using items such as 'To what extent would there be agreement among the people who are important to you that to use a condom every time one had sexual intercourse is a good thing to do?' – 'to a large degree–to a small degree' (White, Terry & Hogg, 1994).

Measuring control perceptions

Self-efficacy has become a part of most major models of health behaviour (see Self-efficacy and health behaviour). It is included specifically in the HAPA, SCT, PMT and has been incorporated

into the HBM and the TTM. Self-efficacy is typically measured using items which contain the wording 'I am confident that I can [perform task X], even if [barrier Y]' (Schwarzer *et al.*, 2003). Velicer, Prochaska, Fava, Norman, and Redding (1998) recommend measuring self-efficacy or temptation when using the TTM, and have developed a measure known as the Situational Temptation Measure. Although many researchers regard self-efficacy and perceived behavioural control as being synonymous, the items which Ajzen (1991) recommended are different from those used to measure self-efficacy. Examples of items used to measure PBC are;

How much control do you
feel you have over eating No control 1 2 3 4 5 6 7 Complete
fruit as part of your midday control
meal tomorrow?
For me to eat fruit as part of Difficult 1 2 3 4 5 6 7 Easy
my midday meal tomorrow
would be.

Ajzen (1991) also recommended measuring the determinants of PBC with control belief measures relating to facilitators and barriers, e.g. 'When eating out there is a limited choice of fruit available' – 'strongly disagree–strongly agree', and corresponding power items, e.g. 'The limited choice of fruit when eating out makes my eating fruit as part of my midday meal tomorrow' – 'much more difficult–much easier'.

Theories which do not specifically measure self-efficacy or PBC include Weiner's (1985) attribution model, the HLC and the PAPM. Attribution theory is concerned with the underlying causes of events, and incorporates cognitions of control. Weiner proposed attributions related to stability (i.e. respondents might be asked to rate if their reasons for not giving up smoking were 'stable over time – variable over time'), locus (e.g. 'Do your reasons for not giving up smoking ... reflect an aspect of yourself – reflect an aspect of the situation') and controllability. Wallston *et al.*'s (1978) Health Locus of Control had split perceptions of control into three separate components a quarter of a century ago; Internal Health Locus of Control (measured with items such as 'If I get sick, it is my own behaviour which determines how soon I get well again' – 'Strongly disagree–Strongly agree'), Powerful Others Locus of Control (e.g. 'Having regular contact with my physician is the best way for me to avoid illness' – 'Strongly disagree–Strongly agree'), and Chance Locus of Control (e.g. 'No matter what I do, if I'm going to get sick, I will get sick' strongly disagree–strongly agree). Although such a measure does not take Ajzen's (1988) compatibility concerns into account, it did undergo more stringent tests for reliability and validity than many of the control measures currently in use and it came in two forms, which allowed for testing of parallel forms reliability.

Measuring disposition to act

Intention measures are employed to measure disposition to act in the HAPA, SCT and TPB and often the protection motivation component of the PMT is operationalized as intention. Conner and Sparks (2005) recommend measuring three components of intention, namely: intention (e.g. 'I intend to eat fruit as part of my

midday meal tomorrow' – 'definitely do not–definitely do'), desire (e.g. 'I would like to eat fruit as part of my midday meal tomorrow' – 'definitely yes–definitely no') and expectation ('I expect to eat fruit as part of my midday meal tomorrow' – 'unlikely–likely'). They note that although multiple-item measures have a psychometric advantage, many studies continue to assess intentions using single-item measures. In the HBM model, disposition to act is termed General Health Motivation and has been measured using items such as 'I frequently do things to improve my health' – 'Strongly disagree–Strongly agree' (Champion, 1984).

Stage theories measure disposition to act in terms of what stage an individual is currently in. For example, Velicer *et al.* (1998) recommend using the following questions to ascertain what stage an individual is currently in: 'Are you currently a smoker' – 'yes' (Smoker), 'no, I quit within the last six months' (action stage), 'No, I quit more than 6 months ago' (maintenance stage), 'No, I have never smoked' (non-smoker). Those who reported being smokers would be asked how many times they have quit smoking in the last 24 hours, and if they are seriously thinking of quitting smoking. Those who state that they are seriously thinking of quitting smoking within the next 30 days and have had one 24 hour quit attempt in the last year are said to be in the 'preparation stage', and those who have not had a previous quit attempt are said to be in the 'contemplation stage'. Those who are thinking of quitting in the next 6 months are also said to be in the contemplation stage, and those who are not thinking of quitting are said to be in the 'precontemplation stage'. The TTM uses items which measure a combination of cognitions (i.e. intention) and behaviour, but has been criticized for numerous reasons, not least because the time periods specified within these measures seem somewhat arbitrary (Sutton, 2005; see also 'Transtheoretical model of behaviour change').

The PAPM uses more of a straightforward measure to categorize an individual into a particular stage; 'Have you ever thought about *behaviour X*' (those who say no are in Stage 1 – unaware of issue), 'Have you *performed behaviour X*' (those who say yes are in Stage 6 – acting), 'Which of the following best describes your thoughts about *behaviour X*' – 'I've never thought about it' (Stage 2 – unengaged), 'I'm undecided' (Stage 3 – deciding about acting), 'I've decided I don't want to ...' (Stage 4 – decided not to act), 'I've decided I do want to ...' (Stage 5 – decided to act). The HAPA similarly includes an additional stage after intention called 'action plans', which are cognitions about how and in what circumstances an intended action is to be implemented. Action plans are assessed using questions such as 'I have my own plans regarding behaviour *X*', 'I have already planned precisely ...': '... when I will perform behaviour *X*', '... where I will perform behaviour *X*', 'how often I will perform behaviour *X*', 'with whom I will perform behaviour *X*' – 'not at all true – exactly true' (Schwarzer *et al.*, 2003). Measured in this way, action plans (or implementation intentions – see relevant entry in this volume) are actually very specific types of intention which take Ajzen's (1988) concerns with action, target, context and time into account.

Alternatives to self-report measures

Problems with self-report measures have led to the development of a range of alternative measures that attempt to minimize problems

of socially desirable responding, either by changing the nature of the self-report measure or avoiding self-report as the basis of measurement. They also tend to have been developed in relation to the assessment of attitude (see Eagly & Chaiken, 1993). It should be noted that while, to differing degrees, these measures avoid problems of socially desirable responding, the reliability and validity of these measures is usually lower than self-report measures.

A range of behaviour measures has been used as alternatives to self-report for example in assessing attitudes. For example, in relation to assessing attitudes toward table salt one might directly assess the amount of table salt used by an individual at a meal and compare this with self-reported attitudes. Alternatively, in judging attitudes towards two different products one might allow individuals to choose one product to take away. In the consumer area, more sophisticated behavioural measures are now used through, for example, examination of supermarket checkout receipts and mapping these onto other measures (cf. Eagly & Chaiken, 1993). Whilst they represent an appealing means of avoiding socially desirable responding their validity is clearly questionable. For example, in relation to the analysis of checkout receipts it is not clear that individual purchase equates with individual use.

Similar problems surround physiological and biomarker measures. For example, both galvanic skin response and pupillary dilation have been used to assess attitudes (see Eagly & Chaiken, 1993). However, whilst strength of reaction may show some mapping onto underlying attitude strength it is not clear that this is a linear relationship and such physiological measures tell us little about the valence of such attitudes. A variety of bio-markers are also increasingly being used. For example, using expelled carbon monoxide levels to tap smoking or blood cholesterol to tap level of fat in the diet. Whilst such measures may provide good predictions of various health outcomes their relationship to behaviour may be weak. Carbon monoxide levels may only tap recent smoking and blood cholesterol is only modestly influenced by dietary changes.

There is also a range of disguised techniques such as the error choice method, estimating the plausibility of different arguments, thought listing and estimating other's responses. In each it is assumed that the individuals underlying attitude will bias their responses in a particular direction (see Eagly & Chaiken, 1993). A different technique is the bogus pipeline (Jones & Sigall, 1971). Originally this was used in relation to attitudes. The original research involved obtaining a prior measure of attitude and then using this information to convince respondents that it will be possible to detect non-accurate responding. A variant on this methodology is to inform respondents that an objective measure of behaviour will be taken and matched with self-report measures. A further set of disguised techniques are so-called projective techniques such as the Thematic Apperception Tests. Here individuals are asked to respond to ambiguous stimuli and their responses are scored in terms of what they indicated about underlying cognitions. The reliability and validity of such measures have been widely questioned, although more recent research has employed them as implicit measures of, for example, personality.

A final set of measures are the so-called implicit measures. These are in fact forms of self-report but are collected in such a way as to minimize socially desirable responding. Probably the most widely applied implicit measure is the Implicit Association Test (IAT, Greenwald, McGhee & Schwartz, 1998). The IAT is a computerized

method for measuring indirectly the strength of the association between pairs of concepts via a discrimination task. It relies on the assumption that, if two concepts are highly associated (congruent), the discrimination task will be easier, and therefore quicker, when the associated concepts share the same response key than when they require a different response key (see Greenwald *et al.*, 1998). Studies have investigated the predictive power of the IAT for behaviours such as smoking (Swanson, Rudman & Greenwald, 2001). The correlations between explicit and IAT measures of attitudes tend to be low (on average in the region of 0.20 to 0.30). A range of other implicit measures have been employed including the Extrinsic Affective Simon Task Dot Probe Tasks and priming measures. Fazio and Olson (2003) provide a useful review of these measures. Whilst minimizing the effects of socially desirable responding there is continuing debate about the aspects of cognitions that these measures tap (Fazio & Olson, 2003).

Summary

The accurate assessment of health cognitions deepens our understanding of why individuals behave in ways that are detrimental

to their health, or fail to behave in ways that are beneficial. The knowledge so gained can be used to develop theory-driven health education programmes and intervention strategies. Health cognitions are commonly assessed by self-reports, although there is a growing level of interest in alternate measures. There are many types of self-report measures, the most popular of which are Likert and semantic differential scales. More attention should be given to the reliability and validity of such scales, for example by the use of multi-item scales or parallel forms. Other factors that should be considered include social desirability, item ordering and the principle of compatibility (matching action, target, context and time). There are many social cognition models which incorporate health cognitions, and there is a great deal of overlap between these theories. Five core cognitive antecedents of health behaviours are: attitude, self-representations, norms, control perceptions and disposition to act.

Since good theory relies upon dependable measurement, it is important that future work in this area pays sufficient attention to the measurement issues described here. Due consideration should be given to issues relating to reliability and validity and the use of alternative techniques in conjunction with well constructed self-report measures is strongly encouraged. (See also 'Illness cognition assessment').

Health status assessment

Ann Bowling

University College London

There is an increasing focus on the measurement of the health outcomes of healthcare interventions. Purchasers of health services want to know how much patients' lives will be improved by potential treatments, evidence of their effectiveness and costs and information about health gain in the broadest sense. But the conceptualization and methods of measurement of health outcomes is still controversial.

In order to measure health outcomes a measure of health status is required which needs to be based on a concept of health. Health indicators have largely been developed within the era of science based on the logical positivist paradigm. This inevitably leads to suspicion when data are presented which are based on subjective experience, rather than objective indicators. Clinicians have traditionally judged the value of an intervention mainly in terms of the five-year survival period. While obviously important in the case of life-threatening conditions, this indicator ignores the living. Many healthcare programmes and interventions will have little or no impact on mortality rates (e.g. in relation to chronic diseases). Survival needs to be interpreted more broadly in terms of the impact and consequences of treatment. And a person's 'ill health' is indicated by feelings of pain and discomfort or perceptions of change in usual functioning and feeling. Illnesses can be the result of pathological abnormality, but not necessarily so. A person can feel ill without medical science being able to detect disease. The World Health Organization's (WHO) (1947) therefore developed a multidimensional definition of health as a 'state of complete physical, mental and social wellbeing and not merely the absence of disease or infirmity'. The WHO (1984) has since added 'autonomy' to this list. Functional theory in sociology regards health broadly, and in the context of society, as the level of fitness and functioning (social, psychological or physical) which a person requires in order to fulfil expected social roles, based on his or her cultural norms. The social sciences not only focus on people's role functioning and social norms, but other perspectives emphasize people's definitions of health and illness and on individuals'

subjective perceptions of their health (see Bowling, 2004 for overview). Phenomenological models hold that humans interpret and experience the world in terms of meanings and actively construct an individual social reality. These models in social science focus on the individual's unique perceptions of their circumstances (O'Boyle, 1997).

Measures of the outcome or consequences of disease, its treatment or care, which are based on patients' own perspectives ('patient-based') can be used to supplement the medical model of disease with a social model of health and ability. Their use helps to answer the question of whether the treatment leads to a life worth living from the patient's perspective. What matters is how the patient feels, rather than how others think they feel. Outcome assessment, then, needs to incorporate patient-based, subjective assessments as well as clinical indicators. In recognition of the need for a more positive focus, there has been an exponential increase in the additional use of indicators of broader health status and health related quality of life over the past two decades (Garrett *et al.*, 2002). However, most measures still take health as a starting point and measure deviations away from it (deteriorating health), rather than also encompassing gradations of healthiness. A perspective which captures the positive end of the spectrum is required to create a balance. In contrast to the emphasis on negative health, Merrell and Reed (1949) proposed a graded scale of health from positive to negative health. On such a scale people would be classified from those who are in top-notch condition with abundant energy, through to people who are well, to fairly well, down to people who are feeling rather poorly and finally to the definitely ill. The word 'health' rather than 'illness' was chosen deliberately to emphasize the positive side of this scale. Despite the existence of single item ranking scales asking people to rate their health from 'excellent' to 'very poor', the development of a broader health status scale along such a continuum is still awaited.

Broader measures of health status generally focus on individuals' subjective perceptions of their physical, psychological and social

health. Many studies in medical sociology have indicated the importance of the perceptual component of illness in determining whether people feel ill or whether they seek help. Standardized items or measures of subjective, broader health status are increasingly included in population health surveys, in evaluations and clinical trials of service interventions. These are measures which ask people to rate their own health status and the impact of their health on various aspects of their lives. They are often referred to as patient-based measures. Detailed information about self-perceived health and its effects can be collected from large numbers of people using self-report questionnaires. They can be administered to the target group of interest by post, telephone, by computers, in clinic settings, or in face to face home interviews. The group of interest may be a patient or client group or a sample of the general population, depending on the aims of the study. Survey information about subjectively perceived health and illness at population level is now collected routinely by many governments worldwide.

Scales of subjective, broader-health statuses are more stable, and have better reliability and validity than single item questions and are the preferred instruments to use. The most commonly used instrument across the world is the Short Form-36 Health Survey Questionnaire (Ware *et al.*, 1993, 1997). On the other hand, some single items, despite some instability, are popularly used in general, multi-topic population surveys. A popular single-item measure consists of simply asking respondents to rate their health as 'excellent, good, fair or poor'. In order to increase the question's ability to discriminate between groups, researchers now insert a 'very good' category in between 'excellent' and 'good' (given that most respondents are affected by social desirability bias and rate their health at the 'good' end of the scale spectrum) (Ware *et al.*, 1993). This single-item measure of self-perceived health status has long been reported to be significantly and independently associated with use of health services, changes in functional status, mortality and to rates of recovery from episodes of ill health (e.g. National Heart and Lung Institute, 1976; Siegel *et al.*, 2003). The increasing emphasis on the patient's perspective has represented a paradigm shift in the approach to the operationalization and measurement of health outcomes (O'Boyle, 1997) (see also 'Quality of life assessment' and 'Disability assessment').

Self-rated health status may be contextual and vary over time with people's varying expectations. It should be cautioned that being in poor mental health can distort perceptions of health and wellbeing; being in poor physical health can lead to poor mental health and wellbeing, and vice versa. People's self-ratings of their health can also be subject to optimism, social desirability and other biases (Brissette *et al.*, 2003). Thus self-ratings of health are often criticized

as subjective, although their subjectivity is their strength because they reflect personal evaluations of health.

Other health measurement formats, which are commonly used in studies of health status, are symptom checklists. These also have their limitations, but are generally considered to be useful tools if used in conjunction with scaled measurement techniques. There are numerous examples of checklists of symptoms presented to respondents in surveys. Respondents are typically asked to indicate which, if any, they currently suffer from. General symptom checklists can be found in the Rand Health Insurance Study Questionnaires (Stewart *et al.*, 1978). Disease specific quality of life questionnaires usually contain a list of symptoms relevant to the condition under study (see Bowling, 2001). However, items focusing on trivial problems are unlikely to have much discriminatory power in terms of monitoring change between groups over time. They may include response errors and diagnostic errors. Reporting of morbidity depends on symptom tolerance levels, pain thresholds; attitudes towards illness and other social and cultural factors.

The researcher also has to decide whether a general and/or specific measure of health status is required, depending on the nature of the study. There is little point in including a health status measure if it is unlikely to detect the effects of the treatment or symptoms specific to the condition. The case for using general health rather than disease-specific measures, in population surveys has been clearly argued by Kaplan (1988). For example, detailed information about specific disease categories may appear overwhelming to many respondents not suffering from them. Also the use of disease-specific measures precludes the possibility of comparing the outcomes of services that are directed at different groups suffering from different diseases. Policy analysis requires a general measure of health status, which research on clinical outcomes also requires the use of disease-specific indicators.

In sum, there are multiple influences upon patient outcome, and these require broad models of health to underpin outcome measurement. Investigators need to be clear about their definition of health status and select a measuring instrument which clearly operationalizes and measures that definition.

Illness cognition assessment

Ad A. Kaptein¹ and Elizabeth Broadbent²

¹Leiden University Medical Center

²The University of Auckland

Introduction

Illness cognitions refer to 'individuals' common-sense definition of health threats' (Leventhal *et al.*, 1998, p. 719), and 'the patient's perception and understanding of the disease and treatment' (Leventhal *et al.*, 1986, p. 176). Concepts used as synonyms are illness beliefs, illness perceptions, illness representations, illness schemata and lay beliefs about illness (Scharloo & Kaptein, 1997). An elaborate and formal definition is proposed by Lacroix (1991): 'a distinct, meaningfully integrated cognitive structure that encompasses (1) a belief in the relatedness of a variety of physiological and psychological functions, which may or may not be objectively accurate; (2) a cluster of sensations, symptoms, emotions and physical limitations in keeping with that belief; (3) a naïve theory about the mechanisms that underlie the relatedness of the elements identified in (2); and (4) implicit or explicit prescriptions for corrective action' (p. 197).

Social cognitive models propose that individuals develop their own mental representation of health threats and these cognitions guide coping responses and set the criteria for appraisal of outcomes. Individuals' responses to stimuli, such as physical symptoms and signs, are partly determined by individuals' cognitions (or ideas, thoughts, views) about those stimuli. Social cognition models aim to shed light on these cognitions in order to describe, understand and change responses of individuals to these stimuli (Conner & Norman, 1996). The concept of 'lay illness models' is related to the illness cognition concept (Schober & Lacroix, 1991) (see 'Lay beliefs of health and illness'). In contrast, the concept of 'health cognition' pertains to items of knowledge or beliefs about health; it is discussed elsewhere in this Handbook

(see 'Health cognition assessment'). The following sections describe the chronological development of assessment tools in illness cognition.

Interviews

A number of face to face interview techniques have been used to assess illness cognitions over the past 50 years. One of the earliest interviews was reported in a study by Bard and Dyk (1956) on the significance of beliefs of patients with various types of cancer regarding the causes of their condition. Interviews identified two categories of beliefs; self-blaming on the one hand and 'projective', i.e. blaming factors external to the patient, on the other. The authors described the relevance of causal beliefs for seeking medical care, adherence and behavioural outcomes, as well as the importance of concordance between patients and healthcare providers regarding causal beliefs.

Anthropologist and psychiatrist Kleinman used open interviews to explore illness representations in patients and healthy respondents in non-western, Asian countries. The theoretical focus was inspired by medical anthropology: to find explanations of how people make sense of health and illness in different cultures. The open interviews aimed at assessing explanatory models, 'the notions about an episode of sickness and its treatment that are employed by all those engaged in the clinical process' (Kleinman, 1980, p. 105). Observations and open interviews resulted in identifying a number of categories of illness representations that respondents used to make sense of illness and its treatment. Aetiology, onset of symptoms, pathophysiology, course of illness, treatment, were the categories observed (Kleinman *et al.*, 1978, p. 256).

These dimensions are quite similar to the ones used in illness cognition theories that were developed some 20 years later, such as the Common Sense Model of illness (Leventhal *et al.*, 1980).

Leventhal and colleagues conducted open-ended interviews with patients with chronic illness and identified four themes for how people think about illness: identity, timeline, consequences and cause (Leventhal *et al.*, 1980; Leventhal & Nerenz, 1985; Meyer *et al.*, 1985). Asking patients why they had recovered from everyday illnesses such as the flu, Lau and colleagues identified an additional cure/control theme to illness representations (Lau *et al.*, 1989; Lau & Hartman, 1983).

Some interviews have been designed for specific populations based on the themes from the Common Sense Model of illness, such as an interview for epilepsy patients (Kemp & Morley, 2001) which incorporates both open and closed questions and takes approximately 30 minutes. The Personal Models of Diabetes Interview (Hampson, Glasgow & Toobert, 1990) is also based on Leventhal's self-regulation theoretical framework and uses a combination of open and closed questions to assess 'personal models', defined as patients' cognitive representations of their disease. This research identified the dimensions: cause, symptoms (identity), treatment (cure/control) and seriousness (course and consequences). A later study (Hampson *et al.*, 1994), found similar results in a sample of patients with osteoarthritis, which lends further empirical support for the dimensions of illness representations.

One open-ended patient interview assesses the accuracy of patients' illness schemata compared with the views of their treatment specialist (Lacroix, 1991). The Schema Assessment Instrument focuses on assessing the patient's symptoms and their interpretation of these with regard to their medical condition. These are matched to medical evidence to attain an overall understanding score. Using this interview, functioning has been found to be better related to schema accuracy than to medical severity of the condition in chronic respiratory patients (Lacroix *et al.*, 1991). However, the Schema Assessment Interview is limited to assessing the objective accuracy of schemata and has received little use, as researchers more commonly assess the content of representations than their accuracy.

A review of the assessment of illness perceptions in chronic somatic patients between 1985 and 1995 found 101 studies; the most common method used to assess illness perceptions in these studies was the open-ended interview (Scharloo & Kaptein, 1997; Kaptein *et al.*, 2001). In the majority of these studies, patients' answers were recorded verbatim and then rated into categories. All interviews in the review assessed causal representations, and some interviews assessed all five dimensions of illness representation.

Many of the in-depth semi-structured interviews conducted in the early explorative phase of illness perceptions were very time-consuming and produced a large variation in the quantity and quality of response (Weinman *et al.*, 1996). Furthermore, in many cases there has been no information published on their psychometric validity. This type of assessment is most suited to the exploratory phase and instruments to assess specific attributes of representations are more useful for hypothesis testing which has led to the development of psychometrically validated questionnaires.

Questionnaires

One of the earliest questionnaires on illness cognition stemmed from the work of Osgood *et al.*, on 'The measurement of meaning', which led researchers in the public health area to use the semantic differential technique as a method to assess the meaning respondents (patients) attach to a certain stimulus or concept, relevant to health and illness (Jenkins, 1966; Osgood *et al.*, 1957). Jenkins adapted the semantic differential technique to health and illness by developing the Semantic Differential for Health (SDH). The SDH had 16 items assessing various dimensions of beliefs about different illnesses (e.g. poliomyelitis, tuberculosis, cancer, mental illness). The three original semantic differential dimensions – evaluative, potency, activity – were operationalized in a questionnaire with the 16 items that had 2 to 6 response categories, depending on the item. Factor analysis produced dimensions of beliefs about illness that were labelled personal involvement, human mastery and social acceptability (Jenkins & Zyzanski, 1968). This work is important in itself within the context of assessing illness cognitions, and it laid the foundations for work on the Health Belief Model (Becker *et al.*, 1977; see 'Health belief model').

Rating scales have been a popular way to assess illness perceptions, but in many cases studies have assessed just one or two dimensions and used separate scales for each dimension (Scharloo & Kaptein, 1997), such as the Multidimensional Health Locus of Control Scale (Wallston *et al.*, 1978) to measure control beliefs. Some measures of illness cognitions have been developed for use with specific populations, for example, the Pain Beliefs and Perceptions Inventory (Williams & Thorn, 1989), which assesses causes and timeline using a 16-item scale scored on a 4-point Likert scale, and the 24-item true-false response Survey of Pain Attitudes (Jensen *et al.*, 1987) (measuring dimensions akin to consequences and control). These scales are limited in their applicability to illness population types other than pain. Other scales have been designed with the ability to be applied to many different patient populations, and an advantage of these generic questionnaires is that they facilitate comparisons across illness populations.

Turk *et al.* (1986) set out to examine 'implicit models of illness' and to clarify differences in outcome between patients with various illnesses and complaints, chronic pain in particular. The Implicit Model of Illness Questionnaire (IMIQ) was developed as a generic instrument to assess illness cognitions. The questionnaire contains 38 items on a 9-point scale that are theoretically based, i.e. it aimed to examine whether the dimensions in Leventhal & Nerenz model (1985) could be identified. It was found via factor analytic techniques that the IMIQ items had four dimensions: seriousness, personal responsibility, controllability and changeability. In this study the respondents were not only groups of patients, but also nurses and healthy students using contrasting illnesses such as the flu, cancer and diabetes. This research has been criticized for not constructing the scale with patient samples rating their own illness (Weinman *et al.*, 1996), as well as the way the data were analysed (Lau *et al.*, 1989). Subsequent research with a rheumatic arthritis sample found a different factor structure: curability, personal responsibility, symptom variability and serious consequences (Schiaffino & Cea, 1995). These problems have resulted in little subsequent use of the questionnaire.

Other studies have also found that factor analysis of theoretically derived items from the Common Sense Model reveals different clustering of items depending on the illness. For example, in a study of chronic fatigue patients, factor analysis revealed four factors identified as manageability, seriousness, personal responsibility and external cause, while in Addison's disease patients the factors were seriousness, cause, chronicity and controllability (Heijmans & de Ridder, 1998). Some researchers argue that assessment should involve factor analysis of the items (Heijmans & de Ridder, 1998; Turk *et al.*, 1986), but analysis usually reveals dimensions that are similar to the theoretical domains (Hagger & Orbell, 2003). Keeping the theoretical factor structure of the core domains keeps the representations true to theory derived from open-ended interviews, and allows comparisons across studies and across illnesses.

The publications by Leventhal and his associates are a major source of theoretical and empirical work in the illness cognition or illness representation field (e.g. Leventhal *et al.*, 2003). This theoretical work led Weinman, Petrie, Moss-Morris & Horne (1996) to develop the Illness Perception Questionnaire (IPQ). The IPQ is a theoretically-derived 38-item multifactorial pencil and paper questionnaire which assesses all five cognitive components of illness representations: identity, timeline, consequences' cause and cure/control. Identity is assessed by asking respondents how frequently s/he now experiences 12 symptoms as part of their illness. The cause, timeline, consequences and control/cure dimensions are assessed with 26 5-point Likert type questions, ranging from 'strongly agree' to 'strongly disagree'. Examples of items are, 'My illness will last a short time' (timeline), 'My illness has major consequences on my life' (consequences) and 'There is a lot which I can do to control my symptoms' (control/cure) and 'Stress was a major factor in causing my illness' (cause). The IPQ timeline scale has lower than desirable internal consistency and the cure/control scale loads on two factors, self-efficacy and treatment beliefs; the IPQ was therefore revised to improve its measurement properties and to extend its scope (Moss-Morris *et al.*, 2002). The Illness Perception Questionnaire – Revised (IPQ-R), extends the original scale by adding more items, splitting the control dimension into personal control and treatment control, incorporating a cyclical timeline dimension, an overall comprehension of illness factor and an emotional representation (Moss-Morris *et al.*, 2002). The IPQ-R assesses identity by asking patients whether or not s/he has experienced each of 14 symptoms since their illness; then they are asked whether they believe the symptom is specifically related to their illness. Causes are assessed by asking patients whether they agree or disagree with a list of causes for their illness and the scale also includes an open-ended item asking patients to list the three most important causes for their illness. However, with all these additions, a drawback of the IPQ-R is that it has over 80 items. In some situations such a long questionnaire can be prohibitive.

The publication of the Illness Perception Questionnaire and its revised form represented a breakthrough in the area of assessing illness perceptions because the scales are theoretically derived, simple to administer, comprehensive, psychometrically validated and easily adaptable to different populations. These scales have been used in over 100 published papers and are available on the IPQ website (<http://www.uib.no/ipq/>).

The Brief Illness Perception Questionnaire is a newly developed 9-item scale designed to rapidly assess illness representations (Broadbent *et al.*, 2006). It has been suggested that instruments assessing specific attributes of illness representation take one of two forms (Leventhal & Nerenz, 1985): specific scales can be used to assess factors, or single-item measures can be used to measure particular variables. As illness perceptions are now well defined, single items may be better suited to their assessment than multiple items designed to assess latent factors (Leventhal & Nerenz, 1985).

In the Brief IPQ, single-item scales from 0 to 10 are used to assess consequences, timeline, personal control, treatment control, identity, coherence, concern and emotional responses; for example, 'How long do you think your illness will continue?', answered from 0 'A very short time' to 10 'Forever' (timeline). Causes are assessed by an open-ended response item. This questionnaire is likely to be especially useful when participants are very ill or elderly, when illness perceptions are measured as only one part of a larger set of psychological constructs, in large population-based studies, when repeated measures are taken on a frequent basis and in longitudinal studies designed to demonstrate changes in illness representations as a result of coping and appraisal.

The Illness Cognition Questionnaire has been recently developed to assess adjustment cognitions, namely helplessness, acceptance and perceived benefits (Evers *et al.*, 2001). Rather than focusing on the mental representation of illness, this questionnaire focuses on the next stage of the Common Sense Model which involves coping and appraisal. Patients are asked to rate 18 items on a 4-point agree-disagree Likert scale, for example 'My illness frequently makes me feel helpless'.

Causal attributions

Causal attribution models examine perceptions of causes of past events. Causal attributions can be assessed through open-ended questions or through participant responses to experimenter-generated causal lists, such as the list included in the IPQ-R. There is some evidence for convergent validity between open-ended and structured questionnaires for eliciting causal beliefs. The responses generated on the causal dimension for heart attacks from studies using open-ended questions have been compared to responses from studies using experimenter generated lists (French *et al.*, 2001). The review found no evidence for different patterns of attributions when the responses were respondent-or experimenter-generated. However, there were differences in the frequency of some of the causal items endorsed when response scales were dichotomous compared to interval-rating scales. The advantage of the open-ended questions is that patients' responses are not limited to the listed items.

The Symptom Beliefs Questionnaire has been developed specifically for the assessment of causal attributions for symptoms prior to contact with a general practitioner (Salmon, Woloshynowych & Valori, 1996). Patients are asked whether they believe a list of 50 items are a cause of their symptoms with the responses 'probably has', 'don't know', or 'probably has not'. Eight dimensions emerge from factor analysis – stress, lifestyle, wearing out, environmental, internal-structural, internal-functional, weak constitution and concern.

Drawings

The assessment of illness representations has largely relied on language-based interviews and questionnaires. An alternative approach to the assessment of illness perceptions asked patients to draw what they thought had happened to their heart after a heart attack (Broadbent *et al.*, 2004). Patients tended to draw damage and/or blockages on their heart. A smaller number of patients drew emotions or the causes of their heart attack on their heart. The drawings were able to quantitatively assess damage perceptions from the percentage of the heart drawn as damaged. Greater damage perceptions predicted slower return to work and poorer perceptions of recovery at three months after the heart attack. Figure 1 shows an example of a patient's drawing of his/her heart. Drawings are able to identify idiosyncratic perceptions of illness that are not easily assessable by questionnaire. Drawings may be particularly useful for patients who cannot express themselves in language or for children. Further work needs to assess the ability of drawings to assess illness cognitions in other illnesses.

Assessment populations

The majority of studies have assessed illness cognitions in adult patient populations with chronic illness, however illness cognitions have also been assessed in other populations including: children (for example, Koopman *et al.*, 2004; Walker *et al.*, 2004); relatives of patients, for example mothers (Leiser *et al.*, 1996) and spouses (for example (Weinman *et al.*, 2000); healthcare providers (for example, Richardson *et al.*, 2001); and society (for example, Liddell *et al.*, 2005). In addition to assessing illness representations in patients with various physical disorders, illness cognitions

Fig 1 A patient's perception of his/her heart after a heart attack assessed through drawing.

have also been assessed in patients with psychiatric disorders (e.g. Lobban *et al.*, 2004).

Most work in assessing illness cognitions has aimed at describing the illness cognitions of various samples of respondents (e.g. patients, physicians, other healthcare providers), without paying attention to whether these cognitions are consistent with 'objective' descriptions of the illness or complaint under study. This emphasis is almost a logical consequence of the idea of illness cognitions in the first place, i.e. examining the idiosyncratic, subjective definition of symptoms and physical states. Two lines of research extend to the examining of illness representations, however, namely the work by Lacroix (1991) on concordance vs. divergence of illness perceptions with health professionals, and the work on match/mismatch between the patients' and their partners' perceptions of illness and symptoms (e.g. Figueiras & Weinman, 2003).

Examining the illness representations of not only the patient but of those around the patient, and using the degree of correspondence between the two parties is increasingly applied in health psychology research. The study by Figueiras and Weinman (2003) is a good example: patients with a myocardial infarction and their partners/spouses both completed the IPQ-R. Higher concordance (i.e. similar positive perceptions) on the dimensions of the questionnaire was associated with a more favourable outcome, expressed as better physical, psychological and sexual functioning and as less impact of the myocardial infarction on social and recreational activities.

Applications from assessing illness cognitions

Assessing illness cognitions not only allows research into how patients understand and respond to illness but also offers a theory-based intervention target to improve outcomes. Petrie *et al.*'s trial of an individually tailored psychological intervention in patients with a myocardial infarction is exemplary in this respect (Petrie *et al.*, 2002): a brief hospital-based intervention designed to alter negative cognitions resulted in quicker return to work and improved functional outcomes following myocardial infarction. In other work, negative consequence beliefs in patients with dizziness have been shown to predict sustained activity restriction and these beliefs have been shown to be modifiable by therapy (Yardley *et al.*, 2001). There has also been some promising work attempting to teach healthcare providers to recognize, challenge and change illness perceptions in their patients in order to improve illness cognitions and adherence (Theunissen *et al.*, 2003).

IQ testing

Robert J. Sternberg

Tufts University

In this chapter, we first consider what intelligence is. Then we discuss the nature of IQ and its relation to intelligence. The two main test batteries that are used to assess IQ are described. Next we discuss the history of intelligence testing that led up to these tests and some of the main psychometric theories which underlie IQ testing. Mean differences among various groups in scores on tests of IQ are defined and illustrated. Finally we draw some conclusions.

What is intelligence?

In 1921, 14 famous psychologists presented their views on the nature of intelligence in a symposium organized in the *Journal of Educational Psychology* (see 'Intelligence and its measurement: a symposium', 1921). Although their responses varied, two themes became clear: intelligence comprises (1) the ability to learn from experience and (2) the ability to adapt to the surrounding environment. These themes are important. Ability to learn from experience implies, for example, that more intelligent people learn from their mistakes. They do not keep making the same ones again and again. Adaptation to the environment means that being intelligent goes beyond getting high scores on tests. It includes how you perform in school, handle a job, get along with other people and manage your life in general.

Sixty-five years after the initial symposium, 24 different experts of a later generation were asked to give their views on the nature of intelligence (R.J. Sternberg & Detterman, 1986). They too noted the standard themes of learning from experience and adapting to the environment. However, these experts also put more emphasis on the role of 'metacognition', i.e., people's understanding and control of their own thinking processes (during problem-solving, reasoning and decision-making), than did earlier experts. Contemporary experts also more heavily emphasized the role of culture.

They pointed out that what is considered intelligent in one society may be considered stupid in another.

Some psychologists, such as Edwin Boring (1923), have been content to define intelligence as whatever it is that what sometimes are called 'IQ tests' measure. This definition, unfortunately, is circular because according to it, the nature of intelligence is what is tested, but what is tested must necessarily be determined by the nature of intelligence. Moreover, what different tests of intelligence test is not always exactly the same thing. Different tests measure somewhat different constructs (Daniel, 1997, 2000; Kaufman, 2000; Kaufman & Lichtenberger, 1998), so it is not feasible to define intelligence by what tests test, as though they all measured precisely the same thing. What they test is due, in large part, to a Frenchman of the early twentieth century named Alfred Binet.

The Intelligence Quotient (IQ)

To this day, schools usually segregate children according to their physical, or chronological, age. In the early twentieth century, Alfred Binet, a Frenchman, suggested that we might assess children's intelligence on the basis of their mental age. This age is a score indicating the chronological age of persons who typically perform at the same level of intelligence as a test taker. If, for example, someone's performance on a test is at a level comparable to that of an average 12-year-old, the person's mental age will be 12, regardless of the chronological age. Suppose, for example, that José is 10 years old, but his performance on a test of intelligence is equal to that of the average 12-year-old. His mental age would be 12. Mental age also conveniently might suggest an appropriate grade placement in school.

William Stern, a German psychologist, noted that mental age is of doubtful usefulness for comparing levels of intelligence in

children who differ in chronological age. Stern (1912) suggested instead that we measure intelligence by using an intelligence quotient (IQ): a ratio of mental age (MA) divided by chronological age (CA), multiplied by 100. This ratio can be expressed mathematically as follows:

$$IQ = (MA/CA) \times 100$$

Thus, if Anita's mental age of 5 equals her chronological age of 5, then her intelligence is average, and her IQ is 100, because $(5/5)(100) = 100$. People whose mental age equals their chronological age always have IQs of 100 because the numerator of the equation equals the denominator, giving a quotient of 1. Suppose Bill's mental age of 4 is only half of his chronological age of 8. Then his IQ is 50, because the quotient is $\frac{1}{2}$, and half of 100 is 50. Subsequent investigators have suggested further modifications of the IQ. As a result, Stern's particular conception of expressing intelligence in terms of a ratio of mental age to chronological age, multiplied by 100, is now termed a ratio IQ.

Unfortunately, the concept of mental age proved to be a weak link in the measurement of intelligence, even when used for calculating a ratio IQ. First, increases in measured mental age slow down at about the age of 16 years. Compare what you knew and how you thought when you were 8 years old with what you knew and how you thought when you reached 12 years old. Quite a difference! Now think about someone who is 30 years old. Do you imagine that person's knowledge and thought processes to be very different from what they will be at age 45? It makes sense to say that an 8-year-old who performs at the level of a 12-year-old has an IQ of 150. But it makes no sense at all to say that a 30-year-old who performs at the level of a 45-year-old has an IQ of 150. The reason is that the intellectual performance of a typical 45-year-old usually differs only minimally from that of a typical 30-year-old. Indeed, in older age, scores on some kinds of mental tests actually may start to decrease. When measuring across the whole life span, it seems less than effective to base the calculation of intelligence on mental age.

Intelligence tests

A number of tests of intelligence measure various kinds of cognitive skills (Daniel, 1997, 2000; Kaufman, 2000). These tests are based largely on the notion that intelligence is a function of judgments of a fairly academic kind. The two main tests derive respectively from the work of Alfred Binet and David Wechsler.

The Stanford-Binet Intelligence Scales

One major test derives from the work of Alfred Binet, mentioned above. The most recent revision, the Stanford-Binet Intelligence Scales, fifth edition (Roid, 2003), or Stanford-Binet V, as it is sometimes called, is designed for age levels ranging from two to ninety+ years and, like the original test, is administered to people individually in an untimed fashion. The ten tests in the scale together measure reasoning abilities, general knowledge, visual-spatial abilities and working memory (simultaneous storage and processing of information). The Stanford-Binet V emphasizes verbal and nonverbal abilities equally. Also, for this scale and all

other modern intelligence scales, the traditional ratio IQ has been replaced by a deviation IQ, which indicates a person's performance relative to other people of the same chronological age.

The Wechsler scales

There are three Wechsler scales. Each of the Wechsler scales currently used is designed for a different age group. The Wechsler Preschool and Primary Scale of Intelligence, Version III (WPPSI-III), is administered to children ranging in age from two and a half years to approximately seven years. Younger children are administered a different part of the scale than are older children. For younger children, the verbal part of the WPPSI-III contains tests of vocabulary and basic knowledge about the world. The performance part of the scale includes tests that require children to create pictures of common objects using jigsaw puzzle pieces and to reproduce a design using building blocks. For older children there are additional tests of verbal comprehension and perceptual classification skills. Also, both the verbal and performance parts of the WPPSI-III for older children contain additional tests which assess reasoning.

The Wechsler Intelligence Scale for Children, Version IV (WISC-IV), is administered to children ranging in age from 6 years to 16 years. The tests on the WISC-IV are similar in nature to the WPPSI-III, though they are more difficult as is appropriate for older children. The WISC-IV also includes tests of memory and reasoning that the WPPSI-III does not include.

The Wechsler Adult Intelligence Scale, Version III (WAIS-III), is administered to adults ranging in age from 16 to 89 years, and contains 14 tests. The primary difference between the WAIS-III and its companion scale for children, the WISC-IV, is the inclusion of several tests that assess working memory and more difficult items. Like Binet, Wechsler (1974) recognized that intelligence goes beyond what his own test measures. We use our intelligence in relating to people, in doing our jobs effectively and in managing our lives in general. In fact, intelligence tests predict performance in a variety of real-world pursuits, such as education (R. Mayer, 2000) and the work force (Schmidt *et al.*, 1992; Wagner, 1997).

Where do tests such as the Stanford-Binet and the Wechsler come from? The next section explores their origins and history.

The history of IQ testing

In 1904, the Minister of Public Instruction in Paris named a commission to find a means to differentiate mentally 'defective' children from those who were unsuccessful in school for other reasons. The commission was to ensure that no child suspected of retardation be placed in a special class without first being given an examination. Alfred Binet and his collaborator, Theodore Simon, devised tests to meet this requirement. Thus, theory and research in the tradition of Binet grew out of practical educational concerns. To Binet and Simon (1916), the core of intelligence is judgement and common sense.

Binet's ideas were brought to the United States primarily by Lewis Terman. The first major revision was completed by Terman (1916), who translated and renamed the test (to the Stanford-Binet Intelligence Scales) for American use. In the United States,

intelligence testing came into its own in World War I. Practical concerns regarding military recruitment and placement required tests that could be administered to several people at one time in order to meet the US Army's demands for the rapid testing of a large number of men. The shift from one-on-one testing to group testing required substantial changes to intelligence test design. These changes included (1) the presentation of brief, written items in lieu of more complicated tasks requiring detailed instructions; (2) the replacement of examiner judgement with objective, right/wrong scoring techniques; (3) the imposition of time limits for test completion; and (4) the development of test problems appropriate for adults. The familiarity of these test characteristics to most readers of this book shows how lasting these changes have proven to be.

The staying power of group intelligence tests can be attributed primarily to their tremendous efficiency relative to assessments that must be administered individually. Brief, written items with simple instructions eliminate the need for a highly trained examiner to explain the requirements of each test in the scale. In addition, objective scoring techniques are much quicker and less prone to error than are scoring techniques dependent on the subjective judgement of the examiner. Time limits for test completion have obvious implications for the efficiency of test administration. An important disadvantage of group testing, however, is that it often limits the kinds of performances which can be assessed. For example, basic motor abilities, such as finger tapping or bodily coordination, are not easily assessed when the examinee-examiner ratio is greater than 1:1.

The Army Alpha, created by Arthur Otis as an adaptation of the Stanford-Binet intelligence scale, was the first group intelligence test developed to meet the army's recruitment and placement needs. It assessed various reasoning skills and basic cultural knowledge. Due to high rates of illiteracy among military recruits, a companion test, the Army Beta, was designed to use nonverbal means for assessing intelligence. Instead of presenting examinees with written instructions, pictorial instructions were used and examiners pantomimed the requirements of each test. The Army Beta assessed perceptual speed, memory and reasoning with pictures. Together, the Army Alpha and Army Beta were administered to over a million men, and proved useful for making placement decisions.

A major contributor to testing in the early twentieth century was David Wechsler, the modern versions of whose tests are discussed above. Based on his experiences scoring and administering intelligence exams for the army, he developed his own series of intelligence scales, starting with the Wechsler-Bellevue Intelligence Scale (Wechsler, 1939). This individually-administered scale featured both verbal and non-verbal, or performance, tests, reflecting Wechsler's belief that intelligence is expressed in both verbal and nonverbal ways. Although Wechsler's ideas ran against the commonsense belief that nonverbal, or performance, testing was inefficient, the revised and expanded versions of his intelligence scales are probably the most widely used today.

Theories of intelligence underlying IQ tests

Underlying IQ tests is a notion of intelligence as some kind of 'map of the mind' (Sternberg, 1990). The view of intelligence as a map of

the mind extends back at least to the 1800s, when phrenology was in vogue. During the first half of the twentieth century, the idea that intelligence is something to be mapped dominated theory and research. The psychologist studying intelligence was both an explorer and a cartographer, seeking to chart the innermost regions of the mind. Like other explorers, those psychologists needed tools. In the case of research on intelligence, a useful tool appeared to be factor analysis. This method of statistical analysis allows an investigator to infer distinct hypothetical constructs, elements, or structures (called factors) that underlie a phenomenon. In this case, some intelligence researchers have believed that these factors form the basis of individual differences in test performance. The actual factors derived, of course, depend on the particular questions being asked and the tasks being evaluated. This approach continues to be used actively today (see e.g. J.B. Carroll, 1993; Brody, 2000; Embretson & McCollam, 2000; Jensen, 1998).

Among the many competing theories, the main ones have been of a single general factor that dominates intelligence; of multiple, equally important abilities constituting intelligence; and of a hierarchy of abilities contributing to intelligence.

Charles Spearman: the *g* factor

Charles Spearman is usually credited with inventing factor analysis. Using factor-analytic studies, Spearman (1927) concluded that intelligence could be understood in terms of both a single general factor (called *g*). This factor pervades performance on all tests of mental ability and a set of specific factors (called *s*), each involved in performance on only a single type of mental ability test. (A specific ability might be arithmetic computation.) In Spearman's view, the specific factors are of only casual interest, due to their narrow applicability. The general factor, however, provides the key to understanding intelligence. Spearman believed that *g* derives from individual differences in mental energy. The view that there is a general factor of intelligence persists among many contemporary psychologists (e.g. Demetriou, 2002; Detterman, 2002; Gottfredson, 2002; Kyllonen, 2002; Humphreys & Stark, 2002; Jensen, 1998, 2002; Petrill, 2002), although other psychologists furiously debate this issue (Berg & Klaczynski, 2002; Grigorenko, 2002; Kray & Frensch, 2002; Lautrey, 2002; Naglieri & Das, 2002; Stankov, 2002; Sternberg, 1999, 2002; Wahlsten, 2002).

Louis Thurstone: primary mental abilities

In contrast to Spearman, Louis Thurstone (1938) concluded that the core of intelligence resides not in one single factor but in seven factors of equal importance. He referred to these factors as primary mental abilities. According to Thurstone, the primary mental abilities and typical measures of them are (1) verbal comprehension – vocabulary tests; (2) verbal fluency – tests requiring the test taker to think of as many words as possible that begin with a given letter, in a limited amount of time; (3) inductive reasoning – tests such as analogies and number-series completion tasks; (4) spatial visualization – tests requiring mental rotation of pictures of objects; (5) number – computation and simple mathematical problem-solving tests; (6) memory – picture and word-recall tests; and

(7) perceptual speed – tests that require the test taker to recognize small differences in pictures or to cross out the A's in strings of various letters.

Raymond Cattell and John Carroll: hierarchical models

A more parsimonious way of handling a number of factors is through a hierarchical model of intelligence. Two models of this sort are those of Raymond Cattell and John Carroll.

The model developed by Cattell (1971) proposes that general intelligence comprises two major subfactors: fluid intelligence and crystallized intelligence. Fluid intelligence represents the acquisition of new information, or the grasping of new relations and abstractions regarding known information. These skills are required in inductive reasoning tests such as analogies and series completions. Crystallized intelligence represents the accumulation of knowledge over the life span of the individual and is measured. This knowledge is required in tests of vocabulary, of general information and of achievement. Subsumed within these two major subfactors are more specific factors. An intelligence test based on this model is the Kaufman Adolescent and Adult Intelligence Test.

A more detailed hierarchical model, based on a reanalysis of many data sets from studies, has been proposed by Carroll (1993). At the top of the hierarchy is general ability; in the middle of the hierarchy are various broad abilities (including learning and memory processes and the effortless production of many ideas). At the bottom of the hierarchy are many narrow, specific abilities such as spelling ability and reasoning speed.

Group differences

Cultural and societal analyses of intelligence render it particularly important to consider carefully the meaning of group differences in measured IQ (Fischer *et al.*, 1996; Loehlin, 2000; Sternberg, 1997, 2004). For example, on average, African Americans score somewhat lower than White Americans on conventional standardized tests of intelligence (Herrnstein & Murray, 1994). Italian American scores used to be considerably lower than they are now. Test scores of African Americans have been increasing over time, just as have scores for other groups. Available evidence suggests an environmental explanation for these group differences (Mackintosh, 1998; Nisbett, 1995), although opinions vary. Moreover, differences between groups in societal outcomes, such as likelihood of graduating from high school or going on welfare, cannot really be attributed simply to differences in IQ, as some people have tried to do. Removing IQ as a source of group differences, African Americans are still considerably more likely than Whites to be born out of wedlock, born into poverty and be underweight at birth (Herrnstein & Murray, 1994). Group differences may thus originate from a number of factors, many of which change over time. The result is that group differences are not immutable. A group that scores, on average, lower than another group at one given time may score, on average, lower, the same, or even higher at another time.

Sex differences

An example of a change in the nature of group differences is that males and females do about the same on cognitive ability tests, although differences have been noted on specific ability tests. Analyses of trends over time suggest that sex differences in scores on these cognitive-ability tests have been shrinking over the years (Feingold, 1988). Nevertheless, there do appear to be some differences that remain. In particular, males, on average, tend to score higher on tasks that require visual and spatial working memory, motor skills that are involved in aiming at a target, and certain aspects of mathematical performance. Females tend to score higher on tasks that require rapid access to phonological and semantic information in long-term memory, production and comprehension of complex prose, fine motor skills and perceptual speed (Halpern, 1997). These differences refer only to averages. There are many individuals of one sex who do better than individuals of the other sex, regardless of the particular skill measured by a given test. In any case, these score differences are not easily interpretable.

Steele (1997), for example, has found that when boys and girls take difficult mathematical tests, boys often do better. But when the two groups are told in advance that a particular test will show no difference, on average, scores of boys and girls converge, with girls' scores increasing and boys' scores actually decreasing.

Socially defined racial/ethnic group differences

Racial and ethnic groups are referred to here as 'socially-defined' because these constructs are culturally constructed, not biological. Different societies have different definitions of what constitute races and ethnic groups. For example, South Africa recognizes two groups of 'Coloured' and 'Black' people who would be lumped into a single category in the United States. In the United States, reference is sometimes made to 'hispanic Americans', but Puerto Rican Americans, Mexican Americans, Dominican Americans and members of many other groups are distinct in numerous ways.

A group difference which has received considerable study is between African Americans and Whites. As mentioned earlier, African Americans tend to score lower than do White Americans on conventional tests of intelligence. The available evidence is largely consistent with an environmental explanation (Nisbett, 1995). For example, in one study, offspring of American servicemen born to German women during the Allied occupation of Germany after the Second World War revealed no significant difference between IQs of children of African American and children of white servicemen (Eyferth, 1961). This result suggests that as a result of similar environments, the children of the two groups of servicemen performed equally on tests of intelligence. Another study found that children adopted by white families obtained higher IQ scores than children adopted by African American families, again suggesting environmental factors contributing to the difference between the two groups (Moore, 1986). Another way of studying group differences has been through trans-racial adoption studies. In such studies, white parents have adopted African American children (Scarr & Weinberg, 1976; Scarr *et al.*, 1993; Weinberg *et al.*, 1992). The results of these studies have been somewhat difficult to interpret. Both White and African American children who were adopted

in the study showed decreased IQ in a 10-year follow-up on their performance.

Environmental differences

There are a number of mechanisms by which environmental factors such as poverty, undernutrition and illness might affect intelligence (Sternberg *et al.*, 2000; Sternberg & Grigorenko, 2001). One mechanism is resources. Children who are poor often do not have the resources in the home and school which are enjoyed by children in more affluent environments. Another mechanism is attention to and concentration on the skills taught in school. Children who are under-nourished or ill may find it hard to concentrate in school. They may therefore profit less from the instruction they receive. A third mechanism is the system of rewards in the environment. Children who grow up in economically deprived environments may note that those who are most rewarded are not necessarily

those who do well in school. Rather, they may be those who earn the money they need to survive, whatever these ways may be. It is unlikely that any one mechanism fully explains the effects of these various variables. It is also important to realize that whatever the mechanisms are, they can start in utero, not just after birth. For example, foetal alcohol syndrome results in reduced IQ and has its initial effects prenatally, before the child even enters the world.

Conclusions

IQ is not the entirety of intelligence but its measurement can serve a useful purpose for predicting school and work performance. The two main IQ used today are descendants of those originated by Alfred Binet, on the one hand, and David Wechsler, on the other. Groups differ in IQ scores, for reasons that are complex and not fully determined.

Assessment of mood

Michele M. Tugade¹, Tamlin Conner² and Lisa Feldman Barrett³

¹Vassar College

²University of Connecticut Health Center

³Boston College

Theoretical and methodological advances in psychology, physiology and medicine have led to rigorous examinations of the role of affect and emotion in health. In this chapter, we review the role of negative

and positive emotions in health research and then discuss some of the most prominent measures currently used to measure mood in this research. We conclude with specific recommendations for the

measurement of mood and emotion in the context of studies of physical health. Across different samples and studies in health psychology, there is little variation in mood assessment procedures. As a consequence, we focus our discussions primarily on the cardiovascular system, with a shorter discussion of relations between cancer and mood.

Negative emotions and health

Much of the research that examines the relation between mood and health addresses the impact of negative or unpleasant affect. Although the experience of negative affect is generally adaptive in preparing the body for fight-or-flight, it can have adverse consequences when the body is continually taxed. In particular, researchers have focused on how particular experiences of negative affect (e.g. anger, anxiety and depression) have emerged as important risk factors in health (see Gallo & Matthews, 2003; Kubzansky & Kawachi, 2000).

Anger

Several studies have reported on the negative health consequences of anger on cardiovascular responses (e.g. Kawachi *et al.*, 1996), particularly in relation to incidence of coronary heart disease (CHD). Hostility appeared to be a greater risk factor than smoking, high blood pressure and high cholesterol (Chaput *et al.*, 2002). Hostility is related to heightened cardiovascular stress (Davis *et al.*, 2000; see also 'Hostility, Type A behaviour and coronary heart Disease') and the speed of cardiovascular recovery from evocative situations, increasing the allostatic load or the total time that cardiovascular indices remain elevated, which itself is an important factor in the development of later hypertension and cardiovascular disease (Faber & Burns, 1996; Gerin & Pickering, 1995; Jamieson & Lavoie, 1987; Lai & Linden, 1992). There is also some evidence that inhibiting anger expression is related to heart disease (including essential hypertension and CHD; e.g. Appel *et al.*, 1983; Diamond, 1982; MacDougall *et al.*, 1985; also see Engebretson *et al.*, 1989). It is also consistent with the more general finding that emotional suppression produces increases cardiovascular reactivity (Gross & Levenson, 1993; see 'Emotional expression and health'). Almost all of the studies assessed anger-related experiences using general or summary type self-report measures (detailed below in the 'Mood assessment procedures' section; e.g. the MMPI-2 Anger Content Scale, Hathaway & McKinley, 1989, in Kawachi *et al.*, 1996; the Spielberger Anger-Out Expression scale, Spielberger, 1988, in Eng *et al.*, 2003; dispositional hostility measured by a composite index including cynicism, anger, mistrust and aggression, in Rozanski *et al.*, 1999). Taken together, this body of research suggests that respondents' reports of anger experiences in general are related to cardiovascular functioning.

Anxiety

Most prospective epidemiological studies have found an association between self-reported symptoms of anxiety and risk of developing CHD, even when other factors were considered (e.g. a family history of heart disease; Kubzansky & Kawachi, 2000). This link could exist

in individuals who report anxiety symptoms because they have repeated activation of the sympathetic nervous system and suppression of immune system function (Schneiderman, 1987), because they are less likely to engage in health-promoting behaviours (Kubzansky *et al.*, 1998) or because they are more likely to engage in risky health behaviours (e.g. increased smoking, alcohol or drug consumption; Kubzansky & Arthur, 2004). Indeed, individuals who report anxiety are at increased risk of atherosclerosis (Paterniti *et al.*, 2001) and hypertension (Markovitz *et al.*, 1991). These studies assessed anxiety-related experiences using global measures of anxiety and anxiety symptoms, such as: the Framingham Tension Scale (Haynes *et al.*, 1978) in Markovitz *et al.* (1991); the Spielberger State-Trait Anxiety Inventory (Spielberger *et al.*, 1970) in Paterniti *et al.* (2001); and the Hopkins Symptoms Checklist (Derogatis *et al.*, 1973). Taken together, these studies indicate that reports of anxiety-related experiences are associated to CHD.

Depression

Studies provide convincing evidence that clinical depression contributes significantly to the onset of heart disease. Clinical depression is a mood-related disorder that can lead to a three-fold increase in risk for heart disease (see Anderson, 2003) and it is therefore especially dangerous for people with existing heart ailments. Numerous epidemiological studies consistently demonstrate a prospective relation between the occurrence of major depressive episodes and the incidence of myocardial infarction, ischemic heart disease and cardiac death (Anderson, 2003), as well as a dose-response association between the magnitude of depression and future cardiac events (cf. Rosanski *et al.*, 1999; see 'Coronary heart disease: cardiac psychology'). These studies use clinical assessments of depression (as reported in Rozanski *et al.*, 1999), such as the Centre for Epidemiological Studies-Depression Scale (CES-D; Radloff, 1977), MMPI Depression Scale (Hathaway & McKinley, 1989) and the Beck Depression Inventory (BDI; Beck, 1996). Together, these data suggest that risk for coronary artery disease associated with depression exists along a continuum, according to the magnitude of depressive symptoms.

The assessment of depression also plays an important role in the diagnosis of cancer. Although the direct pathways by which mood might influence cancer etiology remain unclear (Croyle & Rowland, 2003), evidence indicates that self-reported experiences of negative affect (e.g. depression) are related to an increased risk of developing cancer (Pennix *et al.*, 1998). One groundbreaking prospective study examined the links between depression and cancer incidence in 4825 participants. After controlling for factors such as age, sex, race, disabilities, alcohol use and smoking, the researchers found that participants who had been chronically depressed for at least six years had an 88% greater risk of developing cancer within the following four years. In this study, chronically depressed mood was defined as being present when the number of depressive symptoms exceeded 20 on the Centre for Epidemiologic Studies-Depression scale (CES-D; Radloff, 1977) during three timepoints: baseline, 3 years before baseline and 6 years before baseline. The CES-D measures depressive feelings and behaviours experienced during the past week (e.g. feelings of sadness or feelings that life had been a failure, lack of appetite, having a restless sleep, or having crying spells). Although the results of this study are compelling,

the researchers cautioned that further studies are needed to determine the direction of causality in their findings. For instance, it is possible that depressed mood was a consequence of early-stage cancer that had yet to be detected (Pennix *et al.*, 1998).

Previous to the Pennix *et al.* (1998) study, prospective studies used a single measurement occasion to assess depressed mood and the development of cancer. Obtaining only a single measure of depression in the absence of assessment of duration or frequency, however, may be incomplete. A single estimate may classify persons as depressed as a result of temporary stressful life circumstances or health problems present at that moment. There is also variability in the frequency of depression across the cancer disease course (Croyle & Rowland, 2003). Such variability may reflect an inconsistency among several factors, including type of assessment, timing of assessment, type of cancer, concurrent treatment and comorbidity (e.g. Croyle & Rowland, 2003). Moreover, most clinical assessments rely on patient self-report. Although symptoms of depression (e.g. fatigue, reduced appetite, sleep problems, concentration problems) are best reported by the patient, most depressed cancer patients may not be able to complete assessments or may not seek treatment for cancer-related depression at all (Croyle & Rowland, 2003).

Research also indicates that repression of negative affect (i.e. having no cognitive awareness of feelings of anger, sadness, anxiety, worry, or fear related to cancer) has been identified as the single most important predictor of cancer incidence (McKenna *et al.*, 1999). It is also related to faster cancer progression (Jenson, 1987) and is a risk factor for early mortality in women with breast cancer (Giese-Davis *et al.*, 2004). Examining the links between mood and cancer, therefore, can be important in understanding the course of the disease and a cancer patient's overall quality of life.

Positive emotions and health

Just as individuals with a negative affective style are at greater risk for developing health problems, individuals with a positive emotional style (including a tendency to report positive emotions such as feeling happy, pleased and relaxed) experience potential health benefits. Recent research, for instance, has demonstrated that positive emotional experiences serve as a protective factor against the common cold even after controlling for a number of risk factors (e.g. age, sex, education, race, body mass and season; Cohen *et al.*, 2003). Physical health benefits associated with positive emotions are further established in research on optimism, a dispositional attribute associated with positive emotions. For example, optimists (compared with pessimists) are less likely to suffer from angina and myocardial infarction (Kubzansky & Kawachi, 2002) and they show better physical recovery immediately after coronary artery bypass surgery and up to six months post-surgery (Carver & Scheier, 1998). Other research corroborates this pattern, showing that the tendencies to maintain optimistic (even unrealistically optimistic) beliefs about the future act to buffer against the advancement of disease and death (Aspinwall & Taylor, 1997; Taylor & Brown, 1988; Taylor *et al.*, 2000). Taken together, these studies suggest that the relation between physical health and positive dispositional styles (e.g. optimism) may be due in part to the chronic positive emotional states engendered by the personality style.

One of the most important functions of positive emotion is to undo the cardiovascular reactivity associated with negative emotion. Recent research indicates that positive emotional experiences may be important in accelerating cardiovascular recovery from stressful experiences. Theory and research have shown that positive and negative emotions have unique and complementary adaptive functions and physiological effects (see Fredrickson, 1998, 2001). Experiences of negative emotions are associated with autonomic nervous system activation, such as changes in heart rate, vascular resistance and blood pressure (for meta-analytic evidence, see Cacioppo *et al.*, 2000) that prepare the body for fight or flight. Experiences of positive emotions function as efficient antidotes for the lingering cardiovascular effects of negative emotions, in a sense 'undoing' the lingering after-effects of negative emotional experiences (Fredrickson & Levenson, 1998; Fredrickson *et al.*, 2000). Experimental evidence suggests that participants induced to experience both high activation positive emotions (i.e. joy/amusement) and low activation positive emotions (i.e. contentment/serenity) exhibited faster cardiovascular recovery after exposure to emotionally evocative films than those in a neutral control condition (Fredrickson & Levenson, 1998; Fredrickson *et al.*, 2000). In this way, positive emotions are not only a form of psychological resilience (Tugade & Fredrickson, 2004) but may also serve as a protective factor for cardiovascular and other stress-related illnesses.

Now that we have provided a brief review of the links between mood and health, in the next section, we will highlight some of the most prominent measures currently used to measure mood in health psychology.

Mood assessment procedures in health psychology

Self-report measures

Self-report methods are popular for measuring mood. Their use is grounded in the first-person perspective that the best way to know how people feel is to ask them. This contrasts with a third-person perspective whereby feeling is inferred from instrument-based observational methods (e.g. using physiological measures, facial affect coding, etc.). Self-report procedures vary in the content of the measures (i.e. the experiences that are sampled) and the time-frame of the assessment period. Moods can be assessed as they are currently experienced, called a 'state' or 'momentary report'; over a specified time frame, called a 'retrospective report'; or in general, often called a 'trait or global report'.

Content

There are numerous self-report measures currently used in the health sciences and each assesses different aspects of mood. Some measures target a single type of mood-related experience, for example, feelings of anxiety, depression, or anger. The most widely-used measure of anxious mood is the Spielberger State-Trait Anxiety Inventory (STAI; Spielberger, 1983; Marteau & Bekker, 1992). Popular measures of depressed mood include the 20-item Centre for Epidemiologic Studies-Depression Scale (CES-D; Radloff, 1977) and variants of the Beck Depression Inventory (original, Version II and fast screen for medical patients, Beck *et al.*, 1961, Beck *et al.*, 1996; 2000; see also Richter *et al.*, 1998, for a validity review). Commonly used anger-related mood measures include the

MMPI-2 Anger Content Scale (Hathaway & McKinley, 1989) and the Spielberger Anger-Out Expression Inventory (Spielberger, 1988).

Other measures include a wider range of items to sample more than one type of mood-related experience. For example, the widely-used Profile of Mood States (POMS; McNair *et al.*, 1971/1981) is a 65-item rating scale that yields a total mood index, plus a single index of positive mood (Vigour) and five indices of negative mood (tension/anxiety; depression/dejection; anger/hostility; fatigue; and confusion/bewilderment), the latter two presumably measuring more physically-based mood states. Respondents rate the extent to which they are experiencing or have experienced 65 affect states (e.g. sad, tense, energetic, cheerful) using a 5-point scale (0 = not at all, 5 = extremely). There are also several shortened versions, which appear to show adequate internal consistency (see Guadagnoli & Mor, 1989; Shacham, 1983). Similarly, the Mood Adjective Checklist (MACL, Nowlis, 1965) is a 50-item affect rating scale that yields 12 separate mood indices – aggression, anxiety, surgency, elation, concentration, fatigue, social affection, sadness, skepticism, egotism, vigor and nonchalance. It also attempts to differentiate between physical versus emotion-based mood states, although it should be noted that some of the terms are outdated (e.g. ‘clutched up’ as a marker of anxiety). The 40-item Derogatis Affects Balance Scale (DABS; Derogatis, 1996) measures several positive mood dimensions (joy, contentment, vigour and affection) and several negative mood dimensions (anxiety, depression, guilt and hostility) and is often used in clinical psychology related fields. The Multiple Affect Adjective Check List Revised (MAACL-R; Zuckerman & Lubin, 1985) is a 132-item scale that assesses five dimensions of mood (anxiety, depression, hostility, positive affect and sensation-seeking), and combines these for superordinate measures of dysphoria (sum of anxiety, depression and hostility) and positivity (sum of sensation-seeking and positive affect). All of these scales have shown adequate internal consistency and reliability.

Even though these scales purport to measure distinct mood states, respondents typically have some difficulty distinguishing mood states of the same valence. Reports of negative mood experience tend to correlate so highly that measures of anxiety, sadness, fear and so on, often fail capture any unique variance (e.g. Feldman, 1993; Watson & Clark, 1984; Watson & Tellegen, 1985). Even scales that are explicitly built to measure discrete emotions tend to suffer from high correlations between like-valenced states (e.g. Boyle, 1986; Watson & Clark, 1994; Zuckerman & Lubin, 1985). Individuals also vary a great deal in the tendency with which they represent feelings as distinctive experiences (Carstensen *et al.*, 2000; Lane *et al.*, 1990; Lane & Schwartz, 1987; Larsen & Cutler, 1996), with some individuals making categorical distinctions between like valenced states in their reports of experience and others making fewer distinctions (Barrett, 1998, 2004; Barrett *et al.*, 2001; Feldman, 1995*b*) – an individual difference termed ‘emotional granularity’ (Barrett, 2004).

Several strategies can address the weak discriminant validity in discrete mood reports and granularity differences across people. Single mood measures (e.g. STAI; BDI) are best used in conjunction with other mood measures to determine whether participants are feeling ‘anxiety’ or ‘depression’ per se or whether they using the scales simply to record undifferentiated feelings of negativity (Watson & Clark, 1984) or dysphoric mood (Feldman, 1993;

1995*a*). Measures which sample more than one type of mood-related experience should be analyzed for their psychometric properties, but at minimum can be considered valid measures of positive and negative affective states (Feldman, 1993, 1995*a*; Watson & Tellegen, 1985). Also, regardless of whether people are high or low in emotional granularity, their verbal reports do seem to convey something valid about the two broad dimensions of mood – their feelings of valence (pleasure–displeasure) and arousal (high activation–low activation) (Barrett & Niedenthal, 2004; Barrett *et al.*, 2004).

Another option is to measure the broad dimensions of mood more explicitly. One popular measure is the Positive and Negative Activation Schedule (once called the Positive and Negative Affect Schedule; PANAS; Watson, Clark & Tellegen, 1988; Watson *et al.*, 1999). The PANAS is a 20-item scale that assesses positive and negative activation (that is, high arousal positive and negative states; e.g. excited, interested, proud; ashamed, nervous, scared). Importantly, the PANAS is not a measure of both dimensions of affectivity (pleasure–displeasure; high activation–low activation) (Barrett & Russell, 1998; Carroll *et al.*, 1999), although it is often treated as such, because it does not capture lower activation feelings of calmness, depression, sadness, or even happiness. An extended version, the PANAS-X, is available to measure more discrete feelings including some, but not all, lower level activation states (sadness, serenity, fatigue) in addition to the broader positive and negative activation states (Watson & Clark, 1994). In general, both the PANAS and PANAS-X show good validity and reliability for measuring high activation, valenced mood states in a variety of time frame formats (see Watson, 1988; Watson & Clark, 1997). Other measures have been developed to sample the affective space more completely by including items reflecting all combinations of valence and arousal. For examples, see Barrett and Russell (1998), Carroll *et al.* (1999), Larsen and Diener (1992), Mayer and Gaschke, 1988; Russell, Weiss and Mendelsohn, 1989; and Yik *et al.* (1999).

An alternative to the PANAS and other existing measures is to develop (or modify) one’s own measure. In doing so, it is advisable to include a broad range of adjectives reflecting all combinations of valence (pleasant–unpleasant) and arousal levels (high activation–low activation) (see Barrett & Russell, 1998). Also, accumulating evidence strongly suggests that all self-report scales of mood should use unambiguously unipolar (rather than bipolar) scales, where respondents first judge the absence or presence of affective feeling, and only then judge the intensity of the feeling if it is present (e.g. 0 = no feeling at all, but if feeling is present, and then 1 = mild intensity to 5 = strong intensity; for a discussion of why this is so, see Russell & Carroll, 1999). Failure to do so can cause systematic artifacts in measurement that can influence, among other things, the extent to which self-reports positive and negative affect are correlated (Russell & Barrett, 1999).

The time frame of mood assessment

Time frame is another important issue in the measurement of self-reported mood. Mood can be measured in the present moment (How do you feel right now?), retrospectively over increasingly extended time intervals (How have you felt this day? week? month? past year?) and globally (How do you feel in general?). Momentary and shorter interval retrospective reports capture immediate affective states which fluctuate in response to changing

events and conditions, and constitute a form of episodic or state mood. In contrast, global or longer term retrospective reports capture enduring beliefs about the types of moods we experience, and constitute a form of semantic or trait mood (for a review, see Robinson & Clore, 2002). Many existing mood measures come in state and trait forms or can be easily adapted to different time frames. Choosing the appropriate time frame in measurement is important because state and trait reports are psychologically distinct and each is suited to different types of health-related investigations.

State mood measures reflect people's transient mood states and should be used when seeking to measure mood as it occurs or how it changes in response to events or situations (e.g. laboratory or real-world stressors). The strictest state format is to ask people how they feel right now (a momentary self-report) either at a single time point (typically in the lab), or on repeated occasions (typically outside the lab) using a method called Ecological Momentary Assessment (EMA) or experience-sampling methods (ESM).¹ These intensive, longitudinal self-report procedures are designed to allow respondents to document their thoughts, feelings and behaviours on repeated occasions within the context of everyday life. Sampling is typically accomplished through the use of a device (like a Palm, a pager, or cell phone) that allows respondents to report their momentary experience multiple times a day (either in response to a random signal, a fixed signal and/or self-initiated). Momentary self-reports, like those used in EMA and ESM, are often considered the gold standard of state mood measurement because they capture mood as it happens in real life, unbiased by memory processes. For these reasons, EMA and ESM are playing increasingly vital roles in the scientific study of health. They have been used to evaluate the efficacy of clinical interventions and health treatments with presumed mood components, and to test the links between mood and important health factors including coping, cardiovascular function and salivary cortisol levels *in situ* (for examples see Steptoe *et al.*, 2000; Stone & Shiffman, 1994). For a full review of these procedures, the interested reader is referred to Barrett and Barrett (2001), Bolger, Davis and Rafaeli, (2003), Conner *et al.* (2003), Reis and Gable (2000) and Stone *et al.* (1999).

Short term retrospective reports also measure state mood and can be used when practicalities prohibit the use of EMA, or when researchers are expressly seeking to measure people's retrospections of their mood states. A short-term retrospective report may ask people how they felt over the past hour, day, or week. When people retrospect over such short time intervals, reports tend to be fairly accurate when they are compared to momentary self-reports averaged over that interval (Thomas & Diener, 1990; Hedges *et al.*, 1985; Parkinson *et al.*, 1995); however, retrospections across a span of a week appear to relate more to averaged end-of-day reports than to averaged momentary reports over the interval suggesting that weekly reports are retrospections on already aggregated memories (Parkinson *et al.*, 1995). Although generally accurate, short-term retrospective reports can reflect several systematic biases, deriving from people's attempts to recall and

aggregate past experiences over time. Short-term retrospective reports are often disproportionately influenced by people's affective state at the time of recall (Singer & Salovey, 1988), by the most intense experience that is remembered ('peak effect'), and to a lesser extent by the most recent experience remembered ('end effect') (see Fredrickson, 2000). Also, as a general rule, people tend to over-estimate the intensity of their positive and negative moods in retrospect, in part, because they neglect to incorporate the duration of certain neutral experiences into memory (Barrett, 1997; Thomas & Diener, 1990). These biases should be kept in mind when using short-term retrospective self-reports as proxies for momentary mood.

Despite the biases associated with short-term retrospective reports, there may be times when researchers would want expressly to target these retrospections. Recent research suggests that people make important decisions about their future behaviours based on how they remember their experiences, not necessarily what 'objectively' happened in the moment. For example, retrospective pain, more than momentary pain, has been shown to predict people's decisions about whether to undergo follow-up colonoscopies (Redelmeier, Katz & Kahneman, 2003). The same patterns could hold for other types of decisions regarding mood and health. At the end of a long working week, it may be how people remember their mood – more than an objective average of their moment-to-moment mood – that will predict risky health related behaviours over the weekend (e.g. binge drinking, smoking etc.). Thus, retrospective reports may be the best measure and not simply a more convenient substitute for momentary reports in cases where people retrospect on their mood to make health-related decisions.

When people recollect on their mood over longer time frames (e.g. two weeks or more), they are typically very poor at accurately recalling their states. People forget the details of their original experiences and instead report their beliefs or theories about how they felt during that time (for a review, see Robinson & Clore, 2002). As evidence of this distortion, longer term retrospections of mood are often biased by theories of one's own emotionality (Barrett, 1997; Larsen, 1992), including gender stereotypes (Barrett *et al.*, 1998). For these reasons, longer term retrospections are best considered measures of trait mood and/or recollected experience and should not be used as proxies for actual state experience. While it may be tempting to use long term retrospective reports as a 'short-cut' for measuring state mood over a long time period, such decisions are not justifiable. In that circumstance, researchers would be better served by using a series of daily or weekly reports. Of course, there may be times when it is important and appropriate to measure people's longer term recollections of their mood states (i.e. to the extent that participants use their memories to inform health-related behaviours).

For other investigations, it may be important to tap people's trait beliefs about their mood-related experiences using global self-reports (e.g. How one feels in general). Trait beliefs are typically stable and shaped by a multitude of factors, including one's actual experience. As such, these reports can be strong predictors of

¹ The term 'experience-sampling' is used more in social and clinical psychology, whereas the term 'ecological momentary assessment' is used more in health-related fields, referring to procedures that may also incorporate the ambulatory monitoring of physical states, like blood pressure, in addition to self-report.

enduring health related risk factors. For example, people who describe themselves as generally anxious or high in hostility tend to show a higher risk for coronary heart disease and hypertension, presumably because their global self-reports are tapping something about their enduring affective reactions. But trait beliefs are also shaped by other factors beyond actual experience, including cultural norms (e.g. gender or cultural stereotypes) and personal values. Trait beliefs are also limited by how people filter and label their past experiences. As such, it is important not to use trait ratings as proxies for state mood or to assume that trait ratings will necessarily predict affective experience in a given instance.

A final consideration occurs when adapting an existing measure to alternate time frames. Some measures, like the STAI, the POMS and the PANAS and PANAS-X, already exist in various state and trait forms, which have been validated and found to be reliable. Other measures have only been validated in one form or the other. Most mood measures are robust enough to be adapted to state and trait forms simply by changing the nature of the instructions. Past research has shown that psychometric properties for trait adjective rating scales are typically preserved across time frames (e.g. mood adjectives correlate in the same fashion in both state and trait formats) (Watson & Clark, 1994). This bodes well for adaptive other measures with generally similar formats. Of course, it is crucial to run comparative psychometric analyses for any adapted measure. It is also essential to remember that state and trait forms are not interchangeable and neither is inherently 'better' than the other – they measure different types of mood-related experiences and are suited to different types of research questions.

Psychophysiological measures

William James (1884) proposed one of the most compelling ideas in the science of emotion – that emotional states have specific and unique patterns of somatovisceral changes, and the perception of these bodily events constitutes an emotion. As a result, many researchers have assumed that it is possible to measure anger, sadness, fear and other emotional states more objectively by assessing their psychophysiological correlates. According to this approach, specific emotions are comprised of unique patterns of behavioural and physiological activation and these specific patterns underlie distinct subjective experiences of emotion. Theories which propose emotion-specific physiological patterning often examine cardiovascular (e.g. heart rate, finger pulse amplitude, blood pressure), electrodermal (e.g. digital skin temperature) and facial (e.g. facial electromyography) indices. Despite rigorous research efforts, consistent evidence for emotion-specific patterning of peripheral nervous system responses remains elusive. Certainly, people have well developed beliefs about the patterns of bodily cues that distinguish discrete emotional episodes and these beliefs display great stability across individuals within a culture, as well as across cultures (e.g. see Pennebaker, 1982; Scherer *et al.*, 1986; Wallbott & Scherer, 1986). Despite the intuitive appeal, research has not produced a strong evidentiary basis for distinctive physiological patterns that characterize anger, sadness, fear and so on. Although individual studies sometimes report distinct autonomic correlates for different emotion categories (e.g. Christie & Friedman, 2004; Ekman *et al.*, 1983; Levenson, Ekman & Friesen, 1990), meta-analytic

summaries generally fail to find distinct patterns of peripheral nervous system responses for each basic discrete emotion (Cacioppo *et al.*, 2000). Peripheral nervous system responses do appear to configure for conditions of threat and challenge, however (Quigley *et al.*, 2002; Tomaka *et al.*, 1993, Tomaka *et al.*, 1997), and for positive versus negative affect (Cacioppo *et al.*, 2000; Lang *et al.*, 1993) suggesting that patterns of cardiovascular responding can be used to characterize appraisals (threat, challenge) and affect (positive, negative), but not necessarily discrete emotions per se. Facial electromyography and vocal acoustic assessments generally produce the same findings as the cardiovascular measures. Facial electromyography measurements coordinate around positive versus negative affect (Cacioppo *et al.*, 2000) or intensity of affect (Messinger, 2002). A similar case holds for vocal acoustics, which indicate a person's arousal level (e.g. Bachorowski 1999; Bachorowski & Owren 1995; Kappas *et al.*, 1991), but do not indicate discrete emotional states per se (for a review, see Russell *et al.*, 2003). The fact that people can automatically and effortlessly perceive anger, sadness, fear and so on, in others suggests the hypothesis that they are imposing, rather than detecting, categorical distinctions in the facial configurations or vocal signals that they rate (Barrett, 2005).

Recommendations for measurement

Based on the evidence summarised here, it is possible to offer several recommendations when measuring affect and emotion in health-related research. First, although many scientists continue to assume that each category of discrete or 'basic' emotion, referred to by such English words as 'anger', 'sadness' and 'fear', is an inherited, reflex-like module that causes a distinct and recognizable behavioural and physiological pattern, the empirical evidence does not strongly support this view. Self-reports of experience, cardiovascular measures, facial and vocal measurements, reliably and validly seem to index something about a person's affective state, so it may make the most sense to address the role of affective functioning (e.g. affective reactivity, propensity to be threatened or challenged) in questions about health and human functioning. Second, in the face of evidence that people vary in the granularity of their emotion reports, and in general tend to use discrete emotion scales to report positive and negative affect, it is important to assess the discriminant validity in reports of anger, sadness, fear and so on. Scientific studies that include only one measure of emotion (e.g. hostility) in the absence of others (e.g. anxiety) may mistakenly assume that there is a specific emotional effect driving health effects when in fact it is something about affect more broadly defined. Finally, momentary (state) and summary (trait) reports of emotion are not synonymous, and whether a researcher uses one over the other should not be a matter of convenience, but rather should depend on whether episodic or semantic representations of experience are of interest.

Neuropsychological assessment

Jane Powell

University of London

Organic injury to the brain can have complex and interacting psychological effects, not only at the level of intellectual impairment but also at the levels of affective and behavioural disturbance. These sequelae may be directly or indirectly caused by the brain injury, and may vary in severity from those which are gross and obvious to those which are subtle and detectable only on detailed assessment. Nevertheless, even those which are subtle can have pervasive effects on a patient's social and occupational functioning, whilst those which are gross may arise from a variety of causes with different treatment implications. In either case, neuropsychological assessment can be highly germane to clarification of the problem, to prediction of the functional consequences and to the development of appropriate interventions or environmental adaptations.

To illustrate this, consider the case of a young man who has sustained a head injury in an assault. A year after the incident he has made a good physical recovery, but is very aggressive and has lost his job as a sales manager because of hostility towards colleagues and a general lack of organization in his work. These problems might, on the one hand, arise from organic damage to regions of the brain involved in the genesis or inhibition of aggression, or, on the other, be a psychological reaction to some more subtle cognitive deficit such as a generalized reduction in the efficiency with which information is processed or a mild but specific impairment of memory. In the former case, a pharmacological treatment to control the emotional reactions might be most appropriate, whilst in the latter it would be more relevant to address the underlying cognitive deficit directly and/or help the patient adjust his lifestyle and outlook to his new limitations.

Purposes of neuropsychological assessment

The form taken by any neuropsychological assessment will depend critically on the question which is to be answered. Frequent purpose for assessment include the following:

- description and measurement of organically based cognitive deficits
- differential diagnosis (e.g. to ascertain whether memory problems arise from organic injury or mood disturbances)
- prediction of the consequences of neurosurgical excision of brain tissue (e.g. the cost-benefits likely to accrue from a temporal lobectomy)
- monitoring improvement or deterioration associated with recovery from, or exacerbation of, a neurological condition
- evaluation of the neuropsychological effects, positive or adverse, of pharmacological and non-pharmacological treatments (e.g. to determine whether a psychological intervention has

improved attention, or whether an anticonvulsant might impair learning)

- guiding rehabilitation strategies
- predicting or explaining deficits in social, educational, or occupational functioning
- medico-legal evaluations (e.g. contributing to determination of compensation awards, ascertaining fitness to plead, etc.).

Dimensions and level of assessment

The extensiveness of, and methods employed within, any individual assessment will be largely determined by the specific referral question, though a wide range of other factors will also be influential. These will include characteristics of the patient which affect his or her ability or willingness to carry out certain tests, as well as resource-based considerations, such as the location in which the assessment is to take place, or the amount of time which is available.

A major element of many neuropsychological assessments is evaluation of the patient's intellectual functioning, usually tested via formal pen-and-paper or computerized test procedures. However, this is neither the only form of assessment used nor necessarily the most important. If the presenting problem is one of behavioural or emotional disturbance, assessment may concentrate on the systematic collection of information either from the patient or from others concerning factors which may influence its occurrence. Thus, although neuropsychological assessment is often perceived as a special form of cognitive assessment, it is very often much broader than this. In practice, a referral to a neuropsychologist will often result in a multidimensional assessment in which the presenting problem is analyzed from a number of perspectives rather than just one. Sometimes there may be no formal testing, if the pertinent information can be gleaned from systematic behavioural observations and interviews.

At a general level, the purpose of neuropsychological assessment may be categorized into those which are primarily descriptive and those which are explanatory. The former represents an attempt to identify the type and severity of any problems, whilst the latter entails more theoretically driven procedures designed to illuminate the causes or consequences of an observed deficit. These two aspects will be differentially important depending on the nature of the initial question. So, if the purpose of the assessment is to quantify the extent of any memory deficits (e.g. for the purposes of monitoring change over time, or for medico-legal purposes), then a standardized measurement of different aspects of the patient's memory relative to their general intellectual level may suffice. By contrast, if the purpose of the assessment is to determine why

the patient has difficulty in remembering information in daily life and to make therapeutic recommendations, then more detailed probing of potential causes for the memory problem become relevant. For instance, it may be that the memory deficit is secondary to poor concentration or impaired perception, or that it is related to the form in which the information is presented (e.g. verbally vs. visually). If the assessment clarifies the mechanisms underlying the patients's problems, then treatment can focus specifically on these.

Descriptive assessments will also vary in terms of their breadth, and this again is likely to reflect the referral question. In one case the requirement may be to determine whether a brain injury has resulted in any impairment, whilst in another the emphasis may be particularly on a certain aspect of the patient's functioning. The basis for focusing on one aspect more than on others may consist in observations which have already been made (e.g. that the patient appears forgetful) or on the basis of what is known about the aetiology or location of the brain injury (e.g. that there is a focal lesion to a part of the brain which is implicated in memory functions). The prediction of neuropsychological sequelae which are likely to arise from damage to specified areas of the brain has become an increasingly sophisticated exercise over the last decade with the emergence of complex information-processing models of cognitive function, a framework which is considered briefly below.

Cognitive neuropsychology

This framework guides much of contemporary neuropsychological assessment, and derives from an integration of theory and research bearing on the elements of information-processing involved in normal cognition ('cognitive psychology') with that relating organic brain injury to alterations in psychological function defined broadly to incorporate not only cognition but also mood and behaviour ('neuro-psychology').

To illustrate the clinical utility of this approach, consider acquired deficits of spelling which can follow brain injury. Anatomically, impairments of spelling and writing seem predominantly to be associated with lesions of the left posterior region of the brain (see 'Head injury' and McCarthy & Warrington, 1990, for an overview). Although this by no means implies either that all patients with left posterior lesions will have such deficits, or that the presence of such a deficit definitively indicates left posterior damage, nevertheless the observed association is important in guiding the form of the clinical assessment. Thus, if a patient is known to have sustained an injury to the left parietal or occipital lobe, the neuropsychologist may make an informed decision to include within the assessment tests which will be specifically sensitive to possible spelling or writing difficulties.

At this point, analysis of the information-processing operations entailed in spelling guides the neuropsychologist in assessing the presence of specific deficits. These can vary in their impact, from those which give rise to extensive and very obvious difficulties with spelling to those which produce much more subtle effects that may be less obvious at first glance but which may nevertheless have the effect of slowing the patient down or causing him or her to underperform in certain situations. For instance, Ellis and

Young (1988) have proposed that one route to writing down a single word after hearing it spoken out loud entails the sequential occurrence of the following operations:

- auditory analysis (extraction of individual speech sounds from the speech wave)
- representation of word as a series of individual distinctive speech sounds (phoneme level)
- mapping of sounds on to spellings (phoneme-grapheme conversion)
- representation of letters involved in the spelling (grapheme level)
- representation of the particular form in which the letters are to be written, e.g. in upper vs. lower case (allograph level)
- generation of motor programme for writing the letters (graphic motor patterns)
- writing (activation of the motor programme).

These components have been identified through a combination of theory, experimental studies with neurologically intact individuals, and evidence that brain injury can disrupt some of these processes independently of others. Other aspects of the model are yet to be confirmed, and it is in a continuing process of development.

Using the above framework, the clinical neuropsychologist may test whether the patient's difficulty in writing to dictation reflects difficulty at the level of acoustic analysis, at the level of phoneme-grapheme conversion, or at one of the other stages. The implications are quite different: if the patient has specific difficulty at the level of acoustic analysis, then in parallel with the above problem he may have considerable difficulty in understanding other people's speech but be unimpaired in copying written words or in writing down his own thoughts. By contrast, if the deficit arises at the level of phoneme-grapheme conversion, he is not likely to have a problem in comprehending normal speech but may experience some difficulty in keeping written notes, etc. It may be that a deficit of the latter type actually has very little practical impact, in that alternative routes to spelling (e.g. from vocabulary) may be undamaged; on the other hand, if these alternative routes are not spontaneously used by the patient, then the assessment may have the practical benefit of focusing rehabilitation training and practice in use of these or other functional mechanisms (see 'Neuropsychological rehabilitation').

Approaches to assessment of cognitive functions

Neuropsychological assessments are generally highly structured, one conventional approach being to administer a set of tests which between them assess the following broad cognitive domains (Benton, 1994):

- verbal capacities and aphasia (includes expression, comprehension, fluency)
- visuo-perceptual capacities (e.g. object recognition, visual discrimination, processing of spatial relationships)
- audition (e.g. recognition and identification of sounds; auditory localizations; phoneme/word discrimination)
- somesthesia (e.g. identification of objects through touch; perception of sensory stimulation on the skin)

- motor skills and praxis (e.g. fine motor co-ordination and manual dexterity; manipulation of objects; ability to execute purposeful motor acts on verbal command or by imitation)
- learning, memory and orientation (see 'Neuropsychological assessment: memory')
- executive functions and abstract reasoning (the higher level cognitive capacities such as concept formation, judgement, mental flexibility, creativity, decision-making, insight and planning) (see 'Neuropsychological assessment: attention and executive function').

Other, more general, outputs of neuropsychological assessment include indices of overall 'intelligence', effectively a composite index of the effectiveness of an individual's functioning across all of the above domains and 'intellectual efficiency' which may be manifest (for instance) in the speed with which simple information is processed, or in the ability to maintain vigilance or concentration over an extended period.

These functions are inevitably inter-related, in that deficits in some areas are likely to have adverse effects on functioning in others: for example, an impairment of verbal comprehension will impede verbal learning and memory and will be associated with deficits in many linguistic reasoning tasks. Likewise, attentional deficits will limit the extent to which new information is taken in and is retrievable from memory.

Some neuropsychologists in some settings routinely adopt the approach of conducting a comprehensive descriptive assessment, systematically testing all of the main areas of cognitive function using a standardized battery of tests such as the Halstead-Reitan or Luria Nebraska. A brief description and consideration of these batteries can be found in Kolb and Whishaw's (2003) valuable reference text. In Britain the more common clinical practice is to employ a smaller battery of standardized tests to tap broad dimensions of cognitive function and screen for deficits, and to supplement these with other tests which are of particular relevance to the individual patient.

The best known and most widely used instrument is the Wechsler Adult Intelligence Scale III (WAIS-III; Wechsler, 1997), which comprises 14 subtests from which 'intelligence quotients' (IQs) can be computed. In addition to an overall IQ, separate 'Verbal' and 'Performance' IQs can be calculated from those subtests respectively tapping verbal reasoning abilities/knowledge and visuospatial problem-solving; similarly, indices of other aspects of functioning such as 'working memory' and 'processing speed' can be derived from groups of subtests sensitive to these functions. IQ scores, as well as being of interest in their own right, serve as a reference point against which to evaluate a patient's performance in specific cognitive domains: thus, if a patient of superior intelligence scores only in the average range on tests of memory, this is more likely to represent a deterioration than similar memory test scores in

a patient of average IQ. This example illustrates the importance of considering the profile of a patient's performance across a range of tests in order to gauge where there are anomalies. The same philosophy also holds at the finer levels of description exemplified within the cognitive neuropsychological approach: thus, the interpretation of a spelling deficit will vary depending on whether it is associated with concomitant abnormalities of comprehension, perception, etc.

Within each domain, there exist any number of tests to probe the patterning of a patient's deficits and residual abilities (see, e.g. Lezak, 2004, for a wide-ranging inventory and discussion of specific neuropsychological instruments). Of the tests used, many have been standardized so that a patient's performance can be evaluated by comparison with normative data, but there is, in addition, a significant role for more informal, unstandardized tests which may be sensitive to idiosyncratic or qualitative aspects of a patient's functioning. These may be generated ad hoc during the assessment, as the neuropsychologist formulates hypotheses about the patient's underlying impairments and tests them out in an individualized way.

For instance, if a patient performs poorly on a test of mental arithmetic, he might have a problem either with generating strategic aspects of the computation or with remembering details of the question. The neuropsychologist might decide to pit these explanations against each other, either by presenting the question in a written format (thereby reducing the memory load but keeping the complexity of the calculation constant), or by presenting a strategically 'easier' problem containing approximately the same number of to-be-remembered facts. Although these variations on the basic theme are not standardized, they permit an individualized analysis of the stage at which an observed deficit arises.

Integration with other neurological indices

Neuropsychological assessment has a distinctive role within the multiplicity of tests the patient may undergo following brain injury, and one which is an important complement to other types of information. Physiological, biochemical and neuroimaging techniques are able to identify, often with great precision, the locus of or mechanism giving rise to a brain lesion and this information is likely to be critical in informing medical treatment and often in making a general prognosis. The neuropsychological contribution is a detailed analysis of the patient's functioning based on an understanding of brain-behaviour relationships, thereby allowing the consequences of the lesion for the patient's current and future functioning to be evaluated. An integration of the physiological and the neuropsychological information is therefore critical, both at the level of development of theory and at the level of understanding, predicting and treating the consequences of a neurological event for an individual patient.

Neuropsychological assessment of attention and executive functioning

Melissa Lamar¹ and Amir Raz²

¹King's College London

²Columbia University and the New York State Psychiatric Institute

This chapter describes the cognitive neuroscience and neuropsychological assessment of attention and executive functioning. Each cognitive construct is defined within a theoretical framework. Additional information highlights the neuroanatomical and neurochemical underpinnings of specific aspects of attention and executive functioning. Adequate assessment of attention and executive functioning requires at least a basic knowledge of these features in order to choose the neuropsychological test measures best suited for a particular patient or clinical population.

Attention

Attention is one of the oldest issues in cognitive neuropsychology; its role in assessment is equally as historic and remains integral to the successful evaluation of a presenting patient. Attention is the process of selecting for active processing specific aspects of the physical environment (e.g. objects) or ideas stored in memory (Raz, 2004). Originally, attention was thought of as a unitary concept akin to a filter (Broadbent, 1958) or a spotlight (Shalev & Algom, 2000). More recent theories suggest that attention is a system of disparate networks including alerting, orienting and selection (Fan *et al.*, 2002).

Alerting involves particular changes in the internal state of an individual in preparation for perceiving a stimulus otherwise thought of as vigilance. Alerting is critical for optimal performance in tasks involving higher cognitive functions. With the use of neuroimaging technologies, alerting has been associated with the frontal and parietal regions of the right hemisphere. Lesions within these regions will reduce the ability to maintain the alert state. For example, right frontal lesion patients show an impaired ability to voluntarily sustain attention during continuous performance tests, displaying a larger number of errors over time when compared to left frontal lesion patients (Raz, 2004). It has long been established that right parietal lobe lesions, particularly those secondary to stroke, disrupt one's ability to remain alert and orient to stimuli in left hemispace, producing a profound and sometimes permanent neglect (Heilman & Van Den Abell, 1980). Alerting is thought to involve the cortical distribution of the brain's norepinephrine system arising in the locus coeruleus of the midbrain (Coull *et al.*, 2001).

Orienting involves the selection of information from sensory input which can be triggered by the stimulus or shifted as a result of voluntary control. Thus, orienting can be reflexive as when a sudden target event directs attention to its location, or it can be

more voluntary as when a person searches the visual field looking for a particular target. Even though orienting typically involves head and/or eye movements toward the target or overt orienting, it can also be covert. Orienting has been associated with areas of the parietal and frontal lobes, particularly the superior parietal lobe and frontal eye fields. Lesions within these regions will negatively impair the ability to determine a point of reference to sensory objects. Basal forebrain cholinergic systems play an important role in orienting (Beane & Marrocco, 2004).

Selection involves choosing among multiple conflicting actions or responses. Selection is critical for optimal performance in tasks involving decision making, error detection, or over-riding a habitual response. Neuroimaging data consistently reveals the anterior cingulate cortex as a central node in this attentional network (Posner & Rothbart, 1998). Additional brain areas involved in selection include the lateral prefrontal cortex and basal ganglia. Focal brain lesions to the anterior cingulate reduce and can often annihilate specific aspects of self-regulation and voluntary control making the inhibition of a pre-potent response difficult if not impossible. Selection is thought to involve the dopaminergic system given that both the anterior cingulate and lateral prefrontal cortex serve as target areas to this neurotransmitter system (Deth *et al.*, 2004).

These largely orthogonal attentional networks interact in many practical contexts to compute different aspects of cognitive and emotional tasks; however, they also retain a certain degree of functional and anatomical independence. Variations in the operational efficiency of these various attentional networks serve as a basis for differences in such complex cognitive neuropsychological processes as self-regulation and emotional control as well as more basic mechanisms of volition and sustained effort. Thus, evaluating each aspect of attention that is, alerting, orienting and selection, is advised if one is to gain a complete picture of the attentional functioning of the presenting patient.

Assessment measures of attention

We now highlight measures of attention that assess aspects of the alerting, orienting or selection networks. Please consult the references associated with each test measure for a more in-depth discussion of administration, scoring and interpretation procedures.

- *Digit Span-Forward* (DSp-F; Wechsler, 1981) DSp-F is a measure of immediate attention and rote recall. It requires participants

to listen to increasingly longer lists of digits and recite them in the exact order presented. Scores range from 0–14 and each point reflects successful completion of one trial of a particular list length.

There are visual variants of the traditional digit span task which involve learning increasingly longer lengths of 3-dimensional spatial positions as represented by raised blocks on a stimulus board (Milner, 1971) or 2-dimensional visual locations as represented by coloured circles on a visual display (Wechsler, 1945).

- *Trail Making Test – Part A* (TMT-A; Army, 1944) TMT-A is a test of speeded attention, mental tracking and visual search. Participants are required to connect a series of circles containing numbers randomly arranged in a spatial array. Both time-to-completion in seconds as well as error rate give an indication of an individual's level of attention.
- *Visual Search and Cancellation Tasks* (Diller *et al.*, 1974) Many forms of these measures exist but the underlying instructions remain the same: to 'cancel' or indicate by either crossing out or circling a particular target stimulus embedded in a larger array of distracter items. Traditional cancellations tasks include identifying the letter 'A' within a complex visual array of various letters and finding a variant of a star within a complex visual array of abstract designs. The number of items omitted is an indication of vigilance and the proportion of items omitted in each quadrant of the test page can suggest the presence of a possible neglect.
- *Stroop Colour Word Interference Test* (Stroop, 1935) In the classic Stroop task experienced readers are asked to name the ink colour of a displayed word. Responding to the ink colour of an incompatible colour word (e.g. the word 'RED' displayed in blue ink), subjects are usually slower and less accurate than identifying the ink colour of a control item (e.g. "XXX" or "LOT" inked in red). This difference in performance is called the Stroop Interference Effect (SIE).
- *Global Local Test* (Robertson *et al.*, 1988) Assesses attentional preference and the ability to reorient attention (i.e. from the global, or overall gestalt of a figure, to the local, or more detailed level of analysis). Thus, individuals are presented with a large number or letter (e.g. a 2) made up of smaller numbers or letters (e.g. strategically positioned 1's) at a rapid rate of visual presentation and asked to indicate what number or letter they perceive. Alternatively, individuals may be asked to indicate what object (e.g. number), is represented at either the global or the local level. Reaction time data indicates which level of analysis, global or local, is more taxing with slower reaction times suggesting greater difficulty. Error rates can also be informative.
- *Flanker Tasks* (Eriksen & Eriksen, 1974) Subjects respond to the direction of a central arrow when flanking arrows could either point in the same, that is congruent, or opposite, that is incongruent, direction.
- *Attention Network Test* (ANT; Fan *et al.*, 2002) The ANT, a variation of the Flanker task, requires subjects to determine whether a central arrow points rightward or leftward while the surrounding arrows may be either congruent or incongruent. Targets are arrows above or below fixation, pointing to the left or right and they are flanked on both sides by congruent or incongruent arrows. Targets are preceded by informative or

uninformative spatial cues. The ANT provides three numbers that indicate the efficiency of the networks that perform the alert, orient and conflict resolution functions of attention and can be performed by adults, children, patients and even non-human animals.

- *Lateralized Attention Network Test* (LANT; Barnea *et al.*, in press) A variation of the ANT, the LANT was developed to measure the sensitivity and reliability of the three networks of attention in each hemisphere and demonstrate their validity in relation to standardized clinical measures of attention. The promise of the LANT centres on its potential to critically assess training protocols for modulating the relative attentional engagement of the two hemispheres. Furthermore, the LANT can be used, together with EEG, on self-regulation protocols to rehabilitate normal human attention.

Executive functioning

The role of executive functioning has long been to coordinate other neurocognitive systems through activities such as working memory, planning and monitoring (Stuss & Alexander, 2000). A number of authors have presented conceptual definitions of different aspects of executive functioning including models of working memory (Baddeley, 1992) and the organization of complex behaviours (Luria, 1980). Based on a review of such definitions, executive functioning appears to encompass a network of cognitive operation involving mental coordination of behaviour including planning, monitoring and mental tracking; self-regulation of behaviour including mental flexibility and the capacity to shift mental set; and complex purposive action involving self-initiated and goal-directed behaviour (Lamar *et al.*, 2002). In breaking down executive functioning into a network of cognitive operations, one is better able to determine the neuroanatomical underpinnings of this complex construct and to conduct a more complete neuropsychological evaluation.

There is a long history of non-human lesion studies as well as an increasing amount of in vivo human neuroimaging studies describing the neural substrates involved in various aspects of executive functioning (see Fuster, 1997 for review). The dorsolateral prefrontal cortex, Brodman's area (BA) 46 (Figure 1), is associated with the successful mental coordination and manipulation of information. The dopaminergic system is most affiliated with this aspect of executive functioning although other neurotransmitter systems may modulate performance on select measures of working memory and mental manipulation (Ellis & Nathan, 2001). The orbitofrontal cortex is associated with the acquisition of appropriate behaviours and the inhibition of inappropriate ones with medial orbitofrontal cortex (BA 25) associated with error detection and positive reward and lateral orbitofrontal cortex (BA 11) responsible for the inhibition of a prepotent response (see Elliott *et al.*, 2000 for review). Investigations repeatedly suggest that decreases in serotonin negatively impact various measures of orbitofrontal functioning, particularly decision making (Rogers *et al.*, 2003).

Neuroimaging studies corroborate the notion that there are separable components of executive functioning which may not reside within prefrontal cortex but are nonetheless integral to and supervised by this region. For example, specific areas within the

Fig 1 Brain with Brodmann's areas and prefrontal highlights.

parietal lobe (BA 40; BA 7) have been associated with storage and mental coordination whose purpose is to maintain information online; while Broca's area (BA 44) appears responsible for the rehearsal of information that resides in short-term memory (see Smith & Jonides, 1998 for review). Thus, a thorough assessment of executive functioning should be a part of any neuropsychological evaluation when assessing individuals with frank frontal lobe lesions as well as individuals without obvious damage to prefrontal cortex.

Due to the complexity of the behaviours in question and the multifaceted nature of most tests of executive functioning, it is difficult to say with certainty what any particular executive function task assesses. The variability present in the literature to describe any single measure of executive functioning (Lezak, 1982) illustrates the trouble in measuring a single aspect of executive ability or developing a consensus regarding the specific abilities tapped by any particular executive function task. Therefore, it is advised to rely on several measures to gain a global picture of executive functioning.

Assessment measures of executive functioning

We now highlight measures of executive functioning that primarily assess some aspects of mental coordination, self-regulation or complex purposive action. Please consult the references affiliated with each measure for a more in-depth discussion of administration, scoring and interpretation.

- *WAIS-R Digit Span Backward* (DSp-B; Wechsler, 1981) DSp-B is a measure of mental tracking as well as brief storage and mental manipulation. It requires participants to listen to increasingly longer lists of digits presented for immediate recall in the reverse order from what was originally presented. In addition to the attentional requirements also evident in DSp-F, DSp-B requires mental manipulation for successful completion. Scores range from 0–14 and each point reflects successful completion of one trial of a particular list length. Visual variants of DSp-B are described within the section 'Assessment measures of attention' with the

caveat that these measures require recall in the reverse order from the initial visual presentation.

- *WAIS-R Similarities subtest* (Wechsler, 1981). Similarities is a measure of concept formation and reasoning which relies on continuous monitoring of output. It requires participants to find associations between word pairs of increasing complexity. Points are given based on the nature of the response and calculated using standardized procedures.
- *Trail Making Test Part B* (TMT-B; Army, 1944) The TMT-B is a test of speeded attention, mental tracking and visual search, as well as sequencing and mental flexibility. In addition to the attentional demands evident in TMT-A, TMT-B requires the additional processes of mental flexibility and set shifting as participants alternate between connecting a series of circles containing numbers and letters randomly arranged in a spatial array. Variables indicating an individual's performance include time-to-completion and errors. Some researchers subtract the scores of TMT-B from TMT-A to further isolate executive functioning from attention.
- *Alpha Span* (Asp; Craik, 1990) ASp involves short-term memory and mental tracking. It requires participants to listen to increasingly longer lists of common words presented for immediate recall in alphabetical order. Participants receive two trials of each list length, and the task is terminated after the failure of both trials. ASp scores range from 0–14, and each point reflects successful completion of one trial of a particular list length.
- *Porteus Maze Test* (Porteus, 1959) The Porteus Maze test involves the planning aspect of executive functioning. It requires participants to navigate through increasingly difficult 2-dimensional mazes. A mental age score is calculated according to standard procedures.
- *Rivermead Behavioural Memory Prospective Memory Tasks* (Wilson, Cockburn & Baddeley, 1985) Prospective memory involves planning, monitoring and purposive action. Items require participants to remember to execute different activities in the future (e.g. remembering to: ask about the next appointment when an alarm clock goes off). All tasks are introduced within 15 minutes of the beginning of the test session and interspersed throughout the course of a complete neuropsychological evaluation. Two, one, or zero points are given for each activity depending on the level of cueing needed at the time of recall. Higher scores indicate better performance.
- *Verbal Fluency* (Spreen & Benton, 1969) Although measures of verbal fluency primarily tap language functions, they also assess spontaneous flexibility through the generation of responses within a particular set of constraints and the capacity to shift mental set. Fluency tests require participants to generate as many words as possible in one minute for a given letter (F, A, S) or category (animals, fruits, vegetables), excluding proper nouns and variations of the same word. Separate scores for letter and category fluency reflect total output across all three trials (see also 'Communication assessment').
- *Wisconsin Card Sorting Test* (WCST; Grant & Berg, 1948) The WCST assesses many aspects of executive functioning including mental flexibility and concept formation. Individuals are given individual cards containing one of four forms (triangles, stars, crosses, or circles) in one of four colours (red, yellow, green or blue) presented one of four times per card. They are required

to match each card to one of four target cards based on a series of rules. These rules are not explicitly stated but must be deduced based on examiner feedback. Only when 10 cards have been placed correctly under a specific rule does the rule change. Thus, sorting to colour would require 10 successful matches based on colour before the rules changed to either form or number. A total of 6 rule changes are possible and a variety of scores including the number of categories achieved and perseverative errors may be calculated.

- *The Graphical Sequence Test* (Bilder & Goldberg, 1987); *The Graphical Sequence Test – Dementia Version* (Lamar *et al.*, 1997) These measures, designed to elicit perseverative behaviour across a wide variety of clinical populations, consist of a series of consecutive verbal commands to write or draw simple geometric shapes, e.g. circles and squares, or common figures, e.g. flowers and houses. The total number of errors provides a measure of overall executive dysfunction and various error types represent increasingly lower levels of executive dysfunction.
- *The Self-Ordered Pointing Task* (SOPT; Petrides & Milner, 1982) This task assesses planning and self-monitoring through sequential selection of visual or verbal stimuli. The SOPT consists of a set number of stimuli per page with the number of pages dependent upon the number of stimuli (e.g. 12-items/12 pages). Each page contains all the same stimuli; however, the position of each stimulus on any given page varies so that no stimulus is in the same location twice. For each page, participants are instructed to select a different stimulus from those selected on previous pages in the trial. A trial is complete when all pages in the series have been presented. A total of three trials are administered. The number of items selected more than once is summed across all trial blocks with higher scores indicative of greater executive dysfunction.
- *Intra/Extra-Dimensional Shift Task* (CANTAB, Cambridge, UK). This task assesses participants' ability to attend to specific attributes of compound stimuli and to shift mental set based on feedback. Dimensions for visually presented stimuli consist of colour-filled shapes and white lines. Participants are required to choose the correct stimulus from a set of stimuli. Initial responses are to simple or unidimensional stimuli but as the task progresses, stimuli become more complex, consisting of both colour and line dimensions. Correct responses are based on criterion learned as the task progresses and become increasingly difficult to determine; that is, moving from simple, intra-dimensional shifts (e.g. colour rules only) to more difficult, extra-dimensional shifts, (i.e. colour and line rule combinations). A variety of shift scores

may be determined based on the total correct at each stage of difficulty.

Assessment batteries of executive functioning

- *Delis-Kaplan Executive Function System* (D-KEFS; Delis *et al.*, 2001) This battery consists of nine sub-tests that tap such areas of executive functioning as mental flexibility, planning, concept formation, the ability to attain and maintain mental set and self-regulation. Thus, the D-KEFS evaluates the majority of executive function aspects outlined throughout this chapter. Comprehensive normative data assists in the evaluation of all age ranges and the qualitative scoring system allows for an error analysis that may help explain subtle nuances of behaviour not addressed by more traditional measures of executive functioning.
- *The Executive Control Battery* (ECB; Goldberg *et al.*, 2000) The ECB takes an error production approach to assessing executive functioning through a series of subtests designed to elicit perseverations, inertia, stereotyped behaviour and mimicry. In addition to the Graphical Sequences Test, a version of the Go/No-Go task assesses self-regulation by either rewarding the selection of a prepotent response or the inhibition of it, respectively. Two remaining sub-tests require the repetition or mirroring of various motor programmes and sequences to evaluate more basic aspects of executive control involving the premotor cortex.

Conclusion

We have attempted to highlight the various component parts or networks that constitute attention and executive functioning. Furthermore, we have outlined the neuroanatomy and neurochemistry involved in each of these cognitive constructs and the neuropsychological test measures that may be used to investigate performance. In order to pick the most appropriate measures of attention and executive functioning for a particular evaluation, one should always consider the referral question, the presenting symptomatology and/or diagnosis of the client. Given this information, one can then attempt to predict the expected functional and/or structural areas of involvement. These predictions will make choosing the appropriate neuropsychological test measures easier. However, if little or no information exists, it is advised to select a few neuropsychological test measures that assess various aspects of attention and executive functioning to adequately cover these cognitive abilities (see also 'Neuropsychological assessment: general principles').

Neuropsychological assessment of learning and memory

Nancy D. Chiaravalloti, Amanda O'Brien and John DeLuca

Kessler Medical Rehabilitation Research and Education Corporation

With over 100 different theorized types of memory in existence (Tulving, 2002) it is no wonder that the assessment of learning and memory can be quite complex. However, despite our current

knowledge, memory is often conceptualized as a unitary concept, especially by non-psychologist health professionals. Memory is actually a multidimensional construct with dissociable sub-systems,

or processes. Many of these subsystems are particularly sensitive to impairment following trauma or other acquired brain insult. Therefore, understanding how the brain represents and processes information is essential in the clinical assessment of learning and memory. Despite the major advances in the understanding of cognitive and cerebral aspects of learning and memory in the last century, clinical assessment has lagged behind the research knowledge in this area.

This chapter will present a basic overview of modern clinical assessment of learning and memory in adults. It begins with a brief historical perspective on views of memory followed by a discussion of the different approaches to the conceptual understanding of learning and memory (e.g. ‘process’ versus ‘systems’ approach). The chapter will also touch upon the key brain structures responsible for aspects of memory. We will address the role of learning, current debates in assessment, comprehensive assessment techniques and other cognitive functions that impact memory. Finally, a discussion of future directions and recommendations for improving the quality of memory assessment is presented.

The history of learning and memory assessment

There have been significant advances in the knowledge of learning and memory (and related brain structures) over the past 50 years. However, the ‘formal’ scientific study of learning and memory actually began in the late 1800s, with the work of Ebbinghaus, who established several cognitive principles of memory. By the early 1900s, the existence of an ‘amnesic syndrome’ (primarily Korsakoff’s syndrome) became widely accepted and became associated with damage to diencephalic structures (i.e. thalamic nuclei and mammillary bodies). By the 1950s and 1960s, mesial temporal structures also became a primary focus of understanding the cerebral substrates of human memory. More recent conceptualizations of learning and memory have returned to the important role played by the basal forebrain and the frontal lobes.

Despite a solid body of research, the clinical assessment of memory still largely neglects the experimental study of learning and memory in psychology as well as the vast cognitive psychology and cognitive neuroscience literature. This has often resulted in an assessment which seems clinically meaningful, but is typically not well grounded theoretically. Although the original development of a memory ‘test battery’ was a landmark event in psychology, it was abundantly criticized due to statistical and methodological issues in its development (Prigatano, 1978). More recent memory assessments (i.e. Wechsler Memory Scale (WMS)-III; Wechsler 1997) have made major advances by including a large standardization sample, improving face validity (particularly evident in the visual memory sub-tests) and expanding the sub-tests measuring visual memory functions. However, the clinical assessment of learning and memory continues to lag behind the knowledge gained through research.

Defining learning and memory

It is necessary to understand that memory cannot be properly assessed without first addressing learning. ‘Learning’ can be defined as ‘the process of acquiring new information’, whereas the term

‘memory’ refers to ‘the persistence of learning in a state that can be revealed at a later time’ (Squire, 1987). As such, memory cannot be adequately assessed unless it is verified that the to-be-remembered information has indeed been learned.

Despite the many theories regarding types of memory and memory systems (Lezak *et al.*, 2004) two of the most widely accepted approaches to memory are the systems approach and the process approach. Although distinctly different, these approaches can be seen as complimentary (Schacter *et al.*, 2000). In the ‘systems’ approach to memory functioning, each inter-related but dissociable system is somewhat independent, in that different brain structures and resources may be utilized by each system in order to function (see Figure 1). A major distinction in this approach to human memory is the dichotomy between the procedural memory system and the declarative memory system (Tulving, 2000).

The declarative memory system consists of knowing *that* something, such as a skill or an element of information, was learned. In contrast, the procedural memory system represents knowing *how* to perform a skill, without consciously reflecting on the steps to perform the skill (Bauret *et al.*, 1993). The declarative memory system consists of a complex interaction between mesial temporal (especially hippocampus), diencephalic (primarily anterior structures), basal forebrain and frontal lobe structures and is sensitive to acquired brain damage. In contrast, the procedural memory system is less sensitive to such damage.

One can also conceptualize learning and memory as a process, in an information processing framework (Tulving, 2000) (see Figure 2). In this model, information moves through several stages from temporary to long-term storage in the brain. An important component of this model is ‘working memory’. The term ‘working memory’ refers to the temporary storage, maintenance and manipulation

Fig 1 The structure of the memory system.

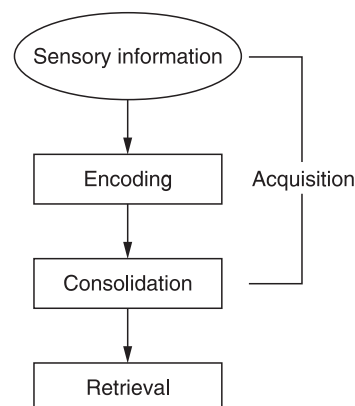

Fig 2 The memory process.

of information in the brain (Baddeley, 2000). This process is vital to the new learning and long-term memory processes.

When information is rehearsed in working memory, it is encoded due to the development of memory traces. Once information is encoded, it is transferred from this short-term temporary store to more long-term storage, a process referred to as ‘consolidation’, or ‘elaboration’ (Squire *et al.*, 1983). Numerous structures, including the hippocampus and surrounding regions, diencephalic structures, basal forebrain and the cingulate gyrus are involved in the consolidation of declarative information (see Markowitsch, 2000). The combined processes of initial encoding and subsequent consolidation of learned material in long term storage is called memory ‘acquisition’ (see Figure 2). ‘Retrieval’ is the process of tapping into previously encoded information from long-term storage for use (Squire *et al.*, 1983).

Interestingly, even the most modern imaging studies have not yet been able to definitively identify the structures responsible for the process of retrieval. As retrieval tasks often simultaneously involve re-encoding of the information retrieved, it makes identification of such structures more complex (Markowitsch, 2000). Tulving and colleagues (1994) posit a model called the Hemispheric Encoding/Retrieval Asymmetry (HERA) model. In this model, a left hemisphere prefrontal pattern of activation for the encoding of episodic memory is seen, with a right hemisphere prefrontal pattern of activation for retrieval from episodic memory. However, additional regions may be involved with distinct types of information. For example, temporo-polar regions may be involved when autobiographical memories are being retrieved (Fink *et al.*, 1996).

Comprehensive assessment of learning and memory

The clinical assessment of learning and memory is multifaceted and is not simply the administration of psychometric tests. Rather, it consists of several levels of evaluation, beginning with the referral question and including activities such as record review(s), the clinical interview and concluding with the actual psychometric testing (see Lezak *et al.*, 2004). The efficient assessment of learning and memory must begin with a specific referral question. Unfortunately, referrals are too often vague and therefore of limited use for identifying the need for an evaluation. Questions such as ‘characterize strengths and weaknesses’, or ‘examine functional versus organic factors’, offer little guidance to the evaluating clinician. The comprehensive clinical interview gathers a complete patient history including topics such as alcohol or substance use, learning disabilities, educational and work history and relevant medical history (see ‘Medical interviewing’). A hypothesis testing approach to assessment gathers all of this data in order to integrate background information and draw conclusions from later testing outcomes.

Psychometric assessment

A psychometric approach to assessing learning and memory is based on quantitative measurements of samples of behaviour (e.g. learning and remembering a list of words), and a subsequent determination as to whether or not a person is ‘impaired’ on that sample of behaviour, compared to a normative group.

Table 1. Common neuropsychological tests of memory ability

Verbal memory	Non-verbal memory

One’s ‘performance’ is considered to be impaired when it is below expected levels, given the patient’s age, education and estimated pre-morbid intelligence. This inference is then used to determine if, and to what degree, a person has a deficit in learning and/or memory (see ‘Neuropsychological assessment: general principles’).

The quantitative assessment of learning and memory includes the use of test instruments or batteries that have been standardized in terms of administration, and evaluated in terms of basic psychometric properties. Some of the more popular instruments are listed in Table 1 (see Lezak *et al.*, 2004 for a thorough discussion). Interestingly, because episodic memory is the system most vulnerable to brain damage or dysfunction, virtually all tests of ‘memory’ that are popularly used are actually tests of episodic memory.

Memory cannot be adequately assessed without first knowing if the target information had been acquired. The importance of learning has been addressed in a series of studies by DeLuca and colleagues (1994, 1998, 2000). In one study (DeLuca *et al.*, 2000), persons with traumatic brain injury (TBI) were equated with healthy controls on the amount of information initially learned. Specifically, target material was presented repeatedly until a pre-set learning criterion was reached by both groups. Once both groups were equated on acquisition, recall and recognition was assessed and was not significantly different between the two groups. Using this design, a better understanding of the nature of impaired learning and memory (i.e. acquisition versus retrieval) was achieved. These data argue that individuals with TBI suffer from significant problems in the acquisition of new information and that recall and recognition abilities are not impaired once acquisition deficits are taken into account. Interestingly, these same results have been replicated by others (e.g. Vanderploeg *et al.*, 2001) and have also been shown in samples of individuals with multiple sclerosis (DeLuca *et al.*, 1994, 1998; Demaree *et al.*, 2000).

Unfortunately, most current clinical tools generally do not assess learning directly or comprehensively. As a result, interpretation of recall and recognition is typically confounded. (See Table 2 for common memory assessment measures and the degree to which they assess learning.)

Today, with an increased understanding of the complexity of learning and memory, a clinical assessment should be designed to determine at what point within the memory process (i.e., encoding–consolidation–retrieval) a patient is exhibiting difficulty, as this issue significantly impacts the approach to treatment. For example the treatment for difficulties in acquisition would be vastly different

Table 2. Common neuropsychological tests of memory functioning, strengths and weaknesses

Name	Form	Adequacy of assessing learning	Strengths	Weakness
California Verbal Learning Test (CVLT)-II	List Learning Test	Good	<ul style="list-style-type: none"> • Multiple trials • Many indices available • Good difficulty level • Good norms • 16 items are in 4 categories allowing assessment of organization 	<ul style="list-style-type: none"> • Fixed number of learning trials
Rey Auditory Verbal Learning Test (RAVLT)	List Learning Test	Not adequate	<ul style="list-style-type: none"> • Multiple trials 	<ul style="list-style-type: none"> • No formal measure of learning
Bushke Selective Reminding Test (SRT)	List Learning Test	Not adequate	<ul style="list-style-type: none"> • Multiple trials • Many alternate forms 	<ul style="list-style-type: none"> • Many versions, making decision of which to use is difficult
Hopkins Verbal Learning Test – Revised	List Learning Test	Not adequate	<ul style="list-style-type: none"> • Multiple trials • Simple words are easier for those with lower education • Many alternate forms • 12 items are in 4 categories allowing assessment of organization 	<ul style="list-style-type: none"> • Many higher functioning patients ceiling out • Only 3 learning trials
Rey Osterrieth Complex Figure	Figure Copy	Not adequate	<ul style="list-style-type: none"> • Figure is complex, allowing assessment of complex figural memory • Allows assessment of organizational ability 	<ul style="list-style-type: none"> • No learning trials
Brief Visual Spatial Memory Test	Figural ‘List’ Learning	Not adequate	<ul style="list-style-type: none"> • Multiple trials • Nonverbal list learning task is fairly rare, but useful 	<ul style="list-style-type: none"> • Only 3 learning trials • Stimuli can be verbalized fairly easily
Biber Figural Learning Test	Figural ‘List’ Learning	Not adequate	<ul style="list-style-type: none"> • Multiple trials • Nonverbal list learning task is fairly rare, but useful • Many learning items in each trial, making the task more difficult 	<ul style="list-style-type: none"> • Fixed number of learning trials • Certain stimuli can be verbalized fairly easily
Wechsler Memory Scale – Revised	Battery of Sub-tests	Not adequate	<ul style="list-style-type: none"> • Multiple types of memory assessed, both verbal and nonverbal 	<ul style="list-style-type: none"> • Nonverbal tasks are easily verbalized and limited in difficulty
Wechsler Memory Scale – III	Battery of Sub-tests	Not adequate, but better than the revised edition	<ul style="list-style-type: none"> • Multiple types of memory assessed, both verbal and nonverbal • Includes facial memory and memory for everyday scenes 	<ul style="list-style-type: none"> • Few measures of learning for a very extensive battery • Time consuming to administer

than the treatment of a patient with difficulties in the retrieval of information from long term storage (Cicerone *et al.*, 2000).

The California Verbal Learning Test (CVLT, Delis, Kramer & Kaplan, 1987) is perhaps the best test available that allows for differentiation between learning and retrieval. The CVLT allows for the examination of the learning process through a variety of procedures, based on principles from cognitive psychology, including quantifying the rate of learning, examining recall consistency and quantifying the learning strategy employed (i.e. serial vs. semantic clustering). The CVLT also generates traditional measures of free and cued recall and recognition.

However, many clinicians continue to rely on the recall versus recognition contrast in their clinical assessments to draw conclusions regarding 'memory' with little or no regard to the learning indices available. By assuming that initial learning is intact due to the presence of adequate recognition abilities, one may make a number of erroneous assumptions. First, one is assuming that recall and recognition procedures are matched for difficulty. However, free recall is a more difficult task than recognition for both healthy and impaired individuals (Lezak *et al.*, 2004; Johnson, 1992). Second, it is often assumed that 'learning' is an all-or-none phenomenon. However, cognitive psychologists often talk about depth or quality of encoding (Brown & Craik, 2000), which refer to the strength of the memory trace. Research in learning and memory present a strong argument that a simple recall vs. recognition analysis of clinical data is insufficient to determine whether impaired performance is due to deficient acquisition or a retrieval failure.

Other considerations for comprehensive learning and memory assessment

It is important to emphasize that the clinical assessment of learning and memory is not simply the administration of tests that measure memory. There are numerous factors, both cognitive and non-cognitive, that affect the ability to acquire and subsequently recall or recognize target material. Some of these factors include working memory, information processing speed, executive abilities and 'effort'. These factors must also be assessed to provide an understanding as to why an individual may perform poorly on tests of learning and memory.

Working memory

As mentioned above, working memory is a pivotal component for many cognitive skills, such as active listening, problem-solving and planning and is often considered the first step in the encoding of information into episodic memory (Johnson, 1992; Jonides, 1995). Impairments in working memory can lead to decreased learning efficiency, which leads to impaired recall and recognition in long-term memory (Kyllonen & Christal, 1990).

The best known theory of working memory was posited by Baddeley (1992) and includes two slave systems and a central executive system. The slave systems (a phonological loop and a visuo-spatial sketchpad) maintain and rehearse information for a limited period of time. The central executive system is then responsible for processing and manipulating this stored information for use.

As working memory has a significant impact on long-term episodic memory, its proper assessment is critical within a comprehensive

evaluation of long-term episodic memory ability. Despite well developed multi-factorial theories, working memory is often conceptualized and assessed as if it is a unitary construct. There is a solid body of research, including neuroimaging studies, which support the assertion that working memory is a multifactorial construct. Unfortunately, many tests that claim to assess working memory do not do so purely. For example, the Paced Auditory Serial Addition Test (PASAT) is commonly utilized to assess working memory. However, performance on this task is confounded by attention and processing speed, making a true determination of working memory skills very difficult. There is a current need for clinical assessments to reflect the current research knowledge in order to properly assess working memory in adults.

Information processing speed

Research demonstrates that an analysis of processing speed must be part of the clinical assessment of learning and memory due to the intricate relationship between processing speed and acquisition of information. For example, in persons with multiple sclerosis, speed of processing has been found to be correlated with the number of learning trials it takes to achieve a learning criterion (DeLuca *et al.*, 1994; Gaudio *et al.*, 2001). There is also research that posits that decreased processing speed is responsible for impaired working memory and skill acquisition in older adults (e.g. Salthouse, 1996).

A challenge in assessing information-processing speed is that clinical tests of pure 'processing speed' are non-existent. Therefore, multiple instruments should be used so that related cognitive constructs can be 'factored out' in an attempt to isolate speed of processing deficits (Kalmar *et al.*, 2004). For example, if a patient's assessment results included an impaired PASAT, coupled with impairment on the WAIS-III Processing Speed Index in the presence of an intact Working Memory Index on the WAIS-III, evidence of a specific impairment in processing speed would be supported. If the same patient had an impaired verbal memory performance on the Logical Memory subtest of the WMS-III, a clinician may conclude that the impairment in verbal memory is at least partially confounded by the processing speed deficit. As this example illustrates, information processing speed can have a significant impact on learning and memory and must be integrated into an assessment in order to correctly interpret results of a learning and memory evaluation.

Executive functions and 'frontal lobe' factors

Executive functions are complex and multidimensional and include complex cognitive processes including initiating, motivating, processing, organizing and planning goal-directed behaviours and are thought to be related to frontal lobe structures (Lezak *et al.*, 2004, Fletcher & Henson, 2001). Although a number of studies point to a significant relationship between executive functions and memory, it should be recognized that not all aspects of executive functions will necessarily be associated with learning and memory, due to its multidimensional nature (e.g. Tremont and colleagues, 2000). Clinical assessment of learning and memory must account for the potential influence of executive dysfunction on tests of learning and memory. See 'Neuropsychological assessment of attention and executive function' for a more detailed discussion of this topic.

Evaluating effort

A participant's level of effort can also significantly influence performance on tests of learning and memory. This is a particularly important issue in the forensic arena where secondary gains (e.g. financial) may provide the motivation to perform below one's true abilities. In addition, the feigning of symptoms, such as cognitive deficits, can be a marker for psychiatric syndromes. The inclusion of tests designed to measure symptom validity is therefore a necessary component in a neuropsychological assessment of learning and memory.

To evaluate 'effort', a number of objective tests have been designed such that even impaired individuals are able to perform adequately (i.e. they are 'too easy to fail') (Lezak *et al.*, 2004). Examples include the Rey 15-Item Memory Task, the Portland Digit Recognition (Binder, 1993) and the TOMM (Tombaugh, 1997). Impaired performance on tasks such as these may suggest poor effort or malingering, but cannot 'prove' either. The results of effort testing must be integrated with information from other sources such as the clinical interview, records, etc. in order to form a meaningful conclusion.

Conclusions and recommendations

The fields of cognitive psychology, neuropsychology and neuroscience have greatly advanced our understanding of the learning and memory process and related brain structures over the past 50 years. However, the clinical assessment of learning and memory has not fully translated research findings into practice. With such a solid base of research as a guide, clinicians must take this information into account in the development of new assessments and in their interpretations of clinical assessment outcomes.

Several conclusions can be drawn from the information highlighted in this chapter. First, research must be translated into practice. Although determining the presence or absence of a memory problem is often the primary referral question, an assessment should also include where in the process of learning and memory (i.e. encoding, consolidation, retrieval) a patient is experiencing difficulty. Such information can be utilized to design more specific and effective treatment interventions aimed toward improving functional ability. Second, it is necessary for clinicians to demonstrate that preliminary steps in the learning and memory process (i.e. attention) are intact before they are able to conclude that a later process (i.e. retrieval) is impaired. A more appropriate conclusion may be that the integrity of the memory system is compromised, potentially secondary to impaired attention or executive functioning skills. Third, learning and memory cannot be assessed simply by the administration of tests of memory alone. Several other cognitive constructs can significantly influence whether information is adequately learned and therefore available for later retrieval from long-term storage. The clinical assessment of learning and memory must include both qualitative and quantitative assessment as well as careful interpretation of results.

Finally, new research-based approaches to the clinical assessment of learning and memory must be developed. One potentially valuable approach is criterion-based assessment. In this approach, tests would be designed to measure the ability to achieve a learning criterion (e.g. number of trials to learn a list of 12 words). However, assessments of learning and memory continue to utilize a traditional normative-based approach to understanding cognitive abilities and impairments (Anastasi, 1988). An integration of both a criterion-based approach with more traditional normative-based approach may provide a more comprehensive and complete clinical picture.

Pain assessment

Sandra J. Waters, Kim E. Dixon, Lisa Caitlin Perri and Francis J. Keefe

Duke University Medical Center

Over the past four decades, approaches to the assessment of chronic pain have evolved substantially within the field of behavioural medicine. During this time, it has become apparent that what we label as ‘pain’ is the result of complex interactions among biological, psychological and social factors. The gate control theory of pain (Melzack & Wall, 1965) supports this paradigm in that it confirms that pain is a complex experience involving sensory–discriminative, evaluative–cognitive and affective–motivational components, thus emphasizing the role of the central nervous system in nociceptive perception and processing. Further, the gate control theory provides a foundation for the development and refinement of integrated pain assessment models, such as the biopsychosocial model of pain (Turk, 1996).

The biopsychosocial model of pain acknowledges that the experience of pain often is the result of physiological changes occurring after peripheral nociceptive stimulation (Turk, 1996). However, this model also emphasizes that the pain experience is modulated by individual differences in various cognitive, affective,

behavioural and social factors. People with the same level of underlying nociceptive stimulation may differ in their pain experience depending on the importance of any factor at any given time during the course of the disease or condition (Asmundson & Wright, 2004). Thus, assessing pain necessitates the examination of relations among various factors across a variety of levels (Stoney & Lentino, 2000).

During the latter part of the twentieth century, Melzack (1999) proposed an expanded model of pain which further highlights the role of psychological processes in pain. This model, the neuromatrix model, proposes the presence of a widespread network of neurons (the neuromatrix) which is distributed throughout many areas of the brain and which integrates information from multiple sources. The neuromatrix outputs information to other brain areas and produces a neurosignature pattern that may be responsible for the development of chronic pain (Melzack & Katz, 2004). The neuromatrix theory is important because it provides a theoretical framework in which a genetically determined template of a whole

body (i.e. the body–self neuromatrix) is modulated by sensory inputs, the stress system and cognitive functions of the brain (Melzack & Katz, 2004). As such, it presents a more complex, psychological model of pain that warrants a broader approach for assessing pain (see ‘Pain’).

Pain assessment

Just as the models of pain have evolved from simple to more complex, integrated designs, so too have the measures used in the assessment of pain. Today, clinicians and researchers utilize measures designed not only to assess pain intensity, but also the psychological and sociological factors which contribute to the pain experience. This chapter provides a brief overview of assessment tools currently used by many clinicians and researchers in the field of pain. The chapter is divided into three sections in which we describe measures that assess (1) pain experience; (2) cognitive and emotional aspects of pain; and (3) functional aspects of pain. Each section includes a brief description of each measure, presents research evidence, and clinical implications of using such measures in pain assessment. The sections conclude with evaluative comments.

Pain experience measures

The experience of pain is typically assessed using single-item or multi-item scales. Pain is very often assessed using brief, single item scales such as a Numeric Rating Scale (NRS) that measures pain using a 0–10 scale on which 0 is ‘no pain’ and 10 is ‘pain as bad as it can be’. The patient chooses the number that best represents the current intensity of their pain. It has been suggested that a reduction of 2 points on a 0 to 10 point NRS represents a clinically important improvement in pain (Farrar *et al.*, 2001).

A Visual Analogue Scale (VAS) is another single-item scale used to measure pain. Patients place a hash mark at the location on a 10 cm line that reflects the intensity of their pain. The scale is anchored on the lower end by ‘0’ (no pain at all) and ‘10’ on the upper end (worst pain ever experienced). Some researchers suggest that older adults with and without cognitive impairments may find this scale hard to use because of the abstract nature of the scaling properties (Varni *et al.*, 1986). Despite this potential shortcoming, the VAS is frequently used to assess pain intensity in both research and medical settings (e.g. Jansen & Karoly, 2001).

Single item Verbal Descriptor Scales (VDS) are also frequently used to assess the perceived intensity and unpleasantness of pain. On a VDS, a group of verbal descriptors is presented to the patient (e.g. ‘none’, ‘mild’, ‘moderate’, ‘severe’ and ‘extreme’) and the patient is asked to select the word that best describes their pain. The VDS is easy to score and interpret and is sensitive to both drug and non-drug treatment changes in pain levels, making it an attractive measure for use in both research and clinical settings (Burckhardt & Jones, 2003).

A drawback of single item scales is that they measure only one part of the pain experience. In an attempt to capture multidimensional aspects of the pain experience, multi-item instruments such as the McGill Pain Questionnaire (MPQ; Melzack, 1975) were developed. The MPQ contains 20 sets of adjective pain descriptors

describing the sensory qualities, affective qualities and subjective intensity of pain. Patients select words from the list to describe their current pain. Pain descriptors are given a rank value based on their position within each group of words. The rank values are used to calculate (1) a Sensory sub-scale; (2) an Affective subscale; and (3) an Evaluative sub-scale. A short form of the MPQ (MPQ-SF; Melzack, 1987) is available for occasions when time constraints negate the use of the original measure. Both forms are valid, reliable and useful measures of subjective pain in clinical and research settings (Dudgeon *et al.*, 1993). However, research has suggested some instability in the MPQ sub-scale factors in different pain populations (e.g. Holroyd *et al.*, 1992; Cassisi *et al.*, 2004).

The Brief Pain Inventory (BPI; Cleeland, 1989) is another multi-item, self-report questionnaire that measures current pain as well as the least, worst and average pain in the past 24 hours. On the BPI, 0 to 10 numeric rating scales are not only used to assess pain intensity but also to assess pain interference in seven quality of life domains (i.e. general activity, walking, mood, sleep, work, relations with other persons and enjoyment of life). Although initially developed to assess cancer pain, the BPI is now widely used to assess chronic non-malignant pain (Tan *et al.*, 2004; White *et al.*, 2003).

Direct observation of pain behaviours can be useful in gathering information on behavioural markers of pain. Pain behaviours are the verbal (e.g. sighing) and non-verbal behaviours (e.g. grimacing, rubbing) which serve to convey to others that pain is being experienced (Fordyce, 1976). In clinical settings, pain behaviours are important because they can influence physicians’ decisions about pain evaluation and treatment (e.g. deciding on whether to order an invasive test or whether or not to prescribe opioids (Turk & Okifuji, 1997). Pain behaviours can be recorded through videotaped observations of overt motor behaviours (e.g. guarded movement, rubbing of the painful area; Keefe & Block, 1982) or facial expressions (Breau *et al.*, 2001; Prkachin *et al.*, 2002).

Comment: Single-item measures of pain are often preferred by clinicians for the assessment of pain intensity because they tap into a key dimension of pain, are quick to administer, easy to score and can be given repeatedly over time (Glajchen, 2001). Multi-item questionnaires take somewhat longer to administer and score but provide a much more comprehensive assessment of different qualities of the pain experience (Dworkin & Sherman, 2001). Observational methods of pain are useful in situations where patient self-report is not a viable option (e.g. in very young children, or in patients with cognitive deficits) or in settings in which clinicians and researchers wish to augment self-report measures with an objective measure of pain behaviour.

Cognitive and affective measures of the pain experience

The challenges of dealing with chronic pain on an ongoing basis can alter cognitive and affective functioning. Of the various measures of cognitive adjustment to pain, catastrophizing has emerged as one of the strongest predictors of poor adjustment to chronic pain Sullivan *et al.* (2001). Catastrophizing, ‘an exaggerated negative ‘mental’ set brought to bear during actual or anticipated pain experience’, (Sullivan *et al.*, 2001, p. 53) has been found to explain 7–31% of the variance in pain in studies across several pain populations (e.g. low back pain, dental pain, experimental pain)

(see 'Coping with chronic pain' and 'Pain management'). Pain catastrophizing has been associated with higher levels of healthcare utilization, more frequent hospitalizations and heightened disability (Sullivan *et al.*, 2001). One of the most reliable and widely used measures of catastrophizing is the Pain Catastrophizing Scale (PCS; Sullivan *et al.*, 1995). The PCS is a 13-item measure with three sub-scales: 'Magnification', 'Rumination' and 'Helplessness'. Scores on the PCS have been found to explain unique variance in key indices of adjustment to pain including measures of psychological functioning, social functioning and physical disability (Sullivan *et al.*, 1998; Severeijns *et al.*, 2002). PCS scores also have been found to significantly predict the physical and emotional distress experienced by participants undergoing experimental pain procedures (Sullivan *et al.*, 2001). A version of the PCS has been developed for use in children and adolescents (PCS-C; Crombez *et al.*, 2003).

Another key cognitive aspect of pain is self-efficacy, or one's perceived ability to adapt to and respond to pain. Self-efficacy is malleable and numerous studies have found that increases in self-efficacy occurring over the course of intervention are related to short- and long-term improvements in pain outcomes (see Tait, 1999, for a review of this topic). The Chronic Pain Self-Efficacy Scale (CPSS; Anderson *et al.*, 1995) is a useful instrument which measures chronic pain patients' perception of their self-efficacy to deal with chronic pain. This brief 22-item measure has three factors; 'Self-efficacy for pain management', 'Self-efficacy for coping with symptoms' and 'Self-efficacy for physical function'. Scores on the CPSS are correlated with pain intensity, affective distress and activity levels (see also 'Self-efficacy and health behaviour').

Emotional responses to pain can have a major impact on the pain experience (Chapman, 2004). In several recent studies, pain-related anxiety has emerged as a critical factor in understanding the pain experience and how an individual responds to the thoughts about pain or the experience of pain flares (see Keefe *et al.*, 2004). The Pain Anxiety Symptom Scale (PASS; McCracken *et al.*, 1992) attempts to capture several dimensions of pain-related anxiety responses. It is a 40-item self-report inventory with four sub-scales; 'Cognitive anxiety', 'Escape/avoidance', 'Fearful thoughts' and 'Physiological symptoms of anxiety'. In a study of rheumatoid arthritis patients, anxiety about pain predicted patient functioning even after controlling for self-reports of health, education, active and passive coping strategies and self-efficacy (Strahl *et al.*, 2000).

In a similar vein, fear of pain can exacerbate the experience of pain. The Fear of Pain Questionnaire-III (FPQ-III; McNeil & Rainwater, 1998) is a 30-item instrument that describes different painful situations. Patients rate how fearful they are of pain associated with each situation using a 5-point Likert scale. Three sub-scales are derived from the ratings: 'Fear of severe pain', 'Fear of minor pain' and 'Fear of medical pain'. The short length and ease of scoring of the FPQ-III make it attractive for use in both clinical and research settings. However, different response patterns have been found for various samples of chronic pain patients (Hursey & Jacks, 1992).

The prevalence of depression (in some studies exceeding 50%; e.g. Banks & Kerns, 1996) occurring after developing chronic pain suggests an aetiological role for chronic pain in the subsequent development of depression. While it is not uncommon for chronic pain patients to develop depression, somatic symptoms presenting in patients with chronic pain may artificially inflate scores

on the most commonly used self-report depression measures (Bradley & McKendree-Smith, 2001). One such instrument is the Beck Depression Inventory (BDI; Beck *et al.*, 1961), which is a 21-item self-report inventory that assesses cognitive, affective, motivational and physiological levels of depressive symptoms. Revisions have been made to the original BDI (i.e. BDI-II; Beck *et al.*, 1996), to better align items with the current major depression criteria from the Diagnostic and Statistical Manual, Fourth edition, Text revision (DSM-IV-TR; American Psychiatric Association, 2000). A similar self-report instrument, the Centre for Epidemiologic Studies – Depression Scale (CES-D; Radloff, 1977), has 20 items rating depressive symptoms on a 0–3 point Likert-like scale, but few items directly assess physical complaints. In either case, the predictive ability of both instruments to detect depression in chronic pain patients is acceptable, but higher cut-off scores (21 for BDI; 27 for CES-D) should be employed in this population before a diagnosis of depression is rendered (Geisser *et al.*, 2000).

Comment: Research has shown that catastrophizing as well as pain-related anxiety and fear are concepts that are important for our understanding of how persons adjust to persistent pain (see Keefe *et al.*, 2004). Use of the measures described in this section may give researchers and clinicians further insight into the interplay between cognition and emotions and the experience of pain (see Price, 2001, for a more comprehensive review) and the factors that contribute to the strong relationship between pain and depression.

Functional aspects of pain

The impact of persistent pain on a person's life can vary substantially. One person with persistent arthritis pain, for example, may be unable to carry out home or work responsibilities, and report being resentful because he or she has become dependent on family and friends. Another person having the same pain level, may be involved in a wide array of social and work activities, and report being satisfied with the support and encouragement received from family and friends. Psychologists have developed several instruments to assess these variations in functional aspects of pain. One of the most widely used instruments is the Multidimensional Pain Inventory (MPI; Kerns *et al.*, 1985), a 13-item scale that assesses the impact of pain on various aspects of the patients' lives including beliefs about how significant others respond to expressions of pain and pain interference with domestic, social and recreational activities. Internal consistency of the original instrument ranges from 0.70 to 0.92 and the test–retest reliability ranges from, 0.62–0.91 (Kerns *et al.*, 1985). Responses on the MPI are often used to classify patients into three pain sub-types (i.e. 'dysfunctional', 'adaptive copier' and 'interpersonally distressed'; Turk & Rudy, 1988). More recently, researchers have suggested that the MPI contains a fourth group, 'repressors', characterized by high pain levels, low activity and low distress (Burns *et al.*, 2001).

Comment: Unlike acute pain, where the focus of assessment is on finding a cure, chronic pain assessment is more likely to be focused on self-management issues (Turk *et al.*, 2004). Multidimensional inventories, such as the MPI, identify aspects of daily functioning and social interactions being impacted by, or having an impact on, pain. The information obtained from these measures may facilitate

individualized treatment planning (see also 'Disability assessment' and 'Quality of life assessment').

underscore the contributions which health psychologists can make in the understanding, assessment and treatment of complex pain conditions.

Conclusion

Over the past two decades, a number of reliable and valid pain measures have been developed by psychologists. These measures are increasingly being incorporated into clinical settings. Their growing use has heightened recognition of the psychosocial impact of both chronic pain and disease-related pain conditions. It has also increased interest in psychosocial interventions designed to improve patients' abilities to manage pain. Considered overall, these measures

Patient satisfaction assessment

Susan V. Eisen

Edith Nourse Rogers Memorial Veterans Hospital

Overview

In recent years, assessment of patient satisfaction has become ubiquitous among health care providers and systems in much of the developed world. In the United States, the Joint Commission on Accreditation of Healthcare Organizations (JCAHO, the accrediting organization for hospitals) and the National Committee on Quality Assurance (NCQA, the accrediting organization for managed health-care plans and physician organizations) have identified patient satisfaction as an important quality indicator, and have required its measurement to meet accreditation requirements (JCAHO, 1997;

<http://www.ncqa.org/about/timeline.htm>.) Specific approaches to meeting patient satisfaction assessment requirements vary. JCAHO allows for patient satisfaction instruments to be incorporated into 'performance measurement systems'. Following submission to JCAHO of documentation regarding reliability, validity and use of specific quality indicators, JCAHO reviews and approves performance measurement systems that meet their standards. Accredited facilities can then choose from dozens of approved performance measurement systems, all of which include quality indicators that meet accreditation requirements. This system allows for potential use of different satisfaction surveys by different facilities.

In Europe, the Verona Service Satisfaction Scale (VSSS) is included in a 5-nation study to develop standardized instruments to facilitate cross-national research, specifically addressing characteristics, needs, quality of life, patterns of care, service costs and satisfaction of individuals with schizophrenia (Ruggeri *et al.*, 2000).

Globally, the World Health Organization (WHO) has developed a framework for measuring health system performance that includes 'responsiveness' as an important criterion. The 'responsiveness' construct includes domains commonly assessed in patient satisfaction instruments such as dignity, communication, access to care, etc. WHO has implemented a health and responsiveness study that includes 70 developed and developing countries across six continents (Valentine *et al.*, 2003).

These efforts and many other smaller scale projects have approached the challenge of assessing patient satisfaction in a variety of ways using varied methods, sometimes derived from different conceptualizations of satisfaction. This chapter presents an overview of current thinking about patient satisfaction, paradigms and strategies for assessing patient satisfaction, challenges for the assessment process and clinical implications.

Conceptualization of patient satisfaction

Early conceptualizations of patient satisfaction were based on a discrepancy model in which perception of services received is compared to expectations or ideals regarding those services. Satisfaction is the difference between perception of actual services vs. expectations or ideals (Campbell & Einspahr, 2001; Pascoe, 1983). Other conceptualizations view patient satisfaction as a global, unidimensional or multidimensional indicator of the quality and/or outcome of care (Attkisson & Greenfield, 1994; Cleary & McNeil, 1988; Davies & Ware, 1988; Donabedian, 1980; Marshall *et al.*, 1993). Donabedian (1980) describes a three-part approach to understanding quality of care in terms of the structure, process and outcome of care. Within this framework, patient satisfaction is seen both as an outcome distinct from health status and as a judgement about the quality of care. Within processes of care, a distinction is made between the technical; that is, the science of care; and the interpersonal, the art of care (Donabedian, 1980). Technical care is the application of medical science and technology to the management of a health problem. It includes accuracy of diagnosis; appropriateness of treatment; clinician competence and skill in performing medical and surgical procedures; and medical errors. Interpersonal care includes communication of information about diagnosis; results of tests; prognosis and treatment options; listening to patients' concerns; mutuality; treatment with courtesy; dignity and respect; and patients' active participation in treatment decisions (Donabedian, 1980). Because of concerns regarding consumers' ability to evaluate technical aspects of care, some satisfaction surveys focus exclusively on interpersonal aspects of care. However, Davies and Ware (1988) provide evidence that in addition to being excellent sources of data on the interpersonal aspects of care, consumers can distinguish between levels of technical quality care as well (see also 'Patient satisfaction').

The recent focus on patient-centred care, recovery and empowerment (particularly with regard to mental health services) has raised questions about earlier conceptualizations of satisfaction.

Campbell and Einspahr (2001) note that focus group participants suggested that 'satisfaction assessments are often guided by political agendas, that serve to support programmes and funding for providers rather than accurately assess the needs and feelings of consumers' (p. 103). They suggest elimination of the 'professional' definition of satisfaction created by providers, and implementation of consumer-oriented measures of quality, with inclusion of qualitative, rather than quantitative data. Recognizing the value of consumer involvement in determining optimal ways to assess healthcare quality and satisfaction, a number of efforts have incorporated consumer input into the development of healthcare quality indicators. The results have identified several concerns expressed by consumers that are not often included in measures of patient satisfaction, such as the threat of involuntary treatments, intolerable side effects of medications and exclusion from the treatment decision-making process (Campbell & Einspahr, 2001). As a result of the consumer movement in health care, more recent efforts to assess patient satisfaction have included consumers and family members in the process of identifying priority areas, in questionnaire development and as interviewers (Kaufmann & Phillips, 2000). For example, both the MHSIP (Mental Health Statistics Improvement Programme) consumer survey and the CAHPS® (Consumer Assessment of Health Plans Study) survey involved consumers in the development and early testing of these instruments (Center for Mental Health Services, 1996; Edgman-Levitan & Cleary, 1996; Harris-Kojetin *et al.*, 1999) (see also 'Patient-centred healthcare').

Purposes of patient satisfaction assessment

The ultimate purpose of assessing patient satisfaction is to improve the quality (including outcomes) of care. For this reason organizations with oversight responsibilities have identified patient satisfaction as an important quality indicator and required its systematic assessment for accreditation, reimbursement or other accountability reasons. Improved quality may occur in a variety of ways, including improving optimal utilization of appropriate services, enhancing patient-provider communication and increasing adherence to treatment recommendations (Cleary & McNeil, 1988; Marquis *et al.*, 1983).

At the programme or facility level, within the Continuous Quality Improvement (CQI) paradigm, results are reported at regular intervals (usually monthly or quarterly) to administrators and clinical providers who work to develop strategies to improve aspects of care identified as needing improvement. The formats and methods for reporting results vary. Eisen *et al.* (2002) discuss the use of control and comparison charts in comparing performance within a facility over time, as well as comparing a programme's performance to external benchmarks derived from multiple facilities that use the same patient satisfaction instrument. Control charts are standardized statistical tools that plot means and standard deviations over time (Lee & McGreevey, 2002a). Recommended by JCAHO, they are used to determine whether variation over time in either standard deviations or mean satisfaction ratings are within or outside expected limits. If they are outside expected limits, facilities are advised to look into possible causes for such variations. Comparison charts show a programme's satisfaction ratings compared with expected performance, based on a benchmark

(Lee & McGreevey, 2002*b*). If performance falls below the expectation, Continuous Quality Improvement teams meet to determine possible explanations for poor performance and develop strategies for improvement.

In addition to improving quality, assessment of patient satisfaction is increasingly used for marketing purposes (Cleary & McNeil, 1988). As the cost of healthcare rises and as the number of for-profit healthcare organizations increases, so does competition among providers. A survey of more than 500 patients reported that over a 5-year period, 85% either changed their physician or were thinking of doing so (Cousins, 1985). Patient satisfaction surveys have potential for increasing business for provider organizations that can show favourable results. At the health insurance plan level, employers commonly use health plan 'report cards' showing patient satisfaction results for the different health plans offered to employees. These report cards can be used by employees to choose a health plan that best meets their needs. However, such report cards are also used by oversight organizations and by states to provide information to consumers that could hurt marketing efforts of health plans whose ratings are unfavourable. NCQA posts results for accredited health plans on its web site (hprc.ncqa.org/Result.asp) for the following quality domains; access and service, qualified providers, staying healthy, getting better and living with illness.

Patient satisfaction assessment paradigms

The great majority of efforts to assess patient satisfaction use quantitative (rating scale) surveys. Across both technical and interpersonal realms, researchers in the field have used conceptual frameworks and empirical (factor analytic) methods to identify satisfaction domains. The CAHPS survey assesses specific domains as well as global ratings of doctors, care received and health insurance plans. The specific domains include access to care (getting needed care and getting care quickly); doctor-patient communication and interaction; respect, courtesy and helpfulness of office staff; and health plan service information and paperwork. Other relevant domains of care that have been identified in the literature include physical surroundings; competence of treatment staff; continuity of care; outcomes of care; and billing procedures (Steiber & Krowinski, 1990). Domains of care that are unique to hospital settings also include nursing care; hospital environment (cleanliness and condition of rooms, quality of food, etc.); admissions process; discharge process; and information provided (Meterko & Rubin, 1990; Eisen *et al.*, 2002).

Although many widely used patient satisfaction questionnaires include multiple domains, correlations among the domains tend to be high, raising questions about their differentiability (Marshall *et al.*, 1993). Despite high correlations, there may be value in assessing different domains depending on the purposes of particular satisfaction assessment efforts. For example, although correlations among domains may be high, average ratings may vary considerably among domains, thus providing important information about specific aspects of care that may need improvement.

Quantitative patient satisfaction surveys are popular because results can be easily summarized and reported. However, they have been criticized for a number of reasons. One problem is that results tend to be positively skewed, that is, respondents tend to

report high levels of satisfaction with care, resulting in poor discrimination among domains of care, inadequate information for targeting quality improvement efforts and insensitivity to detection of areas of dissatisfaction (Campbell & Einspahr, 2001; Steiber & Krowinski, 1990). Positively skewed results are particularly problematic when a small number of response options are offered that are evenly distributed across the spectrum of satisfaction (e.g. 'very dissatisfied', 'somewhat dissatisfied', 'mixed, somewhat satisfied' and 'very satisfied'). This problem can be addressed in a number of ways. One is to include more response options representing the satisfied end of the spectrum. For example, an alternative to response options ranging from very dissatisfied to very satisfied, might be 'not at all satisfied', 'somewhat satisfied', 'moderately satisfied', 'very satisfied', 'extremely satisfied'. These options are more likely to spread out favorable opinions over a wider range and provide better discrimination. Ware and Hays (1988) found that 'excellent ... poor' response options also resulted in greater variance and less skewness. Harris-Kojetin *et al.* (1999) suggest multiple benefits of a 0...10 rating scale in which 0 is the worst possible care and 10 is the best possible care. This rating scale produces greater distribution of responses and increased ability to distinguish among programmes or providers. In addition, the numerical rating scale is easier to translate into foreign languages and can more easily be administered by telephone than rating scales with adjectival descriptors.

Other concerns about quantitative surveys are that they do not adequately reflect consumers' concerns or priorities and that their results contradict information obtained using qualitative methods such as focus groups, open-ended questions, interviews, patient narratives and content analysis of relevant material (Campbell & Einspahr, 2001; Edgman-Levitan & Cleary, 1996; Eisen & Grob, 1982). When qualitative questions supplement quantitative items, the likelihood of identifying important areas of dissatisfaction increases. This point is illustrated by data from a hospital's ongoing assessment of patient perceptions of care which includes 18 forced-choice questions and one open-ended question asking respondents if 'there is anything else you would like to tell us about your care'. The forced-choice questions focus on communication and information received from the provider; interpersonal aspects of care; continuity and coordination of care; and global evaluation of care, with scores that can range from 0 to 100. For each of the four domains scores ranged from 77.8 to 83.0, suggesting high levels of satisfaction. However, in response to the open-ended question many respondents identified areas of dissatisfaction. Open-ended responses were coded as to subject (staff, aspects of treatment and other) and favourability (favourable or unfavourable). Regarding staff, three times as many patients reported favourable comments as unfavourable comments. However, regarding treatment, 57% of patients reported favourable comments compared with 43% of patients reporting unfavourable comments. Regarding 'other' aspects of care, favourable and unfavourable comments were almost evenly divided (51% favourable and 49% unfavourable (Eisen *et al.*, 2001). In addition, many unfavourable comments provided specific information regarding aspects of treatment or services; for example, 'There should be skills-building groups added; more groups would be beneficial'. Favourable comments tended to be more general; for example, 'It's a good hospital'. 'Thank you'. 'Staff were very helpful and caring'.

Assessment challenges

A wide range of methodological decisions must be made in the course of selecting or developing instruments, implementing surveys, analyzing data and reporting patient satisfaction results. A number of these issues are discussed below.

Standardized vs. customized instruments

A basic question to consider is whether to use an existing standardized instrument or to create a new one. Many programmes are tempted to create their own customized instruments that will capture unique features of their programme. However, customized instruments have two major limitations: their reliability and validity would need to be assessed, and they do not permit comparison with other providers, programmes or system of care. In this era of accountability, with increasing emphasis on comparison with other programmes, an instrument that is widely used across a range of programmes can be extremely valuable. Consequently, it is increasingly difficult to justify creation of customized instruments. Dozens of patient satisfaction and/or perceptions of care instruments exist. A thorough review of existing instruments should be undertaken before a decision is made to create a new one. If a programme does have unique features it may be appropriate to use both a standardized instrument with supplemental questions developed for specific programmes.

In developing a new survey or supplemental items the surveyor must select questions and response options that best meet the needs of the commissioning organization are appropriate for the target population. Principles of question and survey design including reading level, survey layout, use of screening questions to determine whether questions are applicable and methods of minimizing response bias should also be considered (Fowler, 1995).

Reports vs. ratings

Ware *et al.* (1983) distinguish between reports and ratings of care. Reports ask factual questions such as, 'Were you given information about the benefits and risks of medication you received?'. Reports may also ask for the frequency with which particular events occurred. For example, 'How often did you have to wait more than 15 minutes past your appointment time?' Response options might include 'never', 'sometimes', 'usually', or 'always'. Ratings ask respondents to evaluate an aspect of care. For example, 'How would you rate the amount of information you received about your medications?'. Response options might include 'poor', 'fair', 'good', 'very good', 'excellent'. Alternatively, one might ask 'How satisfied were you with the amount of information you received about your medications?' ('very dissatisfied', 'somewhat dissatisfied', 'mixed', 'somewhat satisfied', 'very satisfied'). Harris-Kojetin *et al.* (1999) suggest that details about healthcare received (e.g. communication with providers, waiting times, etc.) are better captured using report formats, whereas ratings are more effective in summarizing overall experiences.

Mode of administration

Several modes of survey administration are commonly used including self-administered questionnaires, telephone or personal interviews. More recently, computer-administered and Internet surveys have come into use. Both mode of administration and even setting (home vs. clinic) have been found to affect both response rates and survey results (Fowler *et al.*, 1999). By using a consistent mode of survey administration any effect of mode of administration will apply equally across patients or programmes. If mode of survey administration varies, it would be wise to document mode of administration and control for it in the analysis of results.

Sampling

Sampling is of major importance in assessing patient satisfaction because response rates can vary widely and bias results. Low response rates are unlikely to be representative of the population. Many survey efforts, particularly those done at the point of service, may not be able to compute response rates because the number of eligible respondents is not systematically tracked. Telephone surveys will not reach potential respondents who do not have telephones or stable living arrangements, problems that are more likely to occur among populations who are at greatest risk for poor quality care. Consequently, every effort should be made to obtain representative samples and to maximize response rates.

Risk adjustment

Any attempt to compare patient satisfaction across providers, programmes or healthcare systems should not be undertaken without appropriate risk adjustment. Risk adjustment is a statistical method of adjusting for differences in patient, provider and programme characteristics to allow for more appropriate comparisons of quality and outcome, so that one is not comparing apples with oranges. 'The goal of risk-adjustment is to account for pertinent patient characteristics before making inferences about the effectiveness or quality of care ...' (Iezzoni, 1997, pp. 3-4) Variables commonly used for risk adjustment include age, gender, socioeconomic status, diagnosis and comorbidity, although any data that correlate with the outcome of interest is appropriate to include in a risk adjustment model. Failure to risk adjust for patient characteristics can lead to misleading, embarrassing and even libellous conclusions. For example, the first public release of hospital mortality data by the US Healthcare Financing Administration compared actual mortality with expected mortality based on mortality rates from several hundred US hospitals. At the hospital with the most aberrant death rate, 86.7% of Medicare patients died, much higher than the expected death rate for that hospital (22.5%). However, the model did not account for the fact that the facility in question was a hospice, caring for terminally ill patients.

With regard to patient satisfaction, Medicare beneficiaries with psychiatric disorders have been found to report lower levels of satisfaction with both overall quality of care and with specific aspects of care including health information received, follow-up care and physicians' concern for their health, compared with Medicare beneficiaries without psychiatric disorders (Hermann *et al.*, 1998). Consequently, it would be important to control for presence of

psychiatric illness in comparing patient satisfaction across providers or programmes.

providers' behaviour regarding appropriate treatment of patients, their involvement in treatment decisions and attention to patient preferences and concerns. Increasing emphasis on patients' rights may also be incorporated into the training of new healthcare providers.

Patient satisfaction assessment efforts have also begun to influence policy. More than 35 health plans in the United States, covering more than 30 million patients, have programmes tying doctor bonuses to performance. These 'pay for performance' programmes are likely to further increase providers' interest in meeting patients' needs in ways that will enhance satisfaction with care. Although most of these bonuses are offered for adhering to practice guidelines for preventive care and chronic conditions, extra points can be earned for high levels of patient satisfaction (Landro, 2004). The challenge to the field will be to ensure that patient satisfaction data are appropriately collected, reported and used to improve care. (See also 'Patient satisfaction references').

Clinical and policy implications

To the extent that patient satisfaction assessment efforts are reliable, valid and appropriately used, their results hold promise for improving particularly, interpersonal aspects of healthcare quality. After much concern about increasing impersonalization in the current healthcare system and pressure on providers to see more patients in less time, efforts to assess patient satisfaction should, at least, serve to raise the consciousness of healthcare providers, administrators and health plan organizations about the importance of attending to patients' needs, listening to their concerns and treating them with respect and dignity. At best, efforts to assess patient perceptions of care may help to change

Psychoneuroimmunology assessments

Andrew Baum¹ and Angela Liegey Dougall²

²University of Pittsburgh

Overview

The immune system is a complex system of cells, organs and secretory agents that plays a key role in defence against pathogens, healing and communication with a large number of other systems in the body. It contains a large number of different cells, each with different functions, advantages and limitations, most of which secrete a dizzying variety of substances or cytokines that permit intercellular communication and which enhance or effect the cells' function. There are components of immunity that are primarily responsible for defence against pathogens, altered cells, or other foreign agents and there are components of the system that regulate inflammation and healing of wounds. Communication with nervous and metabolic systems is accomplished by other substances and structures. Many of these processes require coordinated collaboration among cells and substances and nearly all appear to be sensitive to internal rhythms and external events. In the rapidly growing field of psychoneuroimmunology (PNI), this complexity has added to the challenge of studying behaviour or central nervous system (CNS) interactions with the immune system (see also 'Psychoneuroimmunology').

In the face of the rapid growth of molecular biology and bioassay capabilities, PNI investigators now have access to a number of methods and measures that capture this complexity. In this chapter, we will review some of these newer approaches as well as some more traditional, widely used measures. Emphasis will be on what each measure tells us, how feasible and reliable it is and when it is appropriate.

Although there are many different emphases in the field of PNI, a great deal of research has focused on the effects of stress

and emotion on immunity. This work has generally found effects of stress on some measures, accomplished either through stress-related behaviour change (e.g. changes in diet, smoking, exercise) or by virtue of physiological changes tied to stress (e.g. changes in stress hormones, blood flow). Measures that have evolved have been aimed at aspects of the immune system that affect disease susceptibility or general 'immunocompetence'. Other measures have been used in conditioning studies, investigation of interactions with other bodily systems and studies of other phenomena use these and other measures.

Assays of cell numbers

As noted, the immune system includes a large number of cells specialized for the performance of particular functions in detecting foreign substances or altered cells or eliminating them. Measures of the number of each of these different cells can be accomplished by doing simple complete blood counts (CBCs, also known as whole blood counts, or WBCs) which provide an estimate of how many of each of a small number of immune cell types are present in a defined volume of blood. These ordinarily include numbers of lymphocytes and several other types, including eosinophils, neutrophils and monocytes. These measures are gross estimates of very general categories of cells and only reflect the number of cells in peripheral blood flow. These limit the value of these measures, but they are used extensively as rough clinical screens and are often needed to interpret more sophisticated measures of cells and cell subtypes.

Table 1. Measurable cells or functions of the immune system

Immune index	Measure
Cell number	Complete blood count with differential
	Lymphocyte subsets (e.g.)
	T-cells
	CD4 ⁺ T-cells
	CD8 ⁺ T-cells
	NK cells
Cell activity/function	B-cells
	Mitogen-stimulated proliferation
	Cell lysis (e.g. NK chromium release measure)
	Stimulated release of cytokines (e.g.)
	Interleukin-1
	Interleukin-2
	Interleukin-5
	Interleukin-6
	Interleukin-12
	Interferon
	Tumour Necrosis Factor
	Seroconversion/antibody response
Intrinsic function	Chemotactic response
	Adherence
	Phagocytosis
	Release of reactive oxygen species
	Delayed-type hypersensitivity

More fine-grained analysis can be accomplished by flow cytometry and cell sorting. These include measures of T- and B-cell subtypes and natural killer (NK) cell numbers (see Table 1). These technologies use monoclonal antibodies to tag cell surface receptors and these tags are then detected and measured.

In general, flow cytometry provides information about numbers of cells carrying specific proteins on their surfaces that identify them as one or another type of cell. This is done by culturing monoclonal antibodies for a particular protein marker with peripheral blood samples (Ruiz-Argüelles & Pérez-Romano, 2000). These antibodies are previously labelled with a fluorescent dye and bind to cells bearing the appropriate cell-surface proteins, 'tagging' them with the dye. Mononuclear cells from the peripheral blood are sent through a cell sorter that emits a laser which activates the dye and allows the cell to be identified. The detection systems associated with flow cytometry can measure the size and granularity of the cells as well as different intensities of fluorescence allowing evaluation of numbers of each of several subsets of lymphocytes (Table 1), measuring other proteins on cell membranes, detection of activation and amount of intracellular cytokines.

Assessment of cell numbers or of activated cells, cytokines and the like can be useful measures for PNI research, but must be interpreted cautiously. Stress and other psychosocial variables have been associated with changes in numbers of particular cells and other quantitative indices and differential changes may help to explain differences in antecedent conditions. For example, acute laboratory stressors produce increases in some cells (T, NK) but more chronic, naturalistic stressors produce decreases in these same cells in circulation. Although these changes are probably due to cell migration in and out of lymphoid storage areas (e.g. spleen), we typically

do not know the specific causes or clinical impacts of these changes in numbers of cells in peripheral blood.

Cell activity and lytic capacity

In part due to these limitations on interpreting measures of cell numbers, researchers have also devised measures of cell or other structural function. These measures evaluate the capacity of cells, for example, to 'conduct their business', be it cell replication and proliferation, killing, or releasing/evoking release of cytokines and other important components of immunity.

There are several ways to organize the cells of the immune system. One of the most traditional is to separate the overall activity of the system into 'innate' and 'acquired' immunity. Innate immunity refers to elements of the immune system that are not specific to a particular pathogen. They are not antigen-dependent and mount maximal responses immediately upon activation. Because they are not antigen-specific there is no acquisition of memory; each encounter with a particular antigen occurs *de novo*. Barrier structures such as the skin or mucosa and cells such as macrophages, neutrophils, dendritic cells and natural killer (NK) cells are considered key elements of innate immunity.

Acquired immunity reflects more advanced forms of immune response, present only in vertebrate species. It includes immune responses and cells that are antigen-dependent and -specific (specific cells are only active against a particular antigen). Immunologic memory that underlies these characteristics and the strength of immune responses lags behind exposures. After an initial exposure, subsequent contact with an antigen evokes an adaptive response that strengthens over time.

There are two 'branches' of acquired immunity. The first consists of humoral responses that are focused on activity of B lymphocytes and antibodies which are produced by these cells. B cells are plentiful and continuously produced in the bone marrow. They are chiefly responsible for producing antibodies, immunoglobulins, that act to assist in killing or inactivating antigen. There are several classes of antibody corresponding to the type of immunoglobulin (Ig) involved. IgG is the most plentiful, composing nearly three-quarters of all antibodies produced in the body. IgG activates complement and NK cells and opsonizes antigen, coating it to decrease its activity and attract other immune agents (e.g. phagocytes). IgM is less common and shares these functions. IgA is often found in the digestive tract (e.g. in saliva, stomach secretions) and respiratory system and is effective in helping disable antigens for removal by mucosa. IgE is important in allergic responses, shock and in disabling parasites. Antibodies also bind viruses and deactivate them.

Cell-mediated immunity is the second type of acquired immunity, focused primarily on activity by T lymphocytes. There are two main types of T cells; T helper and cytotoxic T cells. Helper cells (CD4 cells) coordinate immune responses by producing cytokines that direct larger responses. Cytotoxic T cells attack and lyse virally infected cells and other pathogens. They are directly involved in killing of pathogens.

Each of these branches of immunity have unique functions and investigators have devised a number of reliable methods of assessing the functions and killing activity accomplished by cells under varying circumstances. Some of these methods are described below.

Proliferation

One general indicator of immune system reactivity is the proliferative response of human peripheral blood mononuclear cells (PBMC) to antigen-nonspecific reagents or mitogens. Proliferation measures estimate the response by selected immune cells when stimulated to proliferate, that is to rapidly make a large number of replicates of specific cell types. The change in number of cells before and after culture with a mitogen is approximated by estimating the incorporation of [³H]thymidine into the DNA of the replicating cells (James, 1994). When T- and B-cells are activated by the mitogen, they begin to replicate. During the replication process [³H]thymidine is incorporated into the dividing cell's DNA. The radiation emitted from the incorporated [³H]thymidine is then measured to estimate changes in cell number. The mitogen chosen determines what type of cells are stimulated. Three commonly used mitogens are phytohemagglutinin (PHA), Concanavalin A (Con A) that primarily stimulate T-cells and pokeweed mitogen which stimulates T-cell dependent activation of B-cells.

The greater the proliferative response, the 'better' the function of these cells, at least to a point and such estimates have consistently been used as an index of immunocompetence in PNI research. However, stimulated proliferation is only one way to measure cell function and it is not clear how well this index models overall efficacy of the system. Other measures model different aspects of immune system function, assessing the ability to kill infected or altered cells, phagocytize foreign material, or release cytokines.

Natural killer cell activity

A good example of one of these measures is a chromium-release assay of NK cell activity (Whiteside, 1996). NK cells are large granulocytes that attack tumours and bacteria, virally-infected cells and parasites by lysing them (drilling small holes in the membrane of the target) and injecting enzymes that kill the target. These cells are able to kill pathogens without prior experience with them. If one can isolate a known number of NK cells, culture them with cells that NK cells will attack and measure the rate at which these target cells are killed, the result would be a good estimate of NK cell activity. This is exactly what the chromium-release-assay for NK cell activity does. After tagging tumour cells with radioactive chromium which is released when the cell is lysed, they are cultured with live NK cells that attack and kill a substantial number of target cells. The amount of radioactivity released in the process can be measured and used as an estimate of lytic activity by the NK cells. Resulting measures of lysis can be combined with counts of the number of NK cells available and yield lytic units, which are reliable estimates of NK cell activity.

Cytokines

Cytokines are endocrine-like substances which are produced by various cells of the immune system (Leonard, 2003; Moldawer, 2003). These chemical compounds act as messengers and also stimulate cells to act or produce components of an immune response. They interact with immune cells, with the nervous system and with endocrines to enhance or regulate immune activity

or facilitate organism activity that is restorative and facilitates healing. For example, interleukin-1 (IL-1) is produced by monocytes and stimulates body temperature to increase. It also induces 'illness behaviour' and contributes to inflammatory responses. Interleukin-2 (IL-2) is produced by T-cells and is integral in the Type 1 Helper T-cell response. It stimulates recruitment, activation and differentiation of B cells and supports local inflammation via activation of monocytes and macrophages. The Type 2 helper T-cell response is stimulated by cytokines such as IL-5 and IL-6 and assists in the activation, proliferation and differentiation of B-cells. Other interleukins (e.g. IL-6, IL-12) contribute to inflammatory responses, as does tumor necrosis factor (TNF) which is released by all cells except erythrocytes and mediates the sepsis response and cell death as well as the development of lymphoid organs. Interferon is released by almost all cells and acts on T- and NK cells to promote antiviral and antitumour responses.

A widely used assay technique, called enzyme-linked immunosorbent assay (ELISA) has become the most common and preferred method for quantifying antibodies, antigens, cytokines, or other immunologic agents. Commercially available kits with well validated procedures and standards are a strength for many measurable entities and the relative ease and safety level are also reasons for the current popularity of this method. Newer developments such as technology designed to yield estimates of panels of interrelated cytokines are more useful in some contexts but when the objective is to measure one or a few cytokines, antibodies, or antigens, ELISA remains an excellent option.

An ELISA is conducted using standard 96-well plates, but for these assays the plates are pretreated with antibody for the substance being measured. If one is interested, for example, in IL-1 the wells will have been pretreated with antibody for IL-1. Serum or plasma from participants are added to the wells and incubated, allowing the target cytokine (IL-1) to bind to the antibody in the wells. The plate is then washed and a second antibody to IL-1 is added, this one linked to an enzyme. The amount of this enzyme-linked antibody that binds depends on the amount of IL-1 in the sample. Once this has been accomplished, a substrate that reacts with the enzyme is added and the intensity of the subsequent chromatic reaction is a measure of the amount of enzyme (and IL-1) that was bound. Determination of the amounts of cytokine is made by comparing the sample with standards that have known quantities of cytokine. A listing of basic ELISA protocols can be found at <http://www.protocol-online.org/prot/Immunology/ELISA/index.html>.

The ELISA can be used to measure the amount of cytokine in the peripheral blood, the amount produced by activated cells (e.g. cells stimulated by mitogens or mixed antigens) and/or quantities of other messengers released by cells trying to communicate with the immune system (e.g. leptin, adipocytes). Differences in study design and purpose will dictate which, if any, of these measures should be used, but once the decision is made, the only major differences in measurement are the kit target and the sample used (i.e. peripheral blood or supernatant from stimulating peripheral blood cells).

B cell activity

Similar ELISA methods can be used to assess antibody production by activated B-cells. Antibodies can be measured from bodily fluids

such as blood and saliva. One common method in PNI is to assay levels of antibody titers in human blood to common viruses that people have likely been exposed to in the past, for example, *herpes simplex* virus (HSV), Epstein–Barr virus (EBV) and cytomegalovirus (CMV) (Ironson *et al.*, 2002; Jenkins & Baum, 1995). Most adults have been exposed and infected with these viruses even if they never displayed illness symptoms. After infection, the cellular immune system acts to contain the virus and keep it in latency. Therefore, some levels of antibody titer are present in most adults. However, if the immune system is compromised by factors such as medication, disease, or chronic stress, it can lose control over the virus and the virus will reactivate. Reactivation of a latent virus prompts a T-cell mediated immune response and production of more antibody titers. In studies assessing naturalistic chronic stressors, such as exam stress, marital discord and exposure to natural and man-made disasters, antibody titers in the blood are assessed as a marker of the overall integrity of cellular and humoral immunity. High levels of latent virus antibody titers suggest immunosuppression.

Another approach in PNI research is to use ELISA to assess the body's ability to mount an antibody response to a novel antigen. An *in vivo* immunization paradigm is used to assess change in antibody titers following inoculation with antigens such as hepatitis B, influenza, keyhole limpet hemocyanin (KLH) and attenuated rubella virus (Cohen *et al.*, 2001). In addition to the first or primary response, antibody production following a subsequent or secondary challenge can also be measured. Seroconversion, or the detection of antigen-specific antibodies in the serum, is usually used as a marker of primary response. Delays in seroconversion or failure to seroconvert are thought to indicate immunosuppression. Likewise, attenuation of antibody production in response to a secondary challenge indicates immunosuppression.

Assays of intrinsic function

Phagocytosis

Cells in the innate immune system also help provide a first-line defence against microbes, tumour cells and cellular debris by ingesting (phagocytosis) and then digesting pathogens. Phagocytic cells, primarily monocytes, macrophages, neutrophils and dendritic cells engulf and destroy pathogens such as bacteria by attaching membrane projections to the pathogen, surrounding the antigen with cytoplasm and ingesting it. Eventually enzymes are released from lysosomes in the phagocytic cell, destroying the antigen. This process is called phagocytosis and can be quantified by culturing phagocytic cells (e.g. macrophages or neutrophils) with appropriate target cells (e.g. bacteria or tumour cells) and then measuring incorporation. Phagocytic activity of macrophages is quantified by staining the bacterial target cells, culturing the bacteria with the macrophages and then counting the number of internalized bacteria in each macrophage using a fluorescence microscope (Campbell *et al.*, 1994). Assays for phagocytic activity of neutrophils are similar, except the target cells are radiolabelled with ^{14}C and counted with a liquid scintillation counter to determine the percentage of phagocytosis (Clark & Nauseef, 1996). The ability of macrophages

and neutrophils to digest or kill the target cells can be assessed by lysing the macrophages and neutrophils after phagocytosis. The remaining live bacteria are cultured and then counted to determine bactericidal activity.

Phagocytic activity can be augmented by the presence of stimulating cytokines. Macrophages can be stimulated by cytokines such as interferon gamma released from antigen-stimulated T-cells (see 'Delayed type hypersensitivity'). Macrophages, in turn, release cytokines that stimulate other immune cells such as T-cells, neutrophils and other mononuclear phagocytes. Activated macrophages release inflammatory cytokines (e.g. IL-6) and other substances that attract other cells (chemotaxis) and can serve antigen-presenting processes important in seroconversion.

Release of reactive oxygen species

During phagocytosis, macrophages and neutrophils release reactive oxygen species (ROS) such as superoxide anion (O_2^-), inorganic nitrite (NO_2^-) and hydrogen peroxide (H_2O_2) that produce cell damage and have potent antimicrobial and antitumour effects themselves. ROS are produced by other cells as well and this reflects normal function of the system. Changes in ROS that produce the potential for cell damage and mutation is referred to as oxidative stress and can be measured in several different ways (Epel *et al.*, 2004; Irie *et al.*, 2001).

Delayed-type hypersensitivity

Delayed-type hypersensitivity (DTH) is an *in vivo* assay of cell-mediated immunity, in which T-cells recognize an antigen, proliferate and secrete cytokines that then induce inflammation and activate macrophages that act to eliminate or resolve the foreign antigen (Abbas & Lichtman, 2005). In the classic animal model, a guinea pig or other animal is immunized with a specific antigen by injecting the antigen subcutaneously (Luo & Dorf, 1993). After 6 to 14 days of sensitization, the animal is then challenged with a new dose of the antigen and the inflammatory response is measured. The delayed-type peak inflammatory reaction occurs 24 to 48 hours after antigenic challenge. The intensity of DTH is quantified by using calipers to measure the swelling and induration (hardness) in the area of the skin at the site of injection. In humans, the challenge test of DTH is used to assess immune response to antigens to which people may have been previously exposed through infection or immunization, such as tuberculin, tetanus, diphtheria, streptococcus and *Candida albicans*.

The DTH response provides important information regarding the *in vivo* functioning of T cells and an overall assessment of immunocompetence. Failure to elicit a sufficient inflammatory response to a battery of common antigens suggests a defect in cellular immunity or a condition known as anergy. These individuals are more susceptible to viral, bacterial or fungal infections that are normally resisted by cell-mediated immunity. Intense DTH reactions indicate an enhanced or hypersensitive immune response that may reflect an underlying susceptibility to allergic or autoimmune disorders such as contact dermatitis and insulin-dependent diabetes mellitus.

Although DTH responses protect a host by eradicating invading micro-organisms, they also cause injury to normal host tissues. If a DTH response is elicited to a non-injurious agent only the destructive and not the protective functions occur (hypersensitivity), such as those seen in allergy and autoimmunity.

Conclusions

This discussion has been limited to immunologic measures that have been used in PNI studies, typically to assess the effects of stress

or emotional expression on immunity. This is not an exhaustive review: it has focused on the most commonly used measures and a few newer assessments that have particular promise. The revolution in molecular biology during the past 25 years has revealed several previously unknown 'layers' of function and ways to assess them. This offers researchers the opportunity to answer questions that were previously not addressable due to measurement limitations. Together with biomarkers and other intermediate measures of pathogenesis, these developments will contribute greatly to successful mapping and prevention of immunologically-mediated diseases.

Qualitative assessment

Felicity L. Bishop¹ and Lucy Yardley²

¹Aldemoor Health Centre

²University of Southampton

Introduction

Qualitative assessment has long made a central contribution not only to psychological approaches to health and illness but also to traditional medical practice itself. In taking a case history a medical practitioner is engaged in a process of interviewing a patient to find out about their experiences. During this process the questioning is flexible and is influenced by the patient's previous answers. The practitioner must listen to and interpret what the patient tells them. The practitioner then uses their own explanatory framework to try to understand the patient's experience and determine an appropriate course of action. These processes of adaptable questioning and interpretation are central to qualitative assessment. In qualitative assessment, the researcher (or practitioner) begins with a question about experience or process, flexibly seeks out the information to answer that question and then uses interpretative skills to provide an explanation and understanding of the phenomena of interest. The development of explanations often highlights changes or interventions which can be implemented to enhance health care provision. Also central to traditional medicine is the use of the concept of cases, for example in everyday clinical practice and as exemplars in teaching. The study of cases in health psychology has been reinvigorated by Radley and Chamberlain (2001) and is well suited to qualitative, rather than quantitative, approaches to assessment.

A wide variety of qualitative methods has been applied to the study of health and illness. In comparison with quantitative methods, qualitative methods focus on providing in-depth analyses of individual perspectives and interpersonal processes. The value of qualitative methods lies in their ability to provide insights into the lived experience of healthcare. Qualitative methods are well suited to questions about patients' experiences of health and illness and the processes involved in health-related behaviours, including healthcare delivery. In an era of patient-centred care, qualitative techniques provide a means to assess patients' concerns and suggest ways in which care can become more patient-centred. Returning to the example of the consultation, qualitative methods can provide answers to such questions as: What do patients want from consultations?, What interpersonal processes are involved in consultations? Qualitative approaches can also improve understandings of the experiences and needs of health care professionals. For example, qualitative methods can answer questions such as: How do health care professionals cope with delivering bad news? How does the working environment constrain and/or facilitate the delivery of health care?

The aims, purposes and methods differ widely across different qualitative approaches. However, there are some typical characteristics of most (though not all) qualitative research.

1. An emphasis on the contextual nature of knowledge, and a view of knowledge as embedded in cultural systems of value and meaning. This means that whereas much quantitative work seeks to minimize the impact of extraneous variables on research, qualitative work embraces the way in which people are shaped by social and cultural situations, such as social networks (family, friends), upbringing, economic factors, the media and so on. Qualitative work acknowledges and often takes as its focus this view of individuals and their stories as contextually situated, seeking to explore this context and trying to generate understandings which do not abstract individuals from their everyday lives.
2. An emphasis on the ways in which people make sense of their experiences and their subjective meanings, rather than causal mechanisms. Because qualitative researchers are usually interested in the variety of different people's perspectives, qualitative work is not intended to establish generally applicable laws, but instead to provide an in-depth understanding of a particular situation that may have relevance to other, similar, situations.
3. An interplay between data and theory. Whereas quantitative assessment generally uses empirical data to test theory, in qualitative research data is often the inspiration for theoretical insights and developments.
4. Since the aim of much qualitative research is to understand the perspective of those who are the subject of research, a close, subjective relationship between researcher and participants is often desirable. It is therefore necessary to acknowledge and examine the influence of the researcher on the data and its interpretation.

Qualitative data

Qualitative data can include naturally occurring data and researcher-instigated data. For example, audio or videotape-recorded consultations, patients' medical records, one-on-one interviews and focus group discussions are all forms of qualitative data. Given that many qualitative approaches understand knowledge to be context dependent, naturalistic data is often highly valued, and where researcher-instigated data is used, the researcher's role in the generation of data is openly acknowledged and reflected on. Indeed, the contributions of a researcher, for example in an interview, may be analyzed as data alongside the contributions of the person being interviewed.

Qualitative interviewing

Interviewing is the most commonly used qualitative data collection technique, but is more involved than may seem at first glance (see Kvale, 1996). One-on-one interviews can provide detailed insights into individual experiences and perspectives. Most qualitative interviews are semi-structured, which means that 'open-ended' questioning is used which does not restrict participants to yes or no answers, or any other predetermined 'closed' set of responses. Some qualitative interviewers use a conversational style of interviewing, in which questions and comments from interviewees are responded to by the interviewer. While the questions asked will necessarily reflect the interests of the interviewer, questions should be worded in a neutral way to avoid leading the interviewee to frame their answer in a particular way. For example, questions such as 'how did you feel about your consultation' or 'tell me about your illness' allow participants to talk freely about whatever aspect of their experiences that they want to. While questions are devised before interviews commence, the interview content should be flexible: the order of questions can be changed and prompts can be used if necessary. Furthermore, the interviewer is able to take the lead from the interviewee and follow up issues of interest which emerge during individual interviews.

Wright *et al.* (2004) conducted an interview study to investigate patients' perceptions of doctors' communication in breast cancer. They interviewed women about the aspects of consultations they valued or disliked, using recordings of consultations as a starting point to guide the interview schedule. Using grounded theory techniques (see below), it was found that women valued the perception that doctors had formed an individual relationship with them, had relevant expertise and demonstrated respect for them as individual people. These findings highlight the need to take patients' views into account in developing training in communication skills, since the aspects of communication valued by the patients were not the same as those emphasized in current communication skills training.

Focus groups

Focus groups are group discussions around a specific topic which commonly involve between 4 and 15 participants (Morgan, 1992). Discussions are often led by the researcher, who acts as a 'moderator', to encourage involvement of all individuals and keep discussions on topic. Focus groups can provide information on the views and understandings of groups of people and it is the interaction between participants which distinguishes focus groups from group interviews (Wilkinson, 1998).

The public nature of focus groups must be considered when deciding whether and how to use them. Participants may be unwilling to 'stand out from the crowd' and voice minority opinions, thus the resulting data can demonstrate socially sanctioned normative perspectives. However, the inherently social nature of focus groups can provide valuable data which would not arise from questionnaires or one-to-one interviews. Focus groups can facilitate the discussion of sensitive issues in that where the participants have shared experiences and understandings they may be more likely

to discuss these issues with each other than alone in an interview with a researcher (Wilkinson, 1998). Participants' talk may be more natural in focus groups than in one-to-one interviews, and the interactions between participants can themselves be an interesting topic (Kitzinger, 1995).

Wilkinson and Kitzinger (2000) conducted focus groups with women with breast cancer. They used a relatively unstructured approach and the topic of the analysis, 'thinking positive', emerged as an important issue from women's general talk about their illness. Through their use of focus groups and discursive analytic techniques (see below) Wilkinson and Kitzinger were able to focus on the social functions of talk about positive thinking, and to examine the ways in which women themselves talk about positive thinking.

Participant observation

Participant observation, often known as 'ethnography', involves spending a prolonged period of time in a particular setting, such as a hospital ward, in order to provide insight into the social processes at work in that setting (Hammersley & Atkinson, 1995). Participant observation is a way to observe actual behaviour, rather than relying solely on verbal reports. By spending time in a setting the researcher can develop relationships and gain the trust of participants, thus developing understandings which are derived from the perspective of the participants themselves. Such observation can provide valuable insights into how things are achieved in real life settings and how changes could improve practice. Participant observation studies generally involve the collection of a wide range of data to supplement and complement observations. This can include informal and formal interviews with a range of participants as well as documentary or even photographic evidence.

An ethnographic study of doctor-patient communication about death was conducted by The *et al.* (2000). Observations of patients and medical staff both in and outside consultations were combined with interviews, medical notes and fieldwork diaries to provide an in-depth analysis of the processes involved in doctor-patient communication about death. The results showed that both doctors and patients colluded in a false optimism about recovery, drawing on a recovery story in which short-term possibilities are prioritized over the future. Doctors found it difficult to break bad news to patients, often mentioning the bad prognosis and then offering short-term hope through further (often palliative) treatments. Patients accepted this hope, focusing on offers of treatment and the action this entailed while not asking about or actively resisting information about long-term prognoses. The ethnographic approach enabled the researchers to develop trusting relationships with participants and to develop an in-depth analysis which incorporated both doctors and patients and the interactions between them.

Documentary evidence

Documents constitute relatively permanent records which have been created for specific purposes, and constitute a valuable resource for qualitative researchers (Prior, 2003). Documents such as

medical records can be analyzed to provide insight into healthcare provision and the doctor–patient relationship. Other documents such as magazine and newspaper articles can be analyzed in terms of examining the social and cultural context of illness. Printed material is commonly used in healthcare and documents such as health promotion leaflets can be analyzed from a qualitative perspective to provide insight into the medical perspective, which can then be compared with patients’ perspectives.
