Lupton (1994) used discourse analysis (see below) to examine the representation of breast cancer in the Australian press. By examining articles in the public domain she was able to show that certain themes, or discourses, dominated the portrayal of breast cancer in the media. Of particular interest was the emphasis on individual responsibility which was central to many of the articles. Lupton argued that such a discourse could have a negative impact not only on women’s beliefs but also on their behaviour. If breast cancer is seen as the individual’s responsibility, then so is the responsibility for prevention and recovery – but in the context of breast cancer where there are no absolute right or wrong answers in relation to prevention or treatment, this puts an impossible burden on individual women to make the right lifestyle and treatment choices.

Major qualitative methods

Qualitative coding: thematic and content analyses

Coding is central to much qualitative assessment. At its most basic, coding involves the organisation of qualitative data into analytically meaningful categories. For example in a study of the experience of pain, all occurrences of talk about pain might be coded into categories such as ‘talk about the causes of pain’, ‘the effects of pain’ and ‘treatments used to alleviate pain’. Coding can also be used to look at latent patterns in the data. For example, some talk about pain might be interpreted as representing talk about coping strategies, such as denial or avoidance.

Coding can be deductive, i.e. codes are established before the coding begins using categories from previous research or theory to code the new qualitative data. However, coding is often inductive, in that codes are developed from the qualitative data itself; rather than applying existing categories to the data the researcher identifies themes and patterns that emerge through analysis and may be new and unexpected. Whichever approach to coding is used, explicit detailed definitions of codes are essential.

Traditional approaches to coding involve making notes on interview transcripts or other texts, and using card index systems to record names, definitions and examples of codes. The advent of computer software designed specifically for qualitative data has somewhat eased the labour intensive management and analysis of large volumes of qualitative data (see Joffe & Yardley, 2003).

Content analysis represents a relatively quantitative approach to coding. In content analysis a qualitative data set is examined and instances of particular words, phrases or codes are counted. Statistical analyses can be carried out on the count measures that result from content analysis. Thematic analysis takes a more qualitative approach to coding. In thematic analysis either theoretically derived or inductive themes are coded in the dataset and the

meanings, context and implications of these themes are examined and described (Joffe & Yardley, 2003).

Grounded theory

Grounded theory was developed in the context of research on healthcare by Glaser and Strauss (1967). Since its inception, different versions of grounded theory have been developed (see Charmaz, 2000). Grounded theory is a complete and rigorous approach to qualitative research which provides an explicit, detailed methodological framework to guide researchers from an initial research topic through to a theory about that topic. The aim of grounded theory is to generate theory which is grounded in data. Data and theory are closely linked, and so are the processes of data collection and analysis (Charmaz, 1990).

Initial data collection is guided by ‘purposive sampling’, which involves gathering data from a wide range of sources relevant to the topic. Data for grounded theory studies can consist of any of the forms mentioned above, but often interviews constitute the primary source of data. A number of analytic procedures are employed in the coding of data and there is a general movement through coding from concrete, descriptive coding which stays close to the data to more abstract, analytical coding which moves towards theory and explanation. The technique of ‘constant comparison’ is a key feature of grounded theory, and refers to the process by which the analyst makes comparisons between examples of the same or different codes or between definitions of codes and examples of codes in the data. This technique helps to refine codes and to keep the emerging theory grounded in the data itself.

The generation of theory proceeds iteratively and initial analyses are used to guide further data collection. Inductive and deductive processes are used throughout this iterative process and as theories evolve and are refined data collection becomes driven by the theory (theoretical sampling), in an attempt to deepen and validate the emerging theory.

Yardley *et al.* (2001) developed a grounded theory model of treatment perceptions. They conducted initial interviews with chiropractic patients and analysed them inductively using techniques such as the constant comparative method, which resulted in the development of a model of the processes involved in patients’ perceptions of treatment that was grounded in the analysis of interview texts but also integrated this analysis with existing literature. The emerging model was then tested by further, deductive, analysis of interviews with a sample drawn from a different treatment population (people consulting their GP for dizziness). The outcome of this study was an explication of patients’ perceptions of treatment which highlighted the influence of processes occurring during treatment, in particular the relationship with the therapist and perceptions of the effects of the treatment on symptoms.

Phenomenological analysis

Phenomenological analysis is concerned with examining the subjective experiences and meanings of individuals. Non-directive in-depth interviews are an important source of data in phenomenology, although naturally occurring texts such as diaries can also be used. Interpretative Phenomenological Analysis is an example of a system of phenomenological research, in which the researcher

attempts to gain an insider view point, engaging with and making sense of participants' own personal accounts and understandings (Smith, 1996). This approach requires the researcher to be open to participants' perspectives and to use their own interpretative skills to produce a co-construction (between researcher and participant) of participants' experiences. Interpretative Phenomenological Analysis is an idiographic approach in that the primary focus is on the experiences of individual participants, and it is only in the later stages of analysis that researchers look for patterns of themes across individuals.

Smith *et al.* (2002) used Interpretative Phenomenological Analysis to investigate perceptions of risk and decision-making about genetic testing in Huntington's disease. They showed that their interview participants (five women, all of whom had children), found it difficult to deal with the objective 50% risk of having the disease and that this risk was often reinterpreted and situated within considerations of the family context and the women's own beliefs about inheritance. The process of decision-making that women went through concerning whether or not to have genetic testing was removed from and in some cases inconsistent with the model of informed decision making favoured by current healthcare systems. By analyzing individual women's accounts and then making comparisons between and examining common themes across the different accounts the analysis provided insight into the complex issues which the participants were dealing with and suggested ways in which genetic testing and counselling might address patients' perspectives (see 'Screening: genetic').

Discourse analysis

Discourse analysis involves a focus on 'discourse', or language, as the way in which the social world is created and maintained. Discourse analysis is not a single unified method, but it is beyond the scope of this chapter to explore the range of forms of discourse analysis (see Willig, 2001). From a discursive perspective, psychological entities such as attitudes and beliefs have no existence beyond their expression, and in the expression of attitudes people are not reporting on an internal state but are engaged in a social act which achieves certain things (Wetherell *et al.*, 2001). Discourse analysts draw on a range of data sources, including naturally occurring dialogue, interviews, focus groups and documentary evidence. Spoken data, such as interviews, are transcribed in full, in other words features such as laughter, pauses, intakes of breath, loudness and emphasis are included in transcriptions. Analysis consists of examining texts for patterns of discourse, paying attention to the possible and actual effects of language both in the immediate context (e.g. the interview) and in the wider social context. Discourse analysis can provide valuable insights into how people talk about their experiences and the implications this has, and analysis can focus on levels ranging from one phrase to complete discourses.

Wilkinson and Kitzinger (2000) carried out a discourse analysis of cancer patients' talk, focusing on the phrase 'thinking positive'. Previous research had investigated positive thinking as a coping strategy related to adjustment to illness. By taking a discursive perspective Wilkinson and Kitzinger showed that rather than being a report of an internal cognitive state, the phrase thinking positive could be interpreted as a conversational idiom which, when used,

demonstrates a speaker's awareness of the socially normative requirement of cancer patients to be optimistic and fight their cancer. Lupton (1994) demonstrated a similar theme in her analysis of media representations of breast cancer, showing how the media linked fighting spirit to cancer survival. Here discourse analysis was able to show how coping strategies are represented in the mass media, and the potential for such discourses to shape social requirements for women to adopt certain attitudes.

Evaluation

Well established criteria for judging the quality of quantitative research, such as statistical validity and reliability, are not appropriate for the evaluation of qualitative work and a number of authors have suggested alternative criteria (e.g. Mays & Pope, 2000; Yardley, 2000). The quality of qualitative assessment can be judged on the clarity, coherence and systematic nature of data collection and analysis. A number of specific individual criteria can also assist in evaluation.

1. Transparency refers to the ability of a reader to follow exactly what a researcher has done, both in the collection and analysis of their data. The provision of excerpts from interview transcripts and worked through examples of the process of analysis can help to create paper trails which enhance the transparency of qualitative work.
2. The role of the researcher in qualitative research is often acknowledged and it is important to know about any techniques used to examine, account for or minimize the impact of the researcher on the data collection and analysis. This enables readers to judge for themselves the influence of the researcher on the project.
3. Negative or deviant case analysis is a technique which involves searching a qualitative data set for instances that do not fit with emerging analytical or explanatory frameworks. This demonstrates rigour and openness to alternative explanations and can help to determine the limits of an analysis.
4. Triangulation involves the use of multiple sources of data or types of data, or multiple analytic strategies or analysts, in order to examine phenomena from a range of angles. Rather than being a technique to examine the reliability of findings, triangulation may be used to provide more complete understandings of phenomena.
5. Respondent validation can be appropriate for some forms of qualitative assessment, and involves feeding back the analysis to participants to check if the results of the analysis correspond to participants' own understandings. This can be particularly important for approaches which seek to explore participants' own subjective understandings and systems of meaning, but may be less appropriate for approaches such as discourse analysis where technical analyses are used which do not focus on participants' meanings.
6. It is important to be able to judge the transferability of qualitative findings, in other words the extent to which findings might hold true in other settings, contexts or population groups. Transparency in terms of the provision of adequate detail about settings and participants can facilitate this process.

Using qualitative and quantitative assessment

The techniques and studies discussed above demonstrate a range of applications of qualitative approaches as stand-alone systems of inquiry. However, qualitative techniques can also be successfully combined with quantitative techniques in mixed method approaches. Qualitative techniques are often used in the development of questionnaire measures, in order to ground questionnaires in participants' own language and understandings and to ensure the questionnaire covers the range of issues important to participants. Qualitative assessment can also be used to investigate in more depth findings from quantitative research. For example Williams *et al.* (1998) used a qualitative approach to explore possible reasons for high levels of patient satisfaction found in questionnaire studies. They showed that patients' evaluations of care were more complex than existing questionnaires suggested and that reports of high satisfaction often masked more negative evaluations.

Recently there has been interest in the integration of evidence from qualitative and quantitative studies. Thomas *et al.* (2004) provide an example of how qualitative research can be integrated with evidence from clinical trials and the value of such

integrations: qualitative findings provide insight into patients' perspectives on interventions and can help to explain heterogeneous trial results, for example through examining the relationship between patients' outcome priorities identified in qualitative work and the measures of outcomes used in trials.

Conclusions

Qualitative assessment techniques are central to patient-centred healthcare. The inclusion of qualitative studies in the *British Medical Journal* in recent times demonstrates the recognition of the valuable insights that they can offer. Qualitative techniques provide a means to explore the subjective, personal, interpersonal and cultural aspects of health and illness. They can offer a sophisticated understanding of linguistic and social processes, as well as the variety of meanings of health and illness for different individuals. Furthermore, qualitative techniques provide a means to go beyond existing theory, to explore new areas and poorly understood phenomena and to incorporate patients' perspectives into the development of interventions and the delivery of healthcare.

Quality of life assessment

Ann Bowling

University College London

Quality of life, and its sub-domain of health-related quality of life (the effects of health on quality of life), are increasingly popular concepts as endpoints in the evaluation of outcomes of health and social care. But the wider research community has accepted no common definition or definitive theoretical framework of quality of life or health-related quality of life. The wide range of definitions of these concepts was reviewed by Farquhar (1995), and the diverse contributions of sociology (functionalism) and psychology (subjective wellbeing) to the theoretical foundations of the concept of quality of life were described by Patrick and Erickson (1993) (See 'Quality of life').

Quality of life is a complex collection of interacting objective and subjective dimensions (Lawton, 1991). Like health, health-related quality of life (and broader quality of life), includes positive as well as negative aspects of wellbeing and life, it is multidimensional and is a dynamic concept: perspectives can change with the onset of major illness. Relevant cognitive or affective processes in individuals when faced with changing circumstances (e.g. in their health or lives) include making comparisons of one's situation with others who are better or worse off, cognitive dissonance reduction, re-ordering of goals and values and response shift whereby internal standards and values are changed – and hence the perception of one's health and life changes (Sprangers & Schwartz, 1999). People may adjust to deteriorating circumstances because they want to feel as good as possible about themselves. The roots of this process are in psychological control theory, with goals of homeostasis. Investigators need to be aware of these problems, and attempt to control for them.

The main theoretical models of quality of life include needs based approaches derived from Maslow's (1954, 1962) hierarchy of human needs (deficiency needs – hunger, thirst, loneliness, security; and growth needs – learning, mastery and self-actualization); (overlapping with) social-psychological models which emphasize autonomy and control, self-sufficiency, internal control and self-assessed technical performance, social competence (Abbey & Andrews, 1986; Fry, 2000); classic models based on subjective wellbeing, happiness, morale, life satisfaction (Andrews, 1986; Andrews & Withey, 1976; Larson, 1978); social expectations or gap models based on the discrepancy between desired and actual circumstances (Michalos, 1986); and phenomenological models of individuals' unique perceptions of their circumstances, based on the concept that quality of life is dependent on the individuals who experience it and should be measured using their own value systems (Rosenberg, 1995; O'Boyle, 1997). In relation to the latter perspective, O'Boyle and his colleagues developed the Schedule for the Evaluation of Individual Quality of Life (SEIQoL), as a generic, individualized quality of life scale (Browne *et al.*, 1997). This has been used in many clinical

contexts. It is based on the rationale that it works within the value system of the individual being assessed, rather than the value systems of others. It derived its cognitive aspects from theoretical studies of perception and their extension to Social Judgement Theory, and enables individuals to nominate the areas of life they consider to be the most important to their quality of life, based on their own values.

Also in recognition of the importance of the individual's perspective, the World Health Organization included in its definition of quality of life in the context of health, individuals' perceptions of their position in life in the context of the culture and value systems in which they live and in relation to their goals. While its measure of quality of life (the WHOQoL) is subjective, it uses structured scales rather than individualized items to tap perceptions (WHOQoL Group, 1993, 1995; Skevington, 1999; Skevington *et al.*, 2001).

It could be argued that multidimensional definitions of quality of life confound the dimensionality of the concept with the multiplicity of their causal sources. Beckie and Hayduk (1997) argued that quality of life could be considered as a unidimensional concept with multiple causes, and a unidimensional QoL rating, such as 'How do you feel about your life as a whole?' could be the consequence of global assessments of a range of diverse and complex factors. Thus it would be logical for a unidimensional indicator of quality of life (e.g. a self-rating global QoL uniscale) to be the dependent variable in analyses and the predictor variables include the range of health, social and psychological variables. An appreciation of the distinction between these types of variables is needed by investigators (Zizzi *et al.*, 1998; Fayers & Hand, 2002).

In addition, the effects of personality on perceived wellbeing and quality of life are controversial, partly because of the debate about causal versus mediating variables. Extroversion and neuroticism have been reported to account for a moderate amount of the variation in subjective wellbeing (the trait of extraversion is associated with positive affect and with wellbeing; emotionality is associated with negative affect and poor wellbeing) (Spiro & Bossé, 2000). However, these personality factors are highly stable traits, while subjective wellbeing has been shown to have only moderate stability over time (Headey *et al.*, 1985) (see 'Personality and health').

Zissi *et al.* (1998) also argued that perceived quality of life is likely to be mediated by several inter-related variables, including self-related constructs (e.g. self-mastery) and these perceptions are likely to be influenced by cognitive mechanisms (e.g. expectations of life). There is still little empirical data to support or refute the distinction between psychological constructs as mediating or influencing variables in determining the quality of life.

Regardless of the conceptual debates and distinctions between health status, quality of life and health-related quality of life,

few health researchers have defined these terms in their investigations and many have inappropriately used measures of broader health status to measure health-related quality of life or broader quality of life. This has been justified on the basis of the untested assumption that broader measurement scales of health status (e.g. the SF-36; Ware *et al.*, 1993, 1997) include the main areas in which health can affect one's life, and which are relevant for health services. These concepts may overlap (Ware *et al.*, 1993), but they are not synonymous. In addition, a plethora of disease-specific quality of life measures has been developed, with little standardization of measurement approaches between studies (Garrett *et al.*, 2002) (see also 'Health status assessment').

The investigator should define the concepts used, and select an appropriate measure, which may be generic, health-related (Bowling, 2004) or designed to relate to a specific disease (Bowling, 2001). It is important that the measure selected for use should include topics relevant to the research question and questions which are considered to be important by the target group (e.g. patients). Measures should be based on a theoretical model; incorporate the perceptions of the target population (i.e. items generated from interviews); be directly relevant to, and appropriate for, the research population; contain items related to the target population's identified needs and outcomes; be reliable, valid, precise and responsive to changes associated with treatment; have scale scores which are interpretable (i.e. associated with severity of condition with a guide to cut-off points/ranges); minimize respondent and interviewer burden and be acceptable to respondents; have

alternative forms available (interviewer and self-administration versions); and have made cultural and language adaptations, in accordance with good practice on obtaining cultural equivalence.

The choice of whether to use a measure of generic quality of life, health-related or disease-specific quality of life depends on the aims of the study and the type of population or intervention studied. There is little point in including a broad generic measure if it is unlikely to detect the specific effects of treatment, although the use of disease-specific measures precludes the possibility of comparing the outcomes of services that are directed at different groups suffering from different diseases. It is not possible within the space of this chapter to review available measures of generic, health-related and disease-specific quality of life and interested readers are referred to the several existing reviews of measures of health status, generic, health-related and disease-specific quality of life (McDowell & Newell, 1996; Spilker, 1996; Bowling, 2001, 2004).

Social support assessment

Brian Lakey and Jay L. Cohen

Wayne State University

In this chapter, we review different approaches to assessing social support, as well as research evidence indicating the psychological and environmental characteristics that these measures reflect. A comprehensive review of all of the major social support measures is beyond the focus of this chapter, and we refer readers to recent comprehensive reviews (e.g. Brissette *et al.*, 2000; Wills & Shinar, 2000). In this chapter, we briefly describe different types of social support measures, and review research bearing on their validity. We focus on the most widely used types of measures, although we also briefly describe under-utilized and more recently developed approaches.

Types of social support measures

There are at least three different types of social support constructs and measures; perceived support, enacted support and social integration/network characteristics (Barrera, 1986) (see 'Social support and health'). Each type is most often assessed by self-report, whereby research participants complete questionnaires about participants' perceived availability of support (perceived support), the amount of specific supportive actions received (enacted support), or the number of different types of relationships in which people participate (social integration). Measures of these different types of support are only modestly related to each other, and relate to mental health, physical health and other constructs in different ways (Barrera, 1986).

Description of types of social support measures

Measures of perceived support

Measures of perceived support (also termed 'functional support', see chapter on 'Social support and health') ask respondents to make subjective judgments about the availability of support, or for some measures, about the quality of the support typically received. Two prototypical measures of perceived support are the Interpersonal Support Evaluation List (S. Cohen & Hoberman, 1983; S. Cohen *et al.*, 1985) and the Social Provisions Scale (SPS; Cutrona & Russell, 1987). Both measures are used very widely in research. Detailed descriptions of a wide range of measures of perceived support are provided by Wills and Shinar (2000).

Measures of enacted support

Measures of enacted support (also termed 'received support') ask respondents to report the frequency by which (or simply whether or not) they have received various supportive actions over a specific period of time (e.g. 30 days). Perhaps the most widely used measure of enacted support is the Inventory of Socially Supportive Behaviours (ISSB; Barrera *et al.*, 1981). Detailed descriptions of a range of measures of enacted support can be found in Wills and Shinar (2000).

Measures of social integration and social networks

Measures of social integration and social networks typically assess the number of important relationships or roles in which respondents participate, or may assess more detailed characteristics of social networks such as the extent to which different network members know each other (i.e. network density). One prototypic measure of social integration is S. Cohen's (1991; Cohen *et al.*, 1997) Social Network Index (SNI). Detailed descriptions of a range of measures of social integration and network characteristics can be found in Brisette *et al.* (2000).

Construct validity

Readers interested in understanding the scientific basis for determining the validity of measures of psychological constructs should study Cronbach and Meehl's (1955) definitive statement on construct validity. An adequate account of construct validity cannot be provided in a short paragraph, but here is a summary of some of the key points, as applied to social support. First, there will never be a single gold standard for the assessment of social support, because social support is a human abstraction used to organize and make sense of complex psychological phenomena. Instead, different measures of social support will be more or less useful for different purposes. Second, the validity of social support measures is based solely on the measures' correlations with other constructs and variables, as determined by quantitative research methods. The label applied to the measure, or the intentions of the measure's developers do not count as evidence for construct validity. Third, validity occurs on a continuum rather than as a dichotomy. That is, measures have more or less validity, rather than are valid or invalid. Further, validity may vary depending upon the purposes for which the measure is used. A given scale might have good validity for predicting mortality, but poor validity for predicting changes in mental health. In the next section, we describe the construct validity of measures of perceived support, enacted support and social integration.

Construct validity for perceived social support

The most important fact regarding the validity of measures of perceived support is the consistent and strong finding that people who report higher levels of perceived support have better mental health and lower rates of psychopathology than do people with lower perceived support (Cohen & Wills, 1985; Sarason *et al.*, 2001). Nonetheless, measures of perceived support are not so highly correlated with mental health as to suggest that measures of perceived support reflect mental health primarily. Similar findings have been observed for a range of physical health indices, although the magnitude of the link between perceived support and physical health often is smaller than the link between perceived support and mental health (Uchino, 2004; see 'Social support and health').

From the beginning of social support research, scholars assumed that measures of perceived support primarily reflected respondents' social environments. If so, then people who perceive their relationships as supportive should perceive other aspects of their

relationships positively as well. In fact, people who perceive their relationships as supportive also report high satisfaction (Kaul & Lakey, 2003), intimacy (Reis & Franks, 1994) and low levels of conflict (Okun & Lockwood, 2003) with important relationship partners, less loneliness (Joiner, 1997) and more secure adult romantic attachments (Davis *et al.*, 1998). Although people who perceive their relationships as more supportive also report receiving more enacted support, the magnitude of this correlation is not as strong as most social support models imply (Barrera, 1986). A recent meta-analysis estimated the link between perceived and enacted support at $r = 0.34$ (Haber *et al.*, 2003). Thus, perceived support is only partly a reflection of the amount of enacted support received.

Another indicator of the extent to which perceived support reflects the characteristics of personal relationships is the extent to which relationship partners agree about the supportiveness of their relationships. A number of studies have found modest agreement among friends, couples and diverse family members on perceived supportiveness, with indices of agreement ranging from $r = 0.32$ to 0.55 (Abbey *et al.*, 1995; Cutrona, 1989; McCaskill & Lakey, 2000; Vinokur *et al.*, 1987).

Although people with high levels of perceived support describe other aspects of their relationships positively, these people also describe their own personality characteristics favourably. People with high levels of perceived support report higher self-esteem, a greater sense of personal control and fewer irrational beliefs (Lakey & Cassady, 1990). With regard to personality traits, people with high levels of perceived support describe themselves as agreeable, extraverted, emotionally stable, conscientious and open to experience (Branje *et al.*, 2004; Finch *et al.*, 1999; Colby & Emmons, 1997; but see Tonga *et al.*, 2004, for an exception). Such people also describe themselves as not sensitive to rejection, not alienated and as having high levels of interpersonal trust (Lakey *et al.*, 1994). They describe themselves as socially skilled (Cohen *et al.*, 1986) and independent observers agree to some extent (Sarason *et al.*, 1985). Thus, although people with high levels of perceived support describe other aspects of their personal relationships favourably, they also describe their own personality characteristics favourably (see 'Personality and health').

Although most research on perceived support has focused on the characteristics of support recipients, other research has focused on the characteristics of people who are seen as good support providers. Recipients see supportive providers as agreeable, similar to recipients in attitudes and values and emotionally stable (Branje *et al.*, 2004; Lakey *et al.*, 2002), although recipients vary substantially in the particular provider personality traits which they use to judge supportiveness (Lutz & Lakey, 2001).

Thus, the evidence reviewed so far provides a murky view of the extent to which measures of perceived support reflect the personal qualities of support recipients and the characteristics of the social environment. Recent research using Generalizability Theory (Cronbach *et al.*, 1972) and the Social Relations Model (Kenny, 1994) provide more precise estimates of the extent to which perceived support reflects the characteristics of support recipients (also termed perceiver or actor effects) and two different forms of social influence; the objectively supportive properties of providers (also termed target or partner effects) and the unique relationships among recipients and providers. The 'recipient' component represents individual differences in how favourably

recipients see support providers, on average, regardless of the characteristics of providers. The provider component represents the extent to which recipients agree on the relative supportiveness of the same providers; that is, the extent to which supportiveness is an objective quality of providers. Here we operationalize 'objective' as inter-rater agreement. Most social support models emphasize the provider component. The 'relationship' component reflects systematic disagreement among recipients about the relative supportiveness of the same providers. This component reflects the extent to which supportiveness is a matter of personal taste and it reflects the unique matches between specific recipients and specific providers.

Our research group's current best estimate of the relative magnitude of recipient, provider and relationship effects, is derived from three studies in which recipients rated individuals who were well known to them (Studies 1 and 2 in Lakey *et al.*, 1996, and one unpublished study). We estimate that approximately 14% of perceived support reflects the personality characteristics of recipients, 6% reflects the objectively supportive properties of providers and 51% reflects the unique relationships among providers and recipients. Branje *et al.* (2002) have conducted an independent replication in Holland and reported very similar findings, although Branje obtained slightly higher estimates for recipient personality and slightly lower estimates for unique relationships. Thus, measures of perceived support reflect a blend of the personality characteristics of recipients, as well as two distinct kinds of social influence. On the whole, however, the large majority of the variance in perceived support measures reflects social influence, although not the kind emphasized by most social support models.

Construct validity for enacted social support

One of the major differences between measures of perceived and enacted support is that measures of enacted support are not consistently linked to mental and physical health (Barrera, 1986; Finch *et al.*, 1999; Uchino, 2004). When measures of enacted support are significantly related to mental health, the direction of the correlation frequently is opposite to expectations: people who receive the most enacted support have the worst mental health (Barrera, 1986). More recent evidence suggests that only enacted support involving positive social exchanges (Finch *et al.*, 1997), support that goes un-noticed by support recipients (Bolger *et al.*, 2000) and support that is desired by recipients (Reynolds & Perrin, 2004) is related to mental health.

Unlike measures of perceived support, measures of enacted support do not appear to have strong links to recipients' reports of self-esteem, irrational beliefs and personal control (Lakey & Cassady, 1990; Lakey *et al.*, 1994), although like perceived support, people who report receiving high levels of enacted support express more positive affect (Lakey *et al.*, 1994) and extroversion (Finch *et al.*, 1997) than people who express low levels.

Although measures of enacted support do not have as many documented links to other constructs as does perceived support, recipients appear to report enacted support more accurately than they report perceived support and personality (Cohen *et al.*, in press). After controlling for a variety of artifacts that inflate agreement, agreement between providers and recipients was

$r=0.50$ for enacted support and $r=0.29$ for perceived support. Agreement on providers' personality traits was much lower. Other investigators also report significant agreement between dyads on enacted support (Antonucci & Israel, 1986; Coriell & S. Cohen, 1995).

Construct validity for social integration and social network characteristics

Most research on social integration and social network characteristics examines links to health outcomes, as reviewed by Wills and Anette (see 'Social support and health') and Uchino (2004). Compared with perceived support, less is known about the construct validity of social integration. In one study (Cohen *et al.*, 1987), people with more diverse social networks smoked less and exercised more, but did not drink less alcohol than people with less diverse social networks. The same study found that people with more diverse social networks were more extraverted than people with less diverse networks, but not more neurotic, conscientiousness, open to experience or agreeable. Cohen (1991) also reported that people with more diverse networks had more positive affect, stronger beliefs in their own personal control and higher self-esteem than people with less diverse networks. Similarly, people with larger social networks (all relationships not limited by type of relationship) reported more extroversion and positive affect, but not negative affect, neuroticism, perceived stress or hostility, than people with smaller networks (Pressman *et al.*, 2005). Thus, social integration appears to be related to extroversion and positive affect, as well as to some positive health practices.

Incremental validity

Incremental validity is the extent to which a given measure predicts outcomes of interest above and beyond other constructs (Sechrest, 1963). For example, do measures of social support predict health beyond other related constructs, or other risk factors? As reviewed elsewhere (Sarason *et al.*, 2001), measures of perceived support and social integration forecast changes in both mental and physical health incrementally beyond pre-existing mental and physical health. With regard to mental health, measures of perceived support show incremental validity beyond social desirability (Cohen *et al.*, 1985; Cutrona & Russell, 1987) and social competence (Cohen *et al.*, 1986). In spite of these favourable findings for measures of perceived support, additional work is needed to demonstrate that measures of social support can predict incrementally beyond other measures of personal relationships. For example, Finch *et al.* (1999) found that perceived social support was related to mental health incrementally beyond interpersonal stress. However, Kaul and Lakey (2003) failed to find incremental validity for perceived support beyond generic relationship satisfaction in predicting mental health, raising the question of the extent to which reports of social support captured social support per se, or a more general evaluation of relationships.

In addition to showing that total social support scores have incremental validity beyond other constructs, it is also important to demonstrate that various social support subscales have incremental validity beyond other subscales. Otherwise, it is difficult to

argue that a given sub-scale measures a unique aspect of social support that is not shared with other sub-scales. Establishing incremental validity for sub-scales is especially important because the sub-scales typically are moderately to strongly inter-correlated and display similar patterns of correlations with other constructs (Cohen *et al.*, 1985; Cutrona & Russell, 1987). Cohen and Hoberman (1983) found that self-esteem support and appraisal support each displayed buffering effects with stressful life events in predicting depression, even when all other sub-scales of the ISEL were controlled. In a sample of married people, Cutrona (personal communication, November, 2004) found that the SPS sub-scales of attachment, guidance, social integration and reassurance of worth each were uniquely related to marital satisfaction. For enacted support, Finch *et al.* (1997) found that positive social exchange was linked to less depression but that tangible assistance and directive guidance were linked to more depression, when all other sub-scales and personality measures were controlled. Although these studies are promising, there are not enough studies of this kind to fully resolve the question of incremental validity for social support sub-scales.

Under-utilized approaches to measurement

The vast majority of studies use self-report measures that assess social support in a global sense. Although such measures are valuable, it is important to remember that they only partly reflect the objective properties of social environments (Lahey *et al.*, 1996). In addition, global measures of social support do not capture moment-by-moment social interactions. Although used infrequently, there are behavioural observation and diary measures of social support that can provide more objective and moment-by-moment assessments.

Cutrona and her colleagues (Cutrona *et al.*, 1997) developed the Social Support Behaviour Code (SSBC), a behavioural observation measure designed to assess the extent to which a provider engages in specific, observable supportive actions in a specific conversation. The SSBC has not been used extensively in research and so there is comparatively little information about its construct validity. However, preliminary findings indicate that extraverted providers give more support than do introverted providers, and providers give more support when they themselves received more support in a previous interaction (Cutrona *et al.*, 1997). Consistent with research based on questionnaires, recipients' perceptions of support are not very closely related to the receipt of support, as rated by observers (Cutrona *et al.*, 1997).

Diary measures are another form of under-utilized social support assessment. For example, Bolger and his colleagues (Bolger *et al.*, 2000) developed a diary method whereby respondents reported social support on a daily basis. In Bolger *et al.* (2000), recipients preparing to take the bar exam reported on a daily basis whether their romantic partners 'listened to and comforted' them. Partners also reported whether they provided such support. Couples agreed on whether support was provided on 61% of diary days, indicating modest agreement on support provision. However, this method revealed a fascinating effect: recipients were least depressed on days in which partners reported providing support, but

recipients did not see it. Recipients were most depressed when they reported receiving support, but providers reported not providing it. Bolger *et al.* (2000) termed this phenomenon, 'invisible support' because recipients appeared to benefit most from support that was invisible to them. Using the same method, Gleason *et al.* (2003) reported that reciprocity in the exchange of support was associated with higher levels of positive affect and lower levels of negative affect.

Summary and conclusions

Perceived support, enacted support and social integration/network characteristics are the three major types of social support constructs and measures. Of these, the construct validity of perceived support is the best understood. Perceived support represents a blend of the personality characteristics of recipients, the objectively supportive properties of providers and the unique relationships among recipients and providers. Of these, relationships are the most important influence. Thus, most of the variance in measures of perceived support reflects the social environment, although it is not the aspect of the social environment that has been emphasized by most social support models. Recipients see supportive providers as similar to recipients in attitudes and values, as agreeable and as providing enacted support. People who report high levels of perceived support also have more favourable scores on a wide range of personal characteristics. The construct validity of measures of enacted support is less well understood than for perceived support. Although people who receive more enacted support express more extraversion and positive affect than people who receive less enacted support, enacted support is not as strongly correlated with the same wide range of favourable personal characteristics as is perceived support. Nonetheless, recipients and providers display good agreement about the enacted support that is received and therefore measures of enacted support appear to reflect the objective features of social interactions more so than do measures of perceived support. Beyond the abundant research linking social integration to health, there is relatively little research on the construct validity of such measures. What is available suggests that people with more diverse social networks express more positive affect and extroversion than do people with less diverse social networks.

In choosing social support measures for research or clinical applications it is essential to verify that the type of social support measure under consideration is relevant to the clinical problem or outcome of interest. For example, although researchers often believe that the more objective types of social support measures (e.g. social integration or enacted support) are preferred because of their apparent objectivity, the more subjective measures of perceived support are much more closely tied to mental health. In contrast, measures of social integration do quite well in predicting a variety of health outcomes, including mortality. It is important to remember that the three different types of social support measures are not closely related and reflect different psychological and social processes.

Stress assessment

Andrew Baum and Angela Liegey Dougall

University of Pittsburgh

Overview

Because stress is a complex process and occurs broadly and at many levels, assessment of it has been difficult and at times controversial. The proliferation of measurement protocols, continued confusion or inconsistency among theories and operational variables and the pervasiveness and depth of stress responses themselves all contribute to these difficulties. Regardless, a useful set of measures of stress-related phenomena has emerged and although several problems remain to be worked out, the development of comprehensive, convergent assessment strategies has allowed significant advances in our knowledge of stress and its contributions to health and illness. These approaches to measuring stress reflect prognostic solutions to key conceptual controversies in the field and permit measurement across different levels of response, points in the stress process, and acute and chronic timeframes. Here, we briefly consider some issues that complicate stress assessment and review available measures.

The most significant of these issues reflects the many different definitions of stress and conceptions of the nature and duration

of its effects. Different assumptions and definitions will affect the operationalization of key constructs and the measures selected or developed. As discussed by Ayers and Steptoe in the chapter on ‘Stress & health’, the stress process includes environmental events and intrapsychic sources of stress that are called ‘stressors’, cognitive interpretation of these events and of one’s capacity to adapt (‘appraisal’), emotional behavioural and biological changes associated with these variables (‘stress responses’, ‘strain’) and effects of these changes (‘consequences’). Measurement can address any one of these levels or can include simultaneous assessments of two or more.

Within these levels of analysis, measures can vary in the way they target aspects of each or in the time frame that is adopted, and because stress is essentially a ‘whole body’ response, it is expressed as changes in all or nearly all bodily systems and psychological dimensions. As a result, the number of variables that can be observed is large. Even brief consideration of these issues should guide choices among potential measurement approaches. Decisions about targets for measurement ultimately rest on the nature of the questions being asked.

Assessment of stressors

Assessment of stressors and/or of appraisal of them will yield different information than will measurement of response or consequence. Measures of stressors are possible and useful because specific events or conditions often cause stress appraisals and/or responses. The frequency and duration of these events or conditions can be reliably quantified. There are clear advantages to these measures but there are major limitations on their use and value as well. To some extent the use of these measures and the choices among them are related to availability of sources of data (e.g. study participants, archival data) and to the questions under investigation.

The most common or well known measures of stressors are counts or descriptions of significant 'life events' or changes. Pioneering studies of the contributions of the frequency and distribution of major life changes used the Social Readjustment Rating Questionnaire and, more recently, the Recent Life Changes Questionnaire (Holmes & Rahe, 1967; Rahe, 1975). These instruments consist of inventories of life events or changes that occur variably in peoples' lives. Respondents indicate which have been experienced and when they were experienced and sufficient data are generated to allow estimates of the frequency and clustering/dispersal of these events over time. These variables are often correlated with physical and psychological outcomes. Some forms of these life event measures ask respondents to rate the impact of each experienced event, and others rely on consensus about the relative effects of different events.

Variability in perceived impact of stressors is one source of error in these assessments and limitations imposed by lack of reliable or standardized impact estimates are key limitations of these measures. Unless detailed records exist or are compiled for other reasons, measures of life events are self-reports and are also vulnerable to recall bias, limiting the time frame that can be reliably measured. Overlap among listed items and common responses to stress have also introduced concerns about some of these measures. However, despite these problems, studies of life events and health outcomes generally produce modest but robust correlations among events and outcomes (Sarason *et al.*, 1975).

A different body of research has focused on studying minor, mundane stressors that occur in everyday life. Lazarus and colleagues have proposed that an accumulation of these daily stressors, or 'hassles', should prospectively predict mood, distress and physical health (Lazarus *et al.*, 1980). Research using the Hassles and Uplifts Scale has confirmed these relationships and has suggested that daily hassles were a better predictor of psychological symptoms than were life events (DeLongis *et al.*, 1988; Kanner *et al.*, 1981). A concern with these measures is that they may reflect mood as much as the occurrence of an annoying event or condition. Hassles are by definition minor and may normally escape detection or recollection: they may be more memorable when one is in a 'bad' mood. As a result, reporting may be inflated and the predictive value of stressor assessments influenced by associated mood changes.

To minimize bias due to an individual's appraisal and mood in the measurement of life stressors, structured interviews have been developed such as the Life Events and Difficulties Schedule (LEDS; Brown & Harris, 1989). These interview techniques are useful for gathering specific information on the actual event and its context

that can then be rated by objective reviewers. This approach has increased the magnitude of the relationships found between life stress and outcomes and has shown that life events and chronic difficulties may contribute to the risk of developing many mental and physical disorders. Training for and administration of interviews like the LEDS are both time-consuming and costly and limit the feasibility and dissemination of this approach. Additionally, these techniques provide little information about how stress works or why it has these effects, nor do they measure mediators or effectors (e.g. response) to allow examination of consequences.

Measures of stressors can also focus on specific types of stressors, as, for example, with the Traumatic Stress Schedule or the Traumatic Life Events Questionnaire (Kubany *et al.*, 2000; Norris, 1990). These target specific types of stressors or general source differences and allow more precise predictions or hypotheses when appropriate. Whether narrowly focused or more broadly inclusive, these measures are useful in evaluating gross relationships in larger samples and in evaluating other sources of stress-related variance when one or a few specific sources are targeted.

Measuring appraisal

Measures of stress appraisal are at once disarmingly simple and deceptively complex. At some level measures of appraisal can serve as 'manipulation checks' and as such can (and often are) measured with single items or brief home-grown scales that ask whether respondents felt stressed at a particular time. These questions can take many forms and can focus on specific sources of stress (e.g. Are you stressed on the job? Do you feel crowded?) or acute responses to laboratory stressors (e.g. Did you find the task stressful?). These measures fulfill the conditions specifying appraisal and appraisal process but do not reflect how this general assessment was generated. For example, part of the appraisal of whether a situation is stressful or not depends on perceptions of one's ability to adapt. Part of this evaluation consists of appraisals of one's resources, including social support or coping style and efficacy. Simple measures of stress may not reflect this complexity and tell us little about the relative contributions of stressor characteristics and appraisals of resources and assets to these summary conclusions.

There have been efforts to develop broader measures of stress appraisal. Folkman *et al.* (1986) developed scales for primary appraisal (determining what is at risk in the stressful encounter) and secondary appraisal (determining coping options) based on their theoretical work on stress and coping (Lazarus & Folkman, 1984). Expanding on this seminal work, investigators have developed other scales that emphasize different aspects of appraisal such as centrality or trait-state differences and include instruments such as the Stress Appraisal Measure (Peacock & Wong, 1990), the Dimensions of Stress Scale (Vitaliano *et al.*, 1993), the Perceived Stress Scale (Cohen *et al.*, 1983) and the Cognitive Appraisal Scale (Skinner and Brewer, 2002). Many researchers have used these scales or a modified version of them to show that the types of appraisals people make predicted the coping strategies used and psychological adaptation.

As part of the ongoing cognitive processing of stressful events, people may experience intrusive thoughts or unwanted, unbidden and uncontrollable thoughts about the event (Creamer *et al.*, 1992;

Greenberg, 1995). A popular measure of intrusive thoughts is the Impact of Event Scale and its revision (Horowitz *et al.*, 1979; Weiss & Marmar, 1997), which also assesses the incidence of avoidance and hyper-arousal symptoms that commonly occur following extreme stressors. Intrusive thoughts may help an individual work through the situation and generally decrease in frequency as people recover from stressful events (Delahanty *et al.*, 1997). However, the unwanted and uncontrollable nature of intrusive thoughts may make them stressful in their own right possibly sensitizing individuals to other reminiscent stimuli. Stressor-related intrusions, combined with other cognitive processes and environmental stimuli, may serve to perpetuate stress by eliciting acute stress episodes and maintaining stress appraisals. Research indicates that intrusive thoughts are a strong predictor of chronic stress responding (Dougall *et al.*, 1999).

Together with the availability of a number of good measures of resource appraisal and efficacy, measures of general or summary appraisals can be used to evaluate individual variation in response to events or conditions that often induce stress (see also 'Coping assessment' and 'Social support assessment'). The essential distinction between appraisal and response measures is derived from the putative role of the variable. Appraisal theoretically initiates responses. Some variables or measures, such as intrusions and the Impact of Event Scale, may represent elements of both.

Stress responses

Stress responses occur at several different levels. Both acute and more chronic stressors are associated with emotional changes, cognitive and behavioural responses and far-reaching biological changes in nearly every system in the body. There are many measures at each of these levels, varying in the extent to which they rely on self-report, the duration and timing of responses, and the system or response that they target. Mood measures, such as the Profile of Mood States (POMS; McNair *et al.*, 1981), anxiety assessments such as the State-Trait Anxiety Inventory (STAI, Spielberger, 1983) and state/trait assessments of one or several mood states, such as the Positive and Negative Affect Schedule (PANAS, Watson *et al.*, 1988) are useful in measuring changes in mood associated with exposure to experimental stressors or naturalistic stressors (see 'Mood assessment'). Cognitive aspects of stress response, including increased use of short-cutting or heuristics in decision making under stress (Shaham *et al.*, 1992), tolerance for frustration (Glass and Singer, 1972) and concentration/problem-solving (Baum *et al.*, 1983) can also be assessed during or after experimental or ongoing naturalistic stressors. Although less common, behavioural measures can be collected through observation or by presentation of experimental conditions that evoke and allow measurement of persistent or over-generalized responses to situational demands (Baum & Valins, 1977). Finally, biological measures include many different estimates of many different bodily processes. The most common include measures of blood pressure and heart rate (particularly in studies of stress reactivity), other peripheral psychophysiological measures (e.g. skin conductance, EMG) and stress hormones (e.g. cortisol, epinephrine and norepinephrine) although recent developments in psychoneuroimmunology have increased use of immune

measures of response as well (see 'Psychoneuroimmunology assessments').

Self-report measures are typically used to assess stress-related increases in negative emotions such as depression, anxiety, anger, fear and overall symptom reporting. In addition to the mood measures mentioned above, instruments used to assess general levels of distress or symptoms such as the Symptom Checklist 90 – Revised (Derogatis, 1994) and abbreviated forms are used extensively to measure general distress. These inventories typically ask a respondent to rate either how frequently a list of symptoms occurred or to rate how much the symptoms distressed or bothered them. A referent timeframe of a week or a month is given so that respondents can provide a general rating of distress.

Stress may also be manifested as decrements in behavioural performance. People may not be able to attend well to routine, mundane tasks, like driving an automobile, balancing a checkbook, or monitoring a computer screen, while their attention is focused on dealing with a stressor (Krueger, 1989). Behavioural tasks such as the proofreading task devised by Glass and Singer (1972) or an embedded figures task (Witkin *et al.*, 1979) have been used to document acute stress effects as well as chronic stress responding in people exposed to stressors such as disasters (Baum *et al.*, 1983). People experiencing chronic stress find fewer errors in the proofreading task or solve fewer puzzles and make fewer attempts to solve puzzles on the embedded figures task. Even exposure to a brief, laboratory task can result in transient performance deficits in tasks given during the stressor or after it (Cohen, 1980). These negative after-effects have been shown to occur even after a person appears to have psychologically and physiologically adapted to an acute stressor.

An important direction for stress research is measurement of stress effects on health and wellbeing. Behavioural responses during or after stress can reflect attempts to cope with a stressor deemed harmful and represent a primary pathway by which stress affects health. Many of these coping behaviours facilitate appropriate responses to the stressful event and promote successful resolution of or adaptation to the stressor. There are several chapters dealing with coping in this Handbook and the reader is referred to these for more detailed discussion of this key construct.

Some of the coping behaviours people use may increase their risk for disease or injury regardless of whether they promote successful adaptation. For example, many people under stress smoke more cigarettes, drink more alcohol and are less likely to engage in physical activity (Alexander & Walker, 1994; Ng & Jeffery, 2003). These behaviours, in turn, can negatively impact health status (see 'Health-related behaviours'). Inventories designed to specifically measure these health behaviours should be included in addition to traditional coping checklists. The Fagerström Test for Nicotine Dependence (Heatherton *et al.*, 1991) is commonly used to assess physical dependence to nicotine and includes items that assess quantity of use as well as smoking habits. Other measures, like the Wisconsin Inventory of Smoking Dependence Motives (Piper *et al.*, 2004), are used to assess the types of motivational domains that promote nicotine use. Frequency and quantity of alcohol use are assessed with questionnaires like the Quantity/Variability/Frequency Scale of Alcohol Use (Q-V-F; Cahalan *et al.*, 1969). The four-item CAGE (Ewing, 1984) and the Michigan Alcoholism Screening Test (Selzer, 1971) are popular inventories used to

screen for problem drinking. Leisure-time physical activity is another important health behaviour and can be measured by having a participant wear a small device such as an actigraph or pedometer that records bodily movement or can be approximated by having people recall their activities using instruments such as the Paffenbarger Activity Questionnaire (Paffenbarger *et al.*, 1986) and the Godin Leisure Time Exercise Questionnaire (Godin *et al.*, 1986).

In addition to psychological and behavioural changes, stress responding is manifested in many physiological systems within the body. The effects of stress on the sympathetic nervous system (SNS) and the hypothalamic–pituitary–adrenal cortical (HPA) axis were introduced and documented in the seminal work of Cannon (1914) and by Selye (1956/1984). The effects generally consisted of measures of heart rate, blood pressure and the release of epinephrine and norepinephrine by the SNS and the release of adrenocorticotrophic hormone (ACTH) and glucocorticoids (i.e. cortisol in humans) from the HPA axis. Heart rate and blood pressure are among the easiest and least expensive measures and have clear implications for health status. In more complex experimental designs an ambulatory blood pressure monitor is attached to a person using electrodes and leads and can be used to record multiple readings and to reduce interference caused by motion.

Depending on the nature of the experiment and the hypotheses tested, neuroendocrine measures such as epinephrine, norepinephrine, ACTH and cortisol can be assessed in the blood, urine, or saliva (Baum & Grunberg, 1997). Acute or momentary changes in these neuroendocrine factors are typically measured in serum. Cortisol can also be measured in saliva, a technique that is less invasive than blood measurements and can be used to examine cortisol's diurnal rhythm. Aggregate measures of neuroendocrine levels over a 15- or 24-hour period of time can be assessed by collecting all urine voided during that time frame. Levels of epinephrine and norepinephrine can also be estimated for the previous seven days by measuring levels of these catecholamines absorbed by blood platelets. Biochemical assays for all of these neuroendocrine factors are readily available and can be performed at

moderate expense. Catecholamines such as epinephrine and norepinephrine are typically assessed using radioenzymatic assay (REA) or high-performance liquid chromatography (HPLC). In contrast, corticosteroid and ACTH levels are often assessed by competitive immunoassay, radioimmunoassay (RIA), enzyme-linked immunosorbent assay (ELISA), or double antibody sandwich immunoradiometric assay (IRMA).

Stress-related alterations in immune system functioning have also been observed and appear to be dependent on the nature and duration of the stressor (Segerstrom & Miller, 2004). Acute stressors of limited duration (i.e. minutes) have been generally associated with activation of natural immunity (the more primitive, non-specific markers of immunity such as natural killer cells and macrophages), but with reductions in markers of specific immunity (the slower, more targeted markers of immunity such as B and T cells). In contrast, stress responding of longer duration has been generally characterized by reductions in both types of immunity and has been associated with the onset and course of many diseases such as infectious diseases, cardiovascular disease, arthritis and Type 2 diabetes (Kiecolt-Glaser *et al.*, 2002). For a more detailed description of immune system changes and measures (see 'Psychoneuroimmunology assessments').

Conclusions

The nature of stress has led to a proliferation of measures which has complicated theoretical consolidation and research on the consequences of stress. Depending on the target of a particular investigation, measures should be selected because of their proximal relationship to outcomes of interest or because they are available and collectable. Systematic consideration of the needs of a particular study, as well as the limitations on data collection and sources of data that are available, will typically yield useful measurement approaches. Combinations of measurement, particularly when convergence is possible, constitute one approach to stress assessment.

Section III

Psychological intervention

Behaviour therapy

Gerald C. Davison

University of Southern California

Behaviour therapy, sometimes also called behaviour modification, developed initially during the 1950s through the work of people like B.F. Skinner (1953) and Joseph Wolpe (1958). The attempt was to create an approach to intervention that relied on experimentally tested principles of learning. In its earliest years the emphasis in behaviour therapy was on classical and operant conditioning and throughout the 1960s and thereafter a number of therapeutic techniques were developed that purportedly rested on these experimental foundations. The word 'purportedly' is used intentionally here because an ongoing scientific controversy has surrounded the extent to which behaviour therapy techniques truly derive their effectiveness from learning principles developed primarily from infrahuman experimentation. Suffice it to say that the most innovative techniques came from practising clinicians whose thinking was guided and enriched by their awareness of certain learning principles and by their creative attempts to apply them in the complex and often chaotic domain of clinical intervention. There is considerable evidence from numerous research settings worldwide that many of these techniques are helpful for dealing with a wide range of psychological disorders (see Davison *et al.*, 2004). This chapter will provide a historical overview of the development on behaviour therapy, followed by a description of some of the techniques encompassed by this approach, and conclude with a consideration of some conceptual issues in behaviour therapy.

An early behaviour therapy effort was by Andrew Salter (1949), whose book *Condition reflex therapy* represented an attempt to rationalize assertion training in Pavlovian conditioning terms. Salter was perhaps the first to argue that many anxious and depressed individuals could be helped by encouraging them to express openly to others both their likes and dislikes. He used Pavlovian theorizing to argue that much human psychological suffering arises from an excess of cortical inhibition, a state that could be reversed by an increase in emotional expressiveness. While the theorizing is doubtful, the approach in general is widely employed and even has links with humanistic emphases on become more aware of and expressing one's basic needs (Perls, 1969; Rogers, 1951).

Also in the classical conditioning camp is Joseph Wolpe, whose book *Psychotherapy by reciprocal inhibition* has had an enormous impact on the thinking and practices of behaviourally oriented clinicians. Trained in medicine and basing his work on Mary Cover Jones's (1924) classic case study with a fearful child, Wolpe conducted experiments with cats to show that pairing the pleasure of eating with graduated exposure to conditioned aversive stimuli (harmless situations that had been paired with painful electric shock) could markedly reduce, if not altogether eliminate, acquired fear and avoidance. Extrapolating from this and related research on conditioned fear (e.g. Miller, 1948; Mowrer, 1939), Wolpe devised his

technique of systematic desensitization, which entails training the patient in deep muscle relaxation, constructing with the patient a hierarchy of situations that elicit varying degrees of unwarranted and unwanted fear and presenting each situation seriatim to the imagination of the person in a relaxed, non-anxious state. The idea is to counter-condition the fear, that is, enable the patient to confront a fearsome event without experiencing the usual anxiety, thereby changing the response to the presumed conditioned stimulus from fear to neutrality or even positive interest. It would appear that the applicability of this technique is limited only by the ingenuity of the clinician in construing a patient's problems in terms that permit the construction of an anxiety hierarchy (Goldfried & Davison, 1994). Usually these imaginal exposures are supplemented, sometimes even replaced, by real-life exposures to what the person needlessly fears, cf. *in vivo* desensitization, especially in the treatment of agoraphobia. Recently the technological innovation of virtual reality (VR) has been introduced to present patients with very realistic representations of what they fear. Driven by high-speed computers, a device mounted on the person's head creates a lifelike depiction of a fearsome situation, enhancing the capacity to become immersed in simulated situations that are more controllable than during *in vivo* exposures and perhaps closer to reality than what the person could imagine.

In recent years the efficacy of extended exposure without anxiety-inhibiting responses like relaxation has been demonstrated for a variety of disorders, especially obsessive-compulsive disorder. It is now argued that gradual approaches, such as Wolpe's technique of systematic desensitization, which allow escape from anxiety-provoking situations, may impede the reduction of unwarranted anxieties (Emmelkamp, 2004). On the other hand, the more confrontive procedures involved in extended exposure can produce greater stress in patients and as a consequence, a greater tendency to drop out of treatment.

Another approach usually considered to derive its efficacy from classical conditioning is aversion therapy, which involves pairing an undesirably attractive event or stimulus with a negative emotional state such as fear or disgust. The effectiveness as well as the morality of aversive procedures have been a subject of heated debate over the past three decades, but many reports attest to its usefulness in dealing with problems such as excessive drinking of alcohol, smoking, overeating and the paraphilias (Emmelkamp, 2004).

The general approach other than classical conditioning that historically lies at the core of behaviour therapy is operant conditioning, deriving from Skinner's work on the importance of contingencies in behaviour, that is, whether a given response is followed by a positive reinforcer like food or praise, or by a negative reinforcer like pain or disapproval. Operant techniques attracted a great deal

of favourable attention in the 1960s through the seminal work of Staats and Staats (1963) and others, who showed that reinforcement contingencies could favourably affect such problems as regressive crawling in children, poor academic performance, inappropriate social behaviour of various kinds and non-compliance to therapeutic instructions. The positive reinforcement of adaptive interpersonal skills is emerging as a likely active ingredient in Aaron Beck's cognitive therapy for depression (see 'Cognitive behaviour therapy'). A notable achievement of the operant approach is the token economy (Ayllon & Azrin, 1968), a system whereby tokens are awarded for desirable behaviour and sometimes also taken away for undesirable behaviour and later exchanged for goodies like sweets or access to better dining facilities for hospitalized adult patients. In a functional sense, the token economy brings to the institutionalized setting the orderliness of a market economy, whereby particular behaviours are given a certain value within the parameters of a monetary system.

A particularly significant example of the power of a token economy is provided by Paul and Lentz (1977), who studied three methods of rehabilitating severely impaired chronic mental patients. The comparison treatments were (1) milieu therapy, which essentially set expectations for the patients but without the highly structured contingencies of the token economy; and (2) a routine hospital management group, which entailed continued usage of heavy doses of neuroleptic medication. The token economy achieved better success in reducing symptomatology and shaping useful self-care and social skills. It should be mentioned that there were cognitive elements as well within the token economy condition, an issue we explore below.

While difficult to categorize as behaviour therapy, modelling is widely used by behaviour therapists as an efficient way to teach complex patterns of behaviour. The early research programme of Albert Bandura (Bandura & Walters, 1963) documented the powerful effects of observing another person perform sometimes complex patterns of behaviour. Evidence indicates that people can acquire behavioural patterns without reinforcement, but that their performance of what they have learned is indeed influenced by expected contingencies. A noteworthy application of modelling can be found in role-playing or behaviour rehearsal (Lazarus, 1971), whereby a therapist models effective behaviour and then encourages the patient to follow suit. This has become a central part of the treatment of social phobia, especially when the patient

lacks the interpersonal skills which are necessary for positive social interactions. It is likely as well that anxiety is extinguished by exposure to situations like talking with others or being evaluated on one's performance. Irrational fears can also be reduced by watching a fearless model interact with the frightening stimulus (Bandura & Menlove, 1968). The fact that something important is learned by watching another person suggests that cognitive processes are important.

The foregoing summarizes briefly the techniques and approaches usually associated with the phrases 'behaviour therapy' or 'behaviour modification'. However, since the late 1960s, there has been increasing recognition of the role of cognitive processes in therapeutic behaviour change, not only in the form of the cognitive therapies described in a separate entry but within those therapies judged to rely on classical and operant conditioning. For example, Wolpe's systematic desensitization has been conceptualized as a cognitive change technique or at least a procedure that relies on the patient's cognitive abilities (Davison & Wilson, 1973). After all, patients imagine what is troubling them and these symbolic exposures lead to anxiety reduction in actual fearsome situations.

What then is behaviour therapy? It can be seen from this chapter that whether behaviour therapy should include explicit attention to cognition or be restricted to conditioning principles is dependent upon the theoretical stance one takes. For example, the Skinnerian legacy would purport that behaviour therapy should concentrate only on overt behaviours; yet the tradition of Mowrer, Miller and Wolpe would also include mediating behaviours. Ultimately answers depend upon who is responding. To this writer and many others, behaviour therapy refers most generally and most usefully to a laboratory-based, empirical approach to therapeutic change. There need not be any prior allegiance to particular theories or principles of change. Behaviour therapists strive to use rigorous standards of proof rather than to rely on untested and sometimes even untestable concepts such as the Freudian unconscious (see 'Psychodynamic psychotherapy'). In sum, behaviour therapy/behaviour modification is an attempt to change abnormal behaviour, thoughts and feelings by applying in the clinical context the epistemologies, methods and discoveries made by non-applied behavioural scientists in their study of both normal and abnormal behaviour. Viewed in this way, any consideration of behaviour therapy would be incomplete without the inclusion of cognitive concepts (see also 'Biofeedback', 'Cognitive behaviour therapy' and 'Group therapy').

³Stanford University

Over the years, there have been various unusual instances of the voluntary control over physiological functions noted in the scientific literature. Luria (1958) presented a case of a mnemonist who had remarkable control of his heart rate and skin temperature to the degree that he could abruptly alter his heart rate by 50 beats per minute, and could also raise the skin temperature of one hand while simultaneously lowering the temperature of the other hand. The modification of physiological activities such as this has been the subject of anecdotal reports for a considerable period of time. Although true empirical investigation into such self-regulation through biofeedback began in the 1960s, gaining voluntary control of various physiological activities has been a goal in many different cultures for a variety of reasons. Gatchel (1999) and Gatchel *et al.* (2003*b*) have reviewed the goals that have been traditionally sought with regard to gaining control of physiological functioning:

- In order to achieve spiritual enlightenment, yogis and other mystics of the eastern tradition have demonstrated that through certain physical exercises, or by a sheer act of will, that individuals are capable of producing significant physiochemical changes in their bodies which, in turn, produce perceived pleasant states of consciousness (Bagchi, 1959; Bagchi & Wenger, 1957).
- In order to test various theories of learning, psychologists have long debated the issue of whether autonomic nervous system responses could be operantly conditioned.
- During the 1960s, biofeedback was viewed as a potential clinical treatment procedure for modifying psychological and medical disorders.

The major focus of this present chapter is on the third category of how voluntary control of physiological activity can be used as a

clinical treatment modality for medically related disorders. This particular area has contributed significantly to the growing field of behavioural medicine and health psychology. Indeed, as mentioned earlier, beginning in the 1960s, clinical researchers have gained control of physiological functions which were previously considered to be outside the realm of volitional control. The biofeedback method was the most popular of these training methods, and it also afforded clinical researchers the ability to translate the research in the laboratory setting to more practical clinical applications. For example, biofeedback was used to teach individuals to lower their blood pressure to manage hypertension, or to decrease muscle tension to treat musculo-skeletal pain. Biofeedback and other techniques, such as relaxation training, were used to address clinical problems and were developed to the point that Birk (1973) eventually coined the term ‘behavioural medicine’ to describe the application of a behavioural treatment technique (biofeedback) that could be applied to medicine or medical problems (e.g. headache pain).

The biofeedback technique

The biofeedback technique itself is based on the fundamental learning principle that people learn to perform a particular response when they receive feedback or information about the consequences of that response, and then make the appropriate compensatory behaviour adjustments. This is how individuals have learned to perform the wide variety of skills and behaviours utilized in the activities of everyday living. The availability of feedback is also of extreme importance in learning how to control internal physiological responses. However, much of our biological behaviour is concerned with maintaining a constant internal ‘homeostasis’ and is not

Table 1. Summary of medical and pain disorders for which biofeedback has been applied

Medical disorder	Summary of findings
Asthma	Although clinical studies have suggested the effectiveness of EMG biofeedback for asthma reduction, there have been a number of methodological problems associated with such studies. Non-specific placebo factors may play an important role in asthma reduction.
Cardiac arrhythmias	The few cases available indicate that heart rate biofeedback seems to be effective in the treatment of cardiac arrhythmias such as sinus tachycardia, atrial fibrillation and premature ventricular contractions. However, judgement must be withheld with regard to therapeutic value of biofeedback for such disorders generally until more research is conducted.
Dermatological disorders	Although there have been some case studies suggesting the therapeutic effectiveness of biofeedback-assisted behavioural treatment techniques, there have been no well controlled studies conducted to date. Moreover, there are various forms of dermatological disorders which may be differentially responsive to such treatment.
Dyskinesias	Biofeedback techniques have been used to treat a number of different dyskinesias, including spasmodic torticollis, Parkinson's disease tardive dyskinesia and Huntington's disease. Individual and multiple case reports suggest a possible use of EMG in the treatment of these disorders. However, the role of biofeedback is unclear because controls were not used.
Epileptic seizures	At this time, the amount of control group research concerning possible therapeutic effects of EEG biofeedback for the treatment of epileptic seizures is limited and all but the most speculative conclusions are premature. Positive results have been reported that are encouraging and it would seem to justify additional research.
Essential hypertension	Research has shown some degree of success in reducing the symptoms of essential hypertension with biofeedback. Blood pressure can be effectively reduced using biofeedback. However, biofeedback is still an experimental form of treatment for hypertension, with little known about the exact physiological mechanisms involved in the process. Thus, it cannot be considered an alternative to pharmacological treatment at this time. Biofeedback is often used as one component in a more comprehensive behavioural intervention.
Gastrointestinal disorders	Research results of the biofeedback-assisted modification of gastrointestinal disorders are encouraging. Biofeedback by means of rectal or anal devices is currently the treatment of choice for many types of fecal incontinence. Moreover, it is likely to become a preferred treatment method for patients with constipation related to the inability to relax the striated pelvic floor muscles during defaecation. In addition, thermal-biofeedback, as part of a comprehensive behavioural treatment programme is a promising approach to the treatment of irritable bowel syndrome.
Insomnia	There is a great deal of evidence indicating that biofeedback and relaxation techniques, as components of a more comprehensive behavioural treatment programme, are effective in the treatment of insomnia.
Lower motor neuron dysfunctions	The case studies reporting the successful application of biofeedback in the treatment of lower motor neuron dysfunction (EEG, peripheral nerve injury, Bell's Palsy) must currently be interpreted with some caution, given the lack of control procedures.
Migraine headache	Research suggests that temperature biofeedback, combined with autogenic training, is more effective than no treatment and possibly superior to placebo treatments. Thus, such an approach is warranted for the treatment of migraine.
Muscle contraction headaches	The effects of EMG biofeedback exceed those for medication placebo, biofeedback placebo and psychotherapy procedures. In addition, although research suggests that biofeedback and relaxation produce similar levels of improvement, biofeedback may offer greater benefits to a sub-set of patients.
Postural hypotension	There is no effective treatment for this disorder, and severely affected patients must remain in the supine position. Although control group studies are not yet available, several good case studies have demonstrated that systolic blood pressure biofeedback training has enabled some patients to sit upright or to stand with crutches, whereas prior to training these actions produced fainting.
Raynaud's disease	Recent controlled research studies involving over 160 patients have shown that behavioural treatment, with biofeedback as a key modality, can be very effective, equalling the best clinical effects of many medical and surgical interventions. In the light of the limitations of current medical and surgical treatments for Raynaud's disease, behavioural interventions appear to have much to offer for these patients.
Sexual dysfunction	Although genital responses have been shown to be responsive to both instructional control and biofeedback, there is no evidence that the direct conditioning of genital responses through biofeedback has therapeutic value. However, biofeedback may have a role to play in guiding the development of erotic and non-erotic fantasy, which can, in turn, have significant therapeutic value.
Tinnitus	There have been a few case studies indicating the effectiveness of biofeedback and relaxation methods in reducing the severity of tinnitus symptoms.
Upper motor neuron dysfunctions	A number of well designed individual and multiple case studies has suggested the therapeutic effectiveness of biofeedback in the treatment of upper motor neuron disorders such as paresis, cerebral palsy and incomplete spinal cord lesion. However, an appropriate number of control group experiments is still lacking except in the biofeedback treatment of paresis, where results are negative of ambiguous.

Table 1. (cont.)

Pain disorder	Summary of research findings
Back pain	Low back pain is one of the most costly of the musculoskeletal disorders. Flor and Birbaumer (1994) have provided some support for EMG biofeedback being more effective than cognitive behavioural therapy or conservative medical therapy with patients suffering from chronic back pain and temporomandibular pain.
Fibromyalgia syndrome	Widespread musculo-skeletal pain, fatigue and multiple tender points characterize fibromyalgia syndrome. Many practitioners use multiple recording sites and simultaneous EMG biofeedback while patients are in multiple postures, positions and acute stressor conditions. While muscle relaxation therapies and EMG biofeedback are logical parts of the recommended multidisciplinary treatment approaches, to date there is very little research on this topic.
Headache	Studies have found successful outcomes using EMG to reduce pain in these disorders. It should be noted that individuals presenting with headaches often suffer from more than one variety, making treatment and debates regarding aetiology difficult. Research, however, suggests that temperature/thermal biofeedback is more effective than no treatment when combined with autogenic/relaxation training for migraine headache. In addition, these treatments may be superior to placebo treatments. For tension/muscle contraction headaches, EMG biofeedback effects may exceed those of medication placebo, biofeedback placebo and psychotherapy procedures. Moreover, while research suggests that biofeedback and relaxation produce similar levels of improvement for this type of headache, biofeedback may offer greater benefits for a subset of patients.
Temporomandibular Disorders (TMD)	The use of biofeedback technique to cultivate low arousal in TMD patients appears to be effective. EMG and other biofeedback techniques can be improved both to improve the comprehension of individual patient issues, as well as to improve functioning. EMG, in particular, is often used to evaluate appliances for particular individuals, re-educate the masticatory, facial, postural and potentially respiratory muscles and aid in proprioceptive deficits and psychophysiological problems. Overall, a considerable number of studies attest to the efficacy of biofeedback training, especially when accompanied by relaxation or general stress management training.
Upper extremity disorders	Upper extremity disorders, such as carpal tunnel syndrome, are a growing problem in occupational settings. Although there have been few well controlled studies in this area, those that exist suggest that biofeedback can aid in treatment effectiveness when used in unison with a more comprehensive interdisciplinary programme.

readily accessible to conscious awareness. Indeed, individuals do not consciously experience some interoceptive awareness of internal biological activity, such as their blood pressure or muscle tension, because there is normally an adaptive advantage to not having to consciously attend or control these activities on a continuous basis. Moreover, interoceptors do not normally have the extensive afferent representation at the cortical level that is needed for a high degree of perceptual acuity or the fine discriminating characteristics of audition or vision (Gatchel, 1999).

Because individuals do not normally receive feedback of these internal events in day-to-day situations, they cannot be expected to control them. However, if they are provided biofeedback of, say, heart rate via a visual display monitor, they can become more aware of the consequences of heart rate changes and the ways adjustments can be made to modify and eventually control it. Receiving feedback serves to remove the 'blindfold', and enables individuals to voluntarily control their response. The development of sensitive physiological recording devices and digital logic technology has made it possible to detect small changes in visceral events and provide subjects with immediate feedback of these biological responses. Thus, biofeedback involves developing an individual's ability to alter a particular physiological response by providing them with feedback about the response which they are attempting to control. For example, an individual may attempt to alter muscle tension, blood flow, or surface skin temperature. Subjects are most commonly provided feedback in the form of a tone, or other auditory signals, or a visual display, such as a line that moves up or down on a computer screen. Electromyography (EMG) which involves feedback of muscle tension is one of the most common types of biofeedback. Other types of biofeedback include thermal biofeedback, which

provides information on skin temperatures; electroencephalography (EEG), which provides information on brain wave activity; an electrodermal response (EDR), which provides information on sweat gland activity. Often, individuals may receive biofeedback information from more than one of these modalities (Green & Shellenberger, 1999).

Today, biofeedback is broadly and loosely, defined as a procedure for transforming some aspect of physiological behaviour into electrical signals that are made accessible to exteroception or awareness (usually vision or audition). Sometimes, the feedback signal is combined with a tangible reward, such as money or the opportunity to view attractive pictures, in an attempt to motivate the individual and strengthen the effect of the target physiological response. In other cases, the clinician provides verbal praise for success in addition to the feedback. These latter practices are also forms of biofeedback, because they too convey information to learners about their biological performance. In most instances, however, response-contingent lights or tones alone can be shown to augment voluntary control of physiological activity.

The growth in the utilization of biofeedback techniques

Borrowing heavily from operant conditioning techniques developed in psychology, the early biofeedback investigators during the 1960s and 1970s began to demonstrate some degree of operant or voluntary control in a wide variety of visceral, central nervous system and somato motor functions. Gatchel and Price (1979) provided an early review of this research that demonstrated learned control by human

subjects of a wide variety of 'involuntary responses' including cardiac ventricular rate, systolic and diastolic blood pressure, peripheral vascular responses, electrodermal activity, gastric motility, skin temperature, penile tumescence and various brain wave rhythms. Encouraged by these early successes demonstrating voluntary control of normal physiological activity, medical and psychological clinicians soon began to address the issue of whether pathophysiological activity could also be controlled with the goal of restoring health or preventing illness. This stimulated a rapid growth of the scientific literature evaluating the clinical effectiveness of biofeedback. This research has been reviewed in a number of different sources (e.g. Green & Shellenberger, 1999; Hatch *et al.*, 1987; White & Tursky, 1982). A journal was also established (*Biofeedback and Self-Regulation*, which is now called *Applied Psychophysiology and Biofeedback*) and a professional society specializing in biofeedback and self-regulation (Association for Applied Psychophysiology and Biofeedback) was founded. There are also a number of useful practitioner guides which have been published (e.g. Basmajian, 1989; Schwartz & Andrasik, 2003).

To date, the clinical research literature has clearly demonstrated that some degree of self-control is possible over behaviours long assumed to be completely involuntary. It has also been shown that, with biofeedback, it is possible to extend voluntary control to pathophysiological responding in order to modify the maladaptive behaviour in the direction of health. Table 1 summarizes the various disorders for which biofeedback has been applied.

As can be seen in Table 1, in some areas, such as treatment of insomnia and headache, biofeedback has been successful. However, as reviewed elsewhere (Gatchel, 1997, 1999), many important questions still remain concerning the extent to which biofeedback and other physiological self-control techniques will be medically effective. Unfortunately, the current research evaluating therapeutic effectiveness of these procedures has been plagued by a number of problems. For example, there have been very few well controlled clinical outcome studies that have been conducted using large numbers of patients having well confirmed medical diagnoses. Moreover, the few comparative outcome studies that have been performed evaluate the relative effectiveness of biofeedback and various other behavioural techniques (e.g. simple relaxation training). It is extremely helpful to also compare biofeedback techniques with more traditional medical treatments, some of which have fairly well established success rates. Combinations of medical and behavioural techniques should also be explored and evaluated.

It should also be pointed out that, unfortunately, there have been claims for the therapeutic efficacy of biofeedback which have been grossly exaggerated and even wrong. Overall, it is justifiable to conclude that relevant and encouraging data do exist but, at the present time, the value of biofeedback still has to be questioned in some areas. Moreover, terms such as 'biofeedback therapist' and 'biofeedback clinic', which are now regularly encountered in many medical centres, are difficult to justify. They imply that a form of treatment exists that is more or less generally applicable for a variety of illnesses. Worse yet, they imply, at least in the minds of some, that biofeedback is a new alternative treatment modality. Currently, in the majority of areas in which it is applied, biofeedback should be viewed merely as an adjunctive treatment modality.

Biofeedback and pain

One area where biofeedback is being increasingly used as an adjunctive treatment modality is pain management. Pain is a complex and debilitating medical condition which affects more than 50 million people in the United States alone. Pain also accounts for approximately 80% of all physician visits (Gatchel & Turk, 1996). The number of Americans utilizing pain management programmes has increased 64% from 1998 to 2000 (Marketdata Enterprises, 2001). The complexity of pain and the absence of any one simple method to treat pain necessitates examining which treatments will have the highest likelihood of success for any given patient (Gatchel *et al.*, 2003a). In an early review of research on the application of biofeedback for the regulation of pain, Turk *et al.* (1979) concluded that biofeedback was no better than other less expensive and less instrument-oriented treatments such as progressive relaxation training and coping skills training. In addition, evidence for the effectiveness of biofeedback in reducing pain was marginal at best. The evidence was based mainly on case studies and poorly controlled research. Although this status has not changed much since the 1979 review, some subsequent studies have found that biofeedback is useful in reducing pain. In fact, since the earlier pessimistic view of biofeedback, training in biofeedback does appear to provide patients with information that enables them to control voluntarily some aspect of their physiology that may contribute to the pain experience. Currently, biofeedback is viewed as beneficial for patients when used as one component of an interdisciplinary pain-management programme (Gatchel, 2004; Gatchel *et al.*, 2003b). For example, biofeedback, in combination with cognitive behavioural therapy, provides powerful evidence of the relationship between thoughts, feelings and physiological functioning. In addition, cognitive behavioural therapy with biofeedback increases the patient's sense of self-efficacy by providing clear and unequivocal feedback about a person's ability to gain control over certain physiological responses. However, because pain is a complex behaviour and not merely a pure sensory experience, biofeedback is most beneficial for patients when used as one adjunctive component of an interdisciplinary pain management programme (Gatchel *et al.*, 2003b). In this context, a true biopsychosocial approach to the patient can be undertaken, and an interdisciplinary team can address the 'whole person', rather than just the pathophysiology. Moreover, biofeedback is then performed not only within the larger context of the interdisciplinary pain clinic, but also in the context of cognitive behavioural therapy. A summary of specific pain disorders in which biofeedback has been effectively utilized appears in Table 1. It should be noted that most of these pain conditions were treated from a biopsychosocial perspective in an interdisciplinary setting.

Biofeedback and the placebo effect

When considering the use of biofeedback as a treatment modality, it should be clearly kept in mind that research has demonstrated the important impact that the placebo effect has in biofeedback and other physiological self-control techniques directed at eliminating emotional distress. The placebo effect itself was originally shown to be an important factor in medical research when it was found that inert chemical drugs, which had no direct effects on physical

events underlying various medical disorders, were often found to produce symptom reduction. An extensive scientific literature on the placebo effect in medicine unequivocally demonstrated that a patient's belief that a prescribed medication is active, even if it was in fact chemically inert, often led to significant symptom reduction (e.g. Honigfeld, 1964; Shapiro, 1971). Indeed, Shapiro (1959, p. 303) noted that 'The history of medical treatment until relatively recently is the history of the placebo effect'. Even response to a chemically active drug to some degree depends on a belief in the drug's actions and faith in the doctor prescribing it (see 'Placebos').

As Gatchel (2004) has recently noted, the placebo effect has been shown to be involved in the reduction of pain. In a number of painful conditions, up to one-third of individuals experiencing pain can obtain significant relief following the administration of a placebo (in the form of either a non-active drug or a strong suggestion that increases a patient's expectancy of therapeutic improvement). The mechanisms involved in this placebo analgesia effect are still not totally understood, although factors affecting endogenous opioid activity appear important (Baum *et al.*, 1997). Moreover, recent imaging studies of the brain are beginning to isolate other biological bases of the placebo effect (e.g. Mayberg *et al.*, 2002). Despite this, it is clear that a clinician can help decrease pain in a certain percentage of patients by simply providing a placebo or a strong expectation of therapeutic improvement. Enthusiastic management of

patients' ability to manage their pain by controlling physiological activity through biofeedback goes a long way in maximizing the efficacy of the biofeedback technique itself.

Conclusions

Physiological self-regulation techniques such as biofeedback have an important place in the rapidly growing field of health psychology. To date, there is a great deal of research demonstrating the efficacy of biofeedback as an adjunctive treatment modality in helping to manage a wide variety of medically related disorders. It should be emphasized, however, that more controlled research is still required to unequivocally document its effectiveness for many of the disorders. In addition, biofeedback should be viewed merely as an important adjunctive treatment modality to use as part of a more comprehensive treatment programme. Many disorders are complex, biopsychosocial illnesses which will not be totally responsive to a single treatment modality. Finally, the therapeutic effects of biofeedback are not due solely to the direct link to physiological activity, but also to the psychological process of perceived control which is often associated with the placebo effect. Further investigation of the complex biopsychosocial mechanisms underlying the therapeutic efficacy of biofeedback should lead to a greater refinement of training methods and a resultant more effective overall treatment strategy.

Cognitive behaviour therapy

Andrew Eagle¹ and Michael Worrell²

¹CNWL NHS Mental Health Trust

²Royal Holloway, University of London

Introduction

Cognitive behavioural therapy (CBT) may be defined as a set of empirically grounded clinical interventions implemented by therapists who understand themselves to be operating as scientist-practitioners (Salkovskis, 2002). These interventions, however, must be understood as being far more than the mere application of ready to hand techniques or 'tools' but rather as direct expressions of an explicit, sophisticated and continually developing, theoretical model(s) of the nature of psychopathology and the processes of human change.

Despite its being a relatively young psychotherapy, CBT has clearly come of age over the past decade and is widely recognized as the 'treatment of choice' for an ever expanding range of clinical presentations. For example, evidence for the effectiveness of CBT has been gained in the treatment of depression (Young *et al.*, 2001), panic disorder (Clark *et al.*, 1994) and eating disorders (Wilson & Fairburn, 1998). The approach has also gained supporting evidence in the area of more severe presentations including personality disorders (Beck & Freeman, 1990) and schizophrenia (Fowler *et al.*, 1995). In addition to its growing empirical support and popularity, the approach has also attracted its fair share of challenges and criticisms. While the field of psychotherapy often continues to be characterized by a competitive 'all or nothing' stance in which only one model may emerge victorious, an important and developing movement in the field is the interest in integrative approaches which emphasize a more respectful dialogue and openness between different styles of approach. CBT has in many respects always been an integrative approach and continues to have much to offer to the development of empirically grounded integrative therapeutic interventions (Beck, 1991).

In this brief article we have set ourselves the following objectives:

1. To attempt to define the 'essence' of CBT and its theoretical underpinnings.
2. To briefly consider the application of CBT to physical health problems.
3. To describe what we regard as some of the most interesting contemporary developments and controversies in the field.

Defining CBT

As is the case with other well known 'branded' therapies such as psychodynamic psychotherapy (see 'Psychodynamic psychotherapy') or systemic therapy, it would be misleading to assert that there is a singular unitary entity called CBT. As early as 1978, Mahoney and Arnkoff noted the existence of a range of therapeutic procedures which are subsumed under the heading of CBT. These included Cognitive Therapy, Rational Emotive Therapy (now known as Rational Emotive Behaviour Therapy), Problem Solving Therapy, Coping Skills Therapy, Stress Inoculation Training, etc. The contemporary scene is even richer with the addition of therapies such as Functional Analytic Therapy (Kohlenberg & Tsai, 1991), Dialectical Behaviour Therapy (Linehan, 1993), Acceptance and Commitment Therapy (Hayes *et al.*, 1999) and Schema Focused Therapy (Young *et al.*, 2003). Each of these may be described as belonging to the family of cognitive behavioural psychotherapies.

In many respects, however, it is Aaron Beck's cognitive behaviour therapy that has come to be taken as the foundational model for what CBT is in its essence (Beck, 1976, Beck *et al.*, 1979). In what follows we outline the defining theoretical and practice based features of this 'Beckian' approach.

The theoretical foundations of CBT

The primacy of cognition

From a CBT perspective, all acts of perception, learning and knowing are the products of an active information processing system which selectively attends to the environment, filters and then interprets the information impinging upon the organism. Such 'processing' of information is seen as evolutionally adaptive. In psychopathological conditions, particular aspects of the information processing system are seen as having become 'distorted', biased or maladaptive, leading to experiences of emotional, behavioural and relational distress. The role of the CBT therapist is seen as that of assisting individuals to clarify their current patterns of information processing and to modify this through a range of strategies which encourage individuals to take on a more 'scientific' stance towards their own experiences and their experience of their interpersonal world. Within CBT, a clear therapeutic priority is placed on cognition. Achieving change in cognitive content, processes and structures is seen as the most effective means of achieving clinically significant change. In a stance of 'technical eclecticism' a wide range of strategies, including experiential, behavioural or relational strategies may be employed to achieve this end.

CBT is a mediational theory

A central tenet of CBT is that cognitive content, processes and structures directly influence both emotional experience and behaviour (Clark, 1995; Dobson & Block, 1988). It is vital to stress that the CBT model does not assert that cognition is *causal* in relation to any of these other factors. Nevertheless there has been considerable debate between cognitive and emotion theorists as to whether or not cognition always or usually precedes emotional experience (see Lazarus, 1984; Zajonc, 1984).

CBT is an empirical approach

One of the strengths of CBT is that it is an empirically based approach where theoretical concepts are operationally defined, measured and subject to research. Consistent with this approach, CBT has emphasized that the relevant cognitive content, processes and structures can be accessed, clarified and measured. No reliance is made on notions of an unconscious to which the client has no direct access but which the therapist may be in a position to interpret. This does not mean however that all cognitive activity is consciously experienced, subject to control or deliberate. An important strand of cognitive research is upon the relatively automatic, involuntary and preconscious processes that may be implicated in a range of psychopathological conditions such as anxiety and depression (see Mathews & McLeod, 1987).

CBT is a 'here and now' therapy

Consistent with its behavioural heritage, CBT asserts that it is current cognitive factors which are central in the maintenance of psychopathological difficulties. Hence, therapeutic attention is focused on the present situation rather than historical or childhood fact. These are not neglected entirely however, and are seen as

particularly relevant in more serious conditions such as personality disorders. Even here however, information concerning development origins is sought primarily to more adequately formulate currently relevant cognitive factors.

Defining procedural features of CBT

CBT is a short-term structured therapy. A typical course of CBT lasts from 12–24 sessions in addition to follow-up sessions to ensure the maintenance of gains. The CBT therapist approaches each session in a structured fashion. There is a shared plan or agenda for each session that the therapist encourages the client to take an active part in co-constructing. Goals are clearly defined in measurable and operationalized terms. Progress is continually monitored and evaluated and feedback is sought from the client during each therapy session.

CBT is based on the principle of 'collaborative empiricism'. Rather than the therapist being seen as the expert on the client's experience, therapist and client work together to resolve the client's problems. The client is seen as the expert on their own problems and experience. In the words of Beck *et al.*:

'The cognitive therapist implies that there is a team approach to the solution of a patient's problem: that is, a therapeutic alliance where the patient supplies the raw data (reports on thoughts and behaviour...) while the therapist provides structure and expertise on how to solve problems. The emphasis is on working on problems rather correcting deficits or changing personality.' (Beck *et al.*, 1985, p. 175).

An explicit goal of the CBT therapist is to teach clients the model of CBT and to assist them in becoming their own therapist. Rather than direct instruction, the therapist adopts a Socratic stance which involves the use of questioning to assist clients in clarifying and challenging their own thoughts and beliefs.

CBT interventions are based on a comprehensive formulation of the client's presenting problems (Needleman, 1999). The CBT formulation is a working hypothesis which attempts to explain the genesis and maintenance of a client's difficulties according to current CBT theory and the data gathered from assessment. The formulation is explicitly shared with the client and modified by his or her feedback. The formulation provides a blueprint or touchstone for the rest of the therapy.

CBT involves the co-construction of therapeutic tasks or homework which the client carries out between sessions. In certain respects what happens between sessions in the client's normal environment is seen as more important than what happens during sessions themselves. While earlier versions of behavioural therapy may have stressed homework tasks in terms of behavioural rehearsal or exposure to feared situations, in CBT, homework tasks are understood primarily in terms of the particular cognitive variables which they are designed to clarify or challenge (Bennett-Levy *et al.*, 2004).

CBT is based on a positive, collaborative therapeutic relationship. In their seminal text Beck *et al.* (1979) clarified that the therapeutic relationship is crucial in the successful practice of CBT. However while 'Rogerian' conditions of empathy, warmth and positive regard and other relational factors are seen as necessary for the application of cognitive change strategies, they are not regarded

as sufficient in themselves to produce the required cognitive changes.

Applications of CBT to physical health problems

While the principles of CBT were established in the treatment of psychiatric problems, there are good reasons why CBT is also proving effective in the treatment of physical health problems. Chronic medical conditions are frequently associated with psychological problems such as anxiety and depression, for which CBT is an effective treatment. There is no reason to anticipate that CBT should be less effective in treating psychological conditions co-morbid with physical illness. Furthermore effective treatment of psychological dysfunction is often an important step in enabling patients to cope better with physical illness.

The central role of 'illness perception' or 'cognitive representations of illness' in adjustment to physical illness is a well established theme in the health psychology literature (Weinman & Petrie, 1997). The way people think about their physical health problems has been explored using a range of social cognition models (Connor & Norman, 1995). The influential Self-regulation Model (SRM) (Leventhal *et al.*, 1984) has focused on five dimensions of health belief (identity, consequences, causes, timeline and control, or cure) which are seen as being key to guiding individual responses to physical illness. The model emphasizes that the coping strategies which people select for coping with health problems are influenced by their perceptions of their illness (see 'Lay beliefs about health and illness').

CBT with its emphasis on the central role of cognition and appraisals in mediating patients' experience of physical illness shares a consistent theoretical rationale with these approaches. The cognitive processes that are targeted by CBT in psychiatric conditions are equally amenable to treatment in physical illness.

Salkovskis (1989) summarizes the cognitive processes relevant to treatment of most physical problems. These include patients' beliefs about bodily functioning and the causation of physical problems; misinterpretations of bodily symptoms and signs; evaluations of the threat to self and future wellbeing associated with illness; and changes in behaviour and mood following perceived impairment which may increase emotional distress and the degree of handicap. CBT is particularly interested in modifying thoughts and behaviours, which may function to maintain physical problems, even when these originally had a physical cause (see, for example, 'Pain management').

Space does not permit any in-depth review of the application of CBT to specific physical disorders. It is sufficient to say that CBT is demonstrating effectiveness in treatment of a wide range of chronic illnesses and disabilities. For example, there is promising evidence for the use of CBT in treating chronic fatigue syndrome (Deale *et al.*, 1997); rheumatoid arthritis, (Sharpe *et al.*, 2003) and chronic pain (Morley *et al.*, 1999). There is also evidence to support the use of CBT to treat somatisation (Kroenke & Swindle, 2000) and hypochondriasis (Barsky & Ahern, 2004; Warwick *et al.*, 1996) (see 'Psychosomatics'). It should be noted that a recurring methodological limitation of certain outcome studies is that they do not adequately measure treatment fidelity and thus cannot reliably determine whether the effectiveness of CBT reflects the training

and experience of the therapist or the efficacy of the intervention (Raine *et al.*, 2002).

Moorey (1996) has discussed the use of Cognitive Therapy in situations where people face objectively adverse life circumstances such as cancer or other potentially terminal illnesses. In these situations the negative thoughts verbalized by patients may reflect an accurate view of their circumstances and are not 'distortions' of external reality. Moorey suggests that in situations where a process of adjustment to life-threatening illness is ongoing, formal cognitive therapy may be inappropriate and a more flexible supportive approach may be preferable. Notwithstanding this, he also argues that maladaptive beliefs such as over-generalization of the consequences of illness, can hinder the normal process of adjustment.

Controversies and developments

As CBT has been applied to an ever widening range of clinical problems, various authors have proposed revisions and adaptations of Beck's original model of CBT. Many of these may be seen as welcome developments that may greatly increase the flexibility and therapeutic power of CBT. Other authors such as Clark (1995), however, have suggested that some of these developments are sufficiently dissimilar to the original model that they could be seen as alternative or competing models.

One of the most significant developments in CBT over the past decade has been the increasing significance given to the role of the therapeutic relationship in CBT. Safran and his colleagues (Safran & Segal, 1990; Safran & Muran, 2000) have strongly argued for the integration of an interpersonal perspective into CBT. These authors have proposed novel understandings of the varieties of 'ruptures' which can occur in the working relationship between therapist and client and how these may be most fruitfully addressed to improve therapeutic outcome. In a review of the available research literature, Waddington (2002) concluded that there is robust evidence for the impact of the therapeutic relationship in determining therapeutic outcome in CBT. Increasing attention is likely to be paid to the complexities of the therapeutic relationship in CBT as the approach continues to be applied to more challenging clinical presentations. The work of Leahy (2001), for example, has provided an interesting analysis of how the phenomena of transference and counter-transference (concepts originating from within psychoanalysis) can be understood and worked with from within a CBT perspective.

A related development has been the influence of what has come to be known as 'social constructivism' in CBT (Mahoney, 2003). Social constructivism emphasizes how human beings 'construct' narratives or 'personal realities' in order for them to be able to make sense of relational experience and maintain a sense of their own continuity through time. Social constructivists have challenged what they have understood to be the overly 'rationalistic' tendencies in standard CBT and have proposed a version of 'post-rationalist CBT' which does not rely on any notion of 'distorted' or 'irrational' thinking (Guidano, 1991). Social constructivist versions of CBT tend to be less structured, pay a great deal of attention to the therapeutic relationship, are more exploratory rather than focused on specific problem solving and tend to take more account of early developmental issues.

A significant development within standard CBT has been that of Schema Focused Therapy (Young *et al.*, 2003) which has been developed specifically to help individuals presenting with varieties of personality disorders. Schema therapy tends to be longer-term, to focus on the therapeutic relationship as a vehicle for achieving change and to emphasize the concept of 'early maladaptive schemas' – deep cognitive structures which have their origin in toxic relationships with care givers when the individual was a child. This new emphasis on 'deep' cognitive structures and early developmental issues has not been uncontroversial however, and a number of authors have suggested caution in using these methods as standard practice and have emphasized the need to submit these models to further empirical testing (James, 2001).

Hayes (2004) has argued that the history of the behavioural and cognitive psychotherapies can be described as having taken place in three 'waves'. The first wave of Behaviour Therapy was characterized by the development of strategies arising from the models of classical and operant conditioning (see 'Behaviour therapy'). The second wave, according to these authors, was characterized by cognitivism and is most clearly expressed in the model of CBT developed by Beck. 'Third Wave CBT' is argued to be a very recent phenomenon. Hayes *et al.* (in press) suggest that recent developments including Dialectical Behaviour Therapy (Linehan, 1993), Acceptance and Commitment Therapy (Hayes *et al.*, 1999)

and Mindfulness Based Cognitive Therapy (Segal *et al.*, 2002) have moved CBT into areas traditionally seen as less empirical and therefore requiring novel philosophical, conceptual and theoretical development and debate. An example of an important concept from Acceptance and Commitment Therapy is that of 'acceptance'. Acceptance strategies are significantly different from standard CBT strategies which attempt to modify the content of cognitive structures. Acceptance strategies encourage the client to distance themselves from their cognitive processes but not attempt to change them. This is held to result in a weakening of the link between cognition and behaviour and to aid the individual in overcoming varieties of 'experiential avoidance' which are seen as intrinsic to psychopathology.

Conclusion

The field of the Cognitive and Behavioural Psychotherapies is a rich, complex and developing one. The model has gained a good deal of empirical evidence for its usefulness and has become the treatment of choice for many forms of psychological disorder. There is a growing body of evidence to support its application to *physical* health problems. CBT continues to grow in novel directions and to develop new understandings of the nature of psychological problems and new treatment strategies for their alleviation.

Community-based interventions

³Indiana University

Public health practitioners who design community-based, health interventions base their work on evidence that social and environmental processes impact upon health and wellbeing, and contribute to health decline, morbidity and mortality. Furthermore, rather than assuming that negative environmental conditions are fixed and immutable aspects of industrial society, designers of community-based interventions believe that with sufficient encouragement, education and skills, citizens can become more active in modifying and overcoming unhealthy social conditions. The goals of

community health interventions, then, are to help set in place social structures that support and reinforce individual and group efforts at improving health and the quality of life.

The emphasis on facilitative social structures is not intended to minimize the efforts that individuals can take to improve their own health. Indeed, much can be accomplished by encouraging patients to change unhealthy practices which contribute to increased risk for disease. For example, convincing patients to adopt a healthy diet, decrease smoking, drug and alcohol intake

and engage in moderate exercise have been prime ingredients in the reduction of cardiovascular risk that has taken place within the last two decades. However, there is a limit to what individuals can do on their own when confronted with adverse environmental conditions. The barriers to continued improvements in community health are not only in the individual citizen's knowledge of proper health practices, but also in economic factors and social customs that maintain risk-producing conditions. Since there is now a substantial body of research indicating that rates of morbidity and mortality are linked to social conditions such as poverty, community disintegration, poor education and social isolation (Adler *et al.*, 1994; Williams *et al.*, 1992), the dilemma for modern community health practice is how to help individuals come together to deal with these negative social conditions.

While the correction of adverse social conditions can be difficult to accomplish, we believe that health practitioners need not wait for some golden age of social enlightenment before acting to improve community health. There are many examples of local projects in which citizens have developed effective action plans in collaboration with health professionals. The key ingredients in these efforts involve a mobilized and informed community group in which social structures have been developed that encourage concerted action. The idea is to find ways to encourage the development of community groups that can provide the structure for citizens to become proactive in health maintenance, and that then become institutionalized as an ongoing part of community life.

The purpose of this chapter is to review key ingredients of successful community-based interventions, discuss impediments to their implementation and how these might be overcome, and outline the possible roles of the healthcare provider in a community-based intervention. Our goal is that by the end of the chapter, the reader will understand the role of community-based interventions in the toolkit of techniques used to address health and disease, be introduced to key ideas and know how to obtain additional information.

Key ingredients in successful community-based interventions

Citizen ownership

Project adoption and retention is enhanced when citizens are seen as equal partners in an intervention project (Wagenaar *et al.*, 1999). Although interventions are sometimes initiated by concerned persons outside the community of interest, the greatest and most lasting changes occur when community members themselves take part in identifying a need and designing an intervention to meet that need. A major weakness of many externally funded health projects is that they do not survive once project demonstration funds are used up because not enough effort was given to ensuring community ownership.

An example of how community members might become involved in a planned intervention is the establishment of a community advisory board to help fashion the content of the programme, publicize it and recruit participants. Choosing an advisory board requires some knowledge of the leadership structure of the community because community leaders can serve a vital 'gatekeeper'

role. Their views of the project can either facilitate or retard acceptance. For example, in a study targeting child malnutrition and pregnant and lactating women in Mexico, a community assembly served a gatekeeper function by approving the list of low-income households who were to receive the intervention (Rivera *et al.*, 2004).

Essential to the success of a community intervention is that the content of the intervention and its manner of implementation be acceptable to the community. So for example, in a study of the efficacy of permethrin-treated bed nets to prevent malaria among children in Western Kenya, open community meetings were held in each of 33 communities to discuss the project and allow villagers to ask questions. At the end of these meetings, participants themselves provided authorization for the trial to be conducted in their communities (Phillips-Howard *et al.*, 2003).

Building trust

Efforts to promote community change are maximized when intervention recipients trust and respect the people promoting the new behaviours. The heart of organizing is careful building of interpersonal relations, often one at a time (Wagenaar *et al.*, 1999). However, this essential process of relationship building can take time. In a study examining mammography adherence in the United States, prior to participant recruitment, 10 months were spent in building community support through group breakfasts for pastors and follow-up involving meetings with the pastor and church governing body (Derose *et al.*, 2000). This extended period of relationship building through community-based activities was a key to the project's ultimate success.

To maximize trust, careful selection of community members to deliver the intervention can be a key element in its ultimate success. Research has shown that intervention specialists are most effective when they are already known to the intervention recipient; have equal or slightly higher status than the recipient; and are credible and empathic. Community workers need to know and understand the people they are working with – their values, perspectives, needs and strengths (Wagenaar *et al.*, 1999). For example, in a study designed to increase the utilization of cervical smear tests among Vietnamese-American women, utilization was greater among women receiving both a media education campaign and outreach visits by a lay health worker than among women receiving the media education campaign only (Lam *et al.*, 2003).

Of course, lay intervention agents must be well trained and must be provided with effective support (Nation *et al.*, 2003). In a study in Pakistan to prevent infant diarrhoea through family handwashing, lay field workers were most effective and were more satisfied with their jobs when they were extensively trained. Their training included discussions of interviewing techniques, how to encourage handwashing by mothers, data recording and measuring and weighing children (Luby *et al.*, 2004).

Changing social norms

Changing social customs and practices is perhaps the most powerful way of instituting changes in health practices that are likely to endure. Psychological research shows that humans are usually motivated to belong to social groups (Baumeister & Leary, 1995).

Furthermore, if they believe that adhering to the social norm of the group requires them to change their behaviour, they will probably be motivated to do so. Thus social norms and recipients' understandings of these norms are crucial in instituting behaviour change.

For example, in a 15-community randomized trial to change policies and practices with regard to the sale of alcohol to minors, the target of the intervention was the entire community rather than individual young people (Wagenaar *et al.*, 1999; Wagenaar *et al.*, 2000). Over a two-and-a-half-year period, contact was made with merchants, hotels, bars, law enforcement personnel, religious organizations and parents, with events and training sessions designed for each group. As a result there was a reduced propensity for merchants to sell alcohol to minors, and a reduction in the tendency for older teens to provide alcohol to younger teens.

Another example is the need for many HIV/AIDS prevention programmes to be aware of social norms associated with men and women's sexual practices. One such programme in rural Uganda used television-based plays and video programmes to raise awareness of risky behaviours and offer culturally acceptable solutions (Kinsman *et al.*, 2002). For example, one video illustrated the problem of extra-marital sex by men working away from home, and how this can lead to HIV contracted by the men and subsequently their spouses. In another play, a wife finds a condom that her husband had hidden in anticipation of introducing it to her. A friend resolves their argument, explaining to her the benefits of condoms as well as how to use and store them (Kinsman *et al.*, 2002).

The influence of social norms and individual beliefs also can be seen in a large scale HIV/AIDS prevention programme developed within the school system for high school students in South Africa. The researchers noted that high-risk behaviours appeared to increase over the evaluation year despite increases in knowledge related to the disease and protective behaviours (Visser & Schoeman, 2004). Focus group discussions with the student participants revealed that possible underlying factors which may have maintained high-risk sexual behaviours despite the change in knowledge were based on social norms. For example, sexual experience was perceived as normative for that peer group, was a status symbol, particularly for boys, and was much more important than engaging in HIV-protective behaviours. In addition, the social norms surrounding girls saying 'no' to sex were unclear, leaving girls confused about what was acceptable and whether they might lose the relationship if they did not comply.

Multiple intervention points

There are several reasons why multiple components in an intervention are important to its success (Nation *et al.*, 2003). Studies have demonstrated that providing information alone is not sufficient to change behaviour (Botvin & Griffin, 2002; Botvin & Tortu, 1988). The research literature is rife with examples of trials that failed because they tried to change behaviour only by providing information. Also, research shows that different people learn in different ways, so having multiple components increases the chances that an intervention will have a broader appeal (Bloom, 1976; Wagenaar *et al.*, 1999). Research also demonstrates the power of repetition in learning. Seeing the same material presented in different ways reinforces

the message. For example, in the study designed to prevent infant diarrhoea described above (Luby *et al.*, 2004), field workers conducted neighbourhood meetings at which information about handwashing was presented in slide shows, videotapes, and pamphlets. Additionally, they made weekly visits to households to describe specifics of the handwashing protocol. Similarly, in a study designed to increase the consumption of fruits and vegetables among rural African American church members in North Carolina (Campbell *et al.*, 1999), church members were encouraged to plant victory gardens and fruit trees and were encouraged to serve fruits and vegetables at church functions. Pastors received a newsletter and were encouraged to promote the project from the pulpit, and church members received personalized, tailored messages based on their responses to survey questions on fruit and vegetable consumption, their health beliefs, readiness to change and support from others for changes in diet. Intervention counties formed coalitions that included representatives from the churches, local agencies, grocers and farmers. Finally a cookbook based on church members' own recipes, modified to meet the dietary guidelines, was created and distributed to all intervention recipients.

In sum, for an intervention to succeed, it is important to collaborate with community members as equal partners in the intervention process. Community members can serve as 'gatekeepers' to the community; they understand the concerns and culturally appropriate responses in their community, and can help to ensure that the content of the intervention is designed in such a way as to be consistent with the community's culture and norms. Additionally, interventions drawing on the knowledge and strengths of both healthcare providers and community members should strive to disseminate their messages through as many different means as possible.

Impediments to community-based health programmes

Professional attitudes

There continues to be an ongoing debate in medical education about the extent to which public health and prevention concepts should be taught in the medical school curriculum (Altman, 1990; Colwill, 2004). Despite the value of community-based prevention programmes, the reward structure in medicine, particularly in the USA, has not been on public health, but on the treatment of complex disorders whose occurrence in the general population may be relatively infrequent. Unfortunately, the model in clinical medicine of treating individuals in isolation from their social milieu has had limited effectiveness in dealing with the health problems of the vast majority of citizens (Ewart, 1991). This is because social factors play a large role in facilitating or inhibiting the adoption of effective health practices. Dealing with these social factors, then, becomes a key ingredient in community health programmes.

Lack of knowledge, distrust and discouragement

Decisions to adopt positive health behaviours are influenced by diverse social and psychological motives. These can include concerns about personal appearance, maintaining perceived respect of one's peers, the desire to avoid social rejection, the need for

material and financial security as well as actual knowledge of effective health practices. These factors either facilitate or impede the adoption of new behaviour, and should be anticipated in the design of health programmes.

Research has demonstrated that those most at risk are usually those who are most reluctant to volunteer for community programmes. For example, Fink and Shapiro (1990) found that mortality rates from all causes were highest among women who refused to participate in a voluntary breast cancer screening programme conducted by their health insurance plan. Reaching these reluctant participants required personal contact and intensive outreach as demonstrated by Lacey *et al.* (1989). In their cancer screening project, public health outreach workers, culturally sensitive to the target population, visited places frequented by women (such as beauty shops, grocery stores, housing projects and currency exchanges) to bring word of the programme and allay fears which only surfaced after personal contact had been established.

Addressing difficulties in recruiting and engaging at-risk participants improves the ability of the intervention to reach its target participants. Lindenberg and her colleagues (2001) recognized that even traditional health education programme approaches using schools, health centres, and churches were not accessible to many of the young, Hispanic women they were targeting in their intervention designed to reduce substance use and risky sexual behaviour. For these young women, commitments to work, studying, childcare and household activities precluded regular attendance at programme classes. These researchers found that mailing health education materials which were personalized, in Spanish, and at a 10–12-year-old reading level was a successful strategy for reaching many woman who many not have participated otherwise. In addition, bilingual telephone consultation was also a useful strategy in contacting participants, especially since the telephone afforded the privacy essential given the nature of the intervention.

Inadequate resources

Despite the advancement of prevention as a science and the success of many community intervention programmes, many communities have been unable to implement effective programming due to limitations in funding, resources, technical and organization capacities and community readiness (Goodman, 2000; Wandersman & Florin, 2003).

The research on preschool education programmes provides a useful illustration. Demonstration projects that serve as models for broader implementation generally show both immediate and long-term benefits. However, the evidence for the efficacy of Head Start programmes which have been implemented community-wide with the model programmes as a guide, show less consistent effects (Haskins, 1989). The reasons for the less successful dissemination of model programmes are not clear, but one reason that widespread

implementation might be less successful is that resources to administer programmes never match what is available to the demonstration projects. Real programmes are usually inadequately funded and are required to service more children with fewer resources than is true for model research programmes.

The lesson is that any large-scale community health programme must be aware of both predictable and unpredictable costs that may occur, and must make plans to deal with inadequate resources. For example, distribution of HIV/AIDS leaflets in a Ugandan community fell significantly for an extended period of time when technical problems with a photocopier arose (Kinsman *et al.*, 2002). However, it is possible to build on community support for the programme in order to restrain costs. In a study of mammography screening in Los Angeles, church-member volunteers were an integral part of developing a cost-effective programme (Stockdale *et al.*, 2000). This strategy could only have been adopted with a sufficient amount of community support for the programme. In addition to saving money, the use of community volunteers reinforced both the importance and acceptability of mammography for the participants.

Conclusion

The strategies for community intervention outlined in this chapter may seem daunting to an individual healthcare practitioner. Although the current medical model focuses more on the treatment of illness in individuals than on the prevention of health problems in a population, healthcare providers can integrate aspects of community-based intervention into their practice. Healthcare providers can assess the important social influences in a patient's life (e.g. spouse, family, friends, other caregivers, co-workers, religious affiliations, employment, social clubs, etc.) and how those persons or structures may facilitate or impede prescribed health behaviour changes. For example, it may be useful to know about the smoking patterns of a patient's co-workers and whether the employer offers on-site cessation clinics. Health care providers frequently hear first-hand from patients (i.e. community members) about community health concerns such as those described in this chapter. For example, patients may tell their physician about common community sexual practices that might put them at risk. Although physicians (nurses, etc.) may not have the resources themselves to initiate a community intervention, s/he may use her standing in the community and expertise to inspire others (e.g. university researcher, public health officials, advocacy groups) or consult with others (e.g. other healthcare providers, community leaders, school officials) who may be able to address the problem. After all, a health professional cannot expect to achieve success by working alone without the involvement of significant others in the community. Working at the community level is worthwhile because even small changes in health care practices on a community level can significantly reduce mortality and morbidity over time. Counselling

Robert Bor and John Allen

Royal Free Hospital

Introduction

It has been estimated that as many as one-third of all patients who consult a doctor do so because they have a 'personal problem', or real physical symptoms, causing them distress and reflecting an

underlying psycho-social problem (Pereira Gray, 1988). Often patients first present with such 'life-problems' or psychosomatic symptoms during a medical consultation lasting a matter of minutes. If the doctor has no psychological training, the 'life-problem', or psychosomatic symptoms may well be medicalized, i.e. treated

solely or principally as an organic complaint. Treatment then tends to take the form of psychotropic drugs. The consequence may well be that the condition becomes chronic, or fails to improve, resulting in yet more frequent consultations and further prescriptions. Many observers have commented on the enormous amount of personal distress that this scenario causes to patients and the huge resulting costs to healthcare providers (Maguire & Pitceathly, 2002).

Counselling, among other forms of psychological help, may well be beneficial for patients presenting with such problems. The counsellor working with people in medical settings can provide time in which patients may express feelings about loss of abilities, roles and self-esteem and assist them in coming to terms and/or coping with these and other changes. In addition to the psychological benefits of counselling, there are at least some indications that the presence of a counsellor in the primary healthcare team leads to a reduction in patients' psychosomatic symptoms, a consequent reduction in drug prescription rates and a reduction in the demand for the time of medical staff. Other claimed benefits include a better shared understanding of the role of counselling in the work of the therapeutic team; fewer inappropriate referrals and investigations; and fewer hospital admissions. Moreover, it appears that the division of workload leads to increased satisfaction for GPs and greater mutual respect within the primary healthcare team.

The nature of counselling

If counselling is to have these beneficial effects, it is imperative that the appropriate conditions should be provided for its effective practice. There needs to be a clear appreciation within each medical team of the nature of counselling and the ways in which it differs from other forms of helping. The definition of counselling has always been problematic but one which is espoused by the British Association for Counselling and Psychotherapy (BACP) states: 'people become engaged in counselling when a person, occupying regularly or temporarily the role of counsellor offers or agrees explicitly to offer time attention and respect to another person or persons temporarily in the role of client' (BACP, 1985). The Code for Counsellors published by the BACP also states:

the overall aim of counselling is to provide an opportunity for a client to work towards living in a more satisfying and resourceful way ... Counselling may be concerned with developmental issues, addressing and resolving specific problems, making decisions, coping with crisis, developing personal insight and knowledge, working through feelings of inner conflict or improving relationships with others. The counsellor's role is to facilitate the client's work in ways which respect the client's values, personal resources and capacity for self-determination. (BACP, 1992)

One of the clear implications of the stress on self-determination is that in counselling, the patient, or client, is involved in an active and to a large extent autonomous, process of exploration, clarification and problem-solving. (This autonomy is often explicitly recognized by the use of the preferred title of 'client' rather than patient in the counselling context.) The emphasis on enabling or facilitating the client's decision-making in 'client-centred' approaches to counselling can be sharply contrasted with the traditional 'doctor-centred', or biomedical model, of patient care. In counselling, the 'expert' role

is abandoned in favour of a consultative style which values client responsibility and freedom. This may well involve the sharing of specialist knowledge, particularly about medical issues but the use of such information is seen ultimately as the client's responsibility. The biopsychosocial model (Engel, 1977) encourages patients, healthcare providers and counsellors to adopt an holistic and integrative approach to health problems. Narratives and experiences of illness and related problems have more relevance than linear or reductionistic explanations within this counselling approach (Bor *et al.*, 2007).

The impact of counselling on medical practice

Interestingly in recent years the 'client-centred' approach has had a significant impact on medical practice especially among those practitioners who have become dissatisfied with the older 'doctor-centred' model of patient care (see 'Patient-centred healthcare'). Both in primary care and in postgraduate training, psychological and social approaches to the understanding of health and illness have led to alternative ways of working with patients. There has, for example, been increasing acceptance by medical practitioners that an understanding of the patient's view is vital to the process of consultation and that medical treatment should be based on shared involvement in decision-making. To facilitate this in practice, many of the skills developed in the counselling context such as active listening, empathic responding and reflection have been adopted by medical practitioners. Davis and Fallowfield (1991) argue that the use of counselling skills within a 'patient-centred' approach to medical care results in many benefits for patients and health professionals. These include increased patient and professional satisfaction, greater diagnostic adequacy and improved adherence to treatment. Where they occur, these benefits are thought to be largely due to improved communication between patients and health professionals. (See 'Compliance among patients', 'Healthcare professional-patient communication', 'Medical interviewing' and 'Patient satisfaction')

Counselling in the medical context

The origins of professional counselling for medical problems lie in efforts to improve patients' knowledge in order to help them to make informed decisions about treatment and care (such as with counselling for treatment for infertility, HIV antibody test counselling and termination of pregnancy counselling among others). More recently, this has extended to psychological support counselling. Counselling in medical settings is frequently associated with the following issues or problems: post-traumatic stress, coping and adjustment, pain management, pre- and postoperative stress, HIV disease, adjustment to coronary heart disease, substance misuse, renal disease, treatment non-compliance, infertility, anxiety, helping sick children and their families cope, among many others. There is rapid growth in the area of counselling in primary healthcare settings. Not only is this a context in which counsellors can work with patients at the first point of diagnosis, treatment and care, but it also provides an opportunity for focused health education and preventative counselling (Bor & McCann, 1999).

Many of the interactions between healthcare professionals and patients may not involve counselling as defined above but they may involve the use of counselling skills. The distinction between the use of counselling skills and counselling as a discrete activity is an important one but one which is often not made explicit. Bond (1993) has pointed out that counselling skills may be seen as a group of interpersonal, or communication, skills which share the common purpose of assisting the self-expression and autonomy of the recipient. Thus the purpose or values they serve are similar, if not identical, to those of counselling; namely empowerment and the encouragement of self-determination.

Counselling skills can, therefore, be regarded as providing ways of helping patients make informed choices from a range of health options. In this way counselling skills may be distinguished from the use of other communication skills such as those employed to advise, influence and persuade. Bond (1993) also points out that counselling and the use of counselling skills may be distinguished from each other, at least in part, by noting whether the contracting between the parties concerned is explicit or not. The BACP definition of counselling given earlier expressly addresses this issue by noting the need for clear understanding of the roles of counsellor and client. Confusion of roles has often arisen, particularly in healthcare and medical contexts because counselling has been practised by those who occupy dual roles such as counsellor and doctor, nurse or health visitor. Where dual relationships apply, it is especially important to make the boundaries between roles clear and appropriately manage overlap between professional roles. The pitfalls of dual relationships in the context of general practice have been examined with insight by Kelleher (1989) and it seems that, in the context of health counselling, such problems can best be avoided by ensuring that where possible the role of counsellor is separate from the provision of other services.

It is possible to envisage the relationship between counselling skills as a continuum as described in Table 1 (although for a contrary view on the relationship between counselling and counselling skills see Pratt, 1990). Here counselling skills and counselling are seen as overlapping activities which play more or less prominent roles in different kinds of health-related consultations.

Evaluation of counselling

In a climate in which competition for resources is acute, it is essential that the effectiveness of counselling be demonstrated in order to justify its continued support. There is now a well recognized need to determine the efficacy of counselling in medical settings (Tolley & Rowlands, 1995). Some studies have attempted to do this by asking whether counselling is cost-effective. Maguire *et al.* (1982), for example, reported considerable savings to the British National Health Service through the early recognition and treatment of psychiatric problems in counselled mastectomy patients, as compared with a control group. Other studies have examined changes in patients' use of medical services or reductions in the number of drugs prescribed following counselling. Whilst the results of these studies have generally been favourable, it is necessary to interpret these outcomes with caution. In many of these studies there have been serious methodical flaws such as the absence of control groups; sample attenuation; non-independent evaluation; and lack of appropriate statistical comparison (Brown & Abel Smith, 1985).

Table 1. Levels of psychological counselling

<i>Counselling skills</i> – the provision of factual information and advice about medical conditions, assessment, laboratory tests, treatment, drug trials, disease prevention and health promotion.
<i>Counselling skills/Implications counselling</i> – discussion with the patient and others which addresses the meaning of the information for the patient, personal relationships and taking into account the patient's unique circumstances.
<i>Support counselling</i> – in which the emotional consequences of implications can be expressed and acknowledged in a caring environment.
<i>Therapeutic counselling</i> – which focuses on healing, psychological adjustment, coping and problem resolutions.

(Adapted from The King's Fund Report, 1991)

Most evaluation studies have concentrated on psychological outcomes such as the alleviation of distress, psychological adjustment and the amelioration of psychiatric conditions. Here again methodological difficulties abound. As with the psychotherapies, efficacy depends on the goals of the counsellor, the conceptual framework used and the methodologies which are employed. The research literature contains many examples of evaluation studies where researchers have used outcome measures of doubtful validity and reliability, research designs have been oversimplified and data has been over-interpreted. Moreover, the situation is not eased by the determination among some researchers to apply criteria for conducting evaluation studies of counselling which are almost identical to those used in clinical drugs trials (Andrews, 1993). However, some recent studies have addressed many of the flaws which bedevilled earlier attempts to establish the psychological efficacy of counselling in the medical context. For example, Milne and Souter (1988) studied the effects of counselling on assessed levels of stress in a study which used patients as their own controls by incorporating a waiting list before counselling began. Significant increases in the use of coping skills and decreases in the levels of strain were found. Moreover, these results were not the results of normal crisis resolution because those with the most chronic problems developed more adequate coping skills whilst showing increased stressor scores. Patients who improved showed significant reductions in treatment cost in terms of hospitalization, visits by primary care physicians and drug prescription rates.

Other studies have examined the efficacy of counselling as an adjunct to medical treatment of cardiovascular problems and cancer. Maes (1992) has pointed out that psychosocial interventions, including counselling, may affect cardiac rehabilitation in two ways. First, such interventions may facilitate psychosocial recovery and thus aid return to everyday activities. Secondly, they may play an important role in secondary prevention, by improving compliance with medical advice concerning medication and lifestyle changes. Many of the studies of counselling and cardiac rehabilitation have been reviewed by Maes (1992) and Davis and Fallowfield (1991), who conclude that there is now considerable evidence that counselling, and related forms of intervention, can have beneficial effects on reported stress levels, professional reintegration, necessary lifestyle changes and even perhaps morbidity and mortality. Davis and Fallowfield (1991) also provide a review of studies in which counselling has been employed as an adjunct to physical treatment for many other medical conditions ranging from diabetes mellitus to spinal cord injury.

Although gross measures may indicate the effectiveness of counselling, we still know little about the psychological processes underlying such changes. We also need to know more about which kinds of counselling interventions are particularly beneficial for which patients and at what stage of their illness. This requires detailed consideration of patient characteristics, the nature and time course of the presenting problems, patients' previous coping strategies and the impact of family and other supports. Research into counsellor characteristics and their impact on counselling is also much needed.

Training issues

To date, there has been enormous variability in the experience and qualifications of those employed as counsellors in medical settings. The situation has been unsatisfactory partly because until recently in the UK, there were no statutory regulations governing the qualifications of counsellors. However, helpful recommendations have been drawn up by the BACP, which also operates a voluntary counsellor accreditation procedure. The Counselling in Primary Health Care Trust has also been active in promoting courses at post-graduate level for counsellors working in general practice and other settings. Chartered Counselling Psychologists in the UK are governed

by statutory regulations through a route to qualification regulated by the British Psychological Society. With more courses emerging in counselling and counselling psychology at masters and post-masters level, it can be hoped that the qualifications of those working as counsellors will improve and higher levels of professional practice will be provided.

Emerging issues

An increasing number of counsellors working in medical settings provide brief, evidence-based counselling sessions focusing on symptom control or alleviation and helping to enhance patient autonomy and coping (Bor *et al.*, 2004). Extending counselling to carers and other family members is an important new trend which requires specialist training beyond traditional one-to-one therapeutic skills. Counsellors also have an important contribution to make to team resource management and patient safety programmes. Lessons taken from team management programmes in the airline industry are being applied to help improve team performance in healthcare settings, reduce error and prevent the risk of litigation. Counselling and communication skills are central to this initiative in healthcare settings.

Group therapy

Peter Hajek

University of London

This chapter will (1) outline the main approaches to using groups to help people deal with psychological problems, (2) examine briefly the relevant outcome research and (3) describe the main applications of group therapy, with particular focus on groups in a medical setting.

Models of group therapy

There is an obvious intuitive and experiential validity in the notion that cohesive groups can provide considerable support and psychological help to their members. Throughout our lives the features of our membership in various groups such as the primary and secondary family, school class, work groups and networks of friends are of great importance. Social interactions within such structures are one of the major sources of human happiness and fulfilment, as well as of human misery.

Various religious and secular groups have always helped to alleviate their members' psychological distress. However, the idea of creating groups for an explicitly therapeutic purpose is relatively new. The first account of such groups was published in 1907. Rather surprisingly, this pioneering report is from a general medical rather than psychiatric setting. An American internist, Joseph Pratt, organized group meetings to provide support and encouragement to patients with tuberculosis, and to demonstrate the benefits of compliance with the therapeutic regimen of the day. In recent years, support groups for people with physical or externally-based problems are becoming popular again. Throughout the intervening period however, group therapy has been practised primarily in psychiatric settings, and the most influential approaches were informed predominantly by the work with neurotic populations.

Groups are a complex and multivariate tool and there exists a large number of styles of group work. Well over 100 'group therapies' have been described in the literature. Most of them, however, derive from four basic approaches, and could be in broad terms allocated to one of them, or to their combinations. These four major strands can be labelled 'analytical', 'interpersonal', 'experiential' and 'didactic'. They correspond to the main work styles a group can adopt, i.e. to analyze motives for group members' behaviour; to provide an opportunity for social learning; to generate emotional experience; and to impart information and teach new skills.

In practice, group therapists working with similar types of clients often converge on a similar integrated package of interventions and skills, spanning across these different approaches. For an observer it would often be impossible to say which particular 'school' the therapist subscribes to. Throughout this chapter, this amalgam which characterizes the practice of many experienced group therapists is labelled 'mainstream practice'. Even the principal proponents of the

four alternative forms of group treatment include at least some elements of the other approaches in their work.

The analytical approach

(See 'Psychodynamic psychotherapy'.) This has a historical primacy as the first to apply a theory of psychological functioning and disorders to group treatment. Its influence is waning, but some of its marks remain visible on the eclectic mainstream practice of group therapy. In broad terms, the goal of treatment is to uncover and resolve hypothetical unconscious conflicts. This is expected to lead to the patient's recovery. The mainstream practice has adopted elements of two particular hallmarks of group analytical treatments, i.e. attention to hidden motivation behind group members' interactions, and attention to the relationship of group members to the group leader (transference).

The interpersonal approach

The interpersonal approach emphasizes the opportunity for social learning which groups can provide. Its origin is in the 'laboratory' groups initiated by Kurt Lewin in 1947 and intended as an in vitro social environment in which group members can learn about how groups function and how participants behave in them. Treatment applications of a combination of this and other approaches are associated primarily with the work of Irvin Yalom (1995). The mainstream practice has adopted the concept of social feedback (i.e. allowing group members to learn how their behaviour affects others), and an empirically derived outline of typical developmental processes and stages in an unstructured group. 'Training groups' also provide a model for training group therapists in awareness of group processes.

The experiential approach

The experiential approach to groups is characterized by working primarily with the client's current awareness of their experience. The most important source for this approach were 'encounter groups' inspired by Carl Rogers and aimed primarily at experiences of closeness and acceptance. Jacob Moreno's psychodrama and other developments such as gestalt therapy by Fritz Perls represent other important influences. The contribution of this approach to mainstream practice is primarily in encouraging group therapists to use techniques aimed at stimulating desirable group experiences. (The label 'experiential' is used here for convenience. It often appears in various other contexts as well.)

Didactic approaches

Didactic approaches are connected primarily with behavioural and cognitive treatments administered in groups, but are also widely practised in various health promotion/education contexts. The therapist usually has a set agenda for each session, group members are given concrete tasks and group interaction and group processes are not the main focus of attention. Behaviour and cognitive therapists and health education workers usually lack a background in group dynamics and tend to automatically adopt the simplest group model we are all familiar with, i.e. that of a classroom with a teacher and pupils. Behaviour approaches have developed in opposition to the older models, and there has been little cross-fertilization so far.

Further details of different approaches to group treatment, and descriptions of group processes and of practical skills involved in running groups can be found in Yalom and Leszcz (2005) and Aveline and Dryden (1988).

Therapeutic factors in group therapy

There are a number of hypothetical processes through which groups are supposed to exercise their therapeutic effects. Different applications of group treatment concentrate on different therapeutic factors. A description of group treatment in terms of therapeutic factors expected to foster specific treatment goals is a useful practical alternative to describing a groupwork style only in terms of the therapist's theoretical orientation. This 'transtheoretical' approach to group treatment is also amenable to empirical research.

Several categorizations of therapeutic factors have been proposed. Table 1 provides one of them, based on a list by Bloch and Crouch (1985) with the last item, Group Pressure, added by the present author. The pressure to conform to group norms seems to go against the individualistic self-actualization philosophy endorsed in most writings on groups and therapy. However, where the goal of the group includes e.g. modification of health behaviours, drug use, or antisocial behaviour and where the group manages to establish norms conducive to desirable behaviour change, group pressure can be a major therapeutic influence. Different factors become prominent in different types of groups. For example, a group aiming at uncovering hidden motives behind self-defeating neurotic behaviours would focus on self-understanding more than on guidance; an Alcoholics Anonymous group would rely on instillation of hope more than on catharsis; and a support group for patients diagnosed with cancer would emphasize universality and altruism more than insight.

Efficacy of group therapy

The main and obvious argument in favour of group treatments is that, assuming there is little difference in efficacy between individual and group approaches, treating people in groups is much more cost-effective. Running a group with ten patients for the same length of time that individual treatment would take means that group therapy achieves the same effect as individual therapy ten times faster; or to put the identical argument differently, in the same time period,

Table 1. Therapeutic factors in group therapy

-
1. *Acceptance* – patients feel a sense of belonging and being valued (cohesiveness).
 2. *Universality* – patients discover that they are not unique with their problems.
 3. *Altruism* – patients learn with satisfaction that they can be helpful to others in the group.
 4. *Instillation of hope* – patients gain a sense of optimism about their potential to benefit from treatment.
 5. *Guidance* – patients receive useful information in the form of advice, suggestions, explanation and instruction.
 6. *Vicarious learning* – patients benefit (e.g. by learning about themselves) by observing the therapeutic experience of fellow group members.
 7. *Self-understanding* – patients learn something important about themselves (insight).
 8. *Learning from interpersonal action* – patients learn from their attempts to relate constructively and adaptively within the group (interpersonal learning).
 9. *Self-disclosure* – patients reveal highly personal information to the group and thus 'get it off their chest'.
 10. *Catharsis* – patients release intense feelings which bring them a sense of relief.
 11. *Group pressure* – patients alter undesirable behaviours/ attitudes to gain or to retain group approval.
-

group therapy helps ten times as many people as the individual approach.

A more involved issue concerns the specificity of any group treatment effects. In most contexts, group treatments have been shown to be effective compared with no treatment, and direct and meta-analytical comparisons have not found much difference between individual and group approaches (Burlingame *et al.*, 2004). Apart from this broad brush conclusion, it is the basic assumption of all types of group therapy that the processes generated in group setting (which are not available in an individual setting) are conducive to patients' recovery. To empirically demonstrate this hypothetical active ingredient of group treatment is not easy. The question of specific efficacy of a treatment which can be applied in different forms with different conditions may appear too unfocused. However, to consider any treatment approach valid and deserving of further study, some proof is needed of the existence of the presumed effect in whatever form and context.

Research in efficacy of psychological treatments is generally difficult and plagued with methodological problems (Kendall *et al.*, 2004). Research in the efficacy of group treatments has the additional handicap of extra demands on sample size because the units of observation are groups rather than individual patients, and it may be even more difficult to find a suitable control condition for group treatments than it is for individual treatments. Comparisons of groups with no treatment or with individual treatments cannot demonstrate the specific effects of groups. More promising are mutual comparisons of group treatments which only differ in group-specific variables. One area uniquely suited to this type of research are smoking cessation groups. This is because there is an almost unlimited supply of patients, treatment is brief and outcome (i.e. tobacco abstinence) is clearly defined and can be objectively verified. In this population there are suggestions that variations in

group format can affect outcome, and that individual's chances of success can be influenced by group membership (group effect) (Hajek *et al.*, 1985). At least in this particular area, processes generated by groups seem to have specific effects on therapeutic outcome.

Research in efficacy of group treatments has some way to go. A telling sign is the fact that, as in psychotherapy literature generally, books advising readers on minutiae of treatment still outnumber studies examining whether such manipulations actually have the promised effect. However, over the last few years, good quality randomized trials, particularly of groups in medical settings, are increasingly appearing in respected medical journals. The most recent review of group therapy outcome studies can be found in Burlingame *et al.*, 2004.

Applications of group therapy

Table 2 lists some of the standard uses of group therapy. The remainder of this chapter concentrates on groups for medically ill people.

Medical patients can derive a number of benefits from participating in support groups. The largest available experimental literature concerns groups for cancer patients. There is good evidence that in this patient category, group treatment leads to improvements in coping skills and quality of life and decrease in emotional distress, anxiety and depression (Burlingame *et al.*, 2004). Medical care traditionally focuses on medical illness, and patients' concerns tend to remain unexplored. Yet it is obvious that learning that one has a terminal or debilitating illness has a profound psychological impact, which deeply affects patient's psychological wellbeing, and can possibly affect the course of the illness itself. It appears that group support can ameliorate some of these effects.

The goals of groups with physically ill members differ from the focus of traditional group therapy. Most 'medical' groups concentrate primarily on providing general support to group members, although some would also aim at influencing their health behaviours (e.g. cardiac rehabilitation groups). The group camaraderie and 'common bond in common disease' have already been described by Yalom and Leszcz (2005). In the current revival of medical groups, the emphasis on sharing mutual concerns and feeling understood and accepted remains central. Other elements include relinquishing the unhealthy 'silent sufferer' role often adopted to protect others; the opportunity to learn from other group members about ways of coping with illness; sharing relevant information and resources; maintaining social interest and involvement; etc. Groups are often also an ideal forum for health professionals to impart and discuss medical advice affecting patients' lifestyle.

Table 2. Common uses of group therapy

<i>Groups for normals</i> – assisting personal development in individuals who are not experiencing specific problems. Examples: staff groups, parents' groups, women's groups, etc.
<i>Group counselling for externally-based problems</i> . Examples: groups for rape victims, disaster victims, relatives of mentally or terminally ill, etc.
<i>Group support for physically ill patients</i> . Examples: cardiac rehabilitation, pain management, groups for cancer patients, etc. (see text).
<i>Group treatment for antisocial and addictive behaviours</i> . Examples: groups for delinquents and inmates, Alcoholics Anonymous, group clinics for smokers, etc.
<i>Group therapy for people with neurotic problems and personality disorders</i> . Traditional area of group therapy, usually psychiatric out-patients.
<i>Groups for people with severe mental disorders</i> . Psychiatric in-patients and out-patients (rehabilitation, occupational therapy, 'living skills', etc.).

Groups with patients are usually dependent on health professionals in both their organization and content. Within the health service, group leaders come from diverse professional backgrounds, including psychology, medicine, social work, psychiatry, nursing and rehabilitation.

Examples of 'disease management' groups include groups for chronic pain sufferers (in addition to general support, cognitive-behavioural principles are usually included), coronary artery disease patients (cardiac rehabilitation programmes are possibly the largest application of disease management groups and typically include exercise, stress management, smoking cessation and health education in addition to group support), cancer patients, diabetics, patients with HIV, etc. Even in didactically oriented groups, elements of group support tend to have bigger impact than other components (e.g. Rahe *et al.*, 1979).

An important branch of this work consists of groups with relatives of patients who have chronic debilitating conditions. These groups often have a self-help format. If health professionals are involved at all, it may be only in the initiation stage, or possibly in an ongoing consulting capacity. Support groups for patients' families have been described for parents of newborn children who died, family members of cancer patients, of patients with Alzheimer's disease, etc. Particulars of some of the developments in groups for physically ill and their families can be found in Roback, 1984.

Group counselling for patients with serious medical conditions and for their families is by no means commonplace. However, the merits of this approach are increasingly recognized and various approaches are being formally evaluated. The idea of using group support to alleviate the psychological distress accompanying certain diseases and to improve disease management has taken root, and is likely to continue to develop.

Health promotion

Gerjo Kok

University of Maastricht

Health promotion, health education and prevention

Health promotion is any planned combination of educational, political, regulatory and organizational supports for actions and conditions of living conducive to the health of individuals, groups, or communities (Green & Kreuter, 2004). Involving the target individuals, groups, or communities in the development of programmes, is a prerequisite for effective health promotion. Three types of prevention are the goals of health promotion: (i) primary prevention; (ii) early detection and treatment; and (iii) patient care and support. Health education is one type of health promotion intervention. Health education is a planned activity, stimulating learning through communication, to promote health behaviour. Other health promotion instruments are resources and regulation. Health education is based on voluntary change, while regulation is based on forced compliance and will only be effective in combination with control and sanctions. In general, interventions that are directed at several levels and which use more means, will be more effective.

An example of this last statement is the prevention of drunk driving. There is regulation: most countries have laws against driving under the influence of alcohol. Often there is control: drivers are stopped by the police and may be tested, although countries differ in their commitment to these control activities. There are resources: public transport is available and, especially in the weekends and during the night, cheap taxis for adolescents. There is education: information is provided about the rules and possible sanctions, about resources and about drunk driving itself, i.e. the consequences of drunken driving, but also on ways to prevent getting into that situation. The combination of control, resources and education is more effective than any one of these elements alone.

Health promotion as an intervention for patient care, and support is usually called patient education instead of health promotion. Sometimes patient education supports patients who recover, for instance, after surgery. Sometimes the focus is on chronic patients, such as patients with asthma or diabetes. Patient education

also includes support for people who are dying, for instance in the case of terminal cancer. Patient education is not only directed at the patient but also at the patient's family, at health professionals and at other environmental factors. Health workers such as physicians and nurses are the primary providers of patient education. Frequently, many different health workers are involved in the treatment of the same patient. Patient education by each of these professionals is not always attuned to the needs of the patient. This calls for the development of patient education programmes that co-ordinate the educational activities of the different health professionals involved, for example, by developing protocols for continuity of care (Mesters *et al.*, 2002).

The planning of health promotion

Health promotion is a planned activity. The best known and most often used planning model in health promotion is Green's PRECEDE-PROCEED model (Green & Kreuter, 2005); see Figure 1.

In short, Green starts with the social assessment: what is the quality of life of a certain group, community or country, and the epidemiological assessment; is health relevant for the quality of life and if it is, what are the most serious health problems? With the epidemiological assessment, the causes of health in terms of behaviour/lifestyle, genetics and environment can be analyzed. With the educational and ecological assessment analysis can be made of the determinants of the relevant behaviours, in terms of predisposing, reinforcing and enabling factors, and selection can be made of the variables that are desired to be influenced. With the intervention alignment and administrative and policy assessment the possible usefulness of health education and other potential interventions, of resources and regulations can be analyzed. Health promotion interventions are developed and then implemented. Finally, evaluation is made of the process, impact and outcome of these interventions, resulting in feedback and improvement of the interventions.

For example, in most western countries, the quality of life in general is high. People value health as one of the most important aspects

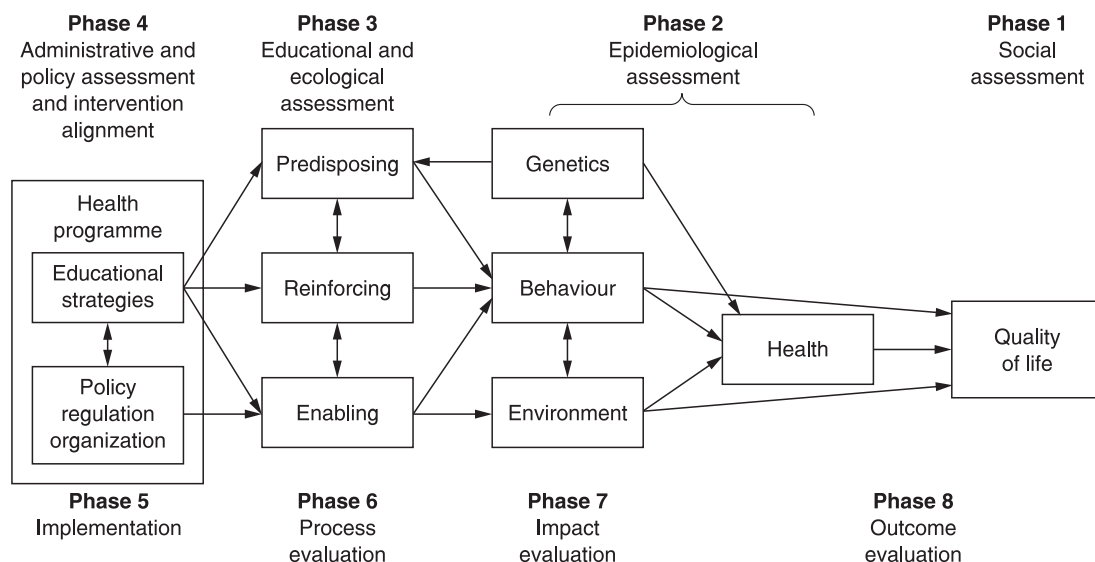

Fig 1 The PRECEDE-PROCEED model for health programme planning (Green & Kreuter, 2005).

of their quality of life. What are the most important health problems? In terms of mortality cardiovascular disease (CVD) and cancer fulfil this role. What are the causes of CVD and cancer? In terms of environment these are, for instance, industrialization and unhealthy working environments. In terms of behaviour and lifestyle, smoking and unhealthy diet are major causes. Let us select smoking and, in particular, the prevention of the onset of smoking, as a relevant behaviour that we might want to influence. Why do adolescents start smoking? Not because they like it and not because they don't know about the dangers. One reason they start smoking is social pressure, mostly from peers, family or mass media. In terms of predisposing factors: adolescents often do not know how to resist social pressure. In terms of reinforcing factors, belonging to a peer group is very important for adolescents. In terms of enabling factors, cigarettes are easy to obtain and sanctions against smoking are weak. What can we do? In terms of health education, we might want to improve adolescents' self-efficacy in resisting social pressure. There are a number of techniques that help adolescents to learn how to resist pressure to smoke, for instance, through positive role modelling (see Bartholomew *et al.*, 2006). In terms of resources and regulation we want to develop anti-smoking policies, for instance, in schools, or through community action against vendors who sell cigarettes to adolescents under legal age. The implementation of such a health promotion programme is organized in co-operation with schools, parents and students. Finally, the effectiveness of the programme is measured. In terms of process evaluation the central question is: was the programme implemented as planned and was the supposed self-efficacy improvement actually realized? In terms of impact evaluation: did fewer students in our programme group start smoking than in a comparison group? It may be clear that an improvement in terms of outcomes, reduction of CVD and cancer and quality of life, cannot be expected for several years.

Quality of the planning

The process of planning health promotion programmes is a cumulative and iterative process. On the one hand, we need answers on

earlier planning questions to decide about later phases. On the other hand, the process is not rigid but flexible and we go back and forth through the model. During the planning process we make use of existing knowledge that is systematized in theories, and which is available as empirical data. Why does it have to be so complex? Certainly not because health promoters admire complicated models, but because careful planning is essential if we strive for effect. A very important study in this respect is a meta-analysis by Mullen *et al.* (1985) on 70 patient education studies that were methodologically sound and which included knowledge and compliance as effect variables. Several diseases and several types of interventions were represented. Mullen *et al.* estimated the quality of the interventions using six criteria that they derived from the literature and that can also be seen as guidelines for intervention development:

1. Consonance: the degree of fit between the programme and the programme objectives.
2. Relevance: the tailoring of the programme to knowledge, beliefs, circumstances and prior experiences of the learner, as assessed by pilot-testing or other means.
3. Individualization: the provision of opportunities for learners to have personal questions answered or instructions paced according to their individual progress.
4. Feedback: information given to the learner regarding the extent of which learning is being accomplished (e.g. blood pressure reading).
5. Reinforcement: any component of the intervention that is designed to reward the behaviour (other than feedback) after the behaviour has been enacted (e.g. social support).
6. Facilitation: the provision of means for the learner to take action and/or means to reduce barriers to action (e.g. subsidies).

Mullen *et al.* show that the best predictor of success was the rating score for the quality of the educational intervention. The choice for a specific educational technique was not related to effectiveness, again demonstrating that there is no such thing as a 'magic bullet'. Thus, the effectiveness of a health promotion intervention is determined by the quality of the planning process.

In the six criteria that Mullen *et al.* used, we recognize different concepts from Green's planning model: the choice of relevant behavioural objectives, tailoring to determinants of behaviour, learning (health education), reinforcement, support and facilitation (health promotion). There are also some additional concepts that have not been described in the PRECEDE-PROCEED model, but which are selected from behavioural science theories.

Using theories in health promotion: determinants

At different phases in the planning process different theories will be most relevant (Glanz *et al.*, 2002). The first phases rely on epidemiological theories; the later phases, when the intervention is developed, rely on theories from the behavioural sciences, especially social psychology. In this and the next two paragraphs we will describe theories that can be applied in the three phases: determinants, intervention and implementation.

In the phase of looking at determinants we try to understand why people behave as they do. Current social psychological models indicate three types of determinants of behaviour (Ajzen, 1988; Bandura, 1997):

1. Attitude: beliefs about advantages and disadvantages of behaviour resulting in an attitude about the behaviour, also described as outcome expectations.
2. Social influence: beliefs about social norms, behaviour of others (modelling).
3. Self-efficacy: beliefs about perceived control, self-efficacy expectations.

Models about determinants of behaviour do not imply a one-directional influence; attitudes, social influence, self-efficacy and habits can be antecedents as well as consequences of behaviour (see 'Health Belief Model'). In interventions we try to change determinants in order to change behaviour, but we also use techniques that influence behaviour rather directly, such as reinforcement and having people publicly commit themselves to the desired behaviour. Positive experiences with behaviour, in turn, may change psychosocial determinants of behaviour, thus creating reciprocal determinism (Bandura, 1997). Recently, there has been greater focus on habitual or automated behaviour (Aarts & Dijksterhuis, 2000); interventions to change this kind of behaviour first have to break through the habitual nature of the behaviour.

Using theories in health promotion: interventions

Current general social and health psychological models on behaviour change distinguish steps, phases or stages of change. Within those steps, a number of different specific theories can be applied. One general framework for theories on behaviour change is provided by McGuire's (1985) persuasion-communication model. He describes different steps that people take, from the initial response to the message to, hopefully, a continuous change of behaviour in the desired direction. Simplified, the first steps indicate successful communication, the next steps involve changes of determinants and behaviour and the last step is concerned with maintenance of that behaviour change. Going through these

steps, McGuire argues that the educational interventions should change with each step. The choices that have to be made about the message, the target group, the channel and the source, will be different, or may even be conflicting, depending on the particular step that is addressed: for example, mass media may reach many people but are not adequate for self-efficacy improvement.

Prochaska & DiClemente's (1984) Transtheoretical or Stages of Change model distinguishes stages of change within the person: precontemplation; contemplation; preparing for action; action; and maintenance or relapse (see 'Transtheoretical model of behaviour change'). An important contribution of the stage model is the specific tailoring of health promotion efforts to groups of people in different stages. Interventions based on the model normally have completely different methods or strategies for each stage. A frequently used application of the theory is the so-called Motivational Interviewing counselling method (Miller & Rollnick, 2002). Recently, computer-based tailoring programmes based on the stages of change model have been shown to be effective in changing people's behaviour (Kreuter *et al.*, 2000).

Within these general frameworks, a number of other theories can be applied (Glanz *et al.*, 2002). To get people motivated for change, we apply theories on risk perception (Weinstein, 1987); to help people change, goal-setting theory (Strecher *et al.*, 1995); to maintain behavioural change, relapse prevention theories (Marlatt & Gordon, 1985). Although these theories often cover only steps, or even only parts of steps, they can be helpful in developing interventions that focus on particular aspects of change.

Theories can suggest techniques, but the actual application of these techniques in the intervention requires practical experience, creativity and thorough pilot testing.

Using theory in health promotion: implementation

Development of an educational intervention includes making plans for programme implementation. The adoption of innovations is a systematic process, following the pattern of diffusion (Rogers, 2003). A number of characteristics of the intervention are related to faster adoption: compatibility; relative advantage; flexibility; observability; 'trialability' (can the innovation be tried before making a decision?); low risk; reversibility; and low complexity.

Currently, diffusion researchers stress the importance of carefully developing the linkage between the change agent system and the target group system (Oldenburg & Parcel, 2002). In the example of smoking prevention in schools, it is important to involve teachers and students in the development of the programme, as well as principals and parents. In the example of co-operation among different health professionals to achieve continuity of care, it is important to involve all those groups in the development of the protocol.

Intervention mapping

Recently, a protocol was published that describes a process for developing theory-based and evidence-based health promotion programmes, i.e. Intervention Mapping (Bartholomew *et al.*, 2006).

Intervention Mapping describes the process of health promotion programme development in six steps: (1) the needs assessment based on the PRECEDE-PROCEED (2) the definition of performance and change objectives based upon scientific analyses of health problems and problem causing factors; (3) the selection of theory-based intervention methods and practical strategies to change (determinants of) health-related behaviour; (4) the production of programme components, design and production; (5) the anticipation of programme adoption, implementation and sustainability; and (6) the anticipation of process and effect evaluation.

An example of Intervention Mapping is the Long Live Love HIV-prevention programme for Dutch adolescents (Bartholomew *et al.*, 2006, Chapter 10):

1. *Needs assessment*: HIV is a serious health problem and young people today face increased risk of infection. In addition health promotion programmes are most effective when the population has not yet formed risky behaviour pattern and habits.
2. One *change objective* for an HIV-prevention programme in schools would be: 'adolescents (target population) express their confidence (determinant) in successfully negotiating with the partner about condom use (performance objective)'. Performance objectives are the specific behaviours that we want the target group (or the environmental agents) to 'do', as a result of the programme. For example, in the case of HIV prevention; buy condoms; have them with you; negotiate with your partner; use them correctly; and keep using them.
3. The *theoretical method* is the technique derived from theory and research to realize the proximal programme objective; the *strategy* is the practical application of that method. For instance, the method for self-efficacy improvement (for negotiating) could be modelling, and the strategy could be peer modelling by video. An important task in this step is to identify the conditions or parameters that limit the effectiveness of theoretical models, such as identification, observability and reinforcement as necessary conditions for the effectiveness of learning by modelling.
4. The actual designing of the *programme* involves organizing the strategies into a deliverable programme and producing and pre-testing the materials. In the example of HIV-prevention in

schools, the programme comprised five lessons, an interactive video, a brochure for students and a workbook for teachers.

5. The first activity to *anticipate implementation*, actually at the start of intervention development, is the development of a linkage system, linking programme developers with programme users. Then, an intervention is developed to promote adoption and implementation of the programme by the intended programme users.
6. Finally, Intervention Mapping step 6 *anticipates process and effects evaluation*. Again, this is relevant from the start. For instance, 'adolescents express their confidence in successfully negotiating with the partner about condom use' is an objective, but is also a measure of that objective, that can be asked in pre- and post-interviews with experimental and control group subjects.

Although Intervention Mapping is presented as a series of steps, Bartholomew *et al.* (2006) see the planning process as iterative rather than linear. Programme planners move back and forth between tasks and steps. The process is also cumulative: each step is based on previous steps, and inattention to a particular step may lead to mistakes and inadequate decisions.

Epilogue: planned health promotion

Health promotion is a planned activity, stimulating learning through communication in order to promote health behaviour. Health promotion planning involves a series of phases where quality of life, health problems, health behaviour, determinants of behaviour and possible interventions are successively analyzed, followed by the development and implementation of the intervention and evaluation of the process, impact and outcome. Careful planning is important, since quality of planning has been shown to determine effectiveness of the intervention.

A wide range of theories from the behavioural sciences may contribute fruitfully to the analysis of determinants and to the development and implementation of health promotion interventions. Intervention Mapping provides a helpful protocol for theory-based and evidence-based health promotion planning.

Hypnosis

Michael Heap

Wathwood Hospital RSU

The nature of hypnosis

Hypnosis is a complex psychological phenomenon. It is an interaction between two people, one of whom is identified as the 'hypnotist', the other as the 'hypnotic subject' (or there may be a group of subjects). In practice it involves a variety of psychological processes and phenomena: selective attention, usually (though not necessarily) relaxation, imagination, expectation, role-playing, compliance and attribution. The significance of each of these ingredients varies according to the situation. There are, however, two additional phenomena related to the above which are central to a discussion of hypnosis, namely suggestion and trance.

Suggestion

Suggestions are communications conveyed verbally by the hypnotist that direct the subject's imagination in such a way as to elicit intended alterations in the way he or she is behaving, thinking, perceiving or feeling. The word 'intended' is meant to convey a key defining property, which is that these changes approximate those that would occur were the imagined events to be taking place in reality. (The reader may also find that the term 'suggestion' is often used to denote the process of responding by the subject to the communication.)

A corollary of the above is that the subjective experience of responding to suggestion has an automatic or involuntary quality. For example, the hypnotist may ask the subject to concentrate on his or her arm; suggestions are then conveyed that the arm is becoming very light and beginning to rise in the air. Associated imagery may be provided – for instance a helium-filled balloon tugging at the wrist. The arm may indeed lift up, but the subjective

impression must be that the arm is lifting unaided (or largely so) by conscious effort; the intended response is not that the subject compliantly lifts the arm to placate the hypnotist.

Suggestions which elicit changes in motor behaviour are described as 'ideomotor'. Inhibition of a movement may also be suggested, such as arm immobility or eye catalepsy, in which case the term 'challenge suggestions' is often used. 'Cognitive suggestions' involve changes in perception or cognitive function, including somatosensory changes (anaesthesia, analgesia, warmth, etc.); visual, auditory, olfactory and gustatory 'hallucinations'; and memory inhibition (amnesia). Suggestions may be intended either to take effect immediately or some time after the session of hypnosis. The latter type, termed 'post-hypnotic suggestions' are widely used in therapy. Two examples which illustrate their characteristic form are 'Each and every time you put a cigarette to your lips, you will immediately experience this terrible taste in you mouth' and 'Between now and your next session you will have a dream at night which will help you understand your problem and how to overcome it'.

Trance and the induction of hypnosis

The concept of 'trance' as an altered state of consciousness is more contentious than that of suggestion but it is a very useful one, at least from the standpoint of the clinical applications of hypnosis. Trance is here defined as a waking state in which the subject's attention is detached from his or her immediate environment and is absorbed by inner experiences such as feelings, cognitions and imagery.

It is useful for therapeutic purposes to distinguish between 'inner experiences' that are consciously driven (that is, effortful,

verbal, reality-based, etc.) and those that are less so (not goal-directed, not concerned with immediate realities, creative, involving spontaneous imagery, etc.), the latter type being more associated with therapeutic trance experience.

The state of mind here identified as 'trance' is traditionally achieved by the process of 'hypnotic induction' administered by the hypnotist. Typically the induction of hypnosis consists of a series of suggestions that direct the subjects to relax and to become absorbed in inner processes, as described above, and to let immediate realities and concerns become part of the background of their experience. Common methods of induction are progressive muscular relaxation and guided imagery. Many therapists include a procedure such as arm levitation, which allows the patient to experience automatic responding. The later stages of this manoeuvre are termed 'deepening'. Note that during this process the hypnotist does not 'become part of the background'; subjects must attend to the hypnotist and allow him or her to guide and orchestrate the content of their subjective inner world. However, during self-hypnosis, subjects go through the process under their own direction.

Further properties of trance, as defined above, have been determined by empirical research and include the following which, though not guaranteed, may be said to have an increased probability of occurrence due to trance:

- i) with regular practice, alleviation of the effects of stress (Benson, 1975);
- ii) alteration in the experience of the passage of time, usually leading to under-estimation (Naish, 2003);
- iii) some amnesia for events which clearly registered because the subject responded overtly to them;
- iv) attenuation of the experience of and increased tolerance of ongoing discomfort and pain.
- v) with physical relaxation, an enhanced predisposition to go to sleep (Anderson *et al.*, 1979).

This description of trance includes everyday daydreaming or meditative states and the aforementioned properties may all be exploited formally or informally for beneficial purposes. Such is obviously the case with property (i); the regular practice of self-hypnosis is a common component of hypnotherapy. Properties (ii) and (iv) are useful in treatments for pain management, either where the pain results from some physical condition or where the patient is undergoing some uncomfortable medical intervention. The possibility of selective amnesia (property (iii)) is occasionally exploited in analytical applications of hypnosis which will be discussed later. Finally, the obvious application of property (v) is in the area of insomnia.

Another, rather more contentious claim is that trance facilitates access to unconscious material – memories, feelings, fantasies and so on – which are normally below the level of conscious awareness but which may nevertheless exert an influence on the patient's behaviour, thoughts and feelings. Evidence for this tends to come from single case illustrations rather than empirical research.

There is in fact a tradition in hypnotherapy of perceiving the unconscious in two ways, firstly in the psychoanalytic manner as a repository of anxiety- and guilt-provoking memories, impulses, conflicts and so on, and secondly as a store of

untapped or under-used strengths and resources which the patient may be assisted in bringing to bear on his or her problem. The latter idea is associated with the late American psychiatrist, Milton Erickson. Other features of this approach are, as in this chapter, a broad definition of trance, and the use of story and metaphor as therapeutic communications by the hypnotist. The latter methods are now popular in the use of hypnosis with children.

A final claim is that during the trance the subject is hyper-suggestible, i.e. is more responsive to the hypnotist's suggestions. This is plausible on the basis that in order to respond to a suggestion, for example that their hand is feeling cold and numb or that they are reliving events of childhood, subjects must focus awareness away from the immediate external surroundings and concerns and concentrate on the suggested ideas and images. Hence, a major purpose of the hypnotic induction in therapy may be to enhance the patient's response to the therapist's suggestions that are to follow. However, laboratory research has now established that the increment in suggestibility observed following hypnotic induction and deepening may be due to enhanced motivation, commitment and expectancy on the subject's part, and any set of instructions that has this effect will suffice to enhance responsiveness to suggestion, even those that call for increased alertness and activity.

Theories of hypnosis

Modern theories of hypnosis have tended to emphasize the importance of one or more psychological processes at the expense of others. One of the major distinctions, however, has been the significance attached to the traditional concept of trance or altered state of consciousness. This controversy has in fact been present since the time of Mesmer, but it was around the middle of the last century that psychologists began to provide detailed accounts of hypnosis, later known as 'sociocognitive theories', which were constructed from concepts provided by mainstream psychology, such as imagination, role enactment compliance, strategic enactment and response expectancy and did not require the assumption that hypnotic subjects were placed in a special psychological state (see 'Expectations and health').

An example of a modern 'state' theory is the dissociated control theory of Woody & Bowers (1994). This hypothesizes that during hypnosis there is a disengagement of the frontal lobe executive control system so that responding becomes more automatic and determined by the suggestions of the hypnotist. An earlier theory that also made dissociation a central mechanism was the neodissociation theory of Ernest Hilgard (1986), which has greatly influenced practitioners of clinical hypnosis. Nowadays there is much greater overlap in the accounts of hypnosis given by prominent theorists and a willingness to acknowledge that multiple processes are involved. A good example of a recent integrative model of hypnosis is that provided by Brown & Oakley (2004).

The clinical application of hypnosis

The above description of hypnosis in terms of trance and suggestion contains most of the ingredients we need in order to develop

therapeutic strategies for a wide range of problems. A traditional hypnotherapeutic intervention consists of the following overlapping stages.

- i) a pre-hypnotic stage of rapport-building, information-gathering, allaying of misconceptions and so on;
- ii) hypnotic induction and deepening which, as was stated earlier, usually consist of suggestions and imagery conducive to relaxation, an internal focus of attention and perhaps the experience of automatic responding;
- iii) the treatment phase, which consists of various kinds of suggestions and imagery, either intended to promote the desired changes in experience and responding or to facilitate access to unconscious processes which may have a bearing on the patient's problem;
- iv) a consolidation phase incorporating post-hypnotic suggestions aimed at reinforcing the therapeutic strategies adopted: this stage often includes a series of positive suggestions of a general nature, intended to encourage a sense of self-confidence and optimism, and termed 'ego-strengthening';
- v) the alerting of the patient and the post-hypnosis phase of enquiry, clarification of the therapeutic work done, recapitulation of instructions for homework assignments and so on.

We may also include as an additional stage the practice of self-hypnosis by the patient between appointments. The purpose of this for patients may simply be to learn to control and alleviate anxiety and tension but they may also be instructed to rehearse suggestions and imagery specific to their problem. For example, migraine sufferers may imagine hand-warming, or smokers or slimmers may repeat self-statements (affirmations) concerning the reasons for their not smoking or over-eating. The self-hypnosis routine may be practised with the aid of an audio-taped recording.

Specific clinical applications of hypnosis

The above format lends itself well to the treatment of a wide range of medical and psychological disorders and there is virtually no problem for which one can confidently assert that hypnosis has no conceivable role. There exist however certain distinctions and constraints which regulate the useful application of hypnotherapeutic procedures.

Firstly, we may draw a distinction between hypnosis intended for direct symptom alleviation as opposed to hypnosis for resolving memories, feelings, conflicts and so on which may underlie the presenting problem. Examples of the former approach, which is often termed 'suggestive', are provided by the use of suggestion and post-hypnotic suggestion, ego-strengthening and self-hypnosis, for problems such as smoking, obesity, social anxiety, medical complaints which may be aggravated by psychological factors (e.g. irritable bowel syndrome, skin disorders and migraine) and painful conditions. We may include here the use of hypnosis to help patients undergo painful or stressful medical or surgical interventions (such as chemotherapy for cancer) and, for the anxious patient, dental treatment and childbirth.

The second approach of hypnosis is termed 'hypnoanalysis' and is based on a rather simplistic dichotomy of the conscious and

unconscious mind. This model has generated a variety of ingenious therapeutic manoeuvres. Examples are the 'uncovering' of material by asking the patient to imagine a theatre stage or cinema screen as a metaphor for 'the unconscious mind' (which, it may be argued, is itself a metaphor), dream suggestion and interpretation, age regression and the use of ideomotor finger signals to denote the responses 'Yes', 'No', 'Don't know', etc. to questions posed by the therapist concerning the possible origins of the patient's problem. Hypnoanalysis may be used for many of the previously mentioned problems, but it tends to be favoured for those in which there is evidence of previous trauma.

A second distinction was made over 20 years ago by Wadden and Anderton (1982) in an influential review of outcome studies using the suggestive approach. These authors contrasted certain problems such as over-eating, smoking and alcoholism with others such as warts, asthma and clinical pain, referring to the former as 'self-initiated' and the latter as 'non-voluntary'. They concluded that the effects of suggestive hypnotherapy for the former were probably largely non-specific and placebo-based (see 'Placebos'). There was, however, good evidence for the specific effects of hypnosis in the treatment of 'non-voluntary' disorders.

We are probably justified in extending the category 'non-voluntary' to a wider range of problems which have a predominantly somatic component and for which we find support in the research literature for the effectiveness of suggestive hypnotherapy (see Heap & Aravind, 2002). Amongst these are certain gastrointestinal disorders such as irritable bowel syndrome and peptic ulceration and eczema. Relaxation and stress control are a substantial component of therapy, but suggestions also target the affected organ or body part. Examples are imagining the warm, healing rays of the sun on the skin in the case of eczema and the release of colonic spasm and the smooth passage of stool in the case of irritable bowel syndrome (see 'Relaxation training'). Whorwell, who has, with his colleagues, undertaken a major study of hypnosis for irritable bowel syndrome (see Gonsalkorale *et al.*, 2003) insists that in the treatment of this disorder, suggestions must focus on bowel activity itself (hence the term 'gut-directed hypnotherapy'): suggestions of general relaxation on their own are insufficient. This claim raises the question of how specifically one can target an autonomic or physiological function by hypnotic suggestion.

Next we may note that it is most appropriate to think of hypnosis not so much as a therapy itself but as a procedure (or a set of procedures) which may be used to augment a broader course of treatment. In fact there is a spectrum of treatments ranging from those where the entire therapy consists of just one or a small number of sessions based on the format outlined earlier, to those where hypnotherapy constitutes a small component of a much more extensive treatment programme. Typifying the former is the single session treatment of warts (induction, deepening, post-hypnotic suggestions of symptom removal, ego-strengthening and de-hypnotising); similarly a single session treatment for smoking cessation. At the other end of the spectrum we see the judicious use of manoeuvres such as age regression and dream suggestion in a course of long-term analytical psychotherapy and the augmentation of a programme of cognitive therapy by hypnotic suggestions and imagery calculated to reinforce the restructuring of maladaptive beliefs and cognitions (Alladin & Heap, 1991; Ellis, 1993).

Contraindications and precautions

It is not easy to define succinctly those occasions when hypnosis should be proscribed. It is generally inadvisable to use it with psychotic patients, although its application here has occasionally been reported. Some caveats concerning hypnosis are applicable to psychological therapies generally, such as the importance of a thorough medical examination, the recognition and treatment of clinical depression and the inclusion of the patient's spouse and family in treatment when they are implicated in the presenting problem. There is concern nowadays about the authenticity of traumatic memories elicited by the indiscreet use of regressive methods, particularly where sexual abuse is claimed. However, probably the most common consequence of misapplying hypnosis is simply time-wasting if a preferred treatment exists, such as in vivo exposure in the case of a phobia or response prevention in the case of obsessive-compulsive disorder (see 'Behaviour therapy' and 'Cognitive behaviour therapy').

Conclusions

In practice, hypnosis is a relatively benign procedure. In the past, its clinical application has suffered through its being uninformed by a rigorous body of academic knowledge and by the unwillingness or incapacity of many practitioners, and indeed authors on the subject, to commit themselves to a proper scientific understanding. There is evidence that this is changing as laboratory evidence on the nature of hypnosis and hypnotic susceptibility accumulates and theory becomes more grounded in mainstream psychology and related disciplines. Reviews of clinical outcome studies for a wide range of disorders have been presented by Heap *et al.* (2001), and Heap and Aravind (2002) as well as for specific purposes such as pain management (Montgomery *et al.*, 2000), weight reduction (Kirsch *et al.*, 1995) and for smoking cessation (Green & Lynn, 2000). This literature confirms that hypnosis provides therapeutic techniques that are simple and of proven efficacy and which can be unreservedly recommended for inclusion in the clinical practitioner's range of therapeutic skills.

Motivational interviewing

Janet Treasure¹ and Esther Maissi²

¹Guy's Campus

²King's College London

Motivational Interviewing (MI) is a directive, patient-centred counselling style that aims to help patients explore and resolve their ambivalence about behaviour change. It combines elements of style, such as warmth and empathy, with technique, for instance, focused reflective listening and the skilful development of discrepancy. A core tenet of the technique is that a patient's motivation to change is enhanced if there is a gentle process of negotiation in which the patient, rather than the practitioner, articulates the benefits and costs involved. A strong principle of this approach is that conflict is unhelpful and that a collaborative relationship between therapist and patient in which they tackle the problem together is essential. The four central principles of MI are shown in Box 1.

Reflective listening is a core skill whereby the therapist encourages patients to explore their thoughts and beliefs by using short summarizing statements which attempt to encapsulate (a) the overt content of the patient's utterance (simple reflection) or (b) the underlying and possibly covert emotional content (complex reflection). Rollnick and Miller (1995) were able to define specific and trainable therapist behaviours that they felt led to a better therapeutic alliance and better outcome. These skills are summarized in Box 2.

The first four items in Box 2 explore the factors that sustain the behaviour and aim to help the patient shift the decisional balance of pros and cons into the direction of change. The last two items cover the interpersonal aspects of the relationship. The therapist provides warmth and optimism, and takes a subordinate, non-powerful position, which emphasises the patient's autonomy and right to choose whether to avail him/herself of the therapist's knowledge and skills.

Motivational therapists need to suppress any propensity they might have to show the 'righting reflex', that is to help solve problems and set things right by giving advice. They need to be flexible

Box 1. The four central principles of Motivational Interviewing

1. Express empathy by using reflective listening to convey understanding of the patient's point of view and his/her underlying drives
2. Develop a discrepancy between the patient's most deeply held values and his/her current behaviour
3. Sidestep resistance to change by responding with empathy and understanding rather than confrontation
4. Support self-efficacy by building the patient's confidence that change is possible

Box 2. The skills of a good motivational therapist

1. Understand the patient's frame of reference
2. Filter the patient's thoughts so that statements conducive of change are amplified and statements that reflect the status quo are dampened down
3. Elicit statements encouraging change from the patient, such as expressions of problem recognition, concern, desire, intention to change and ability to change
4. Ensure that patient is not forced to make premature statements about his or her commitment to change
5. Express acceptance and affirmation
6. Affirm the patient's freedom of choice and self-direction

and have an appropriate balance between acceptance and drive for change towards the desired direction.

Within MI there are special techniques of working with resistance. These are variations on reflective listening, such as 'amplified' reflection, in which the patient's resistance and position is overstated. This works on the assumption that the oppositional tendency of the patient will lead to a withdrawal back to the middle ground. Another approach is to use a 'double-sided' reflection, which highlights the patient's ambivalence. The emphasis is on the individual's autonomy in the matter of change coupled with the therapist holding an appropriate investment in change.

MI helps change behavioural patterns that have become habitual. It works in small doses to produce a large effect. It seems to work by reducing behaviours that interfere with therapy. Patient attributes considered as markers of a poor prognosis, for instance anger and low motivation, are less serious obstacles with MI.

Mode of delivery

Normally MI is a brief intervention lasting for one or two sessions. In various contexts it has also been used as an initial motivational warm-up before other types of treatment, which do not explicitly focus on motivation. Researchers have further adapted MI to suit more specific behaviours and/or research contexts. Motivational Enhancement Therapy (MET) is such an adaptation to MI, which was developed into a manualized four-session therapeutic intervention for alcohol problems (Miller *et al.*, 1992). Similarly, MET has been developed for bulimia nervosa (Schmidt & Treasure, 1997).

MET incorporated, in the context of the Matching Alcoholism Treatments to Client Heterogeneity (MATCH) study, a 'check-up' form of feedback (Project MATCH, 1997). Most recently, motivational techniques have been integrated with cognitive behaviour therapy and used as a combined behavioural intervention.

Theoretical framework for Motivational Interviewing

MI initially started from a basis of clinical empiricism. Empathy, its central principle, and the various forms of reflective listening, are based on Rogers's (1951) client-centred therapy. Through his work with patients with alcohol problems Miller gradually described more accurately the techniques used in MI. The approach has been fine-tuned from the first manual (Miller & Rollnick, 1991) into a second rewritten edition (Miller & Rollnick, 2002). Several theories have been borrowed to provide MI with a research framework, either with regard to its implementation in the clinical context or to its core components.

A theory that has been linked to one of the core elements of MI is cognitive dissonance theory (Festinger, 1957). This is relevant to therapists' encouragement of patients to resolve their ambivalence about behaviour change. Patients are urged to become aware of their dissonant beliefs, feelings and behaviours and are encouraged to reduce the psychological discomfort associated with such a dissonance by changing their behaviours. Bem's self-perception theory (1967) complements aspects of this process by suggesting that once patients start articulating their own beliefs and pro-change arguments, their commitment towards change strengthens as well as their self-efficacy beliefs, i.e. their feeling of being capable of achieving change.

Self-efficacy beliefs and the process of change

The basic principle that underpins most health behaviour models (e.g. Bandura, 1997) is that people hold a range of beliefs about their self, their behaviours, their illness and symptoms. Thus people can be stoical or in denial and neglect themselves and their symptoms. At the other extreme they may display maladaptive illness behaviour and readily adopt the sick role. Most models of health behaviour change include the idea that there are at least two components to readiness to change. These are perceived importance/conviction and confidence/self-efficacy (Keller & Kemp-White, 1997; Rollnick *et al.*, 1999), being encapsulated in the adage 'ready, willing and able' (see 'Self-efficacy and health behaviour'). Importance relates to why change is needed. This concept includes the personal values and expectations that will accrue from change. Confidence relates to a person's belief that they have the ability to master behaviour change. Motivational Interviewing works on both of these dimensions by helping the client to articulate why it is important for them to change and by increasing self-efficacy so that they have confidence to change.

The Transtheoretical Model (TTM) of change is the model most frequently associated with MI. The TTM was developed by Prochaska and co-workers (Prochaska & Velicer, 1997; Prochaska & Norcross, 1994) and it suggests that a person changes by going through a specific sequence of the following five distinct stages: (1) precontemplation ('I am not thinking of changing my

behaviour in the next six months'); (2) contemplation ('I intend to change my behaviour in the next six months'); (3) preparation ('I plan to change within the next month'); (4) action ('I have managed to achieve change from one day up to six months'); and (5) maintenance ('I have not relapsed back to my old behaviour for at least six months') (Prochaska *et al.*, 2002). MI and TTM developed as ideas separately but synchronously. TTM suggested that treatment matched to the stage that a patient is in will be more successful than generic treatments. Two of the core concepts of the TTM are self-efficacy and the cost-benefit analysis pertaining change. One hypothesis drawing from this was that MI might be more useful to those patients who place themselves in the pre-contemplation stage and are hence more resistant to change. Findings, so far, have not supported this hypothesis (Project MATCH, (1997) Treasure *et al.*, 1999; Wilson & Schlam, 2004).

The overall validity of the TTM and, hence its assumed clinical importance, have been criticized by various researchers in the field of behavioural change. With regard to the TTM's relation to MI and MET, there are problems with the stage definition and measurement, their hypothesized distinctness and ability to predict behaviour change following stage-matching according to readiness to change assessments (Sutton, 2001; Weinstein *et al.*, 1998; Wilson & Schlam, 2004; Bandura, 1997). There seems to be no inherent correspondence between TTM and MI or MET (see 'Transtheoretical model of behaviour change').

Resistance to behaviour change

There are two forms of resistance which can impede behaviour change. The first relates to the 'problem' that is being considered and the second to the therapeutic relationship. There may be a conflict between an individual's conceptualization of his or her behaviour and that of family members or society. Thus individuals with drug and alcohol abuse may not see any need to change their behaviour and will have been coerced into treatment by family/friends or statutory agencies. The other source of resistance often relates to unusual representations of helping/parental/authoritarian relationships or to values about individual rights. Individuals possess an inherent intolerance to a perceived lack of choice and can become motivated to do the opposite of what is requested, the so-called 'reactance'. The propensity to this response lies on a dimension with the poles ranging from oppositional to compliant behaviours. Patients who are prone to resistance are those with high levels of anger, aggressiveness and impulsivity and those with a need for control and with high levels of avoidance.

The effect of resistance in therapy has been reviewed in several studies (Beutler *et al.*, 2002). Resistance, which is marked by anger or defensiveness in therapy, is associated with a poor outcome to therapy. MI has an explicit focus on resistance in therapy.

Evidence on the effectiveness of MI

MI and its adaptations have been evaluated in the contexts of various problematic behaviours and study designs. The diversity of these applications and the research quality make it difficult to combine findings meta-analytically and assess the mechanisms through which MI brings about change.

MI has been found to be effective for different forms of health behaviour change (Dunn *et al.*, 2001). Adaptations of MI have been found to be more effective than no treatment or placebo and as effective as other active treatments for people with problems related to alcohol, drug abuse, diet and exercise, diabetes, hypertension and bulimia. Mixed results have been found for its efficacy in smoking and HIV-related risk behaviours (Burke *et al.*, 2003).

In the most recently published meta-analysis of 72 clinical trials (Hettama *et al.*, 2005) where MI and its adaptations were tested across a range of contexts and behaviours, MI was found to have a good effect early (average between-group effect size was equal to 0.77) but the effect diminished at 12-months follow-up (average effect size was about 0.30). In studies where MI was added to a standard/specified treatment, the effect size was either stable or it increased over time, being on average about 0.60.

Exploring the predictors of MI outcome

The process of change within MI interventions has been studied in order to highlight its key and necessary strategies. It has been demonstrated that the style of the therapist's interaction is a critical component in facilitating change (Miller, 1995).

Therapists differ in their adherence to the principles of MI. Within Project MATCH, in which there was intensive training and monitoring to ensure equitable delivery between therapists, therapist effects on outcome persisted even after controlling for the effects of other variables.

Empathy, demonstrated as accurate reflective listening, is a strong predictor of therapist efficacy. Other elements, which are more difficult to measure, include a stance that communicates belief in the patient's innate abilities and judgement. Thus the role of the therapist is to respect the patient and to hold an optimistic concept of the patient's potential for 'goodness' (i.e. high self-esteem and self-efficacy) and to help the patient work within this framework. The therapist needs to be able to be able to flexibly shift between acceptance and change. Therapist expectancies for patient change have been found to influence patient adherence and outcomes.

A low level of resistance within the session seems to predict behaviour change also (Miller *et al.*, 1993). Resistance often arises in the presence of confrontation. When therapists behave in a way that minimizes resistance, change is more likely to ensue. An increase in the rate of change of 'self-motivational statements', i.e. utterances by the patient that express interest and/or intent to change, is associated with behaviour change. Motivational feedback using the 'drinker's check-up' instrument was compared with a standard approach based on confrontation. The outcome, in terms of drinking one year later, was worse in the group of patients who were given confrontational feedback (Miller *et al.*, 1993). In a further study it was found that if the motivational feedback of the drinker's check-up was given as an initial intervention prior to entry into an in-patient clinic, it led to an improvement in outcome (abstinence rates doubled 57% vs. 29% 3 months after discharge). The therapists (unaware of group assignment) reported that patients given this intervention had participated more fully in treatment and appeared to be more motivated (Brown & Miller, 1993;

Bien *et al.*, 1993). A dose-effect via the delivery of MI-based adaptations, rather than 'pure' MI, and the effectiveness of MI when used as a therapy prelude seem to result in better study outcomes. This, however, is an area that needs more carefully designed future research.

One randomized trial of manual-guided one-session MI for drug abusers failed to replicate the positive results found in the pilot study (Miller *et al.*, 2003). The explanation for this was found when the transcripts of the MI session were analyzed (Amrhein *et al.*, 2003). The need to complete the process of commitment to change within one session interfered with the development of the patient's motivation and some therapists, despite patient resistance, were moving ahead of their patients in an attempt to adhere to the study protocol and the manual.

Training in Motivational Interviewing

Training courses in MI are often relatively short (two to three days). Miller and Mount (2001) evaluated the effectiveness of a two-day training workshop in MI by studying samples of practice before and after the training. They found statistically significant changes in counsellor's behaviours consistent with the principles of MI, but these changes were not large enough to make a difference for patients. Patients did not change either in their resistance levels or in the frequency of expressing commitment to change. Thus, continued practice, regular supervision and monitoring are needed in addition to two to three-day training workshops to attain and maintain standards. Instruments to measure therapist adherence to MI principles are being developed. Two of these are currently available: The Motivational Interviewing Skill Code (MISC) and the Motivational Interviewing Treatment Integrity code (MITI) (<http://casaa.umn.edu/tandc.html>).

Conclusion

Motivational Interviewing (MI) is a style of therapy that has many applications within general medicine. It is particularly helpful for use in settings where patients show resistance to change. The principles are simple but practice is less easy, and stringent quality control is needed to ensure that therapists adhere to the spirit of the therapeutic process. However, once the overall skill is integrated, honed and maintained it can be adapted to many situations. Practitioners can be flexible in their use of MI-based interventions; they can use this style particularly with patients who are ambivalent about change and later shift to a style of therapy informed more by cognitive and behavioural techniques when the person is committed to change. This is where the art and judgement of therapy come into play. People do not simply switch into a stable motivational state. A sensitive and empathic therapist will know when to move from a skills-based approach into a more motivational stance. Unfortunately, time-limited and/or manualized therapy does not lend itself to such an approach. There always needs to be room for flexibility to adjust for individual differences in the readiness to change, as this is a psychological state that fluctuates within and between therapy sessions.

Existing theories about behavioural change, and specifically the Transtheoretical Model of behavioural change, do not provide

a solid framework for MI. Some components of MI have been associated with the cognitive dissonance theory and the social perception theory. Variability exists in the efficacy of MI and its adaptations across studies (even in the same behavioural problem domain) and across therapists. Future research should be directed towards conducting well designed and clinically-based randomized controlled trials. This will shed more light on the effectiveness of MI in various contexts, and help us

understand what its 'active ingredients' and the exact predictors of outcome are.

Neuropsychological rehabilitation

Barbara A. Wilson

MRC Cognition and Brain Sciences Unit

Introduction

Neuropsychological rehabilitation is concerned with the assessment, treatment and recovery of brain-injured people and aims to reduce the impact of disability and handicapping conditions and, indirectly, to improve the quality of life of patients.

For the most part, neuropsychological rehabilitation concentrates on cognitive and emotional deficits following brain injury, although physical, social and behavioural disorders are also addressed. It can therefore be distinguished from cognitive rehabilitation in that it encompasses a wider range of deficits.

Modern rehabilitation of brain-injured people probably began in Germany during World War I as a result of improvements in survival rates of head-injured soldiers (Goldstein, 1942). Goldstein stressed the importance of cognitive and personality deficits following brain injury, and described principles which are almost identical to those used in current neuropsychological rehabilitation. A further impetus to neuropsychological rehabilitation came during World War II, with developments in Germany, the UK, the Soviet Union and the USA (Boake, 1989, Prigatano, 1986). An important paper by Zangwill (1947) discussed principles of re-education and referred to three main approaches – compensation, substitution and direct retraining.

At the same time, Luria and his colleagues were treating head-injured soldiers in the Soviet Union, and describing their activities (Luria, 1979). These early papers by Zangwill and Luria still provide a rich source of ideas for contemporary neuropsychologists interested in rehabilitation.

Recent developments in neuropsychological rehabilitation

There have been a number of changes in the practice of neuropsychological rehabilitation over the past 15 or so years. There are five changes that would appear to have been particularly influential: (1) rehabilitation is now seen as a partnership between patients, families and healthcare staff; (2) goal setting is now well established as a means of planning rehabilitation programmes; (3) there is general recognition that cognition, emotion, social functioning and behaviour are interlinked and should all be addressed in the rehabilitation process; (4) there has been an increase in the use of technology to help people compensate for their difficulties; and (5) there is a greater acknowledgement that rehabilitation requires a broad theoretical base; no one theory, model or framework is sufficient to address all the problems faced by people with neuropsychological deficits.

Rehabilitation as a partnership

Over the past 10–15 years, patients and families have become increasingly involved in making decisions about rehabilitation. Gone are the days, in most brain injury rehabilitation centres, when doctors, psychologists, therapists and nurses decided what patients would do, achieve or work on during rehabilitation. Instead, patients together with their families and healthcare staff discuss the aims and goals of rehabilitation and negotiate these. This partnership is reflected in McLellan's (1991) definition of rehabilitation as a two-way interactive process between the disabled person and others to achieve their optimum physical, psychological, social and vocational wellbeing.

Goal setting as a means of planning rehabilitation programmes

Goal planning has been used in rehabilitation for a number of years with various diagnostic groups including people with cerebral palsy, spinal injuries, developmental learning difficulties and acquired brain injury (McMillan & Sparkes, 1999). Because goal planning is simple, focuses on practical everyday problems, is tailored to individual needs and avoids the artificial distinction between many outcome measures and real life functioning, it is used increasingly in rehabilitation programmes.

Houts and Scott (1975) and McMillan and Sparkes (1999) put forward several principles of the goal planning approach. First, the patient should be involved in setting his or her goals. Second, The goals set should be reasonable ones and client centred. Third, they should describe the patient's behaviour when a goal is reached. Fourth, they should spell out the method to be used in achieving the goals in such a manner that anyone reading the plan would know what to do. In addition, goals should be specific and measurable and have a definite time deadline. In most rehabilitation centres, long-term goals are those which the patient or client is expected to achieve by the time of discharge from the programme while short-term goals are the steps set each week or fortnight to achieve the long-term goals.

Cognition, emotion, social functioning and behaviour are interlinked (the holistic approach)

Although cognitive problems are among the most handicapping for brain-injured people, they are not generally seen in isolation. Emotional and behavioural problems are common, and may indeed worsen over time. Depression, anxiety, irritability and aggression may all occur. Social isolation is often reported by

brain-injured people and their families. Different personality characteristics and pre-morbid lifestyles may exacerbate or diminish the relevance of current problems for everyday functioning, and may influence the effectiveness of rehabilitation.

Such a multitude of sequelae following brain injury has led to the development of holistic approaches whereby rehabilitation programmes attempt to deal with the 'whole person'. The original holistic neuropsychological rehabilitation regime for brain-injured people appears to be that of Ben Yishay and his colleagues in Israel in 1974 (Prigatano, 1986), with a few others following Ben Yishay's model elsewhere in the USA and in Europe.

Major themes of these programmes include the development of increased awareness, acceptance and understanding, cognitive retraining, development of compensatory skills and vocational counselling. Evidence is provided of increased self-esteem among patients, reduction in anxiety and depression and greater social interaction (Ben Yishay & Prigatano, 1990).

Increasing use of technology in neuro-rehabilitation

In the early part of the 1980s there was considerable excitement concerning the use of computers, which were expected to revolutionize cognitive rehabilitation. It was thought they would assist neuropsychologists with assessment, monitoring treatment effectiveness and retraining. Numerous software programmes appeared, despite the fact that they were not subjected to controlled investigation at that time. Robertson (1990) published a review of computerized rehabilitation and focused on programmes for language, memory, attention, visuo-perceptual and visuo-spatial disorders. His concern was with adults with non-progressive, acquired brain damage, so he excluded computer programmes used for assessment, recreation, teaching aids, or prosthetic devices. He found no evidence that computerized memory, visuo-perceptual or visuo-spatial training produced significant changes in cognitive functioning. Language training programmes fared a little better, although there was no published evidence for general effectiveness of computerized language training. Only in attention training were there some positive results, although even here the evidence was contradictory. Since Robertson's (1990) review, further studies of computerized attentional training programmes appear to support the tentative evidence from the 1980s that they can be effective.

Already useful as prosthetic devices for people with language or physical impairments, computers are likely to play more important roles in other areas of cognitive disability. For example, they could be used as aids in activities of daily living by providing series of cues to guide patients through the steps needed to perform practical tasks such as cooking, janitorial activities or money management. Kapur *et al.* (2004) point out that computers have great power for storing and producing on demand all kinds of information relevant to an individual's functioning in everyday life.

Another area of current interest is in the use of computers as memory aids. Much of the work in memory rehabilitation involves teaching people to compensate for their impairments by employing aids such as diaries, tape recorders and electronic organizers. Work in this area of rehabilitation is difficult, however, because remembering to use an aid is in itself a memory task that

brain-injured people may forget to employ. Additionally, memory-impaired people will probably experience great difficulty in learning to programme an electronic or computerized aid or they may use them in unsystematic and inefficient ways. Kapur (1995) discusses a number of external memory aids and suggests ways of teaching their use. Wilson *et al.* (2001) report on one particular computerized memory aid, NeuroPage[®], developed by a neuropsychologist, Neil Hersh and Larry Treadgold, the engineer father of a head-injured son. NeuroPage[®] is a simple and portable paging system with a screen that can be attached to a waist belt. The system uses an arrangement of microcomputers linked to a conventional computer memory and, by telephone, to a paging company. The scheduling of reminders or cues for each individual is entered into a computer and from then on no further human interfacing is required. On the appropriate date and time, the reminder is transmitted to the individual, and all that person has to learn is to press one fairly large and obvious button on receipt of the signal. A randomized control trial of the system in which people were randomly allocated to a pager first or to a waiting list first, showed that the pager significantly reduced the everyday failures of memory and planning in people with brain injury. More than 80% of those who completed the trial were significantly more successful in carrying out activities such as self-care, self-medication and keeping appointments when using the pager compared with the baseline period.

Neuropsychological rehabilitation requires a broad theoretical base

People surviving brain injury are likely to have several cognitive problems including attention, memory and planning problems and they are likely to have additional non-cognitive problems such as anxiety, depression and social skills deficits. Consequently, it is unlikely that any one model, theory or framework can address all of these difficulties and neuropsychological rehabilitation requires a broad theoretical base (or several theoretical bases). A theoretical model can be regarded as a representation that may help to explain and increase our understanding of related phenomena. They vary in complexity and detail, ranging from highly complex computer-based structures such as connectionist models of brain damage through to simple analogues that assist in the explanation of relatively complex situations like comparing memory storage to various library systems (Baddeley, 1992).

In rehabilitation, models are useful for facilitating thinking about assessment and treatment, for explaining deficits to therapists and relatives and for enabling us to conceptualize outcomes. No one model can answer all our questions, deal with all the complexities of treatment and management or address all the needs of patients and families. Wilson (2002) attempted to integrate many of the existing models that are useful for neuropsychological rehabilitation into a comprehensive model of rehabilitation. This synthesis of models that have influenced rehabilitation including models of cognitive functioning, emotion, learning, personality, recovery and others. In order to understand which parts of the synthesized model were most used by practising psychologists engaged in neuropsychological rehabilitation, a questionnaire was designed and sent to psychologists working in brain injury rehabilitation. Psychologists were asked to confirm all the

components of the model that they assessed in their practice, e.g. personality, cognitive functioning, emotion, behaviour and to provide further comments. Approaches to treatment were also surveyed.

Forty-five people responded. Some of the main results are summarized. One hundred per cent of the respondents said they tried to find out about patients' likes and dislikes and the same percentage said that they employed a goal-setting approach. All but two said they assessed pre-morbid personality and all but three said they assessed present personality. The most frequently used treatment approaches derived from models of cognitive behaviour therapy, (67%) cognitive neuropsychological theory (37%) and behavioural models (24%) (see 'Behaviour therapy' and 'Cognitive behaviour therapy'). Psychodynamic models were only used by 3% of respondents (see 'Psychodynamic psychotherapy'). Most practitioners tried to reduce disabilities and handicaps rather than impairments. They made use of several strategies to do this, with the most frequent being compensatory techniques, making use of residual skills and restructuring the environment (between 90 and 100% using these) Restorative approaches and attempts at anatomical reorganization were rarely used.

Practising psychologists in rehabilitation use a range of theoretical models and approaches in their clinical work, confirming the view that we need a broad theoretical base when dealing with the complex problems faced by people with brain injury.

Conclusions

Neuropsychological rehabilitation has reached an exciting stage of development with a worldwide growing interest in the subject as reflected in numerous conferences, debates, books and papers in journals relevant to the field. This interest has been stimulated by scientific research, on the one hand, and by improved and more sophisticated clinical practice, on the other. A wide range of methodologies is available to practitioners of neuropsychological rehabilitation, including those from cognitive neuropsychology, learning theory, developmental psychology, linguistics and, more recently, connectionist modelling. It is to be hoped that a recent comprehensive model of neuropsychological rehabilitation will inform psychologists and therapists working in the field and lead to even more improvements. (See also 'Neuropsychological assessment' and 'Head injury').

Pain management

Stephen Morley

University of Leeds

The term pain management applies mainly to chronic pain rather than acute pain. In its broadest sense it includes a range of physical (e.g. spinal cord stimulation) and pharmacological (e.g. opioid drugs, intrathecal pumps, facet joint injections) as well as psychological interventions. Although the purpose of physical interventions is to reduce the intensity, frequency and duration with which pain is experienced, the overall aim of pain management is to ameliorate the experience of pain in its broadest sense rather than to eradicate it. Acute pain, such as postoperative pain, is expected to have a self-limiting time course and treatments are primarily directed at preventing its occurrence or reducing the magnitude of experienced pain during this period of time. This approach has been transferred to many medical treatments of chronic pain (such as those listed above) but while the elimination of pain is a worthy goal for chronic pain sufferers it is generally not possible with our present understanding of the neurobiology of chronic pain. By definition chronic pain is longstanding, usually defined as greater than six months but often many years. Most sufferers will have received a wide range of pharmacological treatments without experiencing complete relief. When pain persists over a period of time its impact becomes widespread, it needs to be considered as a multifaceted construct and its treatment is necessarily more complex. This chapter is therefore concerned primarily with psychological approaches to this problem.

Chronic pain as a construct

In order to understand psychological approaches to pain management, it is necessary to examine the contemporary psychological analysis of pain. This analysis conceptualizes pain as a meta-construct: a set of inter-related components none of which uniquely defines pain. Moreover, each component is itself a complex construct and the subject of scientific and clinical investigation. The experimental analysis of these components has developed considerably in recent years but many problems remain. As a result of this, psychological treatments are only partly based on a fully rational analysis of the problem.

The main biological elements underpinning the experience of pain are nociception, transmission and modification of nociceptive inputs and the central representation of pain in the brain. Pharmacological and physiological therapies (neurostimulation) are all directed at these elements. Although many biological pain processes are not directly addressed by psychological treatments, treatments such as relaxation training and biofeedback are directed at some physiological responses to painful stimuli e.g. increased muscle tension and sympathetically mediated responses (see 'Relaxation training' and 'Biofeedback').

For acute somatic pain there is good evidence that the immediate experience of pain is correlated with basic neurophysiological parameters (Price, 1999). Current thinking considers the primary experience of pain to comprise two inter-related dimensions; a sensory-intensity dimension characterized by the sensory quality of the pain (reflected by descriptors such as 'throbbing' and 'shooting') and a primary affective dimension (reflected by descriptors such as 'unpleasant' and 'agonizing'). The relationship between neurophysiological parameters and immediate pain experience in chronic pain is not well established but the same sensory-intensity and affective experiences are present. However the persistence of pain leads to a more complex range of emotional experiences as would be expected when a person is forced to re-evaluate him- or herself in the face of an adverse experience. The main emotional states observed in chronic pain patients are frustration, anxiety and depression. Understanding what shapes individuals' emotional responses to persistent pain is an important topic of contemporary research, with relevance for the development of treatments (Asmundson *et al.*, 2004; Banks & Kerns, 1996).

Chronic pain is also associated with marked cognitive changes. The phrase 'cognitive' is used broadly to refer to a wide range of psychological phenomena, including a person's attitudes and beliefs about pain as well as more fundamental appraisal mechanisms which incorporate attention, perception and memory processes. It also refers to the mental activity in which people engage while experiencing pain. Current research indicates that certain types of activity, such as thinking about catastrophic outcomes (catastrophizing) intensify the experience of pain and distress (Sullivan *et al.*, 2001). Not surprisingly catastrophizing is a major target for intervention in therapy.

Acute pain is often associated with distinct behavioural acts; the sudden reflex withdrawal from the pain stimulus, para-vocalizations and changes to facial expression. When pain persists the behavioural consequences become greatly elaborated and may include persistent verbal complaints and expressions of pain, postural changes, use of mobility and support aids, reduction in the general activity level, increased medication consumption and a range of other placatory behaviour. Psychological theorizing has applied the concepts of classical and operant conditioning in the analysis to behaviour associated with pain. It is important to note that behavioural activity is a public event and it is therefore subject to modification by social reinforcement contingencies. This process has been invoked to explain variation in pain behaviour between individuals and is also applied therapeutically. The major behavioural treatment is concerned with analysis of the contingent relationship between pain and behaviour and the subsequent modification of the contingencies (Fordyce, 1976; Sanders, 2002).

Finally, we must consider the social context in which pain occurs. Factors known to influence several aspects of pain include the age and gender of the person, family characteristics, culture and the behaviour of professionals and carers. These may all be important when considering treatment options (Morris, 1998). In addition to these features there are influences from work and employment status and, in some cases, the legal status of the person, i.e. whether compensation claims are pending.

Implications

This brief résumé indicates the breadth of factors considered by psychological approaches to pain. It may be useful to simplify the complexity surrounding chronic pain if we construe it as comprising three major components; interruption, interference and identity. A primary feature of pain is to interrupt ongoing behaviour and cognitive activity on a moment by moment basis. The extent of the interruption is related to the intensity, novelty and threat value of the pain. Patients with chronic pain have constantly to manage this interruption and to incorporate it into their daily functioning. Interruption can also lead to interference with behaviour that has a visible impact on the pain sufferer. Patients with chronic pain frequently report high levels of frustration attributable to their incapacity to complete normal behavioural routines or to complete them in an acceptable timescale. For example, even dressing can be a major source of frustration. The degree of interference with life is reflected in the extent of disability reported by patients. Finally when interference occurs in many behavioural activities, or in particularly important ones, then pain has the capacity to impact on a person's identity i.e. his or her sense of who s/he are and perhaps more importantly who s/he might become (Morley & Eccleston, 2004). It is at this level that we can understand the suffering caused by chronic pain (Chapman & Gavrin, 1999).

Not all treatments embrace all the factors. Medical treatments are primarily targeted at reducing the interruptive impact of pain by moderating the sensory-intensity and primary affective responses to pain. Psychological treatments may also target interruption e.g. attention management. They more frequently attempt to modify the extent of interference by increasing meaningful behavioural activity and coping strategies. More recent work on acceptance is clearly targeting identity as a significant focus for treatment (McCracken *et al.*, 2004).

Psychological treatments in pain management

Psychological approaches to pain management are multimodal, presenting the patient with a series of interventions throughout treatment. Meta-analytic reviews of the psychological management of pain (Morley *et al.*, 1999) and of multidisciplinary approaches incorporating substantial psychological components (Flor *et al.*, 1992), testify to the effectiveness of psychological approaches to pain management.

Psychological management is characterized by several features which are common to treatment programmes despite variations in their content. Psychological treatments require the active engagement of the patient. Rather than being a passive recipient of a treatment delivered by a professional the patient is explicitly assigned

personal responsibility for the planning and implementation of treatment. The initial assessment phase provides the therapist with information about the patient's understanding of his or her pain and an assessment of his or her attitudes, beliefs and cognitive state. The assessment also provides the therapist with an educational opportunity to both give information about chronic pain and begin to help patients to elaborate alternative ways of construing their experiences. Emphasis is placed on the co-variation between psychological states and the experience of pain. For example, patients are frequently required to keep pain diaries to help them discover the reciprocal influences between events, their mood, behaviour and pain. Psychological management also requires patients to set specific goals for treatment and specify ways in which they may be achieved. In the case of chronic pain, goal setting often requires the patient to shift from unrealistic outcome expectations of 'no-pain' to expectations that they will be able to manage their pain, so that its impact on their life is reduced. The aim of assessment is to elaborate the patient's view of pain and in doing so help them generate a range of treatment options which they will be able to apply outside the clinic. Psychological management therefore explicitly considers how treatments may be generalized and maintained out of the clinic and over a prolonged period of time.

Education

Education always forms a part of multidisciplinary pain treatment programmes and good practice incorporates this element during the assessment phase. The educational process is active and requires patients to reflect on their own understanding of pain. The educational component of treatment is an integral part of contemporary psychological management (Turk, 2002) and serves to engage the patient as an active collaborator in the process of treatment.

Relaxation and biofeedback

There are two broad classes of treatments; biofeedback and relaxation, which are aimed at modifying a biological aspect of pain. In biofeedback physiological signals (e.g. Electromyography (EMG), skin temperature) are processed and displayed as auditory or visual information to the patient. The patient is instructed to attempt to change a feature of the display in a direction corresponding to the required change in physiological functioning. For example, the pitch of an auditory signal might correlate with EMG activity, so that reduction in EMG will be reflected by a lowering of pitch. Biofeedback has been extensively investigated as a standalone treatment over 30 years (Arena & Blanchard, 2002). There is substantial evidence that it can be effective in the treatment of a variety of painful disorders, e.g. headache. Recent reconsideration of biofeedback as a treatment has been stimulated by experimental analysis of chronic pain problems which has identified specific peripheral dysfunctions hypothesized to be responsible for nociceptive input. For example (Flor & Birbaumer, 1993) treated patients with low back pain and temporomandibular pain with EMG biofeedback derived from the appropriate paraspinal or facial muscles. Their data indicated that biofeedback training was more effective than a relatively brief cognitive-behavioural programme and standard, conservative, medical treatment.

Biofeedback may also be used non-specifically to help induce a general state of relaxation. Relaxation is a widely used component of psychological treatment packages. The primary purpose of relaxation is to reduce the psychophysiological arousal frequently associated with pain. It is also frequently taught as a coping resource which patients can use at times of heightened pain and distress. Biofeedback procedures are not generally necessary as there is a range of relaxation procedures (active progressive relaxation, autogenic training and varieties of breathing exercises) which are relatively easily applied within a clinical setting (see 'Relaxation training' and 'Biofeedback').

Attention management

Methods designed to modify attentional focus are frequently incorporated into cognitive-behavioural pain management programmes and presented as part of a relaxation strategy. The rationale for this approach is a widely held view that the content of conscious awareness is determined by a limited capacity channel with attentional mechanisms controlling which aspects of a person's external and internal environment enter into consciousness (Cioffi, 1991). Pain may be considered as a stimulus which vies for finite attentional resources. The purpose of treatment is therefore to teach patients to switch attention to other sources of stimulation or to change the interpretation placed on the current focus of awareness. For example, a patient may be taught to construct a vivid mental image which includes features from a number of sensory dimensions, e.g. cutting a lemon and squeezing a drop of the juice onto the tongue. The elaborated sensory features of this image compete with the painful stimulus and reduce its impact. Alternatively, the patient may be encouraged to alter the focus of their attention to the pain without switching attention away from the pain. In this instance, the subject may be asked to focus on the sensory quality of the pain and transform it to a less threatening quality (Morley *et al.*, 2004). While these procedures are undoubtedly popular, empirical evidence for their effectiveness is difficult to obtain (Eccleston, 1995). On balance, it would appear that attention switching/distraction strategies do have a role to play in the management of pain although it is probable that they are most effective at low to medium levels of pain intensity (Jensen & Karoly, 1991). Hypnotic methods may also be employed to modify the subjective experience of pain (Syrajala & Abrams, 2002).

Cognitive-behavioural strategies

Cognitive-behavioural strategies are predicated on the hypothesis that it is a person's interpretation of events rather than the events themselves which determines the subjective experience and behavioural response to the event. In the context of pain the critical determinants of individuals' emotional and behavioural adaptations to the pain are their thoughts (appraisals, expectations and beliefs about the origin and consequences of the pain), rather than the nociceptive and biological events per se. Cognitive-behavioural methods seek to modify a person's thinking about pain, and in doing so to change their pattern of adaptation to it. The central technique of cognitive-behavioural strategies is the identification of the sequence of thoughts and actions exhibited during painful episodes. A common content of patient's mental activity is

'catastrophizing', the expectation of worst-state outcomes (Sullivan *et al.*, 2001). These and other dysfunctional methods of thinking about pain can be modified by a set of techniques which include cognitive challenges to the belief, provision of alternative ways of construing events (retribution) and self-instructional behavioural experimentation with alternative adaptive coping responses. Treatment is through guided rehearsal under the supervision of a therapist with subsequent monitoring and modification as patients introduce the methods into their daily lives (Hanson & Gerber, 1990; Keefe *et al.*, 2002; Turk, 2002) (see 'Cognitive behavioural therapy').

Behavioural

Behavioural approaches to pain are directed at modifying pain behaviour rather than the subjective experience of pain. Pain behaviour includes maladaptive postural changes, excessive resting and dysfunctional rest-activity cycles. The application of principles of operant behaviour modification has been paramount in the development of behavioural treatments (Fordyce, 1976; Sanders, 2002). Frequent targets for intervention are patients' activity levels (physical fitness), medication intake and social interactions with family members. Behavioural assessment identifies the events which precede (discriminative stimuli) the target pain behaviour and the consequences of the behaviour (the reinforcers). Treatment consists of manipulating the contingencies between these events in order to decrease non-functional responses and increase positive adaptive ways of behaving. Features of behavioural treatments include graded programmes to increase exercise and alter the contingent relationship between exercise and pain; modification of social reinforcement given by solicitous spouses and family members; and modification of the contingencies between pain and medication intake. Behavioural treatments have been frequently delivered as inpatient programmes as this allows the treatment environment to be carefully controlled. A behavioural approach to pain also implies that it is necessary for family members to change their behaviour towards the patient. The typical pattern of behaviour between spouses is described as 'solicitous'; the patient's partner is unduly attentive and responsive to signs of pain thereby positively reinforcing patterns of rest and non-participation in family and household activity. Family members are therefore, frequently involved in treatment programmes (Kerns *et al.*, 2002) (see 'Behaviour therapy').

Evidence of effectiveness

There is good evidence for the effectiveness of psychologically based treatment for chronic pain problems. Morley *et al.* (1999) reported a systematic review and meta-analysis of the extant published randomized controlled trials. The trials were characterized by marked heterogeneity in a number of respects: (1) the clinical diagnoses of patients included low back pain, osteo- and rheumatoid arthritis, fibromyalgia, upper limb pain and several trials with patient groups with mixed diagnoses; (2) nearly all trials used multiple outcome measures; (3) many trials used more than a simple comparison between a treatment and control group; (4) the trials reported using a wide range of treatment components, while one

or two trials used a single treatment such as biofeedback, most used treatments comprising a number of the components described earlier.

Morley *et al.* (1999) dealt with the problem of heterogeneity in the data in several ways. First, they grouped the outcome measures into domains of measurement; these included many of the concepts described earlier in the chapter, e.g. pain experience, mood and affect. Secondly, they carried out two sets of analyses; in the first they compared active psychological treatments, i.e. those treatments that included one or more of the treatment components described earlier (with the exception of education when delivered alone) with waiting list control groups. In the second analysis they compared active psychological treatments with active control groups such as patients receiving treatment as usual or patients on an active educational programme. A summary of these analyses is shown graphically in Figure 1. These figures display the average effect sizes and their 95% confidence intervals for the two sets of comparisons for each of the measurement domains. The upper panel clearly shows that when considered as a class of treatments (CBT-) cognitive behaviour therapy-based treatments are effective compared with a waiting list control treatment. The lower panel indicates that, on average, CBT-based treatments are at least as effective as other active treatments across the range of measures. In no case was CBT significantly worse than the controls and for several measurement domains it was slightly better.

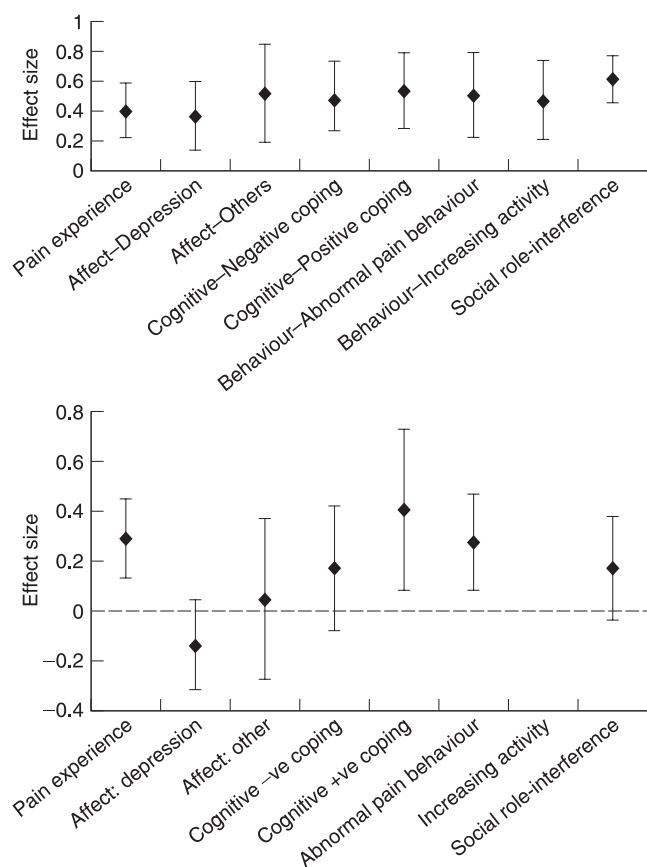

Fig 1 Effect size values for measurement domains (from Morley *et al.*, 1999). The upper shows the effect size values when active CBT is compared with waiting list controls; the lower panel the effect size values when CBT is compared with other active treatments.

Future developments and conclusions

Several additional randomized controlled trials (RCT) of CBT-based treatments for chronic pain have been published since Morley *et al.*'s (1999) review and these generally provide support for the effectiveness of CBT-based treatments for chronic pain management. However the complex multi-component treatment and its multiple outcomes means that it is difficult to discern if different aspects of therapy are responsible for different outcomes and it is not clear whether current treatment is optimal for all patients with chronic pain. In part, this is attributable to the rather general and imprecise way in which the problem of chronic pain has been construed (Morley & Williams, 2002).

Several strands of current research are tackling this problem. One approach has been to identify groups of patients who appear to be psychologically similar and to customize treatment for particular profiles. This line of research has been stimulated by Turk *et al.* (Turk, 2005) who have consistently identified three groups; 'adaptive copers', 'dysfunctional' and 'interpersonally distressed'. These groups have been replicated across research groups in North America, Europe and Oceania and they are found independently of medical diagnoses. There is a small amount of evidence that they respond differently to a standard pain management programme but as yet there is no compelling evidence for a specific treatment by group interaction.

A second approach has been to develop a more precise model of chronic pain with an explicit intervention targeted at particular sub-group of patients. Vlaeyen and Linton (2000) have described a fear-avoidance model which applies to a section of the chronic pain population. These patients are excessively fearful of activity because they believe that movement will result in some catastrophic outcome e.g. a broken back. Vlaeyen and his colleagues have obtained experimental evidence for the elements of this model and preliminary case series have demonstrated a treatment called graded exposure based on well validated fear reduction principles is effective (Vlaeyen *et al.*, 2001). A randomized controlled trial is now being performed.

The fear-avoidance model does not apply to all chronic pain patients and other models may be developed to account for different aspect of pain. Recently, Vlaeyen and Morley (2004) have considered how to account for the development of pain in people who appear to persist rather than avoid when faced with pain. They have suggested an approach based on the phenomenon of stop-rules. This approach also incorporates the fear-avoidance model and appears to account for some observed anomalies in the fear-avoidance model. Other researchers have begun to apply general models in clinical health psychology in an attempt to optimize treatment outcome. A number of researchers have applied the transtheoretical model of behaviour change (see 'Transtheoretical model of behaviour change') (Dijkstra, 2005) while others have developed motivational interviewing protocols to preparing patients for pain management programmes (Jensen, 2002; Jensen *et al.*, 2003). Finally, considerable effort has been invested in trying to identify those at risk for the development of chronic pain (Linton, 2002) and to devise interventions that might prevent chronic pain.

Physical activity interventions

Michael Ussher

St. George's, University of London

Introduction

Sedentary lifestyles are a global public health problem (World Health Organization (WHO), 2004). Those who are physically inactive have an increased risk of premature death and of developing major chronic diseases; including coronary heart disease, cancers and diabetes (Baumann, 2004). Physical activity (PA) refers to any bodily movement resulting in energy expenditure (Caspersen, 1989) and includes routine activities such as walking and housework, as well as structured exercise, sport and occupational activity. For general health benefits, it is recommended that adults accumulate a total of at least 30 minutes a day of at least moderate intensity PA on five or more days a week (Department of Health (DOH), 2004). Children are advised to accumulate at least 60 minutes of at least moderate intensity activity every day (DOH, 2004). Over the last 20 to 30 years PA levels have declined, largely due to a reduction in PA at work, in the home and as a means of transport (DOH, 2004). It is estimated that 60% to 85% of adults are insufficiently active to benefit their health and promoting PA is a priority for health policy in most developed nations (WHO, 2004).

This chapter provides an overview of the application of psychological theory in PA interventions. Discussion is mostly restricted to adult populations as very few studies have examined the effect of psychologically-based interventions on PA levels in children (Lewis *et al.*, 2002). Exercise has been shown to provide psychological benefits, most notably in the management of depression and anxiety; therefore, evidence for the role of exercise in mental health is also summarized.

Physical activity and mental health

There is some evidence to suggest that regular PA can benefit the mental health of both adolescents and adults. There is little research on the psychological benefits of exercise for younger children. Cross-sectional, longitudinal and intervention studies have shown benefits of PA among adolescents for reducing anxiety, stress and depression and for fostering self-esteem and emotional wellbeing (e.g. Calfas & Taylor, 1994; Field *et al.*, 2001; Steptoe & Butler, 1996; Motl *et al.*, 2004). However, many of these studies have methodological limitations including the use of psychological measures which may not be appropriate for adolescents; not controlling for potential confounders, such as smoking status and body mass index; and not considering selection bias, whereby those not completing the study questionnaire due to truancy, sickness or drop-out were more likely to have emotional difficulties. In the cross-sectional studies it is not clear whether those with poorer mental health

have difficulty maintaining PA, or whether taking regular PA results in improved mental health.

Among adults, a number of adequately designed studies have shown that a sedentary lifestyle is associated with an increased risk of developing clinically defined depression (e.g. Camacho *et al.*, 1991; Farmer *et al.*, 1988), although the optimal dose of PA necessary to prevent depression is not known (Dunn *et al.*, 2002). Meta-analyses have established that both aerobic and resistance-type exercise programmes are effective for treating mild to severe depression and that exercise is at least as effective as psychotherapy and medication (Craft & Landers, 1998; Lawlor & Hopkin, 2001). However, many of these studies have flaws (Lawlor & Hopkin, 2001); including, exclusion of drop-outs from the analyses, assessment of outcome not being blinded and use of symptom ratings rather than clinical diagnosis as the outcome.

Those with mental illness have higher levels of mortality and morbidity than the general population (Davidson *et al.*, 2001); therefore the general health benefits of exercise may be particularly important for this population. Exercise may be especially attractive to patients not responding to conventional treatments or those who want to reduce medications. There is some evidence to suggest that where exercise is offered routinely as part of the psychiatric service adherence is likely to be comparable to that of the general population (Martinsen, 1993), although further studies are needed of exercise adherence among those with psychiatric illness.

Exercise has been shown to have some modest benefits for reducing generalized anxiety disorder, panic attacks and stress disorders and for improving psychological health among those with schizophrenia, although insufficient studies have been conducted with these populations to draw firm conclusions (O'Connor *et al.*, 2000; Faulkner & Biddle, 1999). A few studies have shown that PA is beneficial as an aid for achieving smoking cessation and during alcohol and drug rehabilitation, although there are too few well designed studies to evaluate the role of PA in these areas (Donaghy & Ussher, 2005; Ussher, 2005).

In the general population there is some evidence to suggest that regular PA can have beneficial effects on depression, anxiety, emotional wellbeing, self-esteem, perceived stress and sleep disturbance (Biddle & Mutrie, 2001; Department of Health, 2004). However, many of the studies have limitations which are similar to those found in studies with clinical populations; therefore definitive recommendations for exercise and mental health cannot be made at this time. Moreover, the mechanisms underlying any beneficial effects of PA on mental health have yet to be determined (Buckworth & Dishman, 2002).

Psychological theory and physical activity interventions

Psychological theory has been used to generate hypotheses concerning the psychosocial mediators of changes in PA and to provide a rationale for incorporating psychological strategies in PA interventions. This section presents an overview of the main psychological theories which have been applied to PA behaviour and summarizes the evidence for the effectiveness of PA interventions based on these theories.

Behaviour modification and learning theories

(See 'Behaviour therapy').

Behaviour modification and learning theories propose that PA is more likely to occur when environmental and situational stimuli encourage it and when it leads to rewards or avoidance of punishment (Skinner, 1953). For example, signs promoting the health benefits of stair use have been shown to increase stair use (Andersen *et al.*, 1998) and offering incentives, such as attendance lotteries, gifts and behavioural contracts has been shown to increase PA levels by up to 75% (King *et al.*, 1992). Providing rewards is likely to be most important during the early phases of a PA programme when the punishing side of PA (e.g. fatigue, stiffness) is often more apparent than the rewards (e.g. feeling fitter and healthier). Reward-based interventions have been shown to be effective in the short-term, but less so in the long-term (Glanz & Rimmer, 1995; King *et al.*, 1992). In the long-term, intrinsic rewards (e.g. enjoyment) are likely to be more important (Sher, 1998) and enjoyment is a reliable predictor of adherence to PA (Lewis *et al.*, 2002).

Relapse prevention model (RPM)

Fifty per cent of those starting an organized PA programme are likely to drop out within six months (Dishman, 1994) and the relapse prevention model (RPM), (Marlatt & Gordon, 1985) postulates that relapse begins with high-risk barriers (e.g. 'It's raining too heavily to jog') at which point, it is argued, a lapse (e.g. 'I will not jog today') leads to reduced self-efficacy (confidence towards PA), whereas, appropriate coping (e.g. 'I will work out to an exercise video today') leads to enhanced self-efficacy and a reduced chance of further lapses. There is some evidence to suggest that preparing for high-risk situations and setbacks and setting realistic goals leads to increased PA adherence (e.g. Baum *et al.*, 1991; King & Fredricksen, 1984), but other studies have found that such strategies do not aid adherence (e.g. Marcus & Stanton, 1993). Further work is needed to test the RPM for PA and to identify the most critical PA barriers and lapses at different stages of PA adoption and with different populations.

Health belief model

(See 'Health belief model').

The health belief model (HBM), (Becker *et al.*, 1977) proposes that becoming physically active is largely dependent upon a sedentary

lifestyle being perceived as a threat to health. Prospective and retrospective studies, of both healthy and ill populations, have consistently shown either no relationship between perceived threat and PA levels (Biddle & Mutrie, 2001) or have found that a greater perceived threat of illness is associated with less PA (e.g. Lindsay-Reid & Osborn, 1980). This may be because PA is associated with being well and people may be cautious about being physically active when they are unwell. The HBM fails to take account of motives for PA which are unrelated to illness, such as appearance, enjoyment and social contact and has limited applicability to PA behaviour.

Theory of planned behaviour

(See 'Theory of planned behaviour').

The theory of planned behaviour (TPB), (Ajzen, 1988) argues that the main determinant of changes in PA behaviour is intention to be physically active. This intention is said to be influenced by (i) attitudes or evaluative beliefs towards physical activity (e.g. 'Exercise helps with managing my weight, but I find it boring'), (ii) subjective norms (e.g. 'Most of my friends have joined exercise classes') and (iii) perceived behavioural control (perception of resources and barriers for PA). In this theory perceived behavioural control is also considered to be a direct influence on PA behaviour. The constructs in the TPB have consistently been shown to be valid for modelling PA behaviour (e.g. Blanchard *et al.*, 2003; Hausenblas *et al.*, 1997; Okun *et al.*, 2003) and this model is important in that it highlights social influences and barriers as mediators of PA behaviour. Most studies have tested elements of the TPB rather than the whole model and the definition and measurement of constructs (e.g. perceived behavioural control) varies greatly, which makes comparison of studies difficult.

Transtheoretical model

(See 'Transtheoretical model of behaviour change').

The transtheoretical model (TTM), or stages of change model, defines an individual's intention to change towards a more active lifestyle by five main stages: (i) precontemplation – inactive and not intending to become more active in the next six months; (ii) contemplation – inactive but intending to become more active in the next six months; (iii) preparation – active but at less than recommended levels and may or may not intend to become more active; (iv) action – active at the recommended level but for less than six months; and (v) maintenance – active at the recommended level for at least six months (Marcus *et al.*, 1992). The TTM hypothesizes that PA behaviour is influenced by self-efficacy, decisional balance and processes of change (e.g. cognitive processes: increasing knowledge, being aware of risks for lapse; and behavioural processes: enlisting social support, rewarding oneself) which vary in importance according to the stage of change.

The TTM integrates concepts from other models. For instance, self-efficacy is central to Bandura's (1986) social cognitive theory and is similar to perceived behavioural control in the TPB. Decisional balance is derived from decision-making theory (Janis & Mann, 1977) and proposes that we are more likely to be physically

active if we perceive that the benefits of PA (e.g. improved mood) outweigh the costs (e.g. time taken for PA). Through considering the environmental influences on PA (e.g. safe areas for walking), the TTM acknowledges ecological models (McLeroy *et al.*, 1988). The TTM is similar to the TPB in as much as stage of change is partly distinguished by intention. However, stage of change is also distinguished by actual PA behaviours and the algorithm for defining which behaviours are associated with which stage varies greatly between studies, making interpretation of findings difficult.

There is mixed evidence to suggest that interventions which are tailored to an individual's stage and processes of change are effective for increasing PA (e.g. Bock *et al.*, 2001; Calfas *et al.*, 1997; Pinto *et al.*, 2001). Where such interventions have been effective it is not always clear whether this is due to changes in theoretical constructs. There is evidence for some of the constructs in the transtheoretical model predicting changes in PA. For example, increases in PA have been associated with greater self-efficacy and with the behavioural processes of change, but there is little evidence to support the value of the other constructs in the TTM (Lewis *et al.*, 2002).

Multi-component exercise interventions

In practice, psychological strategies for promoting PA are most often employed in combination and as part of an individual or group consultation, whether in primary care, in the community or in the workplace (Marcus & Forsyth, 2003). Different strategies tend to be emphasized at different phases of the PA programme, although there is limited evidence to show the benefits of this approach (Bock *et al.*, 2001) and studies need to compare mediators and interventions at different stages of exercise adoption and maintenance.

Decision-making for PA can be assessed using decision balance sheets and scaling questions can be used to assess self-efficacy, barriers to PA and social support. As part of a relapse prevention plan, strategies can be identified to help the client overcome barriers and lapses. Self-monitoring encourages adherence to the PA regimen and assists health professionals in monitoring their clients' PA levels (Martin *et al.*, 1984; Oldridge & Jones, 1983). Self-monitoring is usually in the form of a brief daily record, for instance, stating the mode and duration of PA (e.g. brisk walking for 20 minutes). Self-monitoring requiring a high level of attention to the process of PA (e.g. using pedometers) has been used in practice but no adequately controlled studies have assessed the impact of such devices on exercise adherence (Croteau, 2004).

As a relapse prevention and motivational strategy, it is recommended that clients set realistic goals and that these goals are revised during future consultations. Realistic goals ensure a gradual

progression in levels of PA and foster self-efficacy for PA. Ideally, goals are specific to the mode, intensity, duration and frequency of PA (e.g. 'To walk briskly so that I am breathing heavier than normal for 30 minutes on five days a week'). The client can be asked to sign a contract outlining PA goals and specifying rewards or penalties relating to the achievement of these goals (e.g. 'If I attend the exercise class twice a week for two months I will receive a free tea-shirt, pedometer and certificate').

Discussion and future directions

Interventions which target multiple psychosocial variables are more likely to lead to maintenance of regular PA (Sallis *et al.*, 1998) and multi-component interventions are often used in research studies; however, in these studies it is not clear which elements of the intervention are effective. More studies are required which examine the effectiveness of specific psychological strategies for promoting PA, which compare different strategies within the same study and which control for the effects of reinforcement and social support. These strategies are most often employed in face-to-face consultations, which are costly and have limited dissemination. Therefore, further research is needed to investigate interventions delivered via telephone, internet contact or leaflet (Marcus *et al.*, 2000; Sciamanna *et al.*, 2002).

Many of the interventions discussed in this chapter have focused on short-term increases in PA levels and further work is needed to understand the processes involved in the maintenance of regular PA for 12 months or longer. Increasing use of personal computers and video games presents a barrier to regular PA and novel theories of PA behaviour are required which address both motivations towards PA and motivations towards sedentary activities. Interventions which target changes in multiple health behaviours; such as exercise, diet and smoking behaviours, are now common (e.g. Avenell *et al.*, 2004; Ussher, 2005); therefore, theories also need to be extended to accommodate changes in multiple health behaviours (King *et al.*, 1996).

In some of the studies described in this chapter the direction of the relationship between the psychosocial mediator and PA behaviour is not clear; for example, research is needed to establish whether individuals become more active as they overcome barriers to PA or whether people perceive fewer barriers following success at raising PA levels. At this time, it is not possible to make definitive conclusions about the importance of psychosocial mediators in the application of PA interventions. Nor is it possible to define the intensity of PA intervention necessary to produce sustained changes in these psychosocial mediators.

Psychodynamic psychotherapy

Jo-anne Carlyle

Tavistock Clinic

Overview

What sets the psychodynamic psychotherapies apart from other traditions of psychological therapy is centrality of a dynamic unconscious. It is not only taken as fact that there are large parts of our psychological life of which we are unaware but also that there is a level of dynamic activity in these unconscious processes which contributes to our emotional and behavioural life (Laplanche & Pontalis, 1973). This idea takes us beyond a notion of a static unconscious where previous thoughts or experiences are 'laid down' in a way that is isolated from relationships with other experiences. It refers to processes whereby aspects of emotional life, particularly conflicts between different instincts, feelings and thoughts, actively impinge on one another. The product or evidence of this activity may be in dreams or symptoms. Shakespeare, who so often anticipates our understanding of the mind, puts it eloquently thus:

And since you know you cannot see yourself, so well as by reflection,
I, your glass, will modestly discover to yourself,
that of yourself which you yet know not of.
(*William Shakespeare, Julius Caesar, Act 1, Scene II*)

Although Freud is recognized as the modern founder of psychoanalysis (on which the psychodynamic therapies are based), the principles and foundations of psychodynamic theory are revealed in many of the compelling and elemental stories which have endured throughout history, from religious texts to the role of myths, as universal means of describing the experience of society and the

individual. These stories speak of key experiences of love and hate, of envy and rivalry, of grievance and forgiveness. Perhaps most importantly, they tell how human beings act beyond their conscious logic and rationality and are affected by their experiences and by one another in profound ways.

There are many strands of psychodynamic theory that derive from the different psychoanalytic traditions as they have developed both in the UK and in other parts of the world. The differences in these are, for the purposes of this chapter, less important than their common features, which will be described below. In addition it should be noted that the theoretical and clinical developments within the psychodynamic traditions have been applied in a variety of modalities, including individual therapy, group therapy, couples work, as well as a particular form of family therapy (see 'Group therapy'). They have also been very influential in the areas of experiential learning, consultancy work for organizations, as well as in some forms of executive coaching, particularly through the area of group relations.

Early experience and the internal world

A key feature of the theoretical models that underpin psychodynamic psychotherapy sets out the importance of early experience. There continue to be debates about how much an individual brings constitutionally (genetically) and prenatally to their situation and also about the effects that such resilience and vulnerabilities

bring to bear on subsequent experience. However, it is generally acknowledged and evidenced that early caregiver experience is crucial for determining later development. (Enns *et al.*, 2002; Fonagy *et al.*, 2002). The theoretical model of Attachment Theory is often used to help understand the importance of early development. Attachment Theory emphasizes the behaviour and responsiveness of the primary caregiver(s) as well as the need for a secure base, the problematic effects of poor attachments, of separation and of loss. It is in some ways a more rational and behavioural approach to key aspects of such early relationships than the more psychoanalytic models, for example, Object Relations Theory. The work of Winnicott, Fairbairn, Klein and Bion takes the Attachment Theory understanding a stage further for psychodynamic psychotherapy, by taking as a key point of focus the 'intra-psyche' experience and the unconscious activity which contributes to or hinders development (see 'Child abuse and neglect').

Being sensitive to the processes and experiences of deprivation and also of intrusion is clearly an important part of the caregiving role to a young child. However, we also play more appropriate games with young infants that introduce them to these processes and through which we begin to help them develop an internal understanding of the boundaries which are fundamental both in external relationships and also in internal object relationships. Peek-a-boo games, hide-and-seek and games of tickling all use processes of withdrawal and separation and also of pain in normal development. These games involve hiding a face or hiding a loved transitional object like a teddy bear to a point where excitation and a level of anxiety is provoked, but is managed and contained. There is a transaction between infant and carer as to what is manageable and exciting and what induces fear or loss. Tickling (an important activity with babies and young children and later incorporated into sexual activity) borders the boundary between pain and pleasure and is a sensitive area in which the carer can interpret the state of mind of the baby and respond. These relational skills are essential to developing both an experience of separateness as well as dependency.

The processes of 'introjection' and 'projection' that make up the relationship between infant and carer are, in Kleinian theory, seen to provide the mechanism for the development of the ego from the very primitive ego with which the child is born. This is the cornerstone of object relations theory, but it does depart from the more stage-dependent model that was originally set out by Freud.

These relational aspects of psychodynamic understanding can be seen in relation to the developments made by Freud. His Topographical Theory, perhaps best set out in '*The interpretation of dreams*' (Freud, 1900) and developed in the late 1880s and early 1900s, comprises of three levels of awareness: the 'Conscious' – what we are aware of and cognisant of; the 'pre-conscious' – sense impressions, things that can be brought to conscious awareness without much effort; and the 'unconscious' – primitive emotions and impulses, drives, phantasies, repressed memories and feelings. These ideas are important in that they state explicitly that there are things of which not only are we unaware, but of which we cannot gain awareness by our own activity.

In 1923, Freud published '*The ego and the id*' (Freud, 1923) which introduces what is known as the Structural Theory. It sets out the concepts of the 'id', 'ego' and 'super-ego' which now form part of

our ordinary language. The id refers to the basic and instinctual impulses or parts of the personality; the ego employs our conscious mind to think about the consequences of our actions and the demands of living in the real world; whereas the super-ego can be understood as a part of the ego in which moral judgement, or perhaps conscience, are located. The super-ego is often thought to embody the authority figures in our lives and to convey censure or approval for our actions.

The structural model conceptually includes the ideas of the dynamic relationship between impulses and fantasies (derived from the id), of which we are not aware, being mediated by other aspects of our experience which are derived from our own capacities (via the ego) and also includes the experiences which we internalize from key figures, parents, carers, teachers, etc. (super-ego). In addition it allows for the experience of unconscious conflict, for example between id and super-ego. The role of the ego as a kind of mediator is relaxed during sleep (which allows for dreaming) and also when we are affected by other factors such as alcohol or drugs and stress.

The therapeutic frame

The theories set out above – attachment theory, object relations theory and also Freud's structural theory – are useful in that, as well as setting out processes of normal development, they also provide an understanding of abnormal development. Where early caregiver containment is inadequate or lacking, or where there are other significant stresses on development, for example through trauma, illness, separation, etc., then these theories set out how problems including difficulties coping with the pressures of life, struggles in relationships and difficulties with dependency or autonomy are more likely to emerge. The nature and particularities of such difficulties are likely to be related to the nature of the developmental failure or impediment. These are not pathological or stigmatizing realities; they are part of the human condition and to a greater or lesser extent are relevant to all of our experiences.

Psychodynamic psychotherapy provides a context where such early deprivations or injuries can be thought about and understood. More importantly it provides a setting based on consistency, regularity, predictability, firm boundaries of time and setting and a protective function. In this way such early difficulties can re-emerge within the therapeutic relationship (transference) and the therapeutic situation can symbolically function in the way that a 'good enough' carer might have done for the young infant.

These often physical manifestations of the containment function of the setting are clearly very important and need to be rigorously applied to be effective. However, as described above, this is not a simple process of ensuring that they take place; it demands an active attention and listening on the part of the therapist. The very fact of consistency in setting means that the therapist can be attentive to the patient's response to the setting or frame, and work with him or her to understand attempts to breach it, or attempts to pretend that it produces no effect or sense of deprivation on the individual.

This begins to bring us to the process of the analytic attitude that constitutes the internal frame which guides the therapist's stance and attitude to the patient. Psychodynamic therapists are sometimes caricatured for being rigid in these attitudes, however the employment of them goes beyond whether the therapist

smiles, or says good morning, or whether she shakes hands (all of which are important). It refers to a process of attuned listening and to the fact that the analyst sets aside his or her other preoccupations and emotions and develops a capacity to focus and concentrate on the patient's communication. This process requires a capacity for neutrality, the ability not to be pulled into personal feelings. It is a process of dual listening – both to the actual content of what the patient says and also to the deeper meanings which are revealed beneath the surface or deeper than the apparent overt content.

As a patient enters the room, the therapist is interested not only in the content of his or her story, that is, the description of difficulties, social situation, experiences etc., but also in the form that the description takes and the ways in which it relates to the therapist. The therapist is watching for particular patterns of coping with difficult experiences or relationships and of constructing the patient's own experience of him- or herself. Psychodynamic theory and experience expects that the way in which the patient sees and relates to the therapist is central (transference in the broadest of terms). There is also the expectation that the way in which the patient describes his or her ideas and the way in which movement is made between ideas will illustrate something of the his or her unconscious processes, the ways of thinking, relating, understanding, behaving etc., which are not available to the conscious awareness of the patient. The focus of sessions is often not particularly on past traumas or disappointments per se, so much as on the current experiences and consequences of those happenings or emotions, i.e. what it is in the person's current conflicts that gets in the way of coming to terms with those painful past events.

Means of protecting the self – defences

One way in which the therapist might begin to understand patients' unconscious processes is to identify the ways in which patients try to protect themselves by keeping uncomfortable or painful thoughts out of conscious awareness. These 'defences' provide clues about the kind of damage that might have happened to the patients' developmental processes. One of the main functions of defences is to keep such thoughts or knowledge out of conscious awareness.

Defences are one of the features of psychoanalytic theory that have been absorbed into our everyday understandings of behaviour and also into our language. 'You are so defensive' is a familiar accusation, as are: 'you are so repressed (or anal)'; 'he is in denial'; 'she projects all the time'; and so on. The fact that they are part of our discourse is partly because they make sense of our experience of ourselves and of those around us, of the people we live with, look after, work with and love.

A crucial point to be made here is that, as with most psychoanalytic phenomena, defences are universal. We all use them, we can observe them in our own behaviour as well as that of those around us – in our families, our social circle, amongst our work colleagues and so on. Thus, although there is some implication that they are 'pathological' or maladaptive, in fact the situation is not as simple as this. In situations of extreme danger, it is quite appropriate to repress previous experiences of being afraid or deny certain aspects of the situation that faces us. These are adaptive strategies which allow us to focus our attention on the more pressing concerns that arise in the situation.

Vaillant (1971) suggested four groups of defences, characterized in hierarchical terms for levels of maturity: psychotic; immature; neurotic; and mature. He tested these on various samples in some longitudinal studies and found that mature defences were associated with adult adjustment (work, marriage, etc.) and that there were negative correlations between immature defences and adjustment. In this hierarchy, mature defences included humour, anticipation, suppression, altruism and sublimation, whereas immature defences included fantasy; hypochondriasis; acting out and passive aggression. More recently, Perry (1989) developed rating scales for 28 different defences, again arranged in hierarchical order. This provided an empirical tool for looking at the relationship of defence mechanisms with particular diagnoses and also with outcomes in psychotherapy (Høglend & Perry, 1998).

Social and cultural relevance

It has been argued that psychodynamic therapies and theories are outdated and are drawn from a Western Judeo-Christian model of the world that is not sufficiently universally applicable to be relevant in a multicultural society. It is not within the scope of this chapter to address the theoretical arguments that support these views other than to acknowledge that they are equally applicable to most other psychological and medical interventions.

What is possible within the psychodynamic model however is the scope to specifically look directly at the interpersonal and intra-psychic (as opposed to societal and economic) impact of features of difference and to understand something of the process of prejudice from this position. The concept of discrimination is an interesting one to look at here. For example, it can be held to mean the capacity to discern the difference between one thing and another, i.e. to distinguish. Sometimes this requires real skill and a balanced understanding of the nature of differences between two things. However 'discrimination' also carries a related but almost opposing meaning – to discriminate is to notice the differences between two aspects of things (for example, gender; ethnicity; religion; disability) and to make judgements based, not on balanced reflections, but on prejudice (born of instinctual wishes or of anxiety). Both definitions of discrimination are served by underlying defences but they operate at different hierarchical levels. For example, attempts to work against inequity are often driven by the more mature defences such as altruism, sublimation. However, the means of justifying discrimination and prejudice are serviced by what we have described as the immature defences (for example, altruism and sublimation). Whereas prejudice is serviced by what we have described as the immature defence (for example, projective identification; omnipotence and grandiosity; and acting out). The intensity and directness of a psychodynamic treatment allows the honest and direct exploration of feelings such as these as they are revealed within the transference and as they represent key internal conflicts and insecurities.

Research evidence

As the Roth and Fonagy (2004) review of the evidence for the psychotherapies indicates, psychodynamic psychotherapy is not marked by evidence against its effectiveness as by a lack of evidence.

It is commonly accepted in most western healthcare systems that strong evidence supporting the effectiveness of treatments must take the form of the randomized controlled trial (RCT), a research design useful for developing and testing drugs. The fact is that insufficient research of this sort has been conducted to look at effectiveness of all the psychotherapies and in particular the psychodynamic therapies. Psychodynamic treatments are practised widely in the Western world for a range of mental health problems and in a range of settings from primary care (e.g. counsellors) to secondary care and dedicated specialist inpatient and outpatient services. Despite this, it is notoriously difficult to get funding for RCTs of psychoanalytic psychotherapy in the UK, where the National Health Service (NHS) has limited funds and where the small proportion of funding designated for mental health research is usually allocated to psychiatric drug trials which are more familiar to funding bodies. Lack of funding breeds further difficulties as there are few publicly funded centres where researcher-clinicians can locate themselves to take up an apprenticeship in good quality programmatic research, whereas those practitioners practising privately do not have the infrastructure or numbers to set up the good quality research trials required. In this context it is interesting to note how much evidence there is, but it also clear that most of it comes from other parts of Europe and North America.

Although psychodynamic treatment is often seen as more costly to deliver (because of longer training and also longer interventions) this should be placed in context. Some studies show that the more complex psychodynamic interventions actually keep working after the end of treatment, with maintained or continued improvement after termination (Svartberg & Stiles, 1999) or that reductions in service utilization after treatment means that they are very cost-effective (Guthrie *et al.*, 1999). Finally the fact that Cognitive Behavioural Therapy interventions for more complex cases are now being set up to include interventions at a greater frequency than once a week (DeRubeis *et al.*, 2005) and over longer periods of time (for example with boosters extending treatment to up to a year, Hollon *et al.*, 2005) supports the need for longer and more complex interventions (see 'Cognitive behavioural therapy').

There are a number of publications reviewing the evidence for the psychodynamic psychotherapies (Fonagy, 2002; Leuzinger-Bohleber & Target, 2003; Richardson *et al.*, 2004; Wallerstein, 1986) and these are supplemented by a developing literature in

counselling (e.g. McLeod, 2001; Rowland & Goss, 2000) much of which is derived from a more psychodynamic model.

It can also be argued that the huge demand for this type of talking therapy by referrers and by clients themselves also provides a kind of evidence for its relevance. In 1998, 40% of primary care practices in the UK employed a counsellor psychotherapist and this number is growing (Counselling in Primary Care, 1998, Report by National Medical Advisory Committee). The lack of an evidence-base means that recommendations made for clinical practice are largely, though not exclusively, derived from clinical settings.

Clinical implications and conclusions

The delivery of psychodynamic treatments varies from short-term, very focussed interventions (as assessments or consultations, usually better for crises or as a way of finding out if the method is one that is found helpful by the client) to time-limited groups; open-ended groups (often called 'slow open'); once-weekly treatment, extending over longer periods of time or being open-ended; and finally to more intensive treatments that take place at a frequency of greater than one session a week. Although all of these options can be found in the NHS, the longer and more intensive ones are more common in the private sector.

In previous decades there had been a suggestion that people being considered for psychodynamic treatments should display certain features (psychological mindedness, average to high intelligence, etc.). It is now recognized that this is not the case. Psychodynamic psychotherapy is used with people with learning difficulties (Sinason, 1992), autism (Alvares & Reid, 1999), severe mental health problems, including personality disorder, (Bateman & Fonagy, 1999) and psychotic illnesses (Martindale *et al.*, 2000).

It is important that patients considering this treatment have some idea of what to expect and recognize that it is not an advice-giving approach and can sometimes seem tough in its attention to the features that maintain difficulties rather than sympathizing with the symptoms. In fact, many people find considerable relief in the consistency of the treatment and the non-judgemental preparedness to face painful and uncomfortable realities.

Psychosocial care of the elderly

Jennifer Q. Morse and Charles F. Reynolds, III

Western Psychiatric Institute and Clinic

Mood disorders are among the most significant and often overlooked disorders in later life (Consensus Development Panel of the Depression and Bipolar Support Alliance, 2003). Because there is relatively little research on late-life bipolar disorder, this chapter will focus on depression. Depression is the most frequently diagnosed psychiatric disorder in late life (Verhey & Honig, 1997), particularly among the chronically or acutely medically ill, those in residential facilities, or community dwellers who have recently been bereaved or assumed caregiving roles (Koenig *et al.*, 1997). The prevalence of major depression in community samples ranges from 1% to 5% (Pahkala *et al.*, 1995) but clinically significant depressive symptoms occur more frequently (Verhey & Honig, 1997).

Barriers to effective treatment

One of the biggest barriers to effective treatment of late-life depression may be under-recognition by older adults, their families and their physicians. Late-life depression is significantly under-diagnosed (Mulsant & Ganguli, 1999), particularly in primary care settings (Harman *et al.*, 2001), the healthcare setting used most often by older adults (Unutzer *et al.*, 1999). Many older adults and their physicians assume that low energy, loss of interest and somatic symptoms are part of being old or physically ill, rather than symptoms of depression (Karel & Hinrichsen, 2000) (see 'Ageing and health behaviour'). Sleep disturbance, failure to care for oneself, withdrawal from social activities, unexplained somatic complaints and hopelessness may be important clinical clues for

depression (Gallo *et al.*, 1997). In addition to under-recognition, under-treatment of late-life depression is common (Hirshfield *et al.*, 1997), despite available and effective pharmacological treatments and psychosocial interventions: the latter will be reviewed in this chapter.

Under-recognition and under-treatment of late-life depression are critical issues because depression is associated with a number of costly consequences: emotional suffering, caregiver burden, excess disability, increased use of health services, risk of hospitalization, decreased quality of life and mortality from comorbid medical conditions or suicide (Ganguli *et al.*, 2002; Unutzer *et al.*, 2000). In fact, depression is likely to be a leading cause of death and disability by 2020 (Murray & Lopez, 1996). On the other hand, mental health treatment may lead to reductions in subsequent medical costs (Mumford *et al.*, 1984), but this remains a controversial point. In this chapter we review the evidence-based psychosocial interventions for late-life depression, considering first a rationale for their use and then what is known about the efficacy of each and the putative mechanism of action (change).

Psychosocial treatments

Rationale

Psychosocial interventions generally address psychosocial risk factors for depression, with the rationale that targeting *modifiable* factors may decrease depression and reduce the risk of later

depression (Bruce, 2002), particularly if medications are not likely to address these vulnerabilities (Niederehe, 1994). The modifiable risk factors for developing late-life depression include stressful life events, low social support, physical illness and disability; more importantly, change in these factors is associated with recovery (Kennedy, 1995). Psychotherapy can also help older adults to cope with psychosocial risk factors that cannot be easily modified, including caregiver strain, bereavement and role transitions (Bruce, 2002) (see 'Disability', 'Social support and health' and 'Stress and health').

Psychotherapy is infrequently prescribed by primary care physicians (PCPs) (Alvidrez & Arean, 2002), but older adults not only consider psychotherapy a viable option, but prefer it over medication (Landreville *et al.*, 2001). In early studies, older adults had better compliance with psychotherapy protocols, lower drop-out rates and more positive responses than younger adults (Brink, 1979; Sparacino, 1978–79). Later work confirmed that the ability to benefit from psychotherapy does not diminish with age (Knight, 1988). Psychotherapy may also be the only viable treatment option for depressed older adults who cannot tolerate antidepressant medications because of dangerous side-effects (like gait instability or falls), comorbid medical illnesses, or drug interactions with medications for comorbid medical illnesses.

Evidence base

There have been several meta-analyses which suggest that psychotherapy in general is a well established treatment for late-life depression (see Arean & Cook, 2002; Niederehe, 1994). Across depression severity levels, depressed older adults receiving psychotherapy showed less post-treatment depression than no-treatment or placebo controls. The average effect size in these meta-analyses is 0.78 or greater – patients in psychotherapy do more than $\frac{3}{4}$ standard deviation better on outcome measures than patients in no-treatment or placebo-control conditions. Most meta-analyses indicate that the immediate effects of treatment are greater than the long-term effects and that improvement on clinician-rated scales of depression is often greater than improvement on self-rated depression scales. In general, the efficacy of acute treatment for late-life depression is not different from that with mid-life adults, with about 60% recovered after six months. We now turn to empirically validated psychosocial interventions for late-life depression.

Specific interventions – classification

The psychosocial interventions that have been empirically validated for treating late-life depression fall into two general classes – behavioural therapies and interpersonal or psychodynamic-rooted therapies – each of which will be described specifically, along with empirical evidence supporting its use. Behaviour therapies include classic behaviour therapy (BT), cognitive or cognitive-behavioural therapy (CT or CBT), dialectical behaviour therapy (DBT) and problem-solving therapy (PST). These interventions largely rest on the assumption that human behaviour, including influencing one's environment, regulating one's mood and managing one's thoughts, is learned. Thus, behaviour therapies focus on skill-building. More interpersonal or psychoanalytically rooted therapies focus on interpersonal relationships and are based on the finding that

depression is associated with long-term and short-term disruption of interpersonal relationships (Coryell *et al.*, 1993), or the absence of social resources like family support or confidants (Barnett & Gotlib, 1988). The interpersonal or psychodynamic interventions include brief dynamic therapy (BDT), interpersonal psychotherapy (IPT) and reminiscence therapy (RT). We will briefly describe each specific intervention along with the rationale for treatment, the purported mechanism for change and empirical support for the intervention in acute treatment, follow-up or maintenance and in combination with medication, as available.

Behaviour therapies

Behaviour therapy (BT) asserts that changes in information processing are attained by experiencing more positive events through new behaviour (Lewinsohn *et al.*, 1984). The mechanism of change is behavioural activation and changing the reinforcement schedule by behaviour. BT is often used as a comparison treatment for CBT interventions. In Arean and Miranda's review (1996), there were no differences between BT, CBT and social PST and each was at least as effective as placebo, usual care and medication in acute treatment. Treatment gains made in BT are generally maintained following treatment (Gallagher & Thompson, 1983) (see 'Behaviour therapy').

According to cognitive-behavioural therapy (CBT), errors in thinking about oneself, one's experience and one's future maintain a depressed patient's negative or depressed mood (Beck, 1983). The central mechanism for change in CBT is 'stepping back', labelling cognitive errors, examining the evidence for specific thoughts and rejecting those that are likely to be false or of low probability and responding to negative thoughts or emotions as transitory events rather than self-defining ones. For depressed older adults, CBT is a superior treatment to usual care (Campbell, 1992), waiting list control (Rokke *et al.*, 2000), pill placebo (Jarvik *et al.*, 1982) and no treatment (Viney *et al.*, 1989). There is evidence that treatment gains are maintained up to two years after treatment (Rokke *et al.*, 2000). Finally, CBT combined with medication has been demonstrated to be more efficacious than medication alone (Thompson *et al.*, 2001) (see 'Cognitive behaviour therapy').

Rather than focusing on affect and cognitive regulation skills, social problem-solving therapy (PST) focuses on problem-solving skills. The mechanism of change in social PST includes behavioural activation, increased exposure to positive events, and increased interpersonal skills, including increased sensitivity to interpersonal cues and improved communication (Nezu *et al.*, 1989). Social PST is superior to waiting list control and reminiscence therapy and equivalent, to or better than, medication (Alexopoulos *et al.*, 2003; Mynors-Wallis, 1996). Treatment gains are maintained three months after treatment (Arean *et al.*, 1993). Social PST may be particularly effective for depressed older adults with cognitive (executive functional) impairment. For these populations, PST has been more effective than supportive therapy (Alexopoulos *et al.*, 2003).

A treatment initially formulated for suicidal and self-injuring women, dialectical behaviour therapy (DBT), has also been adapted for depressed older adults (Lynch, 2000). DBT focuses on skills deficits in several key areas – mindfulness or attention control; interpersonal skills; crisis management skills; and emotion regulation. The mechanism of change in DBT is skill acquisition which

improves emotion regulation. Though not yet studied as a stand-alone treatment, group DBT plus antidepressant had a better remission rate than antidepressant plus clinical management in acute treatment, with gains maintained six months later (Lynch *et al.*, 2003).

Interpersonal therapies

Moving from behavioural interventions to interpersonal or psychodynamic ones, brief dynamic therapy (BDT) views psychopathology, including depression, as rooted in developmental difficulties that promote ineffective coping. Treatment focuses on insight, achieved through the relationship with the therapist, as the mechanism of change. Adaptations of BDT for older adults focus on ineffective coping with losses or stresses in late life. BDT has been as effective as CBT at reducing symptoms (Gallagher & Thompson, 1982), but other therapies may show greater reduction in symptoms (Arean *et al.*, 1993). One problem with the existing literature on BDT is that it has not been directly compared with antidepressants (Arean & Cook, 2002) and while there is some evidence of problem resolution, there is no evidence of increased insight, the purported mechanism of change (Karel & Hinrichsen, 2000) (see 'Psychodynamic psychotherapy').

IPT is a research-oriented operationalization of psychodynamic treatment for depressed patients with foci that are particularly relevant for older adults. It uses exploration, clarification of affect and some change techniques to target four areas: unresolved grief; role transitions; interpersonal role conflict; and interpersonal deficit. The mechanism of change in IPT is resolving the interpersonal context in which depression arose. IPT has been as effective as antidepressant pharmacotherapy in acute treatment and had a lower dropout rate than medication (Schneider *et al.*, 1986). In addition, the combination of IPT plus medication is the most efficacious treatment for depressed older adults (Reynolds *et al.*, 1999a) and bereavement-related episodes (Reynolds *et al.*, 1999b). IPT also receives significant attention as a maintenance treatment. Following stable remission, IPT plus medication produces the best recurrence prevention rates among depressed older adults (Reynolds *et al.*, 1999a). However IPT has rarely been studied as a stand-alone treatment: IPT plus placebo cannot be interpreted as being the same thing as IPT alone because of patient expectations about being treated with a medication or not (Arean & Cook, 2002).

Reminiscence therapy (RT) is also called life review therapy. It bears mention because of its specificity to elderly people. RT argues that reminiscence is a normal experience to resolve Erikson's (1963) final developmental stage, sense of integrity or despair. Techniques to operationalize RT have varied greatly and its treatment manuals are not as well developed than other interventions. RT has been studied predominantly in non-clinical samples seeking personal growth or in cognitively impaired nursing home residents. In these settings it is generally reported to be effective at decreasing mild depressive symptoms (Dhooper *et al.*, 1993) or increasing life satisfaction (Haight, 1988). While RT seems useful for mild to moderate depression, some are concerned about the viability of life review for more severely depressed patients whose characteristics or life histories make a positive review unlikely (Niederehe, 1994).

Comment

A number of adaptations must be made in order to offer older adults effective treatments. More initial education about the nature of depression and the process of psychotherapy, indicating for example that participating in psychotherapy is not a sign that the patient is weak or crazy, is essential. Gaining insight or learning new skills must take into account changes associated with ageing (cognitive changes, memory changes, cohort biases, disability and greater experiences and learning history) by slowing the pace of therapy, emphasizing repetition and using multiple modes of presentation (Karel & Hinrichsen, 2000). Therapist flexibility in delivering care and willingness to communicate with, or involve, family members or other healthcare professionals is also essential. An example of modifications that did not help older adults was an abbreviated version of PST designed for primary care (PST-PC) (Mynors-Wallis, 1996). The modifications included brief sessions, fewer sessions and only one presentation of model, which has been suggested as inappropriate for older adults (Arean & Cook, 2002). These were not responsive to the needs of older adults, but PST in its traditional presentation is effective for treating late-life depression.

Special populations in late life

Now that general treatments have been reviewed, several special populations of older adults deserve attention: depressed medically ill older adults, depression treatment in primary care, depressed caregivers, depressed older adults with cognitive impairment, suicidal older adults, older adults experiencing subclinical depression and populations for whom more research is needed. Exhaustive examination of these 'special populations' is beyond the scope of this chapter: these descriptions are intended to alert the reader and to suggest further reading.

Depression in medically ill older adults

Depression often accompanies chronic illness (see 'Coping with chronic illness'). For example, about 20% of people with coronary artery disease have depression, especially following myocardial infarction (MI) (Frasure-Smith *et al.*, 1993). Recognizing and treating post-MI depression is critical because depression is associated with an increased mortality rate after MI (Frasure-Smith *et al.*, 1993) and with cardiac complications (Roose *et al.*, 1991) (see 'Coronary heart disease: cardiac psychology'). Similarly, depression is the most common psychiatric disorder in post-stroke patients (Robinson & Starkstein, 1990) and has a negative impact on recovery of activities of daily living (ADLs) and the outcome of rehabilitation (Verhey & Honig, 1997). Depression is also common following organ transplant (Dew *et al.*, 1997) and may impact treatment adherence following transplant. Depression is common following hip fracture and negatively impacts recovery and disability (Lenze *et al.*, 2004). Depression is also prevalent among patients with Parkinson's disease, but it is difficult to disentangle the psychiatric, neuropsychological and neurological deficits and symptoms. The bottom line is that recognizing and treating depression among medically ill older adults is essential because of the negative impact of depression has on recovery and treatment adherence.

Depression in primary care

Most older adults receive their healthcare in primary care practices (Unutzer *et al.*, 1999), thus it will be essential to extend empirically validated interventions for depression to this setting. Depressed older adults in primary care are reported to respond well to CBT (Arean & Miranda, 1996) and IPC (a modification of IPT) (Mossey *et al.*, 1996), but not to PST (Williams *et al.*, 2000). A recent innovation was for depression researchers to place a depression care manager in primary care practices in an attempt to increase the recognition of depression, improve its treatment and enhance functional outcomes for comorbid medical illnesses (Williams *et al.*, 2004). A similar strategy was used to reduce late-life suicide (Reynolds *et al.*, 2001). More approaches like these successful integrations of primary care and on site mental health services are needed to meet the needs of depressed older adults and to provide care where it is most accessible to them.

Depression in caregivers

Depression in response to chronic situational stress such as caring for a physically or mentally disabled family member is common, with prevalence rates as high as 50% in some studies of caregivers of dementia patients (Gallagher *et al.*, 1989), even after placement or death of the patient receiving caregiving (Schulz *et al.*, 2004). While studies of caregiver support groups often do not often meet criteria for inclusion in scientific reviews or meta-analyses of depression treatment studies (Niederehe, 1994), there are two points to mention. First, more benefit for caregivers may be derived from psycho-educational groups that specifically target managing depressive symptoms rather than general support groups (Lovett & Gallagher, 1988). And second, the amount of time spent in caregiving may also be critical in treatment recommendations. In a study comparing CBT and BDT, there were no differences between the groups in aggregate. However, for caregivers who had been caring for a family member for more than 44 weeks, CBT was more effective (Gallagher-Thompson & Steffen, 1994). The authors concluded that 'old' dementia caregivers need more structured problem-solving while 'young' caregivers need to cope with processing the affect around the diagnosis of dementia.

Depression in Alzheimer's disease

Approximately 10–30% of Alzheimer's disease (AD) patients will meet criteria for depression (Verhey & Honig, 1997). Reversible depression-induced dementia ('true pseudodementia') is rare. In terms of treating depression among AD patients, BT produced improvements in depressive symptoms for both AD patients and their caregivers (Teri *et al.*, 1997). Reminiscence therapy delivered in nursing homes to AD patients showed greater reduction in depressive symptoms than supportive therapy and no treatment (Goldwasser *et al.*, 1987). As noted previously, PST has been effective in treating depression in older adults with executive dysfunction (Alexopoulos *et al.*, 2003). Many efficacy studies exclude older adults with cognitive impairment, but more research is needed to improve treatment of depression with mild cognitive impairment or dementia.

Reducing the risk of suicide

Suicide rates increase with age, with the highest suicide rates among older white males. Suicide in late life is more directly related to underlying depression than in other age groups, particularly among completed suicides (Conwell & Caine, 1991). Thus this group requires particular clinical attention and suicidality should be directly assessed in depressed older adult patients. The use of depression care managers was found to effectively reduce suicidal ideation more than usual care in PCP practices (Bruce *et al.*, 2004). Additional research efforts to intervene effectively with this high-risk group are needed (see 'Suicide').

Subsyndromal depression

Seemingly opposite to suicidal older adults, those who experience minor or subclinical depression also warrant particular attention. While major depression may decline with age, other depressive syndromes and depressive symptoms that do not meet criteria for major depressive episode increase (Verhey & Honig, 1997). There is evidence that subclinical depression may be more consequential in older adults because of its association with disability, medical burden and vulnerability to further psychiatric disorder or chronic course (Lyness *et al.*, 2002). And while some conclude that psychosocial interventions are equally effective for clinical and subclinical depression (Scogin & Mcelreath, 1994), others point out that the literature is limited and that more research needs to be done (Arean & Cook, 2002).

Minority, homebound or rural and the oldest old

Additional research is also needed to address the treatment needs for other groups of older adults, including minority, homebound or rural elders and the oldest old. Few of the empirically validated interventions have been examined with sufficient minority samples to draw conclusions about which interventions are effective for this group. A single non-randomized trial has found CBT to be effective in treating depressed minority older adults (Arean & Miranda, 1996). Clearly more research with minority older adults is needed. Similarly, there is little research focusing on rural or homebound older adults. Researchers focused on this group have found that bibliotherapy plus check-ups by phone or in person is superior to usual care (Landreville & Bissonnette, 1997). These innovations may help to reach this difficult group. Although research studies are beginning to include older participants, a particular focus still needs to be placed on the needs of the oldest old; earlier work often did not include these participants and it is difficult to know if findings with young old will generalize to the oldest old. Data from our group (Gildengers *et al.*, 2002), suggest that the oldest old can and do respond well to treatment for depression.

Conclusions

In conclusion both behavioural and interpersonal interventions are effective in treating late-life depression in ambulatory older adults. Clinical practice should include therapy plus medication for serious depression and may include psychotherapy alone for those with

mild to moderate depression who are unwilling or unable to tolerate medications (Karel & Hinrichsen, 2000). Intervention research needs to focus on long-term and functional outcomes and the goal of getting well and staying well (Reynolds *et al.*, 1999a). There are still gaps between the efficacy of treatments demonstrated in controlled clinical trials and the effectiveness of treatments in real-world settings (Consensus Development Panel of the Depression and Bipolar Support Alliance, 2003). Thus researchers need to recruit medically ill and/or cognitively impaired patients. In addition, more trials are needed for BDT, IPT alone and for combinations of medication plus CBT, PST and BDT. Empirically validated interventions for late-life depression need to be examined in rural or homebound older adults, minority older adults and subclinically depressed older adults. Perhaps most importantly, because most studies found non-significant differences between psychosocial treatments, other

variables may predict differences in therapy outcomes (Niederehe, 1994). Currently, there are no known factors to help patients, families or care providers choose between psychosocial interventions. Such examinations would be helpful.

Acknowledgement

Manuscript preparation by Dr. Morse was supported by NIMH training grants (T32 MH 18269, PI: Paul Pilkonis, PhD, T32 MH19986-08, PI: Charles Reynolds, MD, and P30 MH52247, PI: Charles Reynolds, MD). We would like to thank Valerie Anderson at the Western Psychiatric Institute and Clinic's Intervention Research Centre for Late Life Mood Disorders for help with the case vignette.

Relaxation training

Michael H. Bruch

University College London

Introduction

Procedures for the relaxation of body and mind have been known for thousands of years. In some cultures relaxation methods have even become an integral part of philosophical, religious value systems. In view of this it is perhaps surprising that relaxation techniques have gained clinical interest only fairly recently. Early pioneers include J.H. Schultz (autogenic training; e.g. Schultz & Luthe, 1959) and Edmund Jacobson (progressive muscle relaxation; Jacobson, 1929). Davidson and Schwartz (1976) found it surprising that the subject had been absent from psychological examination for so long, despite obvious links between psychological and physiological arousal and emotional disorders.

Furthermore, perhaps as a result of its varied nature and ideographic meaning for different individuals, there were no generally agreed definitions of the concept. Jacobson attempted to define relaxation by describing its effects thus: 'respiration loses the slight irregularities, the pulse rate may decline to normal, the knee jerk diminishes or disappears along with the pharyngeal and flexion reflexes and nervous start, the esophagus ... relaxes in all its parts, while mental and emotional activity dwindle or disappear for brief periods' (Davidson & Schwartz, 1976, p. 400).

In modern clinical psychotherapy and behavioural medicine the focus for relaxation is on emotional and health problems which are perceived to be associated with increased levels of tension. In such clinical contexts therapists make frequent use of stress reduction or relaxation techniques. The aim for the patient is to learn to recognize, control and modify somatic and cognitive responses in such a way that they become incompatible with subjective anxiety, pain or tension. Typical targets are reduction of anxiety-provoking thought processes, muscular tension, hyperventilation, tachycardia and

gastrointestinal responses. Other techniques may involve vasodilatation to reduce blood pressure, regular breathing, positive thinking to achieve feelings of relaxation.

Methods

To this day a vast array of methods and respective variations, as well as combinations thereof, has been reported. Comprehensive discussions of this can be found in Lehrer and Woolfolk (1993) or more recently in publications by Smith (2001, 2002).

Methods include progressive relaxation, autogenic training, breathing, meditational techniques (as developed from Hindu philosophy (i.e. yoga) and Zen Buddhism, hypnosis, biofeedback, cognitive approaches, music therapy, aerobic exercises and pharmacological methods. These are the most commonly used techniques which have also been evaluated by research to varying degrees. The wide range of procedures seems to suggest individual differences both in the modes of arousal and in the responsiveness to intervention methods. In addition one may speculate as to what extent respective methods might have generic or more limited specific effects. We shall address these questions later on when discussing theoretical issues and clinical applications.

Brief descriptions of the most commonly used methods are given below, however, for more detailed accounts of these approaches and their variations readers are referred to the above-mentioned sources.

Progressive relaxation

This technique was originally developed by Edmund Jacobson (1929). He regarded it as a therapeutic method to achieve muscular

quiescence to effect cognitive and somatic relaxation. The patient is trained to recognize and to control decreasingly intense levels of muscular tension. As Woolfolk and Lehrer (1984) point out: 'The primary aim is to make the individual able to recognize and eliminate even the most minute levels of tension, to remain as tension free as possible at all times, and to eliminate unnecessary tension continuously during everyday activities.' (p. 5). The method was originally designed as an independent psychotherapy to achieve deep relaxation. The emphasis was for the patient to discover minute changes in tension for him- or herself. The therapist would not make suggestions regarding the expected effects but encourage proprioceptive experience to facilitate learning.

In later use the method was abbreviated for flexible and integrated use with other therapeutic approaches. According to Woolfolk and Lehrer (1984) this was also accompanied by a shift from awareness training to maximum relaxation effect. Such applications are more directive and suggestive with the aim of achieving deep relaxation as quickly as possible. Typical examples can be found within the fields of behavioural and cognitive therapies as described by Hawton *et al.* (1989). These deal mainly with anxiety states and phobic disorders. Such an approach was first pioneered by Wolpe (1958) and labelled 'systematic desensitization'. Here, relaxation is used as a stimulus for counter conditioning. A more recent development is applied relaxation, a comprehensive step by step guide building on progressive relaxation but also utilizing additional methods. (Öst, 1987).

Autogenic training

This method was originally developed by Schultz in the early part of this century (English version by Schultz & Luthe, 1959) on the basis of his experience with hypnosis. Autogenic training (AT) can be described as a form of autosuggestion to influence physiological processes. Similar as in biofeedback facilitation of self-regulation processes is intended. The goal is to reduce excessive autonomic arousal and the patient is asked to concentrate on his bodily sensations in a passive, accepting style. As Linden (1993) has noted, it is especially the principle of passive concentration that distinguishes AT from progressive muscle relaxation and biofeedback, where emphasis is on active concentration. The method is supported by an impressive body of research (Linden, 1990) and, although it had fallen slightly out of fashion, there appears to be growing interest currently.

Meditational techniques

Meditational procedures can be found in many cultures, including western societies. Traditionally meditation was associated with philosophical and religious contexts. As discussed by Patel (1993) it was only recently that such methods were considered to be useful for the reduction of stress induced tension and anxiety. She describes the nature of meditation as follows:

... meditation practice involves taking a comfortable position ... it then involves being in a quiet environment, regulating the breath, adopting a physically relaxed and mentally passive attitude, and dwelling single-mindedly upon an object ... the ultimate idea is to learn the discipline of concentrating on one

thing and only one thing at a time, to the exclusion of everything else ... giving voluntary concentration to a subject not only enables a person to see and think about that subject with greater clarity, but also brings into consciousness all the different ideas and memories associated with the subject. A practical result is an increased ability to find a solution to any problem. (p. 127)

More recently, Smith (2002) has suggested eight types of meditation which are described as follows:

- meditation on a relaxing body sensation
- meditation on movement or posture
- breath meditation
- mantra meditation
- meditation on an internal visual image
- meditation on an external visual stimulus
- meditation on a simple sound
- mindfulness meditation.

Such a comprehensive list clearly indicates that meditation is attempting to address somatic as well as cognitive systems.

Biofeedback

(See also 'Biofeedback').

Biofeedback is a fairly recent method which came into clinical use in the late 1960s. It may be simply defined as any technique which increases the ability of a person to control voluntary physiological activities by providing information about those activities: biofeedback is information about the state of biological processes. The technique of biofeedback is the most technical of the major established relaxation methods, as it requires sophisticated electronic equipment. The main intention is to teach the individual self-control over processes which are normally subject to autonomic functioning. Or, as Woolfolk and Lehrer (1993) describe it '...biofeedback is a method for representing somatic activity as information available to cognition' (p. 7). The procedure is highly specific and focuses on one autonomic response system at a time. Rimm and Masters (1979) have compiled a comprehensive list of clinical applications which can involve heart rate, blood pressure, skin temperature, skin conductivity, electroencephalogram (EEG), electromyogram (EMG) and other responses. According to Stoyva and Budzynski (1993) also pioneers in the field,

the object of such training is to achieve control over biological systems that previously have been operating in a maladaptive fashion and have been beyond conscious control ... biofeedback training essentially involves three stages. The first stage is acquiring awareness of the maladaptive response ... next, guided by the biofeedback signal, he or she learns to control the response. Finally, the client learns to transfer the control into everyday life. (p. 263)

Although it is not entirely clear how feedback control is mediated and, despite mixed results, the method has been firmly established in the behavioural treatment of some psychological and physical disorders.

Cognitive techniques

The relationship between maladaptive thinking and anxiety/stress is well documented (e.g. Beck *et al.*, 1985) and has inspired the development of cognitive behaviour therapy. It is assumed that

negative, irrational thought patterns distort perception and evaluation of threatening stimuli and thus prevent adaptive and coping oriented behaviours. Cognitive approaches to effect relaxation would thus seek to modify negative and dysfunctional thought patterns which are seen to promote tension and anxiety in the first place. The causal role of cognitive appraisal in the genesis of pathological emotionality is emphasized. Typical treatments involve identification and re-interpretation of internal events such as thoughts, images, bodily sensations. Cognitive techniques are employed to raise awareness for negative thoughts, cognitive distortions and dysfunctional schemas which may serve as an underlying condition.

Finally, Woolfolk and Lehrer (1993) list a number of additional relaxation techniques which are increasingly used by clinicians of various persuasions but have not yet been subject to scientific enquiry. These include the Alexander technique which focuses on posture and movement of the body; tai chi, an ancient Chinese technique which focuses on '... balance, muscular relaxation, deep breathing and mental concentration during a complex series of slow, dance-like movements' (p. 4); also, the Japanese method of *Akaido*, which is based on Zen Buddhism, is becoming increasingly popular in the West.

Theoretical issues

Despite recent rigorous development in clinical psychology and behavioural medicine, there have been few attempts to develop general theories of relaxation. To date, only three general frameworks can be identified; the relaxation response theory by Benson (1975), the multiprocess theory by Davidson and Schwartz (1976) and attentional behavioural cognitive (ABC) relaxation theory by Smith (1999).

The relaxation response theory postulates that all applied relaxation techniques produce a similar relaxation response which leads to reduction of sympathetic arousal. The antithesis to this is the multiprocess model which suggest specific effects of the various techniques. More recently Smith (Smith, 2001) has proposed an embracing of both aspects and has offered a somewhat compromise conceptualization which he labels 'Attentional Behavioural Cognitive (ABC) Relaxation Training'. It is claimed, on the basis of reported research evidence, that six basic approaches (largely the ones discussed above – progressive muscle relaxation, autogenic training, breathing exercises, yoga, imagery and visualization, meditation) to relaxation will have quite different effects on different people and different types of problems. More specifically, ABC relaxation theory proposes that all methods work when they evoke one or more 'relaxation states'. Smith has identified 15 of those which he has labelled 'R-states' and described as follows:

- Sleepiness
- feeling disengaged
- feeling physically relaxed
- feeling rested and refreshed
- feeling energized
- feeling at ease/peaceful
- feeling joyful and happy
- feeling mentally quiet

- feeling innocent and childlike
- feeling thankful and loving
- feeling the great mystery of things beyond one's understanding
- feeling awe and wonder
- feeling prayerful
- feeling timeless/boundless/infinite
- feeling aware.

Although Smith acknowledges the existence of a non-specific relaxation response (Benson, 1975), R-states are proposed as outcomes of different methods and should be regarded as targets in a relaxation programme according to individual requirements. Consequently, Smith proposes that clients should become competent in all basic relaxation procedures to enable access to all identified R-states. In a further development, Smith (2004a) has added 'relaxation access skills' and 'initial specific effects' to the model. These two components are designed as a link between the relaxation technique and the relaxation response as well as R-states. This is done to enable an improved matching of individual skills to desired outcomes.

Perhaps it is timely to favour such a compromise position as clinical evidence points to some generalized relaxation effect with most established techniques (Woolfolk & Lehrer, 1993). Smith's model may be regarded as a first attempt towards a unifying framework in trying to explain the effects of various techniques, as well as respective interactions with individual responding and presenting problems.

Another concern is the gap between theoretical understanding and clinical application. For example, when the theorist-researcher attempts to clarify the efficacy of different techniques, the clinician may simply use intuition regarding selection or combination of several methods. Typically, clinicians tend to apply their favourite method and use it to maximum effect. It is not always clear to what extent non-specific aspects, such as the therapeutic relationship come into play, especially when similar results are achieved across different patients and disorders.

Clinical application

Relaxation techniques have been applied as an independent therapeutic approach to relieve problems related to chronically elevated level of arousal. Examples include insomnia, nervousness, headaches, hypertension etc. The goal is to achieve a reduction of a chronically high level of arousal by sustained practice, initially under the supervision of a therapist.

Also, relaxation may be designed as an integral part of a comprehensive treatment programme. Stress inoculation training (Meichenbaum, 1993), anxiety management training (Suinn, 1990) or stress management (Smith, 2002) may serve as the typical examples. In this way relaxation training is employed as a more active and flexible tool. Typically one starts with deep relaxation and once the patient is able to relax, a shortened and individualized version is directly applied to stress- or anxiety-inducing situations. This approach is designed to facilitate coping behaviours and prevent avoidances.

Applied relaxation (Öst, 1987) can serve as a typical example for a well documented and successful relaxation programme in

the cognitive-behavioural framework. Such programmes typically last between 8–12 sessions and consists of the following steps:

- training in recognizing early signs of anxiety
- progressive relaxation
- tension release training
- cue-controlled relaxation
- differential relaxation
- rapid relaxation
- application training
- maintenance.

The main objectives are to provide a rationale and motivate the patient to enable short, effective techniques which can be applied in realistic anxiety situations as opposed to the consulting room. Emphasis is on intensive training and self-control.

Furthermore, the question arises as to whether relaxation techniques should be differentially applied, depending on the nature of problems as well as individual response mechanisms. In clinical work it is useful to seek guidance by the tripartite response system analysis as originally put forward by ŠPeter Lang (1969) who has proposed behavioural responses as three Š behavioural - motoric which have been demonstrated to be highly interactive. This conceptualization allows us to examine the nature of subjective anxiety or stress. For example, one may be able to identify a dominant response mode (e.g. cognitive or physiological) which has causal impact on the other systems. In other cases there may be an enhancing interaction between cognitive and autonomic variables, as is typical for the anticipatory anxiety syndrome.

Such investigations are expected to provide vital clues for relaxation procedures. For example, an anxiety response which is predominantly cognitively manifested would obviously require a different therapeutic focus (e.g. cognitive restructuring) as compared with a strong autonomic reaction (e.g. biofeedback).

Tripartite analysis would thus suggest that tailor-made techniques may be suitable for individual circumstances. Woolfolk and Lehrer (1993) have reviewed this issue by comparing techniques across problems as well as within problems with different individuals. They conclude the following:

We find that each of the various techniques has specific effects, in addition to a global, undifferentiated relaxation effect. There are few kinds of problems for which one technique is clearly superior to another, but, for the most part, the effects of the various techniques are similar. Combinations of techniques often produce better results than single techniques do. Also, there is some evidence that particular individuals may be differentially motivated by and attracted to specific techniques. (p. 11)

However, most studies need cautious evaluation as techniques may have lost their clinical significance through abbreviation and standardization procedures, or non-clinical samples were used. Similar points were made by Smith (2004b); in the context of the

evaluation of mindfulness training, this author urges caution regarding the number of possible factors involved.

Lehrer and Woolfolk (1993) also emphasize the importance of motivation and compliance, especially in consideration of the enormous dropout rate. It seems important that clients understand the rationale of relaxation principles and are prepared to practice on a daily basis. Clients show individual preferences and some data suggest that compliance is best, with meditation followed by progressive relaxation, autogenic training and biofeedback. Subjects who feel more in control of themselves tend to do better with all techniques except for biofeedback.

Summary and conclusion

In reviewing various relaxation approaches one can confirm the prevailing clinical view that the various techniques work differently with different individuals in different problem situations. In more detail, it appears that best results are obtained when modalities of individual responses are matched with corresponding treatments.

In addition, Lehrer and Woolfolk (1993) and Smith (2001) conclude that most methods are likely to achieve also some general relaxation effect. Also, combinations of techniques tend to be more effective than singular treatments. Most experts in the field have developed such treatment packages to enhance relaxation effects (examples were given above). Clinicians tend to use relaxation techniques and combinations on a trial-and-error basis, which makes it difficult to assess the outcome of specific techniques in applied settings. Some clinicians have claimed synergistic effects when using a variety of modalities.

To facilitate relaxation it thus seems crucial to conduct a comprehensive cognitive-behavioural assessment of relevant target complaints in order to identify individual response modalities. Further, non-specific factors such as motivation; the therapeutic relationship; the level of self-regulation ability; and expectations according to personal preferences need to be assessed. Linden (1993) has suggested that it may be useful to present model options and their rationale to the patient in order to encourage a choice. It is assumed that what is understood well, credible and self-chosen may work best for the individual patient. The ultimate goal is to generalize relaxation skills so that they can be applied actively to all relevant settings reported by the sufferer.

Finally, relaxation techniques have been demonstrated to be highly successful in the fields of emotional disorders and behavioural medicine. With emotional disorders, the emphasis appears to be more 'cognitive' as one intends to adjust the perception and evaluation of stress and tension, whereas in behavioural medicine techniques tend to focus predominantly on the modification of somatic states, such as pain, hypertension, or other physical conditions.

Self-management interventions

Kathleen Mulligan and Stanton Newman

University College London

Background

Living with a chronic illness places many demands on the patient. These may include self-monitoring of symptoms or physiological measures, such as blood sugar in diabetes, taking medication and making lifestyle changes. Healthcare professionals provide advice about what action to take, but the responsibility for integrating these actions into their daily lives rests with the patients who also have to cope with changes in life roles and the emotional demands a chronic illness can bring (see 'Coping with chronic illness'). The patients' role in their care is referred to as 'self-management', which has been defined as 'the individual's ability to manage the symptoms, treatment, physical and psychosocial consequences and life style changes inherent in living with a chronic condition' (Barlow *et al.*, 2002). It can, however, be difficult for people to

self-manage all of these aspects of their illness effectively, resulting in poor health outcomes and impaired quality of life.

Theoretical influences

While 'self-management' refers to what individuals do to deal with their illnesses, it is also the term that is increasingly used to describe interventions that have been developed to help patients self-manage more effectively. A traditional approach to addressing self-management is for healthcare professionals to provide patients with more information about their illness and its treatment in the expectation that increased knowledge will lead to enhanced self-management. This approach tends to pay little attention to patients' beliefs about their illness and its treatment or the difficulties they

may have in incorporating medical recommendations into their daily lives. A consistent finding from the literature is that interventions that provide information alone are not usually successful in improving outcomes for people with chronic illness (Coates & Boore, 1996; Gibson *et al.*, 2002; Taal *et al.*, 1997).

As a result of these findings, many self-management interventions now incorporate concepts developed within psychological theories. These theories provide a framework for considering the complex nature of health behaviour change and have drawn attention to the importance of people's beliefs about themselves, their illness and its treatments and how these affect self-management. One of the key concepts to emerge has been that of self-efficacy, which Bandura (1997) described as the level of confidence individuals have in their ability to perform a given behaviour. A number of studies have found that enhancing self-efficacy makes performance of a given health-related behaviour more likely. Self-efficacy can be enhanced through a variety of routes, including modelling, social persuasion and mastery over the skills required. Modelling may involve teaching self-management skills and also learning from others in a group setting. In group based interventions, performance of a behaviour by some participants can act as social persuasion, encouraging others to take part. Skills mastery can be facilitated by setting goals and learning problem-solving skills. Breaking down what is perhaps a complex behaviour into smaller, more manageable, specific goals increases the likelihood of success and each success helps to build self-efficacy and so encourage the maintenance of a behaviour (see 'Self-efficacy and health behaviour').

Other theories which have influenced the development of self-management interventions include the Stress-Coping Model (Lazarus, 1992), the Transtheoretical Model of readiness to change (Prochaska & Velicer, 1997) and the Self-regulatory Model (Leventhal *et al.*, 1984). The Stress-Coping Model focuses on the strategies people use to cope with a stressor such as a chronic illness. The use of passive or avoidant strategies has generally been found to have a detrimental effect on health outcomes and psychological wellbeing, while active coping strategies are more helpful. Interventions based on this model frequently use cognitive-behavioural techniques to encourage the use of more effective coping strategies (see 'Cognitive behavioural therapy' and 'Stress and health'). The Transtheoretical Model highlights the importance of a person's readiness to make behaviour changes. The model incorporates five stages, from 'precontemplation', in which change is not being considered to 'maintenance' in which the self-management behaviour has been performed for some time. Self-management interventions based on this model incorporate strategies such as Motivational Interviewing which focus on increasing participants' readiness to change (see Motivational interviewing and 'The transactional model of behaviour change'). Interventions based on the Self-regulatory Model focus upon altering individuals' views about their illness and its treatments which are seen as the drivers of both coping and health-related behaviours (Hirani & Newman, in press; Petrie *et al.*, 2002) (see 'Lay beliefs about health and illness').

It is apparent that the theories applied in self-management interventions vary in their emphasis, with some focusing primarily on behaviour change and others addressing the more cognitive and emotional aspects of coping with a chronic illness.

Although many of the interventions have roots in a particular theoretical approach, in practice many draw on concepts from more than one theory.

Content of self-management interventions

Over the past two to three decades a large number of self-management interventions have been developed for a range of different illnesses. Three conditions which have placed particular emphasis on self-management are arthritis, asthma and diabetes (Lorig *et al.*, 1987; Norris *et al.*, 2001; Sudre *et al.*, 1999). Self-management approaches have been introduced in several other chronic illnesses, including hypertension, chronic obstructive pulmonary disease, headache and back pain (Barlow, Wright, Sheasby *et al.*, 2002) and a generic chronic disease self-management programme has also been developed (Lorig *et al.*, 1999, 2001). There is considerable variety in the content of these interventions, partly due to the diversity of the routes through which they developed but also due to differences between the illnesses that they have been designed to address (Newman *et al.*, 2004).

Most interventions include some form of general education about the illness and its treatment and discussion amongst participants or with a healthcare professional. Other commonly used components include monitoring features of the illness (symptoms or a physiological measure) and taking appropriate action, management of symptoms (e.g. pain or fatigue) or disability and, as living with a chronic illness involves considerable contact with healthcare professionals, many teach communication skills to enable people to make the most of these encounters. Because most adaptation to a chronic illness involves making and maintaining lifestyle changes, the incorporation of strategies to facilitate behaviour change such as setting goals and learning problem-solving skills, features in many interventions.

Variation in self-management interventions arising from the differing demands of the illnesses can be seen in a comparison of arthritis, asthma and diabetes (Newman *et al.*, 2004). Coping with the emotional consequences and changed life roles, as well as some changes in health behaviours, is required in all three illnesses. However, in arthritis, the major concerns are to manage symptoms, particularly pain and to optimize physical functioning, while asthma self-management has been concerned mainly with minimizing the risk of acute exacerbation of symptoms. Diabetes requires lifestyle changes in order to stabilize blood glucose levels and prevent long-term complications. As a consequence, adherence to medication is an important part of asthma self-management interventions but is not a major issue in osteoarthritis. Pain management is an important part of arthritis self-management but this is not the case for diabetes and asthma. Self-monitoring, of symptoms in the case of asthma and blood glucose in the case of diabetes, is an important aspect of self-management in these illnesses but such detailed self-monitoring is not usually a component of arthritis self-management. Anxiety about and/or during an asthma exacerbation may require quite specific anxiety management techniques that are not necessarily relevant in diabetes and arthritis. In general, however, the asthma interventions have been narrowly focused in comparison to the other two conditions and have not addressed broader psychological issues.

Disease-specific and generic approaches

Traditionally, self-management interventions have been disease-specific but a significant recent development has been the introduction of a generic programme, the Chronic Disease Self-Management Programme (CDSMP), developed at Stanford University Patient Education Research Centre (Lorig *et al.*, 1999, 2001). The approach of the CDSMP is to focus on problems and strategies which are common across illnesses. It consists of community-based group sessions which combine participants with different chronic illnesses. Strategies such as problem-solving techniques, goal-setting and behavioural modelling are included as they are considered to be helpful in all chronic illnesses (see 'Behaviour therapy' and 'Cognitive behaviour therapy'). There is no disease-specific advice but participants are taught to manage their illness through correct medication use; relaxation; diet; exercise; managing sleep and fatigue; and effective communication with health professionals.

Delivery of self-management interventions

The review by Newman *et al.* (2004) found that two-thirds of interventions in arthritis and about half in asthma and diabetes were delivered in group settings. Comparison of the relative benefits of group versus individual delivery is rare but one study that compared them in diabetes found that the group programme resulted in a greater improvement in blood glucose. Group programmes have the advantage of the opportunity for group learning and support as well as reducing costs. In contrast individual programmes can be tailored to each person's needs and can be designed to be more easily incorporated into standard care (Clark & Hampson, 2001). Although it is also likely that some individuals will be less willing to take part in group programmes, there is no research on this issue (see 'Group therapy').

The duration of self-management interventions varies a great deal from brief, single sessions to several sessions over many months. The type of illness has influenced the objectives of self-management interventions and hence their length. For example in asthma, self-management interventions have tended to be brief and focused on symptom monitoring and medication adherence. In diabetes and arthritis, self-management interventions often address a range of health behaviours and strategies for managing many aspects of living with the illnesses and as a consequence involve multiple sessions. There has been little systematic examination of the optimum duration of these interventions in different conditions. In one study, Lorig *et al.* compared their standard 6-week Arthritis Self-Management Programme with a reduced 3-week version and found that the original obtained better results (Lorig *et al.*, 1998). Decisions about duration are affected not only by breadth of intervention content but also by cost implications and the greater time demand that several sessions places on patients, with the consequent risk of lower participation and higher dropout rates.

Self-management interventions have been delivered by a variety of healthcare professionals, including dietitians, nurses, occupational therapists, physicians, physiotherapists, psychologists and social workers. Although many self-management interventions are multi-disciplinary, nursing is the professional group which tends to dominate, perhaps because of nurses' greater numbers and availability,

but also because of their ability to provide detailed illness-related information. There is also a trend, as evidenced in the Arthritis Self-Management Programme (Lorig, 1986), the Chronic Disease Self-Management Programme (Lorig *et al.*, 1999, 2001) and the Expert Patient Programme in the UK (Wright *et al.*, 2003), for trained lay people, most of whom themselves have a chronic illness, to deliver self-management interventions.

Regardless of who delivers the intervention, effective delivery requires appropriate training and experience in facilitation skills and behaviour change strategies. Leaders need to be trained to deal with emotional issues that may arise. These skills are not taught routinely to most healthcare professionals and this raises the issue of what training is needed for both professional and lay leaders. This issue is frequently neglected and inappropriate assumptions are made regarding the ability, of both professionals and lay individuals, to easily take on the role of facilitating self-management interventions.

Uptake and attrition

Many self-management interventions require a considerable commitment by participants in terms of both time and emotional investment. One measure of the acceptability of a self-management intervention is provided by the percentage of people approached who decide to take part. This information is often not reported, but in studies recruiting from a circumscribed population the suggestion is that self-management interventions are not attractive to a proportion of individuals. If the numbers who choose not to participate are large it limits the generalizability of the findings from these studies. The reasons for non-participation are likely to be many and include convenience, scepticism of the process and likely benefits, amongst others. There is a need to assess reasons for lack of participation to understand these processes well.

Another indicator of acceptability is the number of people who begin but do not complete the intervention. Study attrition rates vary widely; the reasons are not clear but there is some indication that longer interventions have higher attrition rates (Newman *et al.*, 2004). The method of delivery of the self-management intervention could also affect uptake and attrition rates. Although most interventions are delivered face-to-face, some with telephone follow-up, they could also be delivered either partially or fully via a self-administered manual or using the internet. These methods have had limited application to date but are likely to grow in use and may prove popular to individuals who find travelling to the clinic and the time of the interventions too burdensome.

Efficacy

Research studies evaluating the efficacy of self-management interventions typically assess several outcomes such as physiological measures, symptoms, physical functioning, psychological wellbeing, performance of health behaviours, quality of life and use of healthcare resources. In assessing self-management interventions it is important to be clear about what a self-management approach can reasonably be expected to influence and to target the assessment of efficacy accordingly. For example, better self-management of diet in diabetes would be expected to affect a

measure of blood glucose (HbA1c), but in rheumatoid arthritis, better self-management of symptoms and physical functioning is unlikely to affect erythrocyte sedimentation rate (ESR), a physiological marker of disease activity. Many studies measure mood state and this is important because depressed mood will affect many other factors, but it is nevertheless unrealistic to expect to see a reduction in depression scores if the study population was not depressed at the outset (see 'Mood assessment'). An understanding of other variables that may influence the effectiveness of a self-management intervention, commonly known as 'process' variables, such as self-efficacy, illness beliefs and coping strategies, is also important.

One approach to assessing the efficacy of self-management interventions has been to combine studies in a meta-analysis, which provides a statistical analysis of their combined effect. A problem with this approach is that it does not take into account the diversity of the interventions and is only suitable where data are homogeneous (Eysenck, 1995). A more descriptive approach to the different interventions and study outcomes is likely to be more informative regarding what interventions, or components of interventions, are efficacious.

Several reviews of the efficacy of self-management interventions have been conducted in individual illnesses (Gibson *et al.*, 2002; Norris *et al.*, 2001; Riemsma *et al.*, 2002) and a small number have compared across illnesses, using arthritis, asthma and diabetes as examples (Barlow *et al.*, 2002; Bodenheimer *et al.*, 2002; Newman *et al.*, 2004; Warsi *et al.*, 2004). These reviews have shown that some self-management interventions have resulted in beneficial outcomes in the performance of self-management behaviours, clinical outcomes, symptoms, physical functioning

and emotional wellbeing. There is, nevertheless, considerable variation both between and within illnesses in the level and duration of effects.

In reviews of specific illnesses, it has generally been found that self-management interventions can be effective in improving HbA1c in diabetes (Norris *et al.*, 2001), small effects have been found on pain and disability in arthritis (Astin *et al.*, 2002; Riemsma *et al.*, 2002; Taal *et al.*, 1997) and reductions in health care utilization for acute exacerbation have been achieved in asthma (Gibson *et al.*, 2002). Self-management interventions have also been quite successful in achieving change in behaviours such as diet, exercise, medication adherence and cognitive coping strategies (Newman *et al.*, 2004).

Further development in the field of self-management requires a better understanding of which component or groups of components of these complex interventions are most important and for which outcomes. Studies that compare two or more self-management interventions, varying a single component, are necessary. This type of design is becoming more common in diabetes but remains relatively rare in other chronic illnesses.

Interventions that can extend the duration of effects are also required. Most evaluations of self-management interventions have not examined their efficacy beyond a few months but where longer-term studies have been conducted, effects tend not to be maintained. Booster sessions at intervals may provide one way of maintaining the benefits of self-management interventions but given that the illnesses, by definition, will last for the patient's lifetime, further research is necessary to examine how frequently and for how long, booster sessions would need to be provided.

Social support interventions

Benjamin Gottlieb

University of Guelph

Introduction

If we knew that our social relationships had the power to shield us from adversity and to prevent us from succumbing to stress-induced anguish and disability, then we would do everything possible to ensure that people are equipped with these protective social resources. However, since some of these people will not have the skills, motivation, or coping propensities to engage in support-relevant interactions with others, we will need to invest effort in determining how to select the best candidates for such interventions and how to design them in a way that has broad appeal. For those practitioners who wish to capitalize on social support's protective potential, all of these activities constitute a challenging agenda for planning and implementing such interventions in the health field.

This chapter begins by setting out the rationale for the development of support interventions, and then distinguishes between interventions in the natural network and interventions that introduce one or more new social ties. In the health field, the latter strategies predominate. Hence, the chapter consists of two main sections, the first concentrating on the design and effectiveness of support groups and the second focusing on ways of marshalling individual supportive allies. Several critical issues and uncertainties about the optimal design of these initiatives are considered, including the importance of properly matching them to certain characteristics of the intended beneficiaries. Questions that need to be

addressed in the next generation of support studies are sprinkled throughout the chapter.

Rationale for support interventions

There are three main justifications for planned programmes designed to augment, specialize, intensify, or prolong social support. First, epidemiological research amply testifies to the proposition that both absolute and relative social isolation are risk factors for numerous adverse health developments (Berkman & Syme, 1979; House *et al.*, 1982 (see 'Social support and health')). Second, there is much empirical evidence showing that people who believe that they can gain support from their social network experience lower levels of stress and its adverse health-related sequelae than those who do not harbour such beliefs (Cohen & Wills, 1985). A third rationale for planned support interventions is based on evidence of the fallibility of natural support. Several studies have documented the ways in which well-intentioned support from network members can miscarry and either aggravate the problems or increase the distress experienced by the would-be recipient (Coyne & Smith, 1994; Dakof & Taylor, 1990; Lehman & Hemphill, 1990). It follows that interventions which remediate the helping skills of natural network members or interventions which replace them with more relevant and effective supporters are needed.

In fact, the two main social support strategies involve either intervening in natural social networks in order to improve their responsiveness to the needs of an associate (Cutrona & Cole, 2000) or introducing the individual to one or more new social ties who presumably can provide more relevant and less flawed support than the natural network (Gottlieb, 1988). Furthermore, both of these strategies offer opportunities to intervene at the dyadic or the group level. Whereas early intervention studies focused on improving natural support (see Cutrona & Cole, 2000 for a review), they have given way to a plethora of grafted tie interventions, of which the most popular in the health field are support groups and individual supportive allies. Hence, this chapter concentrates on recent developments concerning the latter two types of interventions.

Support groups

Support groups usually consist of 6–12 people who share a similar life stressor, transition, affliction, disability, diagnosis, or noxious habit and meet in this face-to-face small group to engage in mutual aid and receive expert information and/or training. Support groups differ from mutual aid self-help (MASH) groups and peer discussion groups by virtue of the fact that they have a professional or quasi-professional leader who usually is responsible for the group's composition, and injects expert knowledge while guiding the group process.

To prepare this chapter, a search was conducted of the PsycInfo database from 1985 onward, specifying that the term 'support group' must appear in the journal article's title. The search yielded 262 English language citations, the vast majority of the studies describing the groups' formats, composition, themes and subjectively rated satisfaction of members. However, compared to a review conducted almost 20 years ago (Gottlieb, 1988), several new developments have occurred in that literature. They include: (1) more studies that adopt the strict procedures of a randomized controlled trial; (2) more studies comparing the effects of support groups with other intervention strategies rather than with a treatment as usual or untreated control group; (3) a new cluster of studies which report on the reasons why prospective support group candidates decline participation, or the factors that distinguish participants from non-participants; (4) a new set of studies which aims to identify the characteristics of those who benefit most and least from support groups; and (5) several reports of on-line support groups. All five of these trends reflect the growth of intelligence about the candidates and the conditions which are most conducive to the beneficial effects of support groups.

Who attends and benefits from support groups?

One indication of the maturation of research on support interventions is the acknowledgement that support groups are not universally attractive or effective vehicles for promoting health and wellbeing. For example, Winefield *et al.* (2003) asked 93 women who had been diagnosed with breast cancer an average of 7.4 months earlier whether they were interested in joining a support group. Almost 60% of the women stated that they would not attend such a group, whereas 22% did enrol in one. These figures are almost identical to those reported for 218 women who tested

positive for the gene mutation associated with breast and ovarian cancer (Hamann *et al.* 2000). Four to seven months after receiving their test results only about 25% of the women expressed interest in participating in a hypothetical support group for women with this gene mutation.

What detracts from support groups? More precisely, what are the characteristics of those who find support groups appealing and those who do not? Although we have some clues, the answers to these questions are largely unknown because so few studies report the characteristics of those who decline participation and those who drop out. We know that some people shy away from support groups because they anticipate hearing frightening stories or meeting people whose disease has progressed further than their own and therefore is interpreted as a preview of their own decline. Others may simply be afraid of the unknown, worried that they will be coerced to disclose too much, or that they will be confronted with a group of strangers with whom they share nothing but a common misfortune. There are also people who cannot commit the time or funds to attend a group and others who are content with the support they already receive from their social network. In fact, a recent study showed that support groups are not only of little measurable benefit to those who have access to natural support, but also can backfire by communicating to participants that their natural supporters are not doing as much as they could to render support (Helgeson *et al.*, 2000). Moreover, such communication need not be direct but can result from private social comparisons.

Empirical data about the people who are attracted to support groups suggest that they are relatively well-educated, white, female, middle-class individuals who are high service users and who report more problems or worse mental health (Taylor *et al.*, 1986; Winefield *et al.*, 2003). Since these are largely demographic variables, the quest should be expanded to other situational and individual differences variables that may affect initial entry and later attrition. For example, McGovern *et al.* (2002) found that men who joined a prostate cancer support group engaged in a coping style that reflected low helplessness and hopelessness and high fighting spirit. Edgar *et al.* (2001) also found that many breast and colon cancer patients who were randomized to support groups did not attend all five of the group sessions because they did not enjoy this format. The authors suggest experimenting with randomized control trials (RCTs) that allow for a preference arm so that the effect of treatment preference can be discerned.

Moreover, the factors that distinguish attenders from non-attenders may also distinguish between participants who benefit most and least from their group experience. Both Andersen (1992) and Helgeson *et al.* (2000) suggest that people who have less support or troubled relationships with their family and friends might benefit most from the compensatory group support, unless the reason for deficient network support stems from poor social skills which make the individual less supportable by co-participants. Perhaps other personal liabilities may limit the gains which individuals derive from support groups. For example, future studies may find that gains are limited by such pre-existing interpersonal vulnerabilities as an insecure attachment history or excessive reassurance seeking (Potthoff *et al.*, 1995), or by individuals' preferences for employing a 'blunting' style of coping that runs counter to the 'monitoring' style of the group (Miller, 1995). In addition, although more educated, middle-class people tend to join support groups,

when less educated people can be recruited, they tend to experience the greatest benefit (e.g. Lepore *et al.*, 2003). Less education may reflect less knowledge about health matters and services, which is another example of the selective benefits of support groups that accrue to those in greatest need.

The effectiveness of support groups

In a *New England Journal of Medicine* editorial, Spiegel (2001) summarized the findings of 10 published RCTs that examined the effects of support groups for cancer patients on both psychological and survival outcomes. He reported that, whereas virtually every study showed improvements in quality of life indicators (e.g. Classen *et al.*, 2001), only half the studies obtained evidence of moderately prolonged survival (e.g. Cunningham *et al.*, 1998). Among these studies is Spiegel's own trial that initiated this line of investigation by documenting an 18-month survival advantage for breast cancer patients who attended a long-term 'supportive-expressive' group (Spiegel *et al.*, 1989). However, it has been suggested that Spiegel's impressive results are attributable to the fact that breast cancer was a hidden disease in the late 1970s, hence the absence of public awareness of breast cancer and the dearth of informational and service resources for its victims (Nekhlyudov & Yaker, 2002). The introduction of a group that openly discussed the disease, promoted emotional expressiveness, and addressed existential issues seemed to mitigate the emotional and social isolation characterizing the lives of women with breast cancer at that time.

Along with other investigators, Spiegel (2001) suggests investing more efforts in screening and identifying people who, still today, are most likely to need and respond to emotional support. Participants who are more distressed (Antoni *et al.*, 2001; Goodwin *et al.*, 2001) and who report inadequate natural support at the outset (Helgeson *et al.*, 2000) would meet these criteria as long as they also have the social skills and adopt a coping style that suits the group's interpersonal processes. An alternative option is to design support groups in ways that suit the varied skills and styles of the prospective participants. For example, the 'blunters' might be more attracted to a group that is highly structured, focuses on overt or cognitive-behavioural training and in which a leader guides the group's interactions rather than fostering unfettered experience-swapping among participants. Indeed, it would be instructive to design several support groups that differ in their organization and social process, create videotaped sample sessions for 'the prospective participants' and then ask them to self-select into the group that appears most comfortable for them. Although this strategy violates the strictures of random assignment, it would yield valuable knowledge about the bases on which people choose supportive milieux and about the effects of people exercising control over the means of coping.

Intervention trials comparing the effects of groups that are strictly educational in nature, groups that are strictly peer discussion and groups that combine the two elements have yielded mixed results. For example, Helgeson *et al.* (1999, 2000) found that pure education had an edge over peer discussion immediately, 6 months and 3 years after the 8-week trial ended. Specifically, the women in the education-only group experienced significant gains in self-esteem and reductions in intrusive thoughts about their illness. But several caveats are in order, including the facts that the sample was

composed of highly educated, middle-income women, the short-term nature of the intervention, which may have limited the extent of mutual aid that arose in the peer discussion groups, and the exclusion from the 3-year analysis of women who experienced breast cancer recurrence. Moreover, questions arise about the distinctiveness of the three conditions; can peer discussion occur without any elements of education about the disease, and can educational sessions that are followed by a question and answer period eliminate any opportunities for peer support, including the indirect support that occurs through social comparisons? In contrast, Lepore *et al.* (2003) found that, compared with a control condition, 6-week groups focusing only on education and groups combining education and peer discussion had equivalent superior effects on the knowledge, physical functioning and health behaviour of men with prostate cancer. In addition, they found that the men in the education plus peer discussion group had significantly more stable employment and felt significantly less bothered by sexual difficulties than those in the other two conditions. The authors speculate that the peer discussion helped to normalize and validate the men's treatment-induced poorer sexual functioning and thereby moderated their distress about it.

Surprisingly, investigators rarely inquire about what prospective support group members want from their group experience, much less whether they prefer a group or a one-to-one supportive ally. Nor do investigators ask whether the outcome measures they plan to adopt coincide with participants' goals or needs. Related to this, several investigators have reported that group members' scores on the outcomes of interest were so high at baseline that it was impossible to detect any significant improvement over time due to this ceiling effect (Demers & Lavoie, 1996; Haley *et al.*, 1987). Investigators also need to more carefully consider the appropriate duration of support groups. The modal duration has been 6–8 weeks or sessions, regardless of the participants' requests and needs for more extensive support. Especially when facing the changing demands associated with the chronic stress of caring for individuals affected by multiple sclerosis, cancer, dementia and intellectual impairments, longer-term support is called for (Helgeson & Gottlieb, 2000) (see 'Coping with chronic illness'). In this regard, Edmonds *et al.* (1999) maintain that, for cancer patients, longer interventions have different effects from short-term interventions because they demand more commitment from the participants, expose them to the harsh realities of the disease and give way to the work of coping after the initial honeymoon period that is marked by enthusiasm and hope.

Research on support groups for the family caregivers of persons affected by dementia shows growing evidence that groups which provide behavioural or cognitive training in addition to peer discussion have effects that are superior to groups which only emphasize education and peer discussion (Bourgeois *et al.*, 1996). Because it has been consistently found that the behavioural management challenges contribute most to the prediction of caregiver burden, it stands to reason that groups delivering problem-solving skills (Lovett & Gallagher, 1988) and anger management (Gallagher-Thompson & DeVries, 1994) should have a value-added positive impact on the caregiver (See 'Cognitive behaviour therapy and group therapy').

Finally, in the future, complete description of the intervention, ideally in the form of a manual, and evidence that actual or

perceived support increased prior to the measurement of the intended outcomes, should become standard components of any assessment protocol. However, increased support is only one possible mechanism through which the intervention may affect its endpoints; other potential mediators include changes in coping and health behaviours, and changes in physiological functioning. In this regard, Andersen *et al.* (2004) implemented an exemplary assessment protocol, measuring not only emotional distress, but also its precursors, including perceived support, health behaviours, adherence to chemotherapy and immune system functioning. This RCT resulted in significant reductions in anxiety, increases in perceived support from network members, improved health behaviours involving diet and smoking, and selective improvements in immune system functioning among women who had been surgically treated for breast cancer. The intervention was more intensive than most, involving 27 hours of weekly small group sessions over a 4-month period. An in-depth review of cancer support group designs and effects appears in Gottlieb and Wachala (in press).

Individual supportive allies

Although far more limited in number, there have been trials of the effects of providing supplemental one-to-one support to people experiencing various stressful health events and conditions. Dyadic support strategies lack the influence derived from the consensual validation and social comparisons that occur in support groups, but they have the advantage that they can be deployed in a more flexible manner. This augmentation and specialization of support can derive from either a peer who is a 'veteran sufferer', and therefore possesses the experiential knowledge necessary to be useful to the recipient, or from someone who has full or semi-professional qualifications and therefore can offer expert knowledge in addition to emotional support. Obviously, from the recipient's standpoint, these two types of support providers will be viewed quite differently, the peer perceived to be capable of communicating an insider's perspective from having 'walked in the same shoes' and the professional perceived as more authoritative. In principle, the peer supporter's influence also derives from being a target of social comparison, as well as a model of healthy adjustment, whereas the professional's influence derives from his or her perceived knowledge of what is best for the patient.

One important implication is that more care needs to be taken in selecting the peer supporter than the professional supporter because the peer must be viewed by the patient as a relevant and similar other. For example, a 50-year-old employed Hispanic man who has opted for a radical prostatectomy would not tend to view a retired Caucasian 70-year-old man who has had radiation treatment for his prostate cancer as a similar peer. In fact, one study has illustrated the extent to which being 'in the same boat' matters to support recipients. Thoits *et al.* (2000) designed a trial in which men undergoing bypass surgery received either routine hospital care or the support of a man who had undergone the same surgery previously and who had been trained to provide simple supportive behaviours. Although they found null effects of the extra support, meaning that the trial was a failure, they discovered that virtually all the study participants had talked with one or more fellow patients while they were in the hospital, before and/or after their surgery.

Moreover, frequent conversations with fellow patients were associated with better perceived health 1 month after surgery, greater health satisfaction 1 and 6 months after surgery fewer activity limitations 12 months after surgery and lower symptoms of depression and distress at all 3 time points after surgery.

The authors argue that the support of other patients was more 'natural' than the introduction of a formal volunteer supporter. In addition, it is very likely that the study participants perceived their hospital mates as more similar to themselves than the volunteer helpers because the former men were in exactly the same stressful circumstances, namely awaiting or recovering from heart surgery, whereas the volunteers had already resumed their daily lives. Not only were hospital mates more relevant targets of social comparison, but they also may have offered less conspicuous expressions of support and accepted whatever support was extended by their mates. The effect was to make the support process more reciprocal, and therefore more acceptable than the more one-sided interactions with the volunteer supporters.

In the most commonly implemented one-to-one support initiatives a professional, paraprofessional, or trained staff member periodically renders face-to-face or phone support. For example, Mishel *et al.* (2002) implemented an 8-week telephone intervention in which nurses were trained to provide information and to enhance the self-efficacy of men recently treated for prostate cancer. The nurses' ethnicity was matched to that of the patients and their emphasis was on helping the patients to reframe their situation as manageable and on improving their problem-solving skills. The results showed improvement in the latter two mediators, and significantly improved bladder control 4 months after the intervention ended. A similar dyadic telephone support strategy was implemented by Dennis *et al.* (2002), except that in this case the support was provided by a peer for the purpose of extending the duration of breastfeeding among primiparous mothers. The support providers were women with breastfeeding experience who were matched to the new mothers on age, cultural background and SES. They were trained to provide optimal telephone support and referral skills. Contact was made with the new mothers within 48 hours of their discharge from hospital, and as frequently thereafter as the new mother wanted. The actual average amount of contact proved to be 5.4 calls over the 3-month study period, the benefit being that significantly more of these mothers continued to breastfeed at 3 months postpartum compared with mothers who had been randomly assigned to the conventional care condition.

Yet a third variation of this method of marshalling support involves more costly and time-consuming home visitation. In a widely cited study, Olds and his colleagues assigned nurses to make home visits to unmarried, low-income teenaged mothers, half the mothers receiving the home visits only during pregnancy and half until the child's second birthday (Olds *et al.*, 1986). The nurses were trained to provide health education, emotional and practical support, parenting skills and links to community services. Both short-term and long-term (15 years) outcomes have shown that the more extensive home visitation resulted in fewer pre-term deliveries, fewer child maltreatment reports, fewer emergency hospital visits for injuries and ingestions up to the child's fourth year and both fewer subsequent pregnancies and a longer interval between those that did occur. In subsequent studies, Olds and his

colleagues have experimented with different types of home visitors and concluded that nurses are the visitors of choice. As Olds *et al.* (1998) observe: 'We have chosen nurses because of their formal training regarding women's and children's health and because of their competence in managing the types of complex clinical situations often presented by at-risk families' (p. 99). Furthermore, the programme planners maintain that registered nurses are in the best position to address mothers' concerns about complications in pregnancy, the biological changes entailed in pregnancy, labour and delivery, as well as the physical health and cognitive and emotional development of the infant. In addition, nurses have been found to have more credibility with low-income, high-risk mothers and can teach them how to use the healthcare system most effectively.

Disappointing and even disquieting evidence about the effects of dyadic support comes from other experimental trials. Frasure-Smith *et al.* (1997) conducted an RCT assessing the effects of dual support interventions on depression, anxiety and survival of 1376 male and female post-myocardial infarction (MI) patients. Specifically, they hypothesized '... that patients who participated, after leaving hospital, in a 1-year programme of monthly telephone monitoring of psychological distress symptoms, combined with home-nursing visits in response to high levels of distress, would be less likely to die from cardiac causes during the first post-MI year than patients receiving usual care' (p. 473). This hypothesis was informed by evidence revealing not only that life events hasten the death of post-MI patients via the mediating role of depressive affect, but also that post-MI men who had received the same support protocol in a prior pilot study were about half as likely to die of cardiac causes as men receiving usual care. Hence, this was a replication of the earlier study, but with a much larger sample that included women patients. The results of this enlarged trial differed vastly from those of the pilot study: after one year, patients in the experimental condition had no overall survival advantage and the women in this condition evidenced higher cardiac and all-cause mortality. At one year, there was a negligible impact of the intervention on the survivors' reports of depressive affect and anxiety, the hypothesized mediating mechanisms.

The study investigators' intriguing interpretation of these disconcerting results serves as a caution regarding the potential adverse effects of support programmes. They argue that the monthly telephone screening for possible distress, combined with an average of 5–6 home-nursing visits paid to 75% of the patients in the intervention condition, may have inadvertently compounded the patients'

distress, especially among the women. This is because the supporters' intense interest in the mental health of the patients may have reminded them of their serious conditions, disrupting their efforts to cope by denying problems, and by uncovering family strains and raising expectations that long-standing problems could be resolved. It is also possible that the psychological symptom threshold for triggering the extra nurse home visits was too low, and alarmed the women who received them.

Whatever the reasons why this intervention backfired, the message it leaves is that the delivery of support must be carefully planned with respect to its source, timing, content and amount. In addition, attention should be paid to the inferences which support recipients draw about themselves and their wellbeing when they are selected or invited to participate in support programmes but have not solicited the support themselves. The social-psychological dynamics affecting the recipient of support deserve as much attention as those which concern the provider and the structure of the larger intervention (Heller *et al.*, 1991; Rook, 1991; Vaux, 1991).

Conclusion

Much thoughtful planning and careful evaluation efforts are yielding valuable knowledge about the combinations of conditions and candidates that make these grafted support interventions most attractive and effective. We know that groups that provide specific cognitive or behavioural skills in addition to support tend to be more effective than those offering only support. We also know that candidates who lack sufficient natural support and who are motivated to compare their own experiences with similar peers tend to benefit most from their group experience. Yet how far the benefits reach and for how long is uncertain: there is no conclusive evidence that support groups alone can affect length of survival from serious disease, even though they exercise a significant improvement in mental health and quality of life. Similarly, few firm conclusions can be drawn about the impact of supplemental support from a peer or professional who is dedicated to this role. More research is needed in order to identify the social-psychological conditions and the interpersonal transactions which are most favourable for relationship development and for the relationship's influence on the intended health outcomes. However, given the substantial progress that has been made in the past 20 years, there is good reason to believe that we are on the threshold of discovering how to mobilize support in ways that are acceptable and health-protective.

Stress management

Dianna T. Kenny

University of Sydney

Overview

What is stress management?

Stress management interventions arose in the 1960s with the growth of the community mental health and crisis intervention movements, disenchantment with medical model approaches to mental health and dissatisfaction with traditional psychiatry, the development of behavioural and cognitive-behavioural therapies, the growing acceptance of psychological problems within the community and the surge of self-help approaches to psychological wellbeing (Auerbach, 1986).

There have been literally thousands of articles written about stress management. A search of the PsychInfo database shows 3433 articles published between 1958 and 2004 on various applications of stress management, such as stress management in health care, occupational settings, educational settings, community programmes and critical incident stress management.

It is difficult to find an adequate definition of stress management that is sufficiently inclusive to incorporate all the stress management strategies and interventions which currently occur in the literature under this nomenclature and to be sufficiently exclusive so as to differentiate these interventions from other types of psychological treatments. In its broadest definition, stress management interventions are designed to assist people to cope with stressors and with the negative emotions, physiological arousal and/or health consequences that arise from these stressors by changing their cognitive and emotional responses to the trigger events. To distinguish stress management from many psychological interventions, a number of caveats must be invoked. Firstly, stress management is generally applied to adequately functioning individuals who may be facing difficult circumstances in their occupational or social settings. Secondly, the focus of stress management is primarily educational rather than psychotherapeutic. Programmes are generally derived from the principles of learning theory; cognitive theory; and stress and coping theory and aim to change some aspect of behaviour or thinking related to a particular environment or circumstance. Thirdly, the duration is shorter rather than longer, usually with a fixed number of sessions. Fourthly, the service is more often delivered to groups than to individuals. Fifthly, the deliverers of stress management interventions do not generally form a therapeutic relationship with participants. Rather, they act as facilitators/educators, encouraging group members to establish their own goals, and to self-administer and self-monitor progress. There is rarely any long-term follow-up once the programme has been completed (Auerbach & Gramling, 1998).

Stress management interventions vary widely in content and duration and may include progressive muscle relaxation,

meditation, guided imagery, autogenics training, biofeedback, cognitive restructuring, problem-solving skills, anger management, social skills training and assertiveness training, as well as educative components related to general health, diet, exercise and wellbeing.

This chapter will review the three main areas in which stress management approaches are applied:

1. Stress management in occupational settings
2. Stress management in healthcare settings
3. Critical incident stress management (psychological debriefing).

The review will conclude with a brief discussion of recent new directions in stress management research.

Stress management in occupational settings

Occupational stress arises in the complex interaction between organizational and work demands and individual and interpersonal characteristics. Candidate occupational stressors include job tasks (e.g. monotonous); the organization of work (e.g. fast-paced, low control, shift work); the physical work environment (e.g. noise, temperature, chemical fumes, ventilation); the fit between the worker and the work (e.g. overload, underload); role in the organization (e.g. lack of status, lack of prospects for promotion, lack of a career path, job insecurity) and the social work environment (e.g. lack of support, exposure to interpersonal conflict, discrimination, bullying); and home and work interface (e.g. conflict between domestic and work roles, lack of spousal support for remaining in the workforce).

Occupational stress has been held responsible for almost every category of ill health, both physical and psychological by both researchers in the area and lay people (see 'Stress and health'). The effects of occupational stress may be direct, as in the case of workers on a fast-paced production line showing chronic increased blood pressure and muscular tension, or indirect, as may occur when work-related stressors trigger pathogenic health-related behaviours, such as increased alcohol or drug consumption. The empirically established connections between occupational stressors and health outcomes are more robust for some conditions than others and some types of occupational stressors appear more closely related to health outcomes than others. For example, high psychological demand, low control, low social support and lack of reward for high effort increase the risk of cardiovascular morbidity and mortality. The evidence is much less conclusive with regard to stroke and cancer. Occupational stress, in the form of job dissatisfaction and interpersonal distress may also mediate injury, compensation claims and poor return to work outcomes following injury (Kenny & McIntyre, 2005).

There is a vast and truly daunting literature on occupational stress, one that can at times generate more heat than light. A number of

recent editions of journals have been devoted to the topic of occupational stress and its management (see, for example, Kenny & Cooper, 2003). There have been many conflicting views of the nature and cause of occupational stress, ranging from a problem that resides within individuals (i.e. personality, cognitions (cognitive appraisals) and coping behaviours) to one that has its roots in the organization of work, organizational climate and the structure of power and authority in the workplace (Kenny & McIntyre, 2005). Context, interactional and multilevel factors may each contribute to the overall stress quotient. That is, occupational stress may be rooted in the job itself, in the way the job is perceived, in the way employees are managed as a group and in the overall organizational climate and leadership of the workplace. For each putative cause, methods of occupational stress management have been developed. Just as root causes have been identified at the level of the individual, the level of interaction between individual and organizations and at the organizational (climate/managerial) level, so too do interventions occur on these three levels:

- individual (relaxation, meditation, cognitive behaviour therapy, exercise, time management, employee assistance programmes)
- individual/organizational (co-worker support groups, role clarification, person-environment fit and participation and autonomy programmes)
- organizational (selection and placement, training and education, interpersonal skill development in managers, work environment changes and job redesign and restructuring) (Giga *et al.*, 2003; Kenny & McIntyre, 2005; Morrison & Payne, 2003).

The critical question is whether any of these interventions has a significant positive impact on measurable outcomes such as absenteeism, sick leave, claims for workers' compensation and productivity. The converging consensus is that individual person-directed stress management programmes – those that attempt to empower workers to deal with demanding situations by developing their own coping skills and abilities – are unlikely to maintain employee health and wellbeing in the long term without procedures in place within organizations to reduce or prevent environmental stressors. Individual level approaches which focus on skill development and job control appear to fare better, but organizational strategies in the form of management/supervisor training and organizational climate yield the best results (Morrison & Payne, 2003). There is some evidence to show that individual distress and morale have different determinants, with personality factors accounting mostly for distress and organizational factors for morale. Low morale is more likely than distress to lead to work withdrawal. Cotton and Hart (2003) argue that workplaces can address organizational factors impacting on morale through provision of a supportive organizational climate and appropriate leadership behaviours.

Stress management in healthcare settings

Since stress has been strongly associated with morbidity and mortality in a number of chronic and life threatening medical illnesses (see 'Stress and health'), it is not difficult to argue that offering stress management programmes to these individuals with these conditions is likely to have a positive impact on the course and outcome of their illnesses. There are direct and indirect pathways through which psychosocial stressors are thought to contribute to

disease onset and exacerbation. In the direct pathway, psychosocial stressors promote pathophysiological processes such as altered immune functioning, atherosclerosis and vascular dysfunction. In the indirect pathway, psychosocial stressors contribute to unhealthy lifestyle choices such as poor diet, smoking, alcohol abuse, risky behaviours and low physical activity that are the direct causes of the pathophysiological processes which lead to illnesses such as coronary heart disease (CHD) and cancer.

The evidence for the effectiveness of stress management in reducing morbidity and mortality from CHD is not strong. Although some programmes that included a cognitive restructuring component reported a decrease in behaviours (collectively called Type A behaviours) known to be associated with myocardial infarction (Friedman *et al.*, 1986), and others have achieved reductions in depression (ENRICH, 2000), neither programme was associated with decreased morbidity or mortality at 12-month and 2-year follow-up respectively, although the Friedman study found small decreases in mortality at 4.5 years and decreased cardiac recurrence in the stress management group. Trials using short duration stress management programmes (Frasure-Smith *et al.*, 1997) reported neither improved psychological functioning, nor heart disease outcomes. However, Blumenthal *et al.* (1997) found decreased incidence of myocardial ischemia and reduced myocardial infarction at 5-year follow-up in stress management participants compared with a standard care control group.

The findings for the effect of stress management on cancer parallel to some extent the findings for CHD. While early studies reported significant improvements in life expectancy of women with breast cancer (Spiegel *et al.*, 1989) and malignant melanoma (Fawzy *et al.*, 1990) as a result of participation in stress management programmes, more recent studies have been unable to replicate these positive findings and concluded that they were due to methodological problems in the early studies (Claar & Blumenthal, 2003). Current studies about the use of stress management programmes in cancer treatment support the conclusion that while such programmes may have a significant positive influence on depression, anxiety and perceived pain in women with breast cancer, there is little evidence for reductions in morbidity or mortality (Goodwin *et al.*, 2001).

Headache (both chronic tension type and migraine) has also been of interest to researchers in stress management. Recent randomized controlled trials have indicated that a combined treatment of antidepressant medication and stress management programmes produces larger reductions in tension-type headaches (64% of participants) than either drug (38%) or stress management (35%) alone. Interestingly, placebo fared only marginally worse (29%) than these active monotherapies (Holroyd *et al.*, 2001). Another study on migraine reported similar improvements in self-reported outcomes such as pain frequency and intensity but no change in medication use or work status compared with the control group (Lemstra *et al.*, 2002).

Critical incident stress management (CISM)

There are many conceptual and classification issues in the psychology of trauma and its attendant psychological manifestations as post-traumatic stress disorder (PTSD), acute stress disorder (ASD) and expectable distress reactions in response, either directly or indirectly, to traumatic events (see 'Post-traumatic stress disorder'). The lack of clear definitional boundaries for psychological

conditions leads to problems in identifying suitable and effective treatments and in evaluating those treatments. An additional complication in PTSD is that diagnosis may change, depending on how long after the traumatic event a person is assessed. Many studies indicate that people are resilient in the face of catastrophe and the majority recover spontaneously, including those with symptoms of PTSD immediately after the event (DeLisi *et al.*, 2003; Kessler *et al.*, 1995). Thus, timing of the intervention is also important, as those who are treated early may have recovered without treatment.

The terms Critical Incident Stress Management (CISM), Critical Incident Stress Debriefing (CISD) and Psychological Debriefing (PD) have been used interchangeably in the literature to describe a form of secondary prevention delivered as soon after exposure to trauma as possible to reduce symptoms and prevent PTSD. PD originated on the battlefields of World War I for use with both combat and peace keeping forces (Litz *et al.*, 2002). Mitchell (1983) applied the principles of PD employed in the armed services to emergency services personnel (firefighters, police, ambulance). Originally intended for the so-called secondary victims of trauma (i.e. those persons assisting the primary victims), Mitchell's model of CISD was applied widely to both primary and secondary victims in diverse settings. CISD is delivered to a group of individuals all of whom have been exposed to, or have assisted a victim of, trauma. It typically occurs immediately or soon after the critical incident, and involves a standard procedure in which a facilitator explains the procedure and ground rules (e.g. confidentiality of the group, suspension of rank, voluntary participation) and invites all members to present their account of the incident and their reactions, thoughts and feelings at the time. The session concludes with an educational component in which participants are advised about the nature of normal stress reactions, what they might expect to experience in the next few days and some stress management strategies that they might employ to alleviate symptoms. The group often ends with an informal, social component (see Mitchell & Bray, 1990). Some countries have made the offer of CISD compulsory to avoid possible negligence claims from employees in the event that they develop PTSD (Rose *et al.*, 2001).

Recently, the terms PD, CISD and CISM have become more differentiated. CISM is the generic term now used for a number of strategies employed in critical incidents. Everly and Mitchell (1999) have described six distinct components as follows: pre-incident preparedness training; individual crisis support; demobilization (provision of food, rest and information about coping to emergency staff as they complete their shifts); defusing (small group meetings along the lines of the CISD model discussed above); family support; and referral. However, Devilly and Cotton (2003) reported continuing difficulty in distinguishing between CISM and CISD and prefer the use of the term PD to describe any immediate intervention following trauma in contrast to structured CISM and CISD programmes, as described by Mitchell (1983).

Despite its intuitive appeal and ubiquitous presence globally, a heated debate is being waged in the academic literature as to whether CISM in its various manifestations is effective in preventing the onset of PTSD (McNally *et al.*, 2003). In order to resolve the question, researchers should consider only those studies which meet the gold standard for treatment outcome studies. Foa and Meadows (1997) itemize the factors needed to meet this yardstick. They include clearly defined target symptoms, specifying a threshold of symptom severity;

exclusion of subjects with comorbid diagnoses; the use of reliable and valid measures; the use of blind evaluators; standardized training of assessors and those delivering the treatment; manualized, replicable, specific treatment programmes; unbiased assignment to treatment; and adherence to treatment. Interestingly, most of the studies cited in support of the efficacy of CISM in reducing stress and the onset of PTSD do not meet some or all of the benchmarks for treatment outcome studies and hence are either difficult to interpret or produce findings in which one can have little confidence (Campfield & Hills, 2001; Deahl *et al.*, 2000; Nurmi, 1999; Yule, 1992).

There is a larger body of better designed studies which is converging on the conclusion that CISD either has no effect (Conlon *et al.*, 1999; Rose *et al.*, 1999) or indeed has a deleterious effect (Bisson *et al.*, 1997; Hobbs *et al.*, 1996; Kenardy *et al.*, 1996; Mayou *et al.*, 2000) on victims of trauma. Ironically, even in studies where debriefed participants fared worse than those who were not debriefed in terms of the number and severity of PTSD symptoms, the majority of those undertaking debriefing reported the experience to be helpful and positive (Carlier *et al.*, 1998; Raphael *et al.*, 1995; Small *et al.*, 2000).

The controversy is not resolved because there are many differences within and between groups of supportive and non-supportive studies; for example, the type of trauma (victims of crime, victims of natural disasters); the type of participants (primary or secondary victims of trauma); the type of service delivery (group vs. individual); the timing of service delivery (immediately after trauma or later); the outcome measures used to assess efficacy of CISD (symptoms of PTSD, depression, adaptive function, return to work, sick leave); and variations in the actual protocol (Everly & Mitchell, 1999; Mitchell, 2002). The assumption underpinning CISM, that it is helpful to express thoughts and feelings about the trauma immediately after the incident, is currently being re-examined in the light of this body of evidence. The emerging view is that the focus should shift from CISD to screening and provision of early intervention for those at risk or actually suffering from adverse reactions as a result of trauma (Deville & Cotton, 2003).

New directions in stress management

Changing views of the nature of stress

In recent years, there has been a gradual shift in the way that stress itself has been understood, and this, in time, will affect the way in which stress management programmes are developed and delivered. Current models of stress emphasize the role of cognitive appraisal (e.g. perceiving the event as a threat or a challenge, as controllable or uncontrollable) in determining stress responses, and that social factors such as social isolation or position in a dominance hierarchy all play a role in the intensity of the physiological response (Kemeny, 2003). These are all factors that will need to be considered in the development of the next generation of stress management programmes.

New approaches to stress management

Mindfulness

Western medicine has been complemented in recent years by the practices of the East. Chinese herbal medicine, homeopathy, acupuncture, various forms of massage therapy, meditation and Tai Chi

have gained increasing acceptance over the past 20 years. A newer form of stress management, called Mindfulness Based Stress Reduction (MBSR) '... is a clinical program originally developed to facilitate adaptation to medical illness that provides systematic training in mindfulness meditation as a self-regulation approach to stress reduction and emotion management' (Bishop, 2002, p. 71). The primary goal is '... to provide patients with training in meditation techniques to foster the quality of mindfulness, broadly conceptualized as a state in which one is highly aware and focused on the reality of the present moment, accepting and acknowledging it, without getting caught up in thoughts that are about the situation or in emotional reactions to the situation' (Bishop, 2002).

The enthusiasm with which this form of stress management has been embraced is not matched by evidence to support its effectiveness from quality controlled studies. However, although such studies are urgently needed, the approach does appear promising and certainly warrants further large-scale investigation.

Service delivery via the Internet

There has been a growing interest in the use of the Internet as a means of delivering psychological interventions (King & Moreggi, 1998). There are some clear advantages to this form of delivery including reduced costs, easy access, particularly for those with agoraphobia or mobility problems, participant control over therapy and anonymity for those who feel uncomfortable with face-to-face contact with psychologists and counsellors. However, obtaining accurate assessment and diagnosis via the Internet may cause difficulty because therapists have no cues on which to form an opinion about their clients other than the completed self-assessments provided electronically. Attrition has also been identified as an issue, but this problem is universal to all forms of therapy. Early indications point to potential benefits of online (i.e. Internet-based), self-help stress management interventions (Zetterqvist *et al.*, 2003) although further research is needed to confirm its effectiveness.

Worksite interventions

Paul A. Estabrooks and Russell E. Glasgow

Kaiser Permanente-Colorado

Overview

There are numerous theoretical and practical reasons for delivering health promotion programmes in work places. First, the worksite is

an environment in which many adults spend a large percentage of their waking hours. Secondly, interventions conducted in a person's relevant physical and social environment – rather than in clinical settings that are not frequented by most individuals – have fewer

problems with generalization. Thirdly, worksites offer the opportunity to combine policy, organizational and individual behaviour change strategies: conceptually the combination of such strategies should be more powerful than any one in isolation (Glasgow *et al.*, 1990; Sorensen *et al.*, 2000). Fourthly, the common and consistent interactions among employees within worksites offers the potential for various social support intervention components such as group rewards, participatory employee steering committees, co-worker support and incentive programmes. Fifthly, worksite programmes can increase the reach of health promotion by getting many persons to take advantage of health promotion offerings who may not otherwise participate (Glasgow *et al.*, 1993). Finally, there are also good reasons for employers to offer such programmes. Worksite interventions can potentially increase employee recruitment and retention, reduce health care costs and absenteeism and enhance employee morale and productivity (Pelletier, 2001; Riedel *et al.*, 2001).

There are also complexities and potential downsides to worksite interventions. Some employees may feel that such programmes are coercive, especially in cases in which there are workplace exposures or safety hazards that are not concurrently addressed. Secondly, even if there is strong top management support, which has been documented as essential (Sorensen *et al.*, 1996*b*), front line supervisors may not be as supportive or allow workers to use company time to participate. Finally, there are also logistical challenges such as competing demands, availability of appropriate meeting rooms and facilities, difficulties of reaching part-time and night shift employees.

Definition and scope

We define worksite health promotion (WHP) as the delivery of educational or behavioural change materials or activities to maintain or improve employee fitness, health or wellbeing and changes in organizational practices and policies conducive to health promotion. The variability in the types of WHP programmes has increased over the past decade. Because of the large amount of literature on this topic, for this review we have restricted our focus to WHP programmes that target one or more of the following factors: physical activity, eating patterns and smoking cessation behaviours. We included programmes that addressed both employee behaviour change and environmental or policy change. We did not include worksite-based employee assistance or mental health interventions, or programmes that focused exclusively on occupational safety or workplace hazards. We also excluded worksite interventions that focused solely on cancer screening or assessment of health risks (that did not provide risk reduction activities) although those are also active areas. Finally, given the increased attention on translation of research findings to practice (Glasgow *et al.*, 1999), we have emphasized studies that have implications for dissemination, generalizability of findings and sustainable interventions.

Research evidence

Given that smoking, poor nutrition and physical inactivity are leading behavioural causes of death (Mokdad *et al.*, 2004) there has been a strong emphasis in developing WHP initiatives with the potential to have a broad public health impact (Bull *et al.*, 2003) (see 'Diet and

health', 'Physical activity and health' and 'Tobacco use'). Unfortunately, although WHP strategies have great potential to have a broad reach into the adult population, there is evidence that this potential is not being realized (Bull *et al.*, 2003). This evidence highlights the paucity of literature that reports on essential WHP programme characteristics related to generalization (or robustness) across different types of employees and worksites.

To evaluate the potential public health impact of WHP programmes, we used the RE-AIM evaluation framework to structure our review of the research evidence (Glasgow *et al.*, 1999). The RE-AIM framework was designed to place balanced emphasis on internal and external validity by addressing five issues that combine to determine the overall public health impact of an intervention (www.re-aim.org). These issues are: (1) Reach, or the percentage and representativeness of employees who are willing to participate in a given programme; (2) Effectiveness, or the impact of a WHP programme on important outcomes, including potential negative effects, quality of life and economic outcomes; (3) Adoption, or the percentage and representativeness of settings where personnel are willing to conduct a WHP programme; (4) Implementation, or how consistently various elements of a programme are delivered as intended and by different types of staff and modalities; and (5) Maintenance, or the extent to which a programme or policy becomes institutionalized or part of the routine worksite practices and policies. Maintenance also refers to the ability of employees to sustain healthy behaviour changes for six months (or longer) following the most recent intervention contact.

Recently, our research team completed a review of 24 WHP studies that were published in prominent health promotion and behaviour change journals between 1995–2000 (Bull *et al.*, 2003). Inclusion criteria for this review included a controlled (but not necessarily a randomized control trial) intervention study published in one of the 11 journals identified. In that review we documented the state of the literature related to reporting on the dimensions of the RE-AIM framework. A summary of our findings across RE-AIM dimensions is given below.

Reach

Employee participation rate was reported in 87.5% of the 24 studies (Bull *et al.*, 2003). Rates varied across studies; from 8–97%, with a median of 61%. An earlier comprehensive review demonstrated that WHPs, on average, recruited approximately 39% of overweight employees and that recruitment rates were better for programmes in which less time and effort was required for participation (Hennrikus & Jeffery, 1996). Further, incentives-based programmes have doubled recruitment to worksite health programmes (Hennrikus *et al.*, 2002). Finally, participation rates could be increased by offering free programmes and allowing participants some choice in programme components (Hennrikus & Jeffery, 1996).

It should be noted that the 'denominator' for estimating reach in many studies was based on volunteers who completed a survey, a risk assessment or who sought information, rather than all employees in the worksite, while other studies included all potentially eligible participants as the denominator. The lack of clarity on the population denominator limits the potential of a study to examine the representativeness of the participants to the entire worksite population. For example, WHP programmes often include time and resource

costs that result in only a sub-set of employees volunteering to participate. As such, a high participation rate like 90% suggests that the sample is likely to be representative of the larger population, but by basing this rate on a denominator of volunteers, or by excluding certain types of employees (e.g. part-time or night shift workers, blue collar employees) the conclusion of representativeness would be erroneous.

Unfortunately, few studies compare the representativeness of the study sample to a sample of non-participants or all eligible workers (Bull *et al.*, 2003). Those that have included these analyses found that participants were more frequently older, retired, better educated and White (Kristal *et al.*, 2000; Marcus *et al.*, 1998). They also found that participants ate more fruits and vegetables and less fat at baseline, suggesting that the participants may have been more motivated to change behaviours than the general worksite population. The limited reporting of recruitment protocols (i.e. volunteer or passive vs. active, or how many participants were excluded a priori) and lack of comparisons between those who enrolled and those who did not reduces our ability to discern how representative study participants were of the general workforce.

The Next Step Trial (Kristal *et al.*, 2000) provides a template for other worksite interventions for the documentation of the reach of an intervention. The protocol included the reporting of recruitment method used, participation rates and representativeness of participants. Kristal *et al.* indicate the voluntary nature of recruitment: 'both active and retired employees were offered all activities (p.118).' They note the total number of eligible employees, total number of employees taking part in each of the intervention activities and overall intervention participation rates by different employee groups (e.g. active vs. retired). Additionally, this study compared characteristics of all eligible employees and the sample of individuals who chose to participate.

Effectiveness

The utility of WHP programmes is typically judged on data that demonstrate if it worked or if it did not in changing employee behaviour(s). This context exemplifies the effectiveness dimension of the RE-AIM framework – with the caveat that it is one of five equally important dimensions. Nonetheless the documentation of effectiveness (or efficacy – dependent on the type of trial) is the most consistently reported RE-AIM dimension. Research on the effectiveness of WHP interventions has been summarized in a number of review articles (Hennrikus & Jeffery, 1996; McTigue *et al.*, 2003). Each of these reviews highlighted both promise and disappointment with the current state of the literature. The reviews demonstrated that published reports on WHP programmes typically have been adaptations of clinic-based approaches (e.g. education classes). Behaviour modification and incentives were also used regularly, while competitions and capitalizing on the worksite organizational characteristics were used less frequently. A recent study which suggested that high intensity interventions (i.e. person-to-person contact more frequently than once a month) were most likely to be successful for behaviour change and weight loss at 12 months following the initiation of intervention (McTigue *et al.*, 2003). The effectiveness of incentives to improve behavioural outcomes has been equivocal. For example, participants who were given incentives for increased walking during a WHP programme, completed more sessions than

those that were not (Jeffery *et al.*, 1998). Furthermore, although the study was not designed to detect a significant interaction, there was a trend that participants who received both incentives and personal coach support completed more walking sessions than those who received only the incentives or the coach in isolation (Jeffery *et al.*, 1998). In contrast, the use of incentives based on weight loss did not significantly improve the effectiveness of standard behavioural therapy and participants in both conditions suffered similar weight re-gain following the completion of the intervention (Jeffery & Wing, 1995). When contrasted with the findings on strategies to improve reach (e.g. incentives, low-intensity programmes) these studies suggest that programme characteristics which will attract a higher proportion of employees may be different from programme characteristics which lead to successful weight loss.

More recent literature has highlighted specific strategies and delivery methods for WHP programmes that show promise for future research. For example, friendly competition seems to promote healthy eating, physical activity and worksite cessation rates, without increasing unintended consequences of rapid weight loss or increasing physical activity at an unsafe rate (Klesges *et al.*, 1986; Patterson *et al.*, 1997). Similarly, utilizing interactive computer technologies such as telephone counselling, web-based education, personalized email support and tailored print strategies to provide behavioural therapy may be as effective as time intensive and costly individual face-to-face sessions (Harvey-Berino *et al.*, 2004). Unfortunately, the optimal content and method of delivery for WHPs is still unknown. For example, Internet education alone does not seem to be very effective; however when offered in conjunction with behaviour therapy which included weekly email contact and individualized feedback, weight loss was significantly enhanced (Tate *et al.*, 2001). Similarly, tailored magazines combined with trained employee volunteers were successful in changing F&V (fruit and vegetables) and fat intake in female blue collar workers (Campbell *et al.*, 2002).

Utilizing more participatory methods in programme development and delivery is also an emerging area of potential promise. Studies that have utilized employee steering committees or advisory boards demonstrated improved delivery of health programmes on site and programmes that are appealing to the employees (Hunt *et al.*, 2000). Interactive technologies, participatory research methods and the use of employee volunteers are all promising, but understudied, avenues for future WHP initiatives.

The effectiveness dimension of the RE-AIM framework is also defined by the assessment of quality of life outcomes in addition to unintended negative consequences – which include programme drop out rate. In our review of the recent literature none of the 24 studies that we reviewed reported on quality of life issues for participants; and none of the papers reported measuring potential negative effects that may have been produced (Bull *et al.*, 2003). Approximately half the 24 studies reported attrition rates, with a median rate of 28%. To compound the issue of attrition only 1 of the 24 studies used an intention-to-treat analysis, opting instead to only examine outcomes based on those present at follow-up, thereby potentially overestimating the effect of the programme.

Adoption

All 24 studies in our review reported the number of worksites, and some characteristics of worksites that participated in the research

(Bull *et al.*, 2003). A quarter of the studies reported on the proportion of worksites that participated compared to those which were eligible and the median adoption participation rate among those studies was 56.5%. Only two studies identified exclusion criteria and the number of worksites that were excluded from the research. Number of employees, high employee turnover and non-English speaking employees were the common exclusion criteria. No study reported on the representativeness of the participating worksites on issues of resources, type of business, or median salaries of the employees when compared to the population of eligible worksites. Adding to concerns about the generalization of findings across settings, only 25% of the studies reported any information on characteristics of or participation among staff or persons who conducted the WHP. The interventions were primarily delivered by research staff rather than by regular employees or the in-house departments who would ultimately deliver the programme if it were taken to scale or sustained.

The Well Works Project (Sorensen *et al.*, 1996a) provides a good example of reporting on organizational adoption of a research intervention. In that study, the investigators reported the protocol for eligible worksite identification (i.e. they used the Dun and Bradstreet Direct Access Database to identify worksites meeting the eligibility criteria), indicated total number of eligible worksites and the proportion of those approached who agreed to participate. The only aspect of adoption not recounted in Well Works articles was a comparison of the characteristics of adopting vs. non-adopting organizations.

Implementation

Given the strong focus on internal validity within the research community and the relationship between internal validity and treatment fidelity, we were surprised to find that only 3 of the 24 studies we reviewed documented the extent to which the WHP programme was delivered as intended; indicating the degree to which the programme was appropriately implemented (Bull *et al.*, 2003). Each of these studies provided a detailed description of the proportion of process objectives related to the intervention that were achieved, for example, the number of class hours that were taught compared with the number that were prescribed.

In searching for a strong example of the need to document implementation activities, we selected a school-based rather than a worksite-based study. Baranowski and colleagues (Baranowski *et al.*, 2000) provide a good example of rigorously documenting implementation rates of the 'Gimme 5 Fruit, Juice and Vegetables for Fun and Health Trial.' In their study, the intervention curriculum included components to be delivered at the school and newsletters with family activities and instructions for intervention at home. Researchers documented the delivery of the curriculum as intended through classroom observations and teacher self-reports of the completion of the curriculum activities. All teachers were observed at least once during the 6-week intervention. The observations revealed that only about half of the curriculum activities were completed. In addition, the components of the intervention that were not delivered were those which were most likely to lead to behaviour changes. In contrast, teacher self-reported delivery was 90%. Baranowski *et al.* (2000) also documented the delivery of 6 newsletters to parents through follow-up telephone calls to a randomly

selected number of households participating in the study. They found that only 1 in 5 parents recalled receiving all 6 newsletters, while half reported receiving between 3 and 5 newsletters. One caveat to these findings, which raises questions regarding the reliability of participant estimates, is that a small proportion of parents reported receiving more than six newsletters (18%), which was not possible. There is a clear and important need for future WHP studies to document consistency in intervention delivery, provide data on the characteristics of intervention staff who best implement programmes and evaluate how programmes are implemented or adapted. Similarly, there is an area of assessment ripe for research which relate to how evidence-based programmes might be adapted rather than implemented in their entirety and the influence adaptation may have on effectiveness (potentially positive or negative).

Maintenance

Because the majority of WHP studies in our review concentrated on reporting early findings related to their interventions, it is not surprising that only 2 of the 24 (8%) discussed long-term follow-up of study participants or programme sustainability (Bull *et al.*, 2003). One study reported on how well intervention effects were sustained at the individual level two years following the first evaluation; the authors of this study did not indicate whether the programme itself was still in place. One other study did return to worksites two years after the research was complete and reported that the intervention was still in place. Nutrition activities in the Working Well intervention worksites declined over time, but that overall many nutrition activities remained viable. The authors point out, however, that this viability was related to the overall support the institution had for nutrition activities from the start of the study and not necessarily to a change in attitude towards nutrition activities during the intervention (Patterson *et al.*, 1997).

Evidence summary

Our brief review of literature demonstrates that, to date, researchers have focused primarily on an individual rather than on an organizational level of evaluation. Specifically, WHP programmes are associated with some encouraging results related to the effectiveness of different intervention strategies to change health behaviours. However, data on characteristics of participants vs. non-participants and participating settings vs. non-participating settings are limited and this reduces the conclusions that can be made related to the generalizability of these findings. Similarly, indices of the extent to which interventions were delivered as intended (or can be successfully delivered by different types of staff, or regular worksite vs. paid research staff) were rarely reported. Finally, there were few WHP studies that reported on either individual and setting level maintenance effects.

Using research evidence and theory to aid WHP practice

In the face of the current state of WHP research, one emerging area is the use of theory as the basis for intervention development.

Historically WHP studies that have capitalized on theoretical models which attempt to predict behaviour from an individual perspective. A number of notable and effective WHP strategies have been developed based exclusively on individually targeted strategies (Kristal *et al.*, 2000). However, recent research suggests that policy and environmental approaches may also be effective for worksite health promotion programmes. Policy and environmental strategies reflect a social-ecological and public health approach to reducing disparities among employees since such policy changes influence all employees, regardless of demographic and worker characteristics. (French *et al.*, 2001) provided an excellent description of the environmental influences on eating and physical activity. They identified a number of environmental change strategies that could be utilized in worksite settings. Unfortunately, such attempts to exploit the worksite environment, communication systems and social context are rare (Sorensen *et al.*, 2004).

Because initial WHP strategies typically focused on a myriad of activities that targeted individuals to change their behaviour or worksites to change their environment, it is hard to identify which components were responsible for effectiveness. As a result of this lack of detailed understanding, a number of authors have posited that any health behaviour intervention should be based on a sound theory. In a review of physical activity interventions, Baranowski and colleagues (Baranowski *et al.*, 1998) found that interventions based on theoretical models were more effective than those that were not. Using a theoretical basis for intervention has two key benefits. First, a sound theory will provide a blue print for strategies that target theoretical variables thought to lead to behaviour change. In the case of WHP interventions, we agree with the work of Sorensen and colleagues which suggests a sound theory should be operationalized as one that identifies the need to develop strategies

to target both environmental (i.e. organizational) and individual strategies for behaviour change (Sorensen *et al.*, 2004). Second, theory provides a description of mediators of intervention effectiveness (or ineffectiveness) that can be measured and tested to determine why an intervention works or not (for examples of theoretical frameworks see 'Health belief model', 'Health promotion', 'theory of planned behaviour' and 'The transtheoretical model of behaviour change').

The Working Well Trial provides a good example of using theory as the basis for intervention development and assessment of potential mediators of health behaviour change. The intervention model was based in social ecology (Krasnik & Rasmussen, 2002) and highlighted the need to understand the interaction between an individual and her/his environment. Based on the findings from the Working Well Trial, a review of current theories of behaviour change and practical experience developing and testing WHP strategies, Sorensen *et al.* (Sorensen *et al.*, 1996b; Sorensen *et al.*, 2004) refined a social ecological framework for WHP which provides an excellent theoretical schematic for intervention development. The model provides the detail necessary to develop interventions and to explicitly test the hypothesis that adding environmental intervention components (i.e. setting and organizational level strategies) will enhance the effectiveness of individually targeted intervention strategies.

The Sorensen *et al.* model describes the importance of social contextual factors that may modify intervention effects, i.e. the social demographic characteristics associated with those factors, and potential social context/setting level and individual level mediating factors. Figure 1 below is a schematic adapted from Sorensen's work and includes example variables for consideration in a WHP. The solid lines in Figure 1 represent hypothesized relationships

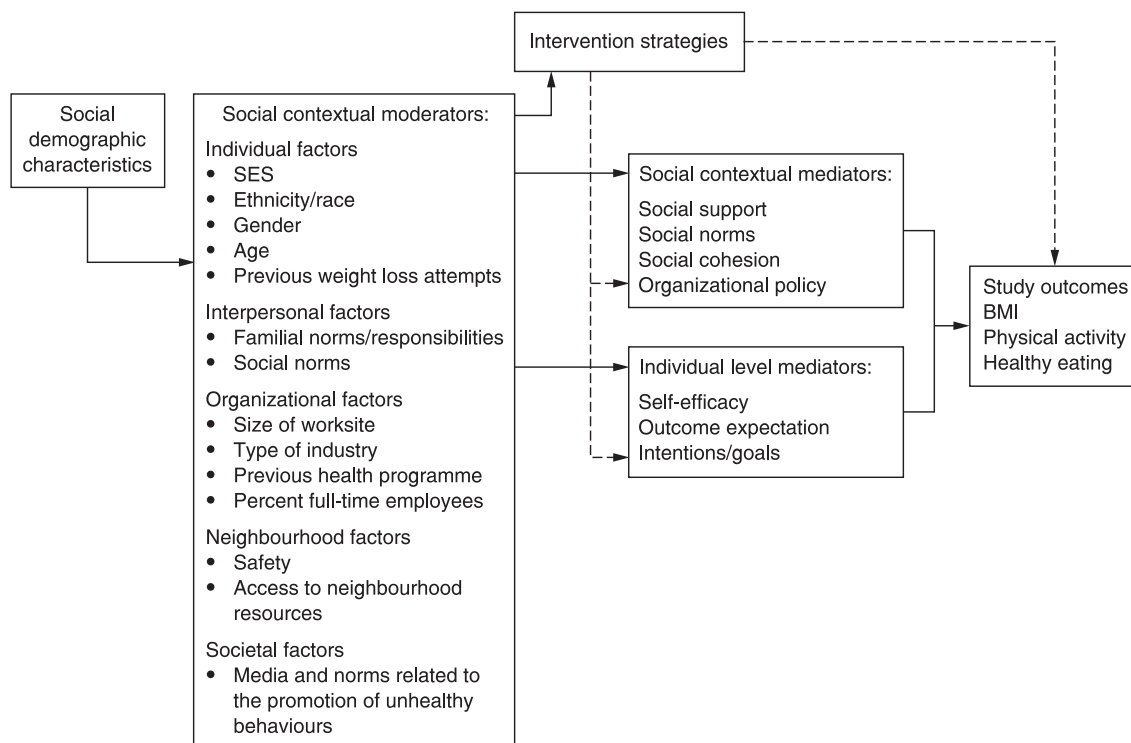

Fig 1 Adaptation of Sorensen *et al.*'s conceptual model (Sorensen *et al.*, 2004).

between variables or sets of variables and dashed lines represent intervention effects. The implication of this model is that comprehensive intervention strategies should be developed to change proposed environmental level and individual level mediators, which in turn are hypothesized to have a direct relationship with changes of health behaviour outcomes. There is also the potential that there are additional mediating variables which may not be accounted for in this model and as such it is hypothesized that the intervention may also have direct effects on the outcomes in addition to the indirect effects through the proposed mediating variables.

Summary and future directions

There has been considerable progress in WHP research over the past decade. In particular, many investigations are now evaluating how well WHP reach all employees and also designing interventions for the types of blue-collar, small worksites that were often left out of earlier investigations. One innovative line of research is that of Linnan *et al.* (Linnan *et al.*, 2002), who have studied beauty parlours as settings for WHPs that also target customers.

Led by a number of investigators from the Working Well and subsequent trials, there has also been a recent increased emphasis on understanding theoretical mechanisms underlying both participation (Linnan *et al.*, 2002a, 2002b; Linnan & Marcus, 2001) and

outcomes (Glanz, 1997; Sorensen *et al.*, 1996b) of WHP. Equally important, the methodological sophistication of WHP research has increased over the past decade, with most studies now including multi-level analyses.

Several challenges remain, however. Few studies have designed interventions for, or evaluated their sustainability after, the time that research funding is removed (i.e. the end of a study). Attrition also remains a challenge in WHP and innovative theoretically based approaches to enhance retention are needed. Greater study of the robustness and generality of WHP effects across key variables such as race and ethnicity; risk level; health literacy; part- vs. full-time status; and of organizational characteristics that may moderate outcomes are needed. Given the social-ecological conceptual model in Figure 1, we predict that the greatest future advances will be made by interventions that address environmental, physical and social as well as individual factors. We predict that such multi-level interventions should be especially effective in producing superior long-term results, but this hypothesis needs to be empirically tested. Although there have been reports of cost-effectiveness (Pelletier, 2001), more such studies, using standard economic methods of determining costs and conducting sensitivity analyses are needed (Gold *et al.*, 2003). Finally, future studies should include both quality of life measures and outcomes important to employers (e.g. presenteeism, impact on recruitment and employee retention).

Section IV

Healthcare practice

Adherence to treatment

Rob Horne

University of London

Introduction

Non-adherence is perceived to be a significant problem in all aspects of healthcare from taking medication to attending counselling sessions. Thousands of research papers have been published on the topic in the last few decades yet non-adherence remains a key challenge in modern healthcare. The main focus of research and reviews has been on adherence to medication prescribed for long-term medical conditions. This is hardly surprising. In affluent countries, most healthcare resources are devoted to the management of chronic diseases such as coronary heart disease, diabetes and asthma. Here, good outcomes depend as much on self-management by the patient as on good medical care and, for most of these conditions, self-management hinges on the appropriate use of medicines. However many patients fail to achieve this. Estimates of the incidence of non-adherence to medication range widely from 2–98%, partly because of differences in the way adherence is defined and measured across studies. Most reviews estimates that 30–50% of medication prescribed for chronic illness is not taken as directed (Meichenbaum & Turk, 1987; Myers & Midence, 1998; World Health Organization, 2003). If the prescription was appropriate, then this level of non-adherence is a concern for those providing, receiving or funding healthcare because it not only entails a waste of resources but also a missed opportunity for therapeutic benefit (DiMatteo *et al.*, 2002). Unfortunately, effective interventions remain elusive (Haynes *et al.*, 2002).

This chapter will focus on medication adherence. It will begin by summarizing our current understanding of the causes of non-adherence and from this explain why interventions have so far met with such disappointing results will then go on to suggest how we might rectify the problem. Although a full review of adherence to all health-related behaviour is beyond the scope of this chapter, many of the insights from research into medication adherence might be applied to other behaviours such as diet, exercise and smoking cessation.

The causes of non-adherence

Dispelling common myths

Non-adherence is not significantly related to the type or severity of disease with rates of between 25–30% noted across 17 disease conditions (DiMatteo, 2004*b*). Furthermore, providing clear information, although essential, is not enough to guarantee adherence (Weinman, 1990). Likewise, a plethora of studies have failed to identify clear and consistent relations between adherence and sociodemographic variables such as gender and age in adults (DiMatteo, 2004*a*;

Horne, 1998). Adherence is positively correlated with income when the patient is paying for treatment (Piette *et al.*, 2004) but not with general socioeconomic status (DiMatteo, 2004*a*). Non-adherence is often lower for more complex regimens, but reducing the frequency of dosage administrations does not always solve the problem (Claxton *et al.*, 2001). There is little evidence that adherence behaviours can be explained in terms of trait personality characteristics. Even if stable associations existed between sociodemographic or trait characteristics, they would serve to identify certain ‘at risk’ groups so that interventions could be targeted but could do little to inform the type or content of these interventions. This is not to say that sociodemographic or dispositional characteristics are irrelevant. Rather, the associations with adherence appear to be indirect and are best explained by the influence of sociodemographic and dispositional characteristics on other relevant parameters. For example, correlations between adherence and educational status or race may simply be a reflection of income and ability to afford prescription costs.

The notion of the ‘non-adherent patient’ is a myth: most of us are non-adherent some of the time. Stable characteristics such as the nature of the disease and treatment, or sociodemographic variables, influence the adherence behaviour of some patients more than others. Non-adherence is therefore best seen as a variable behaviour.

Non-adherence as a variable behaviour with intentional and unintentional causes

There are many causes of non-adherence but they fall into two overlapping categories – intentional and unintentional. Unintentional non-adherence occurs when the patient’s intentions to take the medication are thwarted by barriers such as poor recall or comprehension of instructions, difficulties in administering the treatment or simply forgetting. Deliberate or intentional non-compliance arises when the patient decides not to follow the treatment recommendations. It follows that we need to consider two issues – resources and motivation. Unintentional non-compliance is linked to problems of resources. To understand intentional non-adherence we need to consider the processes influencing motivation to start and continue with treatment. Clearly, there is a degree of overlap between these behaviours: motivation may overcome resource barriers and resource barriers may reduce motivation. However, this simple model is useful because it helps us to understand why previous attempts have met with only limited success.

Why adherence interventions have had limited effect

Literature searches using established search terms (Haynes *et al.*, 2002) suggest that over 120 articles reporting unconfounded

randomized controlled trials of adherence interventions have been published since 1972. This literature has been subjected to a range of systematic reviews (Haynes *et al.*, 1996; Peterson *et al.*, 2003; Roter *et al.*, 1998) including a recent Cochrane systematic review (Haynes *et al.*, 2002). The overall conclusion of these systematic reviews is that, 'complex strategies for improving adherence with long-term medication prescriptions are not very effective despite the amount of effort and resources they consume' (Haynes *et al.*, 2002, p. 9). Even successful interventions have modest or short-lived effects.

The main problem relates to the design of the interventions themselves. Few interventions have targeted proven determinants of non-adherence. Instead they typically use ad hoc approaches that are not well described or standardized. Most interventions are not sufficiently comprehensive. The majority have addressed unintentional non-adherence with an implicit assumption that adherence can be improved through more effective communication of instructions; by better patient education; or by addressing non-volitional barriers such as forgetting or poor recall of instructions (by issuing reminders), or by addressing failure to make plans when attempting to adhere to a complex regimen (see, for example, 'Healthcare professional-patient communication' and 'Neuropsychological rehabilitation'). Although this approach may be helpful for many patients, its efficacy is likely to be limited because it fails to address the causes of intentional non-adherence.

A further problem is that it is difficult to judge why some interventions work and others do not. Interventions that are complex, addressing both intentional and unintentional non-adherence tend to be more effective than single component interventions. Few papers describe the content of the interventions in sufficient detail. Most studies assessing complex interventions did not evaluate the separate components ('black box' approach) or assess process variables, so that we remain uncertain about what was effective or whether all elements of the intervention were required.

Potential solutions

The need for theory-based interventions

A core recommendation of the UK Medical Research Council's (2000) framework for the development of complex interventions to improve health is that the intervention should be based on a sound theoretical model. This is germane to adherence where few interventions have used psychological theories to identify the salient factors influencing motivation to start and persist with medication.

Several theoretical models have been developed to explain how people initiate and maintain actions to preserve or improve health status. These models share the common assumption that the motivation to engage in and maintain health-related behaviours arises from beliefs that influence the interpretation of information and experiences and which guide behaviour (Conner & Norman, 1996; Horne & Weinman, 1998). The capacity of theoretical models to explain variance in adherence and other behaviours is of course determined by the validity of the model and whether it contains the right 'constructs'. It is also influenced by the way in which the constructs are operationalized. In social cognition models, the antecedents of behaviour are specified at the 'process'

level (e.g. attitudes inform intentions and behaviour) (see 'Theory of planned behaviour').

When theoretical models are used to develop interventions then they are likely to be more effective if they also specify content (e.g. the beliefs that contribute to the positive or negative evaluations which constitute the attitude towards the behaviour). This is recognized within the Common-Sense Model of self-regulation (CSM) where the content as well as the process of illness representations is specified (Leventhal *et al.*, 1998) (see 'Lay beliefs about health and illness'). However, theoretical models of health behaviour are likely to be more explanatory as their contents become more specific to the behaviour in question (Fishbein & Ajzen, 1975). Although representations of coping procedures are implicit within the CSM a more explicit consideration of perceptions of treatment may be useful when the model is applied to adherence (Horne, 2003). A better understanding of how people perceive treatments will improve our ability to operationalize theories of social cognition and self-regulation and enhance their power to explain variations in adherence (see also 'Health cognition assessment' and 'Illness cognition assessment').

Operationalizing the salient beliefs influencing treatment adherence: the example of general and specific beliefs about medication

The first step in identifying salient beliefs about treatment (i.e. those beliefs influencing behaviour) is to conduct interview-based studies to examine beliefs about the behaviour, their expectancies and the value they place on the expected outcome (Ajzen & Fishbein, 1980). In the case of medication, qualitative studies have suggested that many people seem to hold prototypic beliefs about pharmaceuticals as a class of treatment and their capacity to produce harm as well as benefit and beliefs about the appropriateness of doctors' prescribing of medicines (Horne, 1997). Moreover, many people seem to be have a fairly negative orientation to pharmaceuticals perceiving them to be fundamentally harmful, addictive substance that should not be taken for long periods of time but that tend to be over-prescribed by doctors (Horne *et al.*, 1999). These 'social representations' of medicines are linked to wider concerns about scientific medicine, lack of trust in doctors and an increasing interest in alternative or complementary healthcare (Calnan *et al.*, 2005). These general beliefs influence the way in which people evaluate specific medication prescribed for a particular medical condition. They frame initial expectations of the outcome of taking the prescribed medication (Cooper *et al.*, 2004), as well as how subsequent events are interpreted – for example whether symptoms are attributed to the illness or the treatment (Siegel *et al.*, 1999) (see 'Symptom perception'). They may even influence outcome directly through the placebo/nocebo effect (see Di Blasi *et al.*, (2001) for a review of non-specific treatment effects) (see also 'Placebos').

Making decisions about adherence: judging perceived necessity and concerns

One method for operationalizing people's initial and subsequent evaluation of medicines prescribed for specific conditions ('specific medication beliefs') that has been quite widely applied in adherence research is the necessity-concerns framework (Horne *et al.*, 1999).

This suggests that the motivation to start and persist with prescribed treatment regimens is influenced by the way in which the individual judges their personal need for the treatment relative to their concerns about potential adverse effects of taking it as recommended. Studies involving patients from a wide range of illness groups including asthma (Horne & Weinman, 2002), renal disease (Horne *et al.*, 2001), diabetes, cancer and coronary heart disease (Horne & Weinman, 1999), hypertension (Ross *et al.*, 2004), HIV/AIDS (Horne *et al.*, 2004), haemophilia (Llewellyn *et al.*, 2003) and depression (Aikens *et al.*, 2005) have consistently found that low rates of adherence are related to doubts about personal need for medication and concerns about potential adverse effects.

It is worth noting that perceived necessity is not a form of efficacy belief. Although views about medication efficacy are likely to contribute to perceived need, the constructs are not synonymous. We might believe that a treatment will be effective but yet not perceive a personal need for it. Conversely, we might perceive a strong need for a treatment that we believe to be only moderately effective, because we know that it is the only treatment that is available. Necessity beliefs are influenced by perceptions of the condition being treated (Horne & Weinman, 2002) as well as by symptom expectations and experiences (Cooper, 2004).

There is a striking similarity in the type of concerns that patients report about prescription medicines. One obvious source of concern is the experience of symptoms as medication 'side-effects' and the disruptive effects of medication on daily living; but this is not the whole picture. Many patients receiving regular medication who have not experienced adverse effects are still worried about possible problems in the future. These often arise from the belief that regular use can lead to dependence, or that the medication will accumulate within the body and lead to long-term effects and these problems are related to the social representations of medicines as being harmful and over-used as discussed above (Horne *et al.*, 1999). Other concerns are specific to the particular class of medicine (Horne & Weinman, 2002). For example, worries that corticosteroid inhalers prescribed for asthma will result in weight gain (Hand & Bradley, 1996) or that regular use of analgesic medication now will make it less effective in the future (Gill & Williams, 2001).

Evidence to date is consistent with the notion that medication adherence is influenced by a cost-benefit analysis in which patients' beliefs about the necessity of their medication are weighed against concerns about the potential adverse effects of taking it. The 'cost-benefit analysis' may be implicit rather than explicit. For example, in some situations, non-adherence could be the result of a deliberate strategy to minimize harm by taking less medication. Alternatively, it might simply be a reflection of the fact that patients who do not perceive their medication to be important are more likely to forget to take it. The impact of perceptions of treatment on adherence will also be influenced by beliefs about adherence, such as the importance of strict adherence to achieve the desired outcome (Siegel *et al.*, 2000).

Prior to treatment, necessity beliefs and concerns may be thought of as higher order outcome expectancies which are influenced by beliefs about the illness and treatment as well as more general 'social representations' of, and preferences for, classes of treatments. Once treatment has commenced they are influenced by appraisal processes (Horne, 2003).

Preliminary evidence suggests that the framework can be used to operationalize 'treatment representations' within Leventhal's CSM and adds to the variance in reported adherence than can be explained by illness representations alone (Horne & Weinman, 2002; Ross *et al.*, 2004). Recent research suggests that the necessity-concerns framework may also be applied to other treatment-related behaviours such as attendance at cardiac rehabilitation classes (Cooper *et al.*, in press). However, further research is needed to establish the utility of the framework in prospective studies and in interventions studies.

Other factors and challenges

Several other important issues need to be addressed in operationalizing social cognition and self-regulatory theories as a basis for adherence interventions. The effects of emotion and mood are likely to be important. A meta-analysis of 25 high quality studies investigating the relationship between depression (12 studies) and anxiety (13 studies) found that the relationship between depression and non-adherence to medication prescribed for chronic illnesses (other than depression) was substantial. Anxiety had little effect (DiMatteo *et al.*, 2000). A further aspect that needs attention is how we enable patients to overcome the resource and capacity limitations that act as barriers to the implementation of intentions to adhere to treatment. An example of promising work in this area utilizes the concept of 'implementation intentions' or action plans (Gollwitzer, 1999) to tie specific behaviours to environmental cues by prompting the planning of when and how the behaviour can be carried out (Sheeran & Orbell, 1999) (see 'Theory of planned behaviour').

A further area for future research is the effect of social support. Social support appears to have broadly positive effects on adherence but we know little about the mechanism or the type of support that works best in what situations (DiMatteo, 2004). A further challenge to adherence research includes the issue of measurement and how to reduce self-presentational bias so that adherence behaviour can be reliably and accurately assessed.

Developing complex intervention to facilitate adherence

The main priority for research is to develop effective, equitable and efficient interventions to facilitate informed adherence where adherence matters most. Previous interventions have had limited effects partly because they have not been comprehensive enough. Many have focused on single causal factors whereas adherence is best seen as unintentional and intentional behaviours with internal and external determinants. The 'internal' factors influencing motivation and capacity may be moderated by 'external' variables, such as the quality of communication between the patient and healthcare provider and by the wider societal contexts such as access to resources and societal policy and practice. Future interventions may be more effective if they address both the perceptual factors influencing motivation to initiate and persist with the recommended behaviour, as well as facilitating the implantation of intentions to adhere, for example by addressing the capacity and resource limitations that act as barriers.

Attitudes of health professionals

Hannah M. McGee

Royal College of Surgeons in Ireland

Introduction

Research on attitudes of health professionals has been a relatively marginal activity until recently. This has been because of what Marteau and Johnston (1990) describe as the implicit model of health professional attitudes and beliefs, i.e. that they are knowledge-based and invariant. Health professionals have been seen as having an empirically derived set of shared beliefs. However, a developing literature demonstrates wide variability in health professional attitudes. The importance of this variability is illustrated here in a range of studies which depict the presentation of treatment options for healthcare users, the professional choices made about access to services and the overall outcome of healthcare for patients and professionals. Many of the studies to date have been atheoretical, focusing instead on a description of attitudes themselves or on their associates. Attitudes of health professionals are often inferred rather than being directly assessed. For instance, previous experience is often assessed in relation to current behaviour with attitudes then inferred, as in the finding that patterns of greater hospital referral for childhood gastroenteritis by general practitioners was associated with prior specialist training in infectious diseases settings (McGee & Fitzgerald, 1991). Divergent current behaviour, e.g. higher levels of referral to cardiac surgery for male than female patients (King *et al.*, 1992) are also documented and attitudinal influences inferred (in this case a range of attitudes including those relating to the severity of symptoms as presented by men and women). Some cognitive and social psychological constructs have been incorporated in research studies of health professional attitudes, and these are illustrated alongside methodological strategies in the next sections.

Attitudes of health professionals to varying characteristics of healthcare users

Health professionals attribute a range of treatment-relevant characteristics to service users based on information available to them. Thus patients who are reported to practice lifestyle habits associated

with the disorder which has been diagnosed, e.g. smoking with lung cancer, are believed to be less concerned about their health and less adherent to medical recommendations (Marteau & Riordan, 1992). Recall of details regarding individuals is greater when it fits with the expected stereotypes of health professionals. For instance, when specific characteristics (e.g. 'promiscuous') were paired with particular background details (e.g. 'homosexual'), they were recalled more readily by counsellors (Casas *et al.*, 1983). Professional attributions may also differ in relation to patient gender. Cardiac staff have been shown to attribute psychological difficulties following coronary artery bypass surgery to 'emotional problems' in women and to 'organic problems' in men (King *et al.*, 1992) (see 'Gender issues and women's health'). Attitudes also vary in relation to the particular type of health professional involved and in relation to the type of health problem under consideration. In general, health professionals are less willing to work with patients with more chronic disorders and with those individuals having a poorer prognosis. Margolies *et al.* (1983) demonstrated that medical students want more professional distance from psychiatric than from cancer patients and from cancer than myocardial infarction patients. Similarly, they want more distance from male than female patients and from those with a poor rather than good prognosis. With regard to differences associated with the type of health professional training undertaken, occupational therapists and physiotherapists have been found to rate the likely benefit of health care to disabled individuals as being higher than do nurses (Johnston *et al.*, 1987).

Professional choices about access to health services

It is difficult to directly document how professional attitudes per se influence choices about treatment for particular patients. A classic experimental study by McNeil and colleagues (1982) demonstrated that the format in which information is presented can influence healthcare choices for patients, students and physicians. The research task involved choosing between surgical and medical management of cancer given various facts about short- and long-term

risks and framing the information in either a positive (survival statistics) or a negative (mortality statistics) manner. For all groups, information presented in a positive framework led to higher levels of adoption of the treatment alternative than did the same statistics presented negatively (i.e. as mortality data). Service availability may be influenced by implicit beliefs about appropriate behaviour by different groups, e.g. women and men. One illustration in the cardiac setting showed that physicians were perceived as providing stronger recommendations to attend cardiac rehabilitation programmes to male than to female patients (Ades *et al.*, 1992). In a study of prescribing of antibiotics by primary care physicians, Walker *et al.* (2001) showed that professional attitudes influenced intention to prescribe. This study used a theoretical model to consider the relationship of factors such as social norm and attitudes in determining professional behaviour (see 'Theory of planned behaviour'). More generally, a theoretically based approach to changing health professional, as distinct from patient, behaviour has recently been described. The PRIME project includes assessment of professional attitudes, alongside other factors in a variety of professional settings (Walker *et al.*, 2003). This work explicitly uses social cognition models (in particular the Theory of Planned Behaviour) to assess health professional attitudes. The work focuses on variation in adoption of evidence-based recommendation, rather than just prescribing behaviour.

Outcome of health services for users and professionals

The attitudes and behaviour of health professionals are often influenced by expectations regarding individuals or health problems. Thus, a review of studies which have documented the under-diagnosis of mental health problems in patients with physical disorders and vice versa (Lopez, 1989) suggests a dualist understanding of physical and psychological health problems and illustrates that those with both types of problem may be under-served by the current approach of health professionals. More generally, the literature on the placebo effect demonstrates how the attitudes of professionals to health service users and their health problems may be a powerful influence in accelerating or retarding recovery (Di Blasi *et al.*, 2001) (see 'Placebos').

Health services may be withheld because of a range of attitudes and beliefs of health professionals; thus advice on smoking cessation may be withheld because professionals either believe that patients are not receptive to advice or because they believe that they themselves are not capable of providing the appropriate advice (Braun *et al.*, 2004) with differences across professionals, e.g. nurses less

willing to provide advice than physicians. The attitude of the health professional may be expressed in his or her interactions and may thus influence the health outcome. In an early study, Milmo *et al.* (1967) demonstrated that the degree of hostility expressed in a physician's voice tone while talking about alcoholic patients was positively associated with physician failure in getting patients into treatment for alcohol problems.

Future directions

The developing literature on attitudes of health professionals is complemented by a more rapidly expanding research focus on cognitive aspects of decision-making in health settings. From the work of Tversky and Kahneman (1981), a large literature on clinical decision-making has evolved (see 'Medical decision-making'). There is overlap between these two approaches, i.e. one approach which focuses on cognitive processes which are seen to be universal influences on health professional decision-making and another which documents attitudes (affective processes) seen to be exhibited by particular individuals or groups of professionals. Attention to this overlap may lead to a greater understanding of the nature of health professional behaviour and to more effective methods of educating health professionals as active evaluators of their own influence on the practice of, and outcome from, their interventions. An illustration of research at this level is the evolution of work on adherence to health professional recommendations. Here, rather than searching for the 'non-compliant personality' of the 'patient', recent research has focused on the interaction between health professional and service user and on how characteristics of the health professional and the context influence levels of adherence to health recommendations. Another example of the likely application of a joint approach is the area of professional preferences where, for instance, professionals and service users are both influenced in their choice of treatment by a positive framing (survival rather than mortality data) of information (McNeil *et al.*, 1982). Here, the evaluation of affective influences on choice for individual professionals, e.g. the influence of exposure to the disorder in one's own family or the influence of a poor outcome for a previous case in one's care, could complement the documentation of these general cognitive processes as displayed in decision-making.

Further study of the attitudes of health professionals may counterbalance previous attention which was restricted to the attitudes of service users only. If included in a wider research agenda as suggested here, the findings should positively influence the individual professional's understanding and management of his or her role and thereby improve the delivery of health services in the future.

Breaking bad news

Katherine Joeke

Leiden University

What constitutes 'bad news'

Many healthcare professionals will find themselves in a situation where they have to break bad or difficult news to patients and/or their relatives. A broad definition of what constitutes bad news includes situations where there is a threat to a person's mental or physical wellbeing, a risk of upsetting an established lifestyle, or where a message is given which conveys to an individual fewer choices in his or her life (Ptacek & Eberhardt, 1996). This indicates that bad news contains an element of loss or anticipated loss and will, to a certain extent, be subjective. Generally, news of death, terminal illness or deformity constitute the more extreme situations, and will generally be accepted as 'bad news' for the recipient. However, news of chronic illnesses or the need for medical intervention, which at first glance would appear less disastrous, could for the recipient have far-reaching or negative implications for their personal or working life, or their hopes for the future.

The breaking of bad news is stressful for both the messenger and the recipient. Because the manner in which bad news is given will impact the recipient and the decisions he or she needs to make (e.g. Roberts *et al.*, 1994), there has been increased emphasis over the last decades on teaching appropriate communications skills to healthcare professionals. Factors that may create barriers to breaking bad news appropriately are outlined in this chapter, followed by general guidelines on how to break bad news. A review of the literature on how patients perceive bad news gives further insight into the relevance of these guidelines. Furthermore, issues related to communication skills training will be discussed.

Barriers to breaking bad news

Healthcare professionals are faced with a difficult task when having to impart bad or sad news (Buckman, 1984) and several obstacles to delivering bad news appropriately may arise. Factors such as age, gender, social status and race can generally create barriers in communication. Further to this, there are factors related to chaotic hospital settings (including lack of private spaces, time restraints and lack of support from team members) which can hinder the process of communication. The physician's lack of training, fears or sense of powerlessness can result in inadequate or incomplete information giving, and in particular may affect the way in which the clinician deals with the patient's emotions. These emotions (e.g. guilt or fear) can also cause the patient to behave in a manner that hampers the process. Furthermore, differences between what is perceived as bad news by the patient and by the clinician (Dosanjh *et al.*, 2001) can create misunderstanding and confusion. On the other hand, physicians and patients will often collude to limit the communication (The *et al.*, 2000; Dias *et al.*, 2003).

Guidelines and recommendations

It is now generally accepted that breaking bad news appropriately rarely comes naturally to healthcare professionals. Different 'models' for breaking bad news can be identified in the literature. One model distinguished between non-disclosure, full disclosure

and individualized disclosure (Girgis & Sanson-Fisher, 1995), whilst Brewin (1991) differentiates the ‘unfeeling way’ from the ‘kind and caring way’ and from the ‘understanding and positive way’ of breaking bad news. Such descriptive models may be too abstract to create useful guidelines for clinicians, but will have aided in the generation of more detailed recommendations on how best to break bad news. Several guidelines or protocols for the delivery of bad news have been drawn up in the past decade (e.g. Baile *et al.*, 2000; Buckman, 1992; Dias *et al.*, 2003; Girgis & Sanson-Fisher, 1995; SCOPE, 1999). Although such guidelines have primarily been generated from a consensus process rather than based on empirical findings, there is an increasing emphasis in the literature on assessment of the relevance and efficacy of these guidelines.

The six-step approach

A six-step approach to breaking bad news has been suggested (Buckman, 1992; SPIKES by Baile *et al.*, 2000), which shows considerable overlap with the principles suggested by other authors. The six steps are outlined below.

Setting up

Setting up the interview starts with the clinician preparing thoroughly and ensuring that he/she has all relevant information to hand. A private setting without disruption, where both clinician and patient or relatives can sit and feel comfortable, helps all parties to focus on the conversation and respond more freely. The clinician should allow enough time to impart the information and deal with the recipient’s response. Patients may prefer to have a significant other present. If the situation allows this, the clinician could check with the patient whether he/she would wish for a relative or friend to attend the interview.

Assessment of patient’s perception

It is important to assess the patient’s perception of the medical situation by using open questions (e.g. ‘What have you been told about the tests that have been carried out?’). This gives the clinician insight into what the patient knows and understands and allows him/her to tailor the bad news appropriately. It can also give the clinician an indication of the recipient’s expectations of the interview.

Agreement about amount of information

Obtaining a patient’s invitation about the amount of information he/she desires to receive about diagnosis, prognosis and treatment allows the clinician to match the amount of detail given to the patient’s wishes. In a situation where medical tests are ordered, the clinician can ascertain in advance how much the patient may wish to know about the test results. Patients will have different coping styles (Miller, 1995), and the clinician should allow for this.

Imparting knowledge and information

The consultation centres on giving knowledge and information to a patient or relative. A verbal warning that bad news is coming can help prepare the recipient and may lessen the shock (Maynard, 1996). Following this, the use of clear and unambiguous

(but not blunt) language avoids misunderstanding or confusion. Information should be given in small chunks and may need to be repeated. This, and checking that the patient or relative has understood, will help him/her to take in as much of the information as possible.

Emotional responses

When addressing patient’s emotions, it is important to keep in mind that a wide array of emotions can be experienced (e.g. shock, disbelief, anger, fear), and that clinicians should respond with empathic statements, exploratory questions and validating responses. Responding appropriately to a patient’s emotions is perceived to be one of the most difficult aspects of breaking bad news (Ptacek & Eberhardt, 1996), but also one of the most important elements of the bad news consultation. The clinician needs to identify the emotional response, check this with the patient and indicate that he/she understands the reason for this emotion (e.g. when a patient responds with disbelief and shock to news, the clinician may respond with ‘I realize that this is not what you expected to hear. I understand this must be a shock for you’). Non-verbal behaviour should match the verbal messages, i.e. facial expression and touch (where deemed appropriate).

Summarizing and future strategy

Before ending the interview, the clinician needs to summarize and consider a strategy for the future. This should match the patient’s readiness to move on. In cases of chronic or terminal illness, a discussion of continuous, curative or palliative treatment can provide the patient with a sense of certainty and a clear plan for the future. This could include future appointments and/or lines of communication. At this stage additional sources of support can usefully be identified.

Evaluation of guidelines

The six-step approach and similar guidelines make intuitive sense, and certain aspects of the guidelines find resonance in research on patient’s experience of hearing bad news, as described in the following section of this chapter. More systematic research on the validity, efficacy and practicality of these guidelines is necessary (Baile *et al.*, 2000; Fallowfield & Jenkins, 2004). There is an indication that the presence of a protocol specifying how to proceed following disclosure of bad news may reduce stress for health care professionals (Simpson & Bor, 2001). Therefore, implementation and evaluation of these guidelines in medical education, both at undergraduate and postgraduate level, should continue to be developed.

The patient’s perspective

The general view is that the manner in which bad news is conveyed can have an impact on factors such as patient satisfaction (Fallowfield & Jenkins, 2004), comprehension of information (Maynard, 1996), coping and psychological adjustment (Roberts *et al.*, 1994) and levels of hopefulness (The *et al.*, 2000)

(see 'Coping with chronic illness' and 'Patient satisfaction'). In the last decade there has been increasing emphasis on research to further investigate these preferences in delivery of bad news. Reviews of this research (Fallowfield & Jenkins, 2004; Ptacek *et al.*, 2001) identify three main areas of research, i.e. in cancer care, in acute trauma situations and in obstetrics and paediatrics settings. The issues in these three areas will be quite different. Cancer patients receive news about diagnosis or recurrence of terminal or serious illness, which will be followed by information and discussion about curative or palliative treatment. In instances of acute trauma, family members are likely to be confronted with unexpected bad news (e.g. of death after a road traffic accident) delivered by a person they have never met before. In obstetrics and paediatrics departments parents or prospective parents can be confronted with news of a child's death or disability. Although the news and settings vary widely, the research generates three themes. Firstly, recipients of bad news tend to value the informant being kind, confident, sensitive and caring. They appreciate the informant showing concern and distress, rather than a cool or detached attitude. This underlines the necessity for showing empathy and having an understanding of the impact that the news will have on the patient and the family. Secondly, there is a strong desire for information to be imparted in a clear and unambiguous manner using simple terms, whilst blunt or abrupt communication is perceived as distressing. Patients appreciate being given time to talk and to ask questions. For cancer patients there is an important balance to be struck between the physician being truthful and not being too negative. There appear to be large personal differences between patients regarding the amount of detail they wish to know, for example about prognosis (Salander, 2002; Dias *et al.*, 2003). Such findings underline the guideline of matching information given to the patient's desire for such information. The third main theme is the setting in which a patient receives the bad news, with privacy being of importance. These themes, also identified in other studies (Parker *et al.*, 2001; McCulloch, 2004), give credence to the guidelines set out above.

There has been less emphasis in research on the potential consequences of the bad news consultation on longer-term psychological adjustment, and results are equivocal. Barnett (2002) reported no difference on psychological distress between cancer patients who had negative perceptions of the interaction with the physician (i.e. displaying brusque, unsympathetic or impatient behaviour) and those who had a positive perception of the interaction. Mager and Andrykowski (2002), however, found a weak correlation between a negative consultation experience and increased levels of distress in cancer patients. Furthermore, a study by Schofield and colleagues (2003) provides preliminary evidence that communications strategies recommended in the literature are associated with reduced anxiety and depression in patients with newly diagnosed melanoma.

Teaching skills for delivering bad news

Medical education in developed countries increasingly incorporates relevant communications skills training (see 'Teaching communications skills' and 'Medical interviewing'). One aspect of this training should deal with appropriate communication skills

for breaking bad news. Although a detailed discussion of such training lies beyond the scope of this chapter, a brief overview is given. The literature identifies that adequate education of communication skills requires evidence-based rationale for the training (Maguire & Pitceathly, 2002), multiple sessions and opportunities for demonstration, reflection, discussion, practice and feedback (Fallowfield, 1996; Rosenbaum *et al.*, 2004). Postgraduate workshops may also benefit physicians (Ladouceur *et al.*, 2003). Whilst training sessions on breaking bad news emphasize acquisition of skills, they should simultaneously pay attention to the clinician's own emotions. Many clinicians report that breaking bad news remains a difficult task throughout their career, which can be accompanied by negative emotions, in particular feelings of guilt. It is important for them to understand that the manner in which the news is imparted can support the patient and their family and make a positive contribution in such difficult times. This knowledge may give the clinician a sense of purpose and hope and can assist effective and compassionate communication.

Evaluation of training and workshops is vital in order to establish both short-term and long-term efficacy. Rather than assessing clinician satisfaction and confidence, evaluation procedures should include observation of actual behaviour (Rosenbaum *et al.*, 2004).

Other issues

Cultural diversity

The medical profession in the western world will increasingly be treating patients from a culturally diverse background, which has repercussions for the patient's response to medical issues. This will be reflected in communication of bad news and end-of-life decisions (Searight & Gafford, 2005). Although it may be too much to expect practitioners to be fully conversant with all subtleties of cultural diversity, it is important that they are sensitive to the needs of the specific ethnic minority groups that they mostly encounter in daily practice (see 'Cultural and ethnic factors in health').

Breaking bad news to children

When children are seriously ill or lose a parent, the bad news will be all the harder to impart appropriately. The child's developmental stage and understanding of death and illness needs to be taken into consideration. Clinicians need to work closely with parents or other relatives whose response may greatly influence the child's perceptions (Forrest, 1989) (see 'Children's perceptions of illness and death' and 'Coping with death and dying').

Summary

In summary, research has shown that the manner in which bad or sad news is broken influences patient satisfaction and possibly their future psychological adjustment. Guidelines have been generated primarily from a consensus process: however, these can aid the healthcare professional. The available literature shows that guidelines are relevant, in particular with regard to the settings, language used and the manner in which the clinician responds

to the patient. Future research would benefit from audiotapes, videotapes or direct observation of bad news consultation, although there are ethical issues to consider. The patient's and family's wellbeing will always be a priority: asking consent to take part in a research project could be perceived as difficult or indeed

inappropriate. Medical education increasingly focuses on teaching and evaluating communications skills, including those skills relevant for breaking bad news.

Burnout in health professionals

Christina Maslach

University of California, Berkeley

Burnout in health professionals

Burnout is a psychological syndrome that involves a prolonged response to chronic emotional and interpersonal stressors on the job (Maslach, 1982; Maslach *et al.*, 2001). As such, it has been an issue of particular concern for human services occupations where: (a) the relationship between providers and recipients is central to the work, and (b) the provision of service, care, treatment or education can be a highly emotional experience. Within such occupations, the norms are clear, if not always stated explicitly: to be selfless and put others' needs first; to work long hours and do whatever it takes to help a client or patient or student; to go the extra mile and to give one's all. When such norms are combined with work settings that are high in demands and low in resources, then the risk for burnout is high (Maslach & Goldberg, 1998). All of these criteria certainly apply to health professions, which have long been recognized as stressful occupations (Cartwright, 1979). Indeed, much of the earliest research on burnout was conducted in the area of healthcare (Maslach & Jackson, 1982), and this focus has continued up to the present (Maslach & Ozer, 1995; Leiter & Maslach, 2000).

The multidimensional model of burnout

Burnout has been conceptualized as an individual stress experience that is embedded in a context of social relationships and thus involves the person's conception of both self and others (Maslach, 1998). The three key dimensions of this experience are exhaustion; feelings of cynicism and detachment from the job; and a sense of ineffectiveness and lack of accomplishment. Exhaustion is the individual stress dimension of burnout, and it refers to feelings of being physically over-extended and depleted of one's emotional resources (it has also been described as wearing out, loss of energy, depletion, debilitation and fatigue). Cynicism (or depersonalization) refers to a negative, callous or excessively detached response to other people, who are usually the recipients of one's service or care (it has also been described as negative or inappropriate attitudes towards patients, loss of idealism and irritability). Inefficacy refers to a decline in one's feelings of competence and successful achievement in one's work (it has also been described as reduced productivity or capability, low morale, withdrawal and an inability to cope).

These three dimensions of burnout can be illustrated by the experiences of healthcare professionals. Clearly, there are significant emotional experiences linked to the caregiving relationship between health worker and patient. Some of these experiences are enormously rewarding and uplifting, as when patients recover

because of the worker's efforts. However, other experiences are emotionally stressful for the health practitioner, such as working with difficult or unpleasant patients, having to give 'bad news' to patients or their families, dealing with patient deaths or having conflicts with co-workers or supervisors. These emotional strains are sometimes overwhelming and lead to exhaustion.

To protect themselves against such disruptive feelings, health professionals may moderate their compassion for patients by distancing themselves psychologically, avoiding over-involvement and maintaining a more detached objectivity (a process known as 'detached concern'; Lief & Fox, 1963). For example, if a patient has a condition that is upsetting to see or otherwise difficult to work with, it is easier for the practitioner to provide the necessary care if he or she thinks of the patient as a particular 'case' or 'symptom' rather than as a human being who is suffering. However, the blend of compassion and emotional distance is difficult to achieve in actual practice, and too often the balance shifts toward a negative and depersonalized perception of patients. A derogatory and demeaning view of patients is likely to be matched by a decline in the quality of the care that is provided to them.

Many health professionals have not had sufficient preparation for the emotional reality of their work and its subsequent impact on their personal functioning. Thus, the experience of emotional turmoil on the job is likely to be interpreted as a failure to 'be professional' (i.e. to be non-emotional, cool and objective). Consequently, these health workers begin to question their own ability to work in a health career and to feel that their personal accomplishments are falling short of their expectations. These failures may be as much a function of the work setting as of any personal shortcomings: providing good healthcare may be difficult to accomplish in the context of staff shortages, poor training or inadequate resources. Nevertheless, health workers may begin to develop a negative self-evaluation, which can impair their job performance or even lead them to quit the job altogether.

Consequences of burnout

Burnout has been associated with various forms of negative responses to the job, including job dissatisfaction, low organizational commitment, absenteeism, intention to leave the job and rapid turnover (see Schaufeli & Enzmann, 1998, for a review). People who are experiencing burnout can have a negative impact on their colleagues, both by causing greater personal conflict and by disrupting job tasks. Thus, burnout can be 'contagious' and perpetuate itself through informal interactions on the job. When burnout reaches the high cynicism stage, it can result in higher

absenteeism and increased turnover. Furthermore, burnout is linked to poorer quality of work, as people shift to doing the bare minimum, rather than performing at their best. They make more errors, become less thorough and have less creativity for solving problems. For example, one study found that nurses experiencing higher levels of burnout were judged by their patients to be providing a lower level of patient care (Leiter *et al.*, 1998), while another study found that the risk of patient mortality was higher when nurses had a higher patient workload and were experiencing greater burnout (Aiken *et al.*, 2002).

Because burnout is a prolonged response to chronic interpersonal stressors on the job, it tends to be fairly stable over time. Unlike depression, which is considered to be context-free and pervasive across all situations, burnout is regarded as job-related and situation-specific. Burnout symptoms tend to manifest themselves in normal persons who do not suffer from prior psychopathology or an identifiable organic illness. As such, burnout seems to fit the diagnostic criteria for job-related neurasthenia (Schaufeli *et al.*, 2001).

As one would expect from the research on stress and health, the exhaustion dimension of burnout has been correlated with various physical symptoms of stress: headaches, gastrointestinal disorders, muscle tension, hypertension, cold/flu episodes and sleep disturbances (see Leiter & Maslach, 2000a, for a review). Although there has been less research on how burnout affects one's home life, studies have found a fairly consistent negative 'spillover' effect. For example, nurses who experienced burnout reported that their job had a negative impact on their family and that their marriage was unsatisfactory (Burke & Greenglass, 2001). (See also 'Psychosomatics' and 'stress and health').

Job engagement

Burnout is one end of a continuum in the relationship people establish with their jobs, standing in contrast to the positive state of engagement with work. Recently, the multidimensional model of burnout has been expanded to this other end of the continuum (Leiter & Maslach, 1998). Job engagement is defined in terms of the same three dimensions as burnout, but at the positive end of those dimensions rather than the negative. Thus, engagement consists of a state of high energy (rather than exhaustion), strong involvement (rather than cynicism) and a sense of efficacy (rather than inefficacy).

The concept of a burnout-to-engagement continuum enhances the understanding of how the organizational context of work can affect workers' wellbeing. It recognizes the variety of reactions that people can have to the organizational environment, ranging from the intense involvement and satisfaction of engagement, through indifference to the exhausted, distant and discouraged state of burnout. One important implication of the burnout-engagement continuum is that strategies to promote engagement may be just as important for burnout prevention as strategies to reduce the risk of burnout. A work setting designed to support the positive development of the three core qualities of energy, involvement and effectiveness should be successful in promoting the wellbeing and productivity of its employees.

Key risk factors for burnout

Although there is some evidence for individual risk factors for burnout, there is far more research evidence for the importance of situational variables. Over two decades of research on burnout have identified a plethora of organizational risk factors across many occupations in various countries (see Maslach *et al.*, 2001; Schaufeli & Enzmann, 1998). Building on earlier models of job-person fit, in which better fit was assumed to predict better adjustment and less stress, Maslach and Leiter (1997) formulated a burnout model that focuses on the degree of match, or mismatch, between the individual and key aspects of his or her organizational environment. The greater the gap, or mismatch, between the person and the job, the greater the likelihood of burnout; conversely, the greater the match (or fit), the greater the likelihood of engagement with work. In analyzing the research literature, Maslach and Leiter (1997, 1999) identified six key areas of worklife in which a job-person mismatch is predictive of burnout: workload, control, reward, community, fairness and values.

Work overload

A commonly discussed source of burnout is overload: job demands exceeding human limits. People feel that they have too much to do, not enough time to perform required tasks and not enough resources to do the work well. There clearly is an imbalance, or mismatch, between the demands of the job and the individual's capacity to meet those demands. Not surprisingly, work overload is the single best predictor of the exhaustion dimension of burnout.

Patient workload has consistently been found to predict burnout in healthcare professionals. Both the quantity and quality of the contact between health professional and patient are important risk factors. The strain of working with patients can be multiplied by the need to deal with the patients' families as well, and by the challenges of working with colleagues.

Lack of control

Burnout is consistently linked to job factors in the healthcare setting that entail greater ambiguity and less control. Health professionals must often work closely and interdependently with each other, but may differ in status and power (as in the case of physicians and nurses). Consequently, some people have little control over the decisions that determine their daily activities and may receive little feedback about the results of their efforts. They may feel they are being held accountable, and yet they don't have the ability to control what it is they are being held accountable for. In other cases, people will feel a lack of control because working life has become more chaotic and ambiguous as a result of economic downturns. Many health professionals find themselves worrying about mergers, downsizing, layoffs and changes in management. In some cases, health workers have no influence on institutional policies that govern the hours and conditions of their work, and few opportunities for creativity and autonomy in carrying out their job tasks.

Insufficient rewards

Another type of job–person mismatch occurs when health professionals believe they are not getting rewarded appropriately for their performance. The standard rewards that most people think of are salary or benefits or special ‘perks’. However, in many cases the more important rewards involve recognition. Lack of recognition from patients, colleagues, managers and external stakeholders devalues both the work and the workers, and is closely associated with feelings of inefficacy. It matters a great deal to people that somebody else notices what they do and that somebody cares about the quality of their work. When employees are working hard and feel that they are doing their best, they want to get some feedback on their efforts. The value of such concepts as ‘walk-around’ management lies in its power to reward: there is explicit interest in what people are doing, and the direct acknowledgement and appreciation of their accomplishments. Employee morale is heavily dependent on rewards and recognition.

Breakdown in community

Community is the overall quality of social interaction at work, including issues of conflict, mutual support, closeness and the capacity to work as a team. Work relationships include the full range of people that health professionals deal with on a regular basis, such as their patients, their co-workers, their boss, the people they supervise or people in the larger community (such as the patients’ families). When these relationships are characterized by a lack of support and trust and by unresolved conflict, then there is a breakdown in the sense of community. If work-related relationships are working well, then there is a great deal of social support, and people have effective means of working out disagreements. But when there is a breakdown in community and there is not much support, there is real hostility and competition, which makes conflicts difficult to resolve. Under such conditions, stress and burnout are high and work becomes difficult (see also ‘Social support and health’).

Absence of fairness

The fifth area, an absence of fairness in the workplace, seems to be quite important for burnout, although it is a relatively new area of burnout research. The perception that the workplace is unfair and inequitable is probably the best predictor of the cynicism dimension of burnout. Anger and hostility are likely to arise when people feel they are not being treated with the respect that comes from being treated fairly. Even incidents that appear to be insignificant or trivial can, if they signal unfair treatment, generate intense emotions and have great psychological significance.

When people are experiencing the imbalance of inequity, they will take various actions to try to restore equity. Some actions might involve standard organizational procedures (e.g. for resolving grievances), but if employees do not believe there is any hope of a fair resolution, they may take other actions in areas that they can control. For instance, if employees think they are not being paid as well as they deserve, they may leave work early or take company supplies home with them, because ‘they owe it to me’. It is possible

that, in some extreme instances, employees might take action against the person (or persons) whom they may consider responsible for the inequity.

Value conflicts

Although there has not been a lot of research on the impact of values, current work suggests that it may play a key role in predicting levels of burnout (Leiter & Maslach, 2004). Values are the ideals and goals that originally attracted people to their job and thus they are the motivating connection between the worker and the workplace (beyond the utilitarian exchange of time and labour for salary). Value conflicts arise when people are working in a situation where there is a conflict between personal and organizational values. Under these conditions, people may have to grapple with the conflict between what they want to do and what they have to do. For example, people whose personal values dictate that it is wrong to tell a lie may find themselves in a job where it is necessary to lie or to shade the truth (e.g. to get the necessary authorization, or to avoid upsetting the patient). People who experience such a value conflict will give the following kinds of comments: ‘This job is eroding my soul’, or ‘I cannot look at myself in the mirror any more knowing what I’m doing. I can’t live with myself. I don’t like this’. If workers are experiencing this kind of mismatch in values on a chronic basis, then burnout is likely to arise.

Implications for intervention

What can be done to alleviate burnout? One approach is to focus on the individual who is experiencing stress and help him or her to either reduce it or cope with it. Another approach is to focus on the workplace, rather than just the worker, and change the conditions that are causing the stress. A focus on the workplace is the clear implication of the organizational research on burnout, which posits that the six key areas of work–life affect people’s experience of burnout or engagement, which, in turn, affect attitudes and behaviour at work. Thus, an effective approach to intervention would be to change workplace policies and practices that shape these six areas. The challenge for organizations is to identify which of the areas are most problematic, and then designing interventions that target those particular areas (see ‘Worksite interventions’).

Assessment of these six areas, as well as assessment of burnout, is a key element in the organizational checkup survey (Leiter & Maslach, 2000*b*), which has proved to be a useful tool for mobilizing both individual and organizational self-reflection and change. This organizational approach, which utilizes the six-area framework, makes a major contribution to making burnout a problem that can be solved in better ways than having employees either endure the chronic stress or quit their jobs. For the individual employees, the organizations for which they work, and the clients whom they serve, the preferred solution is to build a work environment that supports the ideals to which people wish to devote their efforts. This is a formidable challenge, but one that becomes more possible with the development of effective measures and a conceptual framework to guide intervention.

The practice of medicine has long been regarded as one of the noblest of occupations. To cure illness, repair injury, promote health and even forestall death are skills that are highly esteemed in all societies. Although the personal rewards and satisfactions of a health career are many, it is not without its hazards, including

that of burnout. However, recent research has improved our understanding of the workplace dynamics of this syndrome and provides new insights into possible solutions to this important problem.

Communicating risk

David P. French¹ and Theresa M. Marteau²

¹University of Birmingham

²King's College London

Introduction

There is an increasing move towards communicating risk information to both patients and the wider public, fuelled by increasingly precise epidemiological estimates, technological developments allowing the use of biomarkers of risk as communication tools and the rise of interest in informed choice (see, for example, 'Screening in healthcare'). As a consequence, concern about how best to communicate risk information and evaluate the impact of different methods of communicating risk has risen correspondingly. Communicating risk information should not be seen as an end in itself, but rather as a means to achieving one or more ultimate aims. Principally, these include communicating risk information to (a) facilitate informed choices; (b) motivate behaviour change to reduce identified risks and (c) provide reassurance while avoiding false reassurance. This chapter discusses why the current focus on communicating probabilistic information is insufficient for achieving these outcomes and describes other approaches which have shown more promise.

Risk communication as presenting probabilities

Much recent discussion of risk communication has centred on how numerical probability information should be presented (Calman & Royston, 1997; Edwards *et al.*, 2001, 2002, 2003; Paling, 2003). At face value, presenting risk information in a probabilistic form is entirely reasonable: the information derives from epidemiological studies, which yield information about disease risks in terms of probabilities. However, there are reliable and systematic differences between estimates of actual risks, as calculated from mortality statistics and the public's perception of these (Lichtenstein *et al.*, 1978) (see 'Risk perception'). These include a tendency to under-estimate the frequency of large risks and over-estimate small risks, with over-estimation being more likely when the risks were dramatic, e.g. murder, than when they were less so, e.g. diabetes (see Schwarz & Vaughn, 2002). An understandable response to this has been to try to reduce this gap by providing people with the epidemiological risks, presented in terms of the probability of an adverse outcome, such as disease or death. However, providing probabilities to people has made little impact on informing choices, providing reassurance or altering risk-related behaviour.

Why does providing probabilistic risk information have little impact?

It is now well established that providing information about the probability of health risks alone has, at best, only a small influence

on how people think about those risks and on their risk-related behaviour. One review concluded: 'it would appear that people cannot reliably understand and interpret numerical probability statistics' (Rothman & Kiviniemi, 1999, p. 46). Similarly, meta-analyses of studies investigating the effects of fear-rousing communications show that perceptions of vulnerability have on average a small effect on intentions to change behaviour and on concurrent and subsequent behaviour (Floyd *et al.*, 2000; Milne *et al.*, 2000; Witte & Allen, 2000). We now consider three of the reasons why providing probabilistic risk information has minimal effects on how people think and behave: (a) people have difficulty understanding and remembering probabilities, (b) people find it difficult to evaluate probabilities without supplementary information and (c) even if probabilistic information is understood, perception of risk comprises more than perception of probability.

Understanding and remembering probabilities

Both health professionals and patients have difficulties in understanding probabilities (Rothman & Kiviniemi, 1999). Several studies have shown that many people are unable to handle even simple numerical operations, such as converting a percentage into a proportion (e.g. Lipkus *et al.*, 2001; Schwartz *et al.*, 1997). Many people, including physicians, are unable to correctly calculate the likelihood that a person being screened has a particular condition, when provided with information in the form of percentages about the base rate, sensitivity and false-positive rate of the screening test (Hoffrage *et al.*, 2000). Even when probabilistic information is understood, people still tend to remember it in terms of a small number of discrete categories (Axworthy *et al.*, 1996; Lippman-Hand & Fraser, 1979). For example, while over 90% of those testing negative for being a cystic fibrosis carrier understood at the time of testing that they had a residual risk of being a carrier (about 1:130), three years later, fewer than 50% had retained this information, with many believing they were at no risk (Axworthy *et al.*, 1996). Thus, even when numerical probabilities appear to be understood, what is often remembered is only the 'gist' of the communication (Reyna & Brainerd, 1991).

Evaluating probabilistic information through comparisons

People do not generally carry around accurate numerical estimates of probabilities of harm in their heads, only vague senses of 'riskiness'. For this reason, when they receive a new piece of probabilistic risk information, it can be difficult to evaluate this, if they

have nothing against which to compare it. At a minimum, people need additional information to clarify the implications of absolute risk information. This includes the risk that others similar to them have, or their own risk if they were to adhere to recommended medical advice. Thus, when asked what information they want in order to understand a health risk, people typically ask for comparative information about the probability of other risks (Roth *et al.*, 1990). In keeping with the evaluative function of relative risk information, presenting information about relative risks generally has more impact on perceptions of likelihood, emotion and decision-making, than information about absolute risks (Edwards *et al.*, 2001; Klein, 1997; Nexoe *et al.*, 2002).

Beyond probability

One fundamental problem with viewing risk as probability is that it fails to take into account the value that people attach to different outcomes. Thus, although two people may have identical beliefs about the probability of the same adverse outcome, such as having a child with Down's syndrome, their decision about whether to have a screening test depends critically upon their evaluation of that outcome (Lawson, 2001). Equally, people vary widely in their perception of how severe they view even common conditions such as diabetes (Farmer *et al.*, 1999). Reviews of experimental studies which have provided people with information about both the severity and the likelihood of health threats have shown that perceptions of severity have as much impact as perceptions of likelihood on motivation to take protective action against the threat and on behaviour itself (Milne *et al.*, 2000; Witte & Allen, 2000). The impact of likelihood information may even be reduced in the presence of information about severity (Hendrickx *et al.*, 1989).

Towards effective risk communication

The aims of communicating risk information are often implicit. However, to be able to judge the effectiveness or otherwise of risk communication, explicit criteria are needed. These criteria will vary with the aims of the communication. The aim of communicating risk information should affect both the content and framing of the information provided. This is described below in considering effective ways of achieving three of the more common aims of communicating risk information: informing choices; facilitating risk reducing behaviour; and providing appropriate reassurance.

Informing choices

Changes both within and outside of healthcare have resulted in an increasing emphasis upon providing services in ways to facilitate patients making informed choices (see 'Patient-centred healthcare'). Core elements of definitions of informed choice are an understanding of the different options and their likelihoods (Bekker *et al.*, 1999; Marteau *et al.*, 2001a). Despite understanding being a central outcome to risk communication, there have been few attempts to define what it means to understand a risk (Weinstein,

1999). In addition to likelihood of harm, other important dimensions include an appreciation of the nature of the potential harm, the risk in comparison with other hazards, the factors that lead to this risk, the excess risk due to these factors and the difficulty of avoiding the harmful consequences of these factors, once exposed (Weinstein, 1999). Although people may have a good appreciation of some of these dimensions, e.g. that smoking is bad for one's health, appreciation of other elements of understanding, e.g. the nature and severity of the health consequences of smoking, can still be lacking (Weinstein *et al.*, 2004). Thus, the first choice in communicating risk information to facilitate informed choices concerns selecting the appropriate information to communicate.

A general framework for selecting the appropriate strategy for communicating risk information and supporting decisions has been developed (O'Connor *et al.*, 2003). According to this framework, the most appropriate risk communication strategies depend upon whether patients are faced with decisions concerning either 'effective' health services, where the benefits are large compared with harms, or 'preference-sensitive' health services, where it is unclear how much benefit is provided relative to harms, or where the ratio of benefits to harms is dependent on patient values. Where clinicians are discussing 'effective' health services with patients, consultations surrounding risk may be more directive and may concern motivations and barriers to change. On the other hand, where clinicians are discussing 'preference-sensitive' health services, counselling is non-directive, where more discussion of potential benefits and harms, probabilities and options is suitable.

Where probabilistic information is to be communicated, understanding and manipulation of that information is facilitated when it is presented using natural frequencies (Hoffrage *et al.*, 2000). Natural frequency information is given when all the information provided relates to an overall sample, e.g. of 1000 people, 40 people are infected, of whom 30 test positive and 10 test negative (see Hoffrage *et al.*, 2002). More generally, there is now an evidence base for how to communicate other written information to maximize the likelihood that people will understand it and be able to extract the information in which they are particularly interested (Wright, 1999).

As noted above, over time people tend to remember risk information in terms of simpler discrete categories: they extract the 'gist' of the message (Reyna & Brainerd, 1991). How this 'gist' is recalled depends critically upon the prior understanding of the health threat. Such information is better recalled if it is congruent with how people already think about that disease (Bishop, 1991). The important point is that people are not blank slates onto which risk communications can be written: people already have an understanding of health and disease, albeit often simplistic and discrepant from current medical understanding (Bostrom *et al.*, 1992; Leventhal *et al.*, 1997).

There are many areas where disease-related communications may not fit with pre-existing understandings of disease. For example, many women appear to lack a plausible explanation for how smoking increases the risk of cervical abnormalities (Marteau *et al.*, 2002). Consequently, informing women with cervical abnormalities that quitting smoking would help them will not make sense to them and they are therefore unlikely to do so (McBride *et al.*, 1999). Providing such women with a coherent model of the nature of the

risk is more effective at promoting understanding and recall of likelihood of cervical abnormalities, than probabilistic information which will soon be forgotten (Hall *et al.*, 2004).

Facilitating risk-reducing behaviour

It has been known for some time now that communicating risk information on its own is rarely sufficient to bring about changes in behaviour to reduce risk, and under some circumstances may even be counter-productive (Leventhal, 1970). Behaviour change is more likely when information about likelihood and severity are presented alongside information about the action needed to reduce this threat (Witte & Allen, 2000). Experimental manipulations of information about the effectiveness of behaviour change in reducing health threats have been consistently shown to have as much of an impact on behaviour as do manipulations of likelihood and severity combined (Milne *et al.*, 2000). Thus, although most smokers have some awareness of the high likelihood that their smoking will lead to severe disease (Weinstein, 1998), whether they even attempt to stop smoking is highly dependent on whether they believe that quitting will substantially reduce their chances of avoiding disease (Christensen *et al.*, 1999), as well as whether they think they can stop (Dijkstra & deVries, 2000). These beliefs depend critically upon how people understand the process by which the risk leads to disease, and how avoidance of the risk can reduce chances of disease.

Health communications aimed at achieving behaviour change should therefore aim to provide a clear and simple explanation of these factors, rather than just a bald statement of likelihood. They also need to be accompanied by an explicit plan concerning exactly when and where the recommended risk-reducing behaviour will be performed (Sheeran, 2002). However, even when all these recommendations are followed, risk communications will not provide a 'magic bullet' to alter behaviour. They need to be seen as part of a broader strategy to reduce population risks of common conditions (Crawford, 2002) (see 'Health promotion').

Providing appropriate reassurance

The majority of health risk assessments and many diagnostic test procedures yield 'negative' or 'normal' results. Such results indicate that there is a low chance, but do not indicate that there is absolutely no chance, of developing or having the tested condition. An important aim when communicating negative results, therefore, is to present these results to provide appropriate reassurance. That is, to communicate that the result is 'good news' and hence anxiety about the residual risk is unwarranted, whilst avoiding false reassurance, i.e. the belief that low risk means no risk.

A major concern in much risk communication to date has been to avoid generating high levels of distress. Information on test sensitivity, i.e. the proportion of cases that it can detect, and by implication, the number of cases it can not, is often not provided. For example, one analysis found that information on the proportion of breast cancers detected by screening was mentioned in just 15 of 58 patient information leaflets (Slaytor & Ward, 1998).

This lack of provision of information on test sensitivity may lead to a number of unfortunate consequences due to false reassurance, i.e. erroneously believing that negative or normal test results indicate an absence of residual risk. These include reinforcement of unhealthy lifestyles (Tymstra & Bieleman, 1987), poorer adjustment following the birth of a child with a disability (Hall *et al.*, 2000) and delay in seeking help when symptoms of disease arise, as well as delay in health professionals responding to such symptoms, along with associated litigation (Petticrew *et al.*, 2000). There is evidence that using the term 'normal' to describe test results encourages false reassurance with as many as 50% believing their results indicate no residual risk (Axworthy *et al.*, 1996; Marteau *et al.*, 2001b).

Communicating residual risks using numbers rather than words has been found to have a small beneficial effect of increasing awareness of residual risks without raising anxiety (Marteau *et al.*, 2000). Further, whilst only 52% of women who were informed that their smear test result was 'normal' understood that cervical smear tests entail a residual risk, 70% of women given an additional sentence explaining the meaning of a normal smear result using a verbal probability of absolute risk, appreciated that there was a residual risk (Marteau *et al.*, 2001b). To date, however, few studies have been conducted on how to reduce rates of false reassurance and there is a particular need to understand the emotional and cognitive processes that affect longer-term recall.

Conclusions

To help people understand risk information, they should be presented not only with the likelihood of harm, but also with a clear description of the nature of the harm to which they are exposed. To help people make informed decisions, any information about risk communicated should take into account their likely prior understanding and what are the features of the risk information in which people will already have an interest. To help people change their behaviour to reduce risk, they should be given explicit information about how altering their behaviour might result in a reduction in risk and helped to develop a clear plan of action to alter their behaviour. To provide reassurance but avoid false reassurance, information on test sensitivity and in particular on residual risk with 'normal' test results should be presented. In all these cases, these recommendations are tentative: there is insufficient reliable data on the long-term effects of different approaches to communicating risk information to be more conclusive.

It is important to appreciate that these different aims of risk communication may sometimes conflict: although presenting information on the sensitivity and specificity of screening programmes should promote informed choice, it may lead to lower programme uptake and possibly reduce their public health impact (Marteau & Kinmonth, 2002). However, a clear idea of why risk information is being communicated will undoubtedly be helpful in optimizing risk communication and in evaluating whether the goals of such communications have been met (see also 'Risk perception').

Healthcare professional–patient communication

John Weinman

King's College London

Effective healthcare professional–patient communication is necessary to ensure not only that the patients' problems and concerns are understood by the healthcare professional (HCP) but also that relevant information, advice and treatment is received and acted upon by the patient. HCP–patient communication has been the object of considerable research, which has attempted not only to describe the interaction processes involved but also to show how these affect a range of patient outcomes. Early research revealed quite high levels of patient dissatisfaction which were often associated with insufficient information, poor understanding of the medical advice and subsequent reluctance or inability to follow recommended treatment or advice (Korsch & Negrete, 1972). The development of relatively unobtrusive audio- and video-recording techniques allowed researchers to obtain an 'inside view' of the consultation and many studies have analyzed the process of the consultation and attempted to relate process variables or characteristics to outcome. However, these studies, while identifying important themes, have not always been successful in making clear links between process and outcome (Stiles, 1989). One reason for this is that patients vary in their expectations and preferences. As a result, many current frameworks for understanding HCP–patient communication (e.g. Friedrikson, 1993) are based on the relations between inputs (i.e. the attitudes, beliefs, expectations, etc., which patient and HCP bring to the consultation), process (the nature of the encounter) and outcome (the short and longer-term effects on the patient).

Input factors in communication

Patients cope with health threats in diverse ways and show consistent differences in the extent to which they want to be involved in the healthcare process (Krantz *et al.*, 1980) as well as in the amount of information which they would like to receive about their health problems. Similarly, a distinction has been made by Miller (1995) between 'monitors' and 'blunters', with the former being more inclined to need and seek out information about their problem and treatment, whereas the latter group prefer consultations in which relatively limited information is provided. Miller and colleagues have shown how these two different styles of coping with health threats can influence how patients respond to communication in many areas of healthcare, including cancer screening and treatment.

Patients have differing expectations for specific consultations. Contrary to medical opinion, patients do not always want or expect diagnosis or treatment since they may be looking to the consultation to gain more understanding of their health problem or may be hoping for support or understanding from their HCP (Barry *et al.*, 2000). These prior expectations can be important in determining outcomes since consultations in which patient expectations are met result in greater satisfaction and an increased willingness to follow advice or treatment (Williams *et al.*, 1995). Thus an important starting point for any consultation is to identify the patients' own expectations, as well as their own preferences and beliefs.

Healthcare professionals can also vary considerably in the attitudes and beliefs, which they have not only about their own and the patient's role, but also about the function and conduct of the consultation. For example, doctors have been categorized in various ways according to their role perceptions and the extent to which they concentrate on the technical or more psychosocial aspects of patient care, as well as their beliefs about whether patients should be actively involved in the consultation and in decision-making about the management of the clinical problem (e.g. Grol *et al.*, 1990). Inevitably these broad attitudinal differences are reflected in differences in the way in which the consultation is conducted (see 'Attitudes of health professionals').

The consultation process

There is a range of methods and frameworks for analyzing and describing the process of the consultation. One of the broadest distinctions made has been between consultations which are described as patient-centred and those which are doctor-centred, reflecting the extent to which the doctor or patient determines what is discussed (see 'Patient-centred healthcare'). Doctor-centred consultations are ones in which closed questions are used more often and the direction is determined by the doctor atypically with a primary focus on medical problems. In contrast, patient-centred encounters involve more open-ended questions with greater scope for patients to raise their own concerns and agendas. Related to this are consistent differences in the extent to which the doctor responds to the emotional agendas and the non-verbal cues of the patient. Although there has been a tendency to consider the more patient-centred/emotion-focused approach as preferable, the evidence of the effects on health outcomes is equivocal (Kinmonth *et al.*, 1998; Michie *et al.*, 2003). What may be more important is for HCP and patient to be in agreement over the nature of the problem and the best course of action (Starfield *et al.*, 1981).

A number of specific methods have been developed for carrying detailed analyses of the social interaction between HCP and patient based on audio or videotapes or transcripts of the consultations. Good overviews of these different approaches are available elsewhere (e.g. Roter & Hall, 1989) and attempts have been made to define a number of more general ways of classifying doctor-patient interactions. For example, one can distinguish between verbal and non-verbal information and within the verbal domain, six broad categories can be defined (information-giving; information-seeking; social conversation; positive talk; negative talk; partnership building). From a meta-analysis of these broad categories (Roter, 1989) it has been found that for the doctor, information-giving occurs most frequently (approximately 35% of the doctor's communication) followed by information-seeking (approximately 22%), positive talk (15%), partnership building (10%), social conversation (6%) and negative talk (1%). In contrast, the main type of patient communication consists of information giving (approximately 50%) with less than 10% involving question-asking. Using cluster analysis of these different categories of communication, Roter and colleagues (Roter *et al.*, 1997) identified five broad patterns of relationship in primary care consultations: narrowly biomedical; biomedical (in transition); biopsychosocial; psychosocial; and consumerist. They also showed

that doctors show a fair degree of consistency in their style of communication.

A more specific approach to process analysis is found in the studies of Ley and colleagues (Ley, 1988), who concentrated on the informational content of the consultation and the quality of information provided by the HCP. In particular, they analyzed the content in terms of its level of complexity, comprehensibility and the extent to which the information was organized. They and others have found that medical information may be too detailed or too complex with the result that important information may not be understood or retained by the patient. There is even evidence that patients and HCPs may interpret the same information in different ways: this communication gap can occur around anatomical information or other technical terms which are used to describe illness or treatment.

These various ways of conceptualizing and analyzing the consultation process have given rise to a large number of indices or categories which have been related to outcome, often in quite a limited fashion. Outcomes, such as patient satisfaction or adherence to treatment are likely to be determined by a range of factors, reflecting a complex interaction of input, process and situational variables. Hence it is not surprising that attempts to derive simple process-outcome models have been disappointing in their predictive value (Stiles, 1989). Moreover, there are various ways of defining outcomes and it is very likely that different process variables will affect different outcome indicators.

Outcomes of the consultation

One of the most common outcomes which has been used in studies of healthcare communication is patient satisfaction. This has been investigated as an endpoint in its own right as well as a possible mediator of more distal outcomes including treatment adherence and health. Fitzpatrick (this volume) maintains that the concept of patient satisfaction is important because it focuses on the need to understand how patients respond to healthcare. As a result, it is increasingly being assessed in surveys of healthcare settings, as a marker of quality of care, along with such other dimensions of quality as access, relevance to need, effectiveness, equity and efficiency. Patient satisfaction is a multidimensional concept since patients have been found to have differing views about different aspects of their healthcare, such as the HCP's behaviour towards them, the information provided and their technical skills. Nevertheless there is evidence that the HCP's behaviour during the consultation is the critical determinant and one which can significantly influence satisfaction ratings of all the other aspects of healthcare. Although patient satisfaction can provide a useful general indicator of the patient's experience, there are some associated problems with its use, since many measures appear to be insensitive to variations in patient satisfaction and often do not distinguish between different categories of satisfaction (see 'Patient satisfaction').

In their studies of the quality of information transmission, Ley and colleagues have used patient knowledge and recall as outcome measures and these do show a clearer relation with process variables, such as the complexity and level of organization of the information presented (Ley, 1988). Moreover, their interventions to improve the clarity or comprehensibility of the information

consistently resulted in better recall and understanding (see below). Despite this, there is still abundant evidence that patients often emerge from consultations with insufficient information or understanding of their problems. As a result, they forget a great deal of what they have been told. Consultation skills which facilitate the effective communication of information include using language that is readily understood, presenting information in a way that takes account of the patient's beliefs and checking understanding of any information that has been given (Ley, 1988). Videorecordings of consultations show that these skills are frequently absent in routine consultations (Braddock *et al.*, 1997; Campion *et al.*, 2002). Thus, for example, recording of consultations conducted by primary care physicians in the United States revealed that in just 2% were direct questions asked of the patient to check understanding (Braddock *et al.*, 1997). Similarly in an analysis of videotaped consultations selected by candidates as part of a qualifying examination for membership of the Royal College of General Practitioners, checking patient understanding was evident in just 20% of the consultations (Campion *et al.*, 2002).

Patient satisfaction, understanding and beliefs can play a major role in influencing another important and widely studied outcome variable, namely compliance or adherence with treatment or advice. This is discussed in detail elsewhere in this volume (see 'Adherence to treatment') and is obviously an important outcome in situations where non-adherence results in adverse health consequences. There is evidence of high levels of non-adherence and this can clearly affect other outcomes including health and wellbeing. The latter have not often been studied as communication outcomes but there are a few studies which demonstrate positive effects on patients' health and wellbeing arising from positive experiences in medical consultations (Stewart, 1995).

Improving healthcare professional–patient communication

In the undergraduate and postgraduate medical curriculum, communication skills training is now regarded as a fundamental component, but this varies considerably in terms of the amount and type of teaching and the stage at which it is taught. Typically, students are provided with an overview of the basic skills of 'active' listening, which facilitate patient communication. At a basic level these include the importance of developing good rapport and the use of open-ended questions early in the consultation, appropriate eye contact and other facilitatory responses to help the patient talk, together with the ability to summarize and arrive at a shared understanding of the patients' problem. These skills can be taught in a number of ways, but the successful courses inevitably involve active learning, using role-plays with simulated patients as well as real patient interviews. Feedback is important to identify problem areas and directions for improvement and increasing use is made of videotape for this purpose. There is now consistent evidence that this type of training can result in clear improvements in basic communication skills which are maintained for a number of years. In addition to these basic packages, it is also necessary for students to learn how to communicate about sensitive or difficult areas of medical practice, including dealing with distressed patients or relatives and giving 'bad news'. Given the intrinsic difficulties in

many of these areas, training packages have made good use of role-play often involving the use of actors, for developing these skills (see 'Teaching communication skills').

A recent Cochrane review of training interventions to increase patient-centredness in consultations showed that these are generally successful in modifying styles of communication and increasing rates of patient satisfaction (Lewin *et al.*, 2004). However the evidence was much less convincing as to whether these interventions result in improvements in either adherence to treatment or advice or in more positive health outcomes. Moreover, some studies (e.g. Kinmonth *et al.*, 1998) have shown negative effects and this has led to a more critical approach to this area (Michie *et al.*, 2003) and the proposal that facilitating patient adherence and/or behaviour change needs to involve the use of motivational strategies as well as patient-centred communication skills.

A number of studies have also evaluated training packages for patients prior to medical consultations with the aim of helping patients to be clear about their needs and to maximize the chances of achieving these. While early studies provided some encouraging findings, particularly for health outcomes (e.g. Greenfield *et al.*, 1985), the results have been equivocal. Just as with training interventions for doctors, the evidence indicates that while specific behaviours (e.g. question-asking) can be modified, the impact on adherence and health outcomes is less clear (Harrington *et al.*, 2004) and there is considerable scope for further research on this.

Finally, mention should be made of two specific patient-based approaches which have been very successful. The first by Ley and colleagues (see Ley, 1988) involved hospital patients and an additional short visit, which allowed them to ask for any information to be clarified. Compared with control groups these patients had a much higher level of satisfaction with communication, indicating that effective interventions need not be complex or time-consuming. In the more difficult area of the 'bad news' consultation, Hogbin and Fallowfield (1989) describe a simple yet effective intervention which consisted of tape-recording the consultation and allowing patients to keep the tape. Since this type of consultation is often very distressing, patients may often find it very difficult to take in all the information. Thus it was found patients welcomed the use of these tapes as something which they could go back to, and which other could also listen to. A review of consultation audio-taping studies in cancer care showed that this provision of a tape-recording holds promise as an effective adjunct to communication in this setting (McClement & Hack, 1999).

Communicating with different groups

There are ethnic and social inequalities in healthcare and health outcomes and there is some evidence to show that the quality of healthcare professionals' communication with these groups may contribute to these inequalities (Cooper & Roter, 2003). Ethnic minority patients report less involvement in consultations and lower levels of satisfaction with care, and patients from lower socio-economic groups are given less information in consultations. Cooper and Roter (2003) recommend that communication skills training programmes need to be more broadly based to train healthcare practitioners to communicate in a culturally more sensitive way, and that strategies are needed to empower patients across

ethnic and social groups to participate more in their care. Communicating effectively with those with low levels of literacy and those from minority ethnic groups requires some different considerations to those that govern communication with those who are literate and those from dominant ethnic groups.

With patients from different backgrounds, HCPs also need to be aware of possible differences in their beliefs about illness and treatment. Since these beliefs are very likely to play a major role in patients' evaluation of and use of treatment, effective communication will need to incorporate the elicitation and acknowledgement of patients' beliefs as a fundamental part of the consultation.

The benefits of good communication

One of the most widely reported effects of good medical communication is a higher level of patient satisfaction which also brings other benefits, such as increasing adherence to advice or treatment, for a number of reasons (Ley, 1988). First, effective communication should result in increased patient understanding recall of the information given in the consultation. Second, if the patient feels that the HCP understands their concerns and is empathic towards them, they may have more confidence in the advice which is offered. Furthermore, empathic communication may result in reduced levels of patient anxiety, which may not only facilitate recall of information but also promote better coping with the problem. With chronic conditions, improved self-management resulting from a greater involvement in the consultation has also been shown to lead to improved health outcome (Stewart, 1995).

Effective medical communication may be crucial in the many situations where patients are required to make important decisions relating to their own or another's health. For example, in genetic counselling, individuals may be required to process quite complex risk information, which is often couched in terms of probabilities and may be difficult to take in (see 'Communicating risk'). However, since the information may relate to the individual's long-term health prospects or may influence reproductive decisions, it is clearly vital not only that communication is clear but also that it takes account of the beliefs, expectations and needs of the individual in order that these major decisions can be taken in an informed way and that any recommended behavioural changes can be achieved more effectively (Marteau & Lerman, 2001).

A final example of a situation in which effective communication can be beneficial is prior to stressful medical procedures or investigations. There is now considerable evidence that the provision of clear sensory and procedural information about an impending medical procedure can be extremely beneficial in helping patients to cope with the procedure as well as promoting better recovery (Johnston & Vogeles, 1993) (see 'Coping with stressful medical procedures').

In view of the many problems which have been identified in HCP-patient communication and the documented benefits arising from effective communication, it is not surprising that communication teaching is now regarded as a critical component of medical training. The evidence from the detailed studies of input, process and outcome components of communication can provide an excellent basis for this training and for improving the quality of patient care.

Healthcare work environments

Rudolf H. Moos, Jeanne A. Schaefer and Bernice S. Moos

Center for Health Care Evaluation, Veterans Affairs Health Care System and Stanford University

Introduction

Over the past 80 years, organization theorists have formulated three main conceptual frameworks to examine the relationship between employees and their work environment. An emphasis on employee productivity in the 1920s led to Taylorism and the scientific school of management, which focused on how to maximize task efficiency and production. Scientific management sees the work environment as a set of conditions for ensuring task performance and controlling employees: there is little regard for interpersonal issues or individual differences.

The human relations approach was shaped by concern about employee alienation and the conviction that a narrow focus on productivity could lead to poorer job performance. This approach emphasizes the value of individual and small group relationships and focuses special attention on organizational development and the quality of work life. Most recently, proponents of the socio-technical school have encompassed the technological or task attributes of a job as well as the interpersonal and organizational context in which it is performed.

These three approaches provide a gradually evolving perspective on the work environment and its connections to personal characteristics and work outcomes. We use these ideas here by describing a systems perspective that considers job-related and personal factors, the salient aspects of healthcare work environments and their impact on healthcare staff and how staff morale and performance can affect the quality of patient care and treatment outcome.

An integrated systems framework

The model shown in Figure 1 depicts the healthcare system (Panel I) as composed of organizational structure and policies; staffing and task factors; and work climate. The personal system (Panel II) encompasses staff members' characteristics, including their job position and work role; level of experience; demographic factors; and personal resources such as knowledge and self-confidence.

The model posits that the link between healthcare system factors (Panel I) and work morale and performance (Panel V) is affected by the personal system (Panel II), as well as by specific work stressors (Panel III) and staff members' coping responses (Panel IV). Work stressors (Panel III) and the organizational and personal factors (Panels I and II) that contribute to them can shape coping responses (Panel IV) and staff morale and performance (Panel V). For example, organizational factors, such as the adequacy of staffing and resources, the level of staff autonomy and control and an emphasis on good interpersonal relationships, affect staff outcomes. In turn, these staff outcomes ultimately affect the quality of care and patient outcomes (Panel VI). As the bi-directional paths in the model indicate, these processes are transactional: feedback can occur at each stage.

The healthcare system

Within the healthcare system, the work climate is linked to specific work stressors that affect employees directly. The work climate and

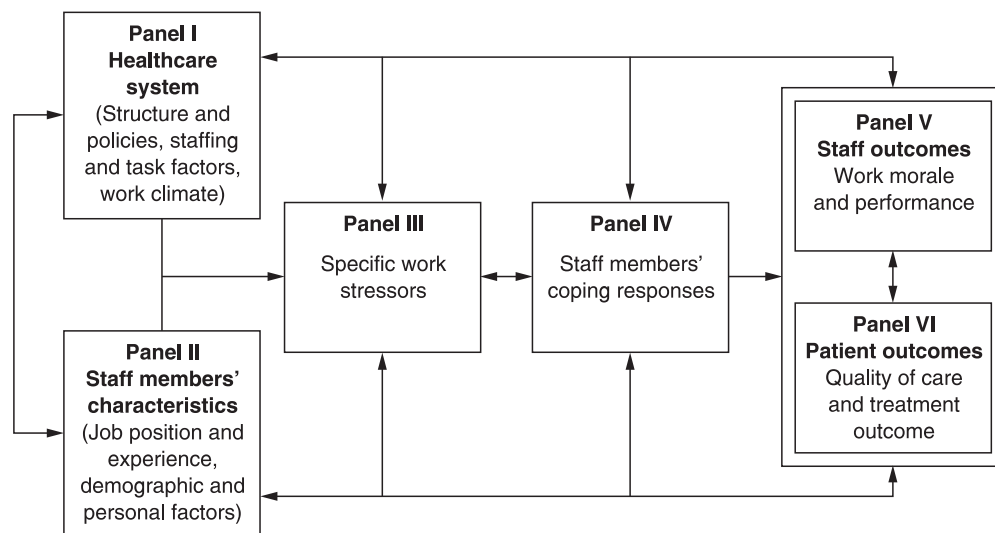

Fig 1 Conceptual model of healthcare system, staff members' personal characteristics and staff and patient outcomes.

work stressors transmit and alter the influence of other sets of healthcare system factors on staff and patient outcomes.

Work climate and work stressors

The underlying facets of work climates and specific work stressors can be organized into relationship, task and system maintenance dimensions (Moos, 1994). Relationship dimensions measure the extent to which employees and supervisors are involved with and supportive of one another. Relationship stressors arise from interactions with co-workers, supervisors and other healthcare staff and typically include communication problems, lack of teamwork and interpersonal conflicts among employees.

Task dimensions cover the goals and responsibilities in the work setting, such as the level of autonomy, task orientation and work pressure. Task-related stressors stem from the duties staff members perform in their job and how well prepared they are to handle them. Some salient task stressors are caring for dying, chronically ill or uncooperative patients; facing distraught and angry family members; and learning how to use increasingly complex equipment.

System maintenance dimensions assess the amount of structure, clarity and openness to change in the workplace. System stressors stem from problems in how the work unit or facility is managed and the lack of resources available to staff. Staff members frequently cite heavy workload and understaffing as major stressors. Other system stressors arise from scheduling problems; scarcity of equipment and supplies; and adverse aspects of the physical environment, such as too little space and too much noise.

Work-related stressors have increased exponentially in the last decade. Healthcare staff members are confronted with increasingly heavy responsibilities; more acutely ill patients and higher caseloads; a shortfall of resources; lack of management concern and support; and continual restructuring of the workplace. Extensive cross-cultural research highlights these special problems. Compared with employees in other types of work settings, healthcare employees report less job involvement, co-worker cohesion and supervisor support. Moreover, they see healthcare settings as lacking in autonomy and clarity, characterized by high work

demands and managerial control and short on physical amenities that make for a pleasant workplace (Aiken *et al.*, 2002a; Moos, 1994).

As the model indicates, these aspects of the work climate elicit specific work stressors. A difficult work climate typically is associated with more relationship and task stressors. For example, when the workplace has high work pressure and managerial control and lacks support, autonomy and clarity, staff members are likely to experience conflicts with co-workers and supervisors and problems associated with patient care tasks, such as incongruence between multiple job demands and distress resulting from patients' suffering and death (Hemingway & Smith, 1999) (see 'Burnout in health professionals').

Determinants of work climates and work stressors

Healthcare work settings vary widely in the quality of interpersonal relationships, the level of task stressors and work demands and the adequacy of clarity and management support. Organizational structure and policies, and staffing and related patient care tasks account for these differences.

Organizational structure and policies

The guiding policies of a healthcare organization can affect the workplace. Compared with healthcare facilities that follow a professional model, those with a bureaucratic model are likely to have more centralized decision-making and formalized jobs, which are associated with a lack of support and autonomy, ambiguous work-related practices and high work demands and managerial control. In contrast, participative leadership helps to foster a clearer, more task-focused and innovative work climate.

The organization of nursing services also influences the work environment. In primary nursing, each nurse is responsible for the care of specific patients; in team and functional nursing, however, the head nurse retains overall responsibility for patient care and each nurse performs specific limited tasks for a group of

patients. Nurses in Primary Nursing Units tend to report more involvement, support and autonomy and less management control than their team and functional nursing counterparts. Similarly, Nursing Development Units, which provide nursing staff with opportunities for decision-making and career development, tend to create supportive and stimulating work climates that emphasize autonomy and innovation (Avallone & Gibbon, 1998; Thomas, 1992).

Some work settings, such as magnet hospitals that attract and retain nurses and specialized units for the care of patients with Acquired Immune Deficiency Syndrome (AIDS), are designed to provide nurses with more autonomy and status and to enable them to widen their scope of practice. In these settings, nursing services tend to be organized in a flat structure with few supervisory personnel: decision making is decentralized, giving nurses more authority; management supports nurses' patient care decisions; and there is good communication between nurses and physicians. Nurses in these settings tend to report more job satisfaction and less emotional distress; patients in these settings are more satisfied with their care (Aolen *et al.*, 1999).

Staffing and task factors

The primary task performed by healthcare personnel can influence the workplace. Compared with staff members not involved in patient care, such as dietitians and laundry workers, staff involved in patient care, such as nurses and nurses' aides, tend to report less support, autonomy and clarity and experience their work as more demanding. Staffing and the amount of patient contact are related to work climate also. Compared with healthcare personnel in well staffed units, personnel in poorly staffed areas typically see their workplace as less cohesive and supportive, less independent and clear and more demanding. Employees who spend more time in direct contact with patients tend to rate their workplace as less innovative and higher on managerial control: they also report more alienation from their patients (Moos, 1994).

Lack of adequate staffing and resulting work overload are key factors that contribute to poorer quality care. For example, after adjusting for nurse and hospital characteristics, each additional patient per nurse may contribute to a 15–20% increase in the odds of emotional distress and job dissatisfaction among nurses. Moreover, each additional patient per nurse has been associated with a 7% increase in patient mortality within 30 days of hospital admission and a 7% increase in the odds of failure-to-rescue (deaths within 30 days of hospital admission among patients who experience complications). Nurses monitor and intervene when patients' conditions deteriorate; more patients per nurse contribute to a more harried work milieu and distress and make this job more difficult (Aiken *et al.*, 2002b).

Consistent with the socio-technical perspective, both patient care tasks and social systems factors, such as authority patterns and the division of labour, affect nurses' work-related attitudes and distress. Thus, the specialized nature of the tasks in intensive care units (ICUs) may create a particular work climate. For example, ICU nurses reported more involvement, support and task orientation than did nurses working in general medical-surgical units (Hipwell *et al.*, 1989) (see 'Intensive care unit'). These findings imply that

social systems factors, such as a supportive work milieu, can reduce the perception of high work demands and that, in a task-focused workplace in which there is a strong sense of involvement, high demands may contribute to team spirit and a sense of accomplishment.

The impact of work climates and work stressors

Healthcare work climates and work stressors are predictably linked to staff morale and job performance. In turn, as indicated by the conceptual model (Figure 1), characteristics of the workplace and staff members' reactions to it can influence the quality of patient care and patient outcomes.

Staff outcomes: work morale and performance

Staff members in more positive work climates typically have higher morale and are more likely to intend to stay in their job. Staff members who experience high job autonomy, empowerment, task focus and innovation tend to have more positive mood and a stronger sense of personal accomplishment and to be more satisfied with their work. In contrast, staff members who lack support and job clarity and have little influence on decision making are likely to experience emotional distress related to their work and detachment from their patients (Aiken *et al.*, 2002a; Laschinger *et al.*, 2004; Moos, 1994; Vahey *et al.*, 2004).

Work stressors are also predictably associated with staff members' satisfaction and job-related mood. In general, staff members who experience more work stressors, especially with regard to relationships with fellow employees and supervisors and workload and scheduling problems, report less satisfaction and more job-related distress and depression. However, staff members who are challenged by patient care tasks and successfully manage them may put more effort into their work and, in turn, be given more autonomy and responsibility (Schaefer & Moos, 1996).

Lack of organizational support and inadequate staffing are also associated with more risk of injuries to staff. Compared with nurses on units with adequate resources and staffing, nurses on units with scarce resources, poorer staffing, heavy workloads, less administrative support and innovation and more emotional distress are more likely to experience needlestick injuries. Nurses on these units also report more injuries due to staff carelessness and inexperience, lack of patient cooperation and inadequate knowledge or supplies. The mechanisms underlying these effects likely involve the impact of the organizational climate on safety-related resources, as well as a direct influence of staffing levels and working conditions on how well nurses carry out risky procedures (Clarke *et al.*, 2002a; 2002b; Hemingway & Smith, 1999).

Patient outcomes: satisfaction, involvement in care and improvement

As the model indicates, the healthcare work environment affects staff members' morale and performance and, in turn, influences patients' satisfaction and other outcomes of care. Patients on units where nurses had a high sense of accomplishment and less

emotional distress were more than twice as likely to be satisfied with their nursing care as were patients on units where nurses lacked a sense of professional efficacy and experienced more emotional distress. When nurses find their work meaningful and fulfilling, patients are more satisfied with their care and the outcomes of care (Leiter *et al.*, 1998; Vahey *et al.*, 2004) (see 'Patient satisfaction').

High morale may be especially important in enhancing staff members' relationships with patients who have mental health and behavioural problems. Staff members who take pride in their work accomplishments and are resilient to emotional distress may be better able to support patients and provide high quality mental health care. Consistent with these ideas, patients treated by staff members who experienced more professional self-efficacy and less distress were more satisfied with their treatment and preparation for independence. When the therapeutic relationship is a key aspect of service provision, problems that interfere with a staff member's ability to develop a strong alliance with patients are likely to diminish patients' satisfaction with their care (Garman *et al.*, 2002).

The work environment may also be associated with staff members' attitudes toward patients and, in turn, patients' reactions toward staff. For example, mental health staff members who perceive less autonomy and task orientation and more managerial control in the workplace are likely to be more authoritarian and restrictive; that is, to believe that persons with mental illness are threatening and require coercive management. These work-related and staff characteristics may be associated with less job satisfaction and, in turn, with more anger and violence directed from patients to staff (Morrison, 1998) (see 'Attitudes of health professionals').

Most broadly, there is a connection between the work environment and staff members' beliefs about treatment, the quality of the treatment environment, patients' involvement in treatment and self-help activities and patients' improvement during treatment. For example, staff members in substance abuse treatment programmes with supportive and goal-directed work environments were more likely to develop supportive and goal-directed treatment environments. Patients in these treatment environments participated in more treatment services, were more involved in self-help groups, were more satisfied with the programme, improved more during treatment and were more likely to participate in outpatient mental health care after discharge (Moos & Moos, 1998). Taken together, these findings confirm that the healthcare workplace is a key component of the overall healthcare treatment system.

The interplay of relationship, task and management factors

It is important to consider the connections between relationship, task and management factors when examining the impact of healthcare work settings. Work groups characterized by independence and task orientation tend to enhance morale and performance. In contrast, the combination of high job demands and lack of autonomy has a detrimental influence on employee health and satisfaction. However, challenging work can compensate somewhat for an unfavourable organizational climate.

Good management can promote task orientation and job performance. Clear job tasks and policies, adequate performance feedback and moderate structure all contribute to satisfaction and effectiveness. In the relative absence of these factors, staff members

experience low morale and distress. However, personal relationships in the workplace can alter these associations. In general, cohesive co-worker and supervisor relationships can amplify the influence of autonomy and task orientation and moderate the problematic consequences of demanding and constrained work settings.

Improving healthcare work settings

The framework we have described can be useful to healthcare managers and staff who wish to improve the quality of their work settings. In this respect, Shinn *et al.* (1993) proposed a tripartite model of coping with work stressors. There are coping strategies used by individuals (setting limits on one's activities, focusing on the positive aspects of work), strategies undertaken by groups of individuals to aid one another (mutual support groups) and strategies initiated by agencies themselves (changing job designs, providing recreational facilities). Many of the stressors which staff members confront stem from the organization of the healthcare system and are beyond the control of individual employees. Thus, management interventions to improve group and agency coping are required.

Team building and collaborative change

One type of intervention is to provide supervisors and staff with feedback about the work climate and work stressors and use it to increase communication among them. In one mental health centre, for example, staff members appraised the workplace as below average in co-worker cohesion, supervisor support, clarity and innovation, and they wanted more emphasis in each of these areas. This information was used in a teambuilding workshop to address these issues, set new goals and strengthen staff team functioning. At follow-up six months later, cohesion and support increased, but work pressure rose, perhaps because staff focused primarily on the need to complete work-related tasks (Davidson & Elliot, 1997).

Staff mutual support groups also can use feedback about the workplace to identify major problems such as lack of staff communication and confusion about work procedures and guide staff problem-solving efforts. In one example, information about the work climate enabled a staff support group to increase clarity and organization closer to the levels staff members preferred (Tommasini, 1992). This process can be taken one step further by developing a collaborative design process in which staff and management work with patients to improve the healthcare work climate and quality of care. In one chronic care hospital, the design process resulted in staff and patients identifying workplace problems, feeling more empowered to voice their concerns and enhancing their understanding of the impact of the social context and management style (Belicki & Woolcott, 1996).

Process consultation and continuous quality improvement

Over the last decade, there has been a shift away from quality assurance to process consultation and continuous quality improvement (CQI), and to a 'bottom-up' approach with ongoing

feedback about the quality of care from line staff and sometimes also from patients. CQI procedures embody the principles that quality management should be a systematic and integral part of everyday healthcare work, be focused on patient-centred practice and encompass information about ongoing care and outcomes.

In one controlled trial, nurse managers were paired with nurse consultants in problem-solving leadership development meetings. On units in which nurse managers participated more fully in the intervention, staff reported greater increases in co-worker cohesion and clarity and less alienation from work than did staff on units in which nurse managers participated less (Weir *et al.*, 1997).

In another relevant project, a CQI process was used to evaluate clinical supervision and its effect on the quality of care. CQI was implemented on five medical wards with team supervision supported by ongoing self-appraisal of work and systematic feedback from patients. After the intervention, staff monitored their work more carefully and the quality of care and patient satisfaction improved (Hyrkas & Lehti, 2003). Overall, studies in this area show that staff involvement in decision-making and team problem-solving can improve the work climate, reduce job stressors and promote better individual and organizational outcomes.

Future directions

Work stressors are likely to continue to intensify as healthcare staff encounter more acutely ill patients; cost containment efforts and competition; new medical technologies and associated ethical dilemmas; and performance monitoring and quality improvement programmes that demand ever greater accountability and perfection. To cope with these changes, healthcare staff members need to be empowered; that is, to be involved in the development of responsive organizations in which they can participate actively in improving the workplace and healthcare services. Such an approach can enhance the work climate and contribute to better staff performance and patient outcomes.

Informed consent

Robin N. Fiore

Florida Atlantic University

Introduction

“Respect for persons requires that . . . to the degree that they are capable, [they] be given the opportunity to choose what shall or shall not happen to them. This opportunity is provided when adequate standards for informed consent are satisfied.” (Belmont Report, 1979)

The doctrine of informed consent is the cornerstone of contemporary ethical practice in clinical medicine and psychology, and in research involving human subjects or human tissue. For the last quarter of a century, the principal framework for understanding informed consent in ethics and at law has been its role in promoting personal autonomy. The central ethical idea is that self-determination – here with regard to medical care/participation in research – is desirable in and of itself; it is through consent or refusal that we make our lives consistent with our values. Valid informed consent is the practical means by which the fundamental moral value of autonomy, in the sense of self-determination, is realized in healthcare decision-making.

Additionally, the practice of informed consent is thought to facilitate other factors integral to healthcare relationships. In both clinical and research encounters, patients and subjects are vulnerable parties in virtue of their lack of knowledge and in many cases, their ill health. Information and shared decision-making are thought to be potentially empowering. First, the information deficit is repaired. Secondly, since patients personally bear the burden of healthcare decisions, assisting them to make the best possible choices for themselves also realizes the professional goals of healthcare providers. Lastly, transparency encourages healthcare professionals to act responsibly in their interactions with patients and subjects.

Development of doctrine of informed consent

The association of informed consent with the facilitation of autonomous choices by patients and research subjects is relatively recent.

Indeed, modern-day elements of informed consent date only to the second half of the twentieth century (Faden & Beauchamp, 1986). For centuries, physicians followed the Hippocratic instruction to ‘reveal nothing of the patient’s future or present’ in order to keep them from harm, deciding what information, if any, to tell patients and families and making treatment decisions on their behalf. Any responsibility to inform and obtain consent was derived from the principle of beneficence, the overarching obligation to benefit the patient: what the patient was told was largely a matter of therapeutic judgement and professional custom.

The legal history of informed consent is grounded in common law protections of bodily integrity. Physicians who did not obtain the consent of competent adult patients to medical interventions committed bodily trespass, or the intentional tort of battery. Later developments linked consent to disclosure, with the idea that consent to treatment based on inadequate or defective information was invalid, a violation of the person. Today, most jurisdictions now consider a failure to disclose as a matter of negligence rather than medical battery, that is a failure on the part of physicians with respect to regulatory standards of care.

Advance directives and ‘living wills’ are now recognized as part of the apparatus of informed consent. Typically, healthcare providers who abide by advance directives are protected from civil or criminal liability. In the event of provider conscientious objection, immunity and ethical practice requires that the patient be referred to someone willing to implement the advance directive or living will. Some jurisdictions expressly permit legal actions for non-compliance with valid advance directives or living wills. Institutions and physicians have been sued for medical battery and/or wrongful life (intentional or negligent interference with an individual’s right to refuse medical treatment) for example, resuscitating someone who didn’t want to be resuscitated or, continuing dialysis for patients with final stage renal disease who have declined dialysis (<http://www.painlaw.org/>).

Following revelations of experiments by the Nazis on concentration camp prisoners, the emerging doctrine of informed consent

underwent specification for the special circumstances of non-therapeutic research and the promulgation of voluntary informed consent as an essential ethical prerequisite in the following international conventions for the protection of human subjects of research: *Nuremberg code on medical intervention and experimentation* (1945/1964); *Declaration of Helsinki: ethical principles for medical research involving human subjects* (World Medical Association, 1964/2004); and later *Belmont Report: ethical principles and guidelines for the protection of human subjects of research* (National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research, 1979). More detail is given below in the section on clinical research.

Elements of informed consent

According to the most widely referenced conceptual analysis of informed consent, five elements distinguish valid consent: competence; disclosure; understanding; voluntariness; and authorization (Faden & Beauchamp, 1986). The translation of ethical principles into practical guidelines for healthcare providers has been largely a function of court decisions and, to a lesser extent, legislation. Thus, legal requirements of disclosure and valid consent vary by jurisdiction. The discussion that follows offers general guidance with respect to ethical considerations: appropriate authorities must be consulted for specific legal rules and institutional policies.

As with all bureaucratic institutions, healthcare is replete with policies and protocols, as well as procedures for documenting compliance. Informed consent discussions usually conclude with the execution of a consent document. The signature attests to the authorization (or refusal) but does not add to the effective force of the authorization, which is only effective in virtue of the ethical elements having been satisfied.

Competence

Valid consent can only be obtained from a competent individual, or a designated proxy or surrogate on behalf of an incompetent individual. Adults are presumed competent, subject to medical and legal protocols for rebuttal. At a minimum, individuals must be able to communicate, to evidence a preference; thus unconscious or completely paralyzed persons are paradigmatically incompetent.

Competence is best understood as a contextual rather than a global concept; the capacity required for a determination that an individual is competent should be adjusted to the issues in question and their consequences. One might not be competent to stand trial yet still have the capacity to make certain medical decisions, or have the capacity to assent but not to refuse. Physical and mental status, as well as external factors (e.g. medication) and situational issues (e.g. language competency) must be taken into account.

Certain individuals, such as minors, may be incompetent by statute, though empowered in some jurisdictions to authorize specific kinds of medical care, such as reproductive healthcare.

Disclosure

The two most common standards for determining the adequacy of disclosure, and thus the validity of consent, are ‘the professional

standard’ and the ‘prudent or reasonable patient standard’. The professional standard, adopted in a British case in 1767, requires that patients be given information that physicians similarly situated (possessing the same skills and practicing in a similar community) would disclose (*Slater v. Baker & Stapleton*, 95 Eng. 860, 2 Wils. KB 359 1767). The more common standard obtaining in the United States requires that physicians disclose information that a hypothetical ‘reasonable patient’ in similar circumstances would regard as material to decision-making (*Canterbury v. Spence*, 464 F.2d 772, D.C. Cir. 1972). Courts in England, Canada and Australia have been moving recently towards the latter lay standard (Mazur, 2003).

There is general agreement that satisfactory disclosure includes: purpose of seeking consent (treatment authorization, research participation); nature of proposed treatment or research (therapeutic or non-therapeutic, invasive or diagnostic, investigational status); alternatives (including no treatment/non-participation); associated risks and benefits of alternatives (including likelihood and degree); and professional recommendation. There is less agreement about whether provider-specific information – such as HIV status, financial interests, success rates, experience level – should be disclosed routinely.

Understanding

Valid consent requires that the individual or surrogate must be able to comprehend general information regarding condition and prognosis, possible treatments, risks and benefits and so forth. Moreover, the patient’s or subject’s understanding must encompass the relevance of the information to the decision being undertaken. The patient or subject must be able to make use of the information in forming preferences, that is, must be able to weigh alternatives and to appreciate the implications of information for the individual’s own situation, given that individual’s particular goals, values and other preferences. Depression, anxiety, pain, etc. may interfere with the evaluation of information. However, the decision-maker’s capacity may be enhanced by addressing the sources of incapacity, providing assistance, moderating external influences, etc.

Voluntariness

In order to be valid, consent or refusal must not only be un-coerced, it must be free of excessive or inappropriate influence by healthcare providers or researchers, caregivers, family members and friends. Desperate prognosis, financial distress and fear of abandonment may also invalidate consent. What counts as excessive or inappropriate influence is a normative judgement that must take particular facts about particular cases into account. However, autonomous decision-making is consistent with the idea that various moral actors and relationships may strongly influence beliefs, value commitments and judgements concerning personal wellbeing. For example, cultural traditions of family decision-making do not necessarily compromise autonomy if the individual is genuinely committed to those values. This is explored further in the section on cultural pluralism below.

Authorization (consent or refusal)

The requirement that healthcare providers/researchers obtain valid consent before initiating treatment or research protocols protects persons' interests in preventing unwanted treatment. The philosopher John Harris has characterized consents and refusals as 'the Janus faces of autonomous capacity to choose' (Harris, 2003). Competent adults may refuse care or cure, including life-saving treatment (exceptions noted below); they may consent and subsequently revoke consent. In some jurisdictions, surrogates may refuse on behalf of incompetent individuals, although the refusal of life-saving treatment on behalf of others, especially minors, usually becomes a matter for the courts. There are several standards variously available for proxy decision-making, depending on jurisdiction: 'substituted judgement', 'best interests' and 'reasonable person' standards. Under substituted judgement, the proxy does not choose but rather attempts to give the best account of the patient's hypothetical choice based on available information, including the patient's written directives and reliable oral declarations. Where no such directives or declarations are available, less subjective standards may be implemented by courts or authorized persons. Since these are not based on patient specific understandings, such standards are often controversial.

Exceptions to informed consent

Exceptions to some elements of informed consent requirements may be justified when complying would be impossible or pose a detriment to the patient's welfare.

Emergency

In an emergency situation, time and/or the patient's condition may not permit full disclosure or valid consent. If a surrogate decision maker is unavailable, procedures necessary to stabilize the patient are authorized unless the patient has a valid advance directive refusing such procedures, e.g. a 'Do Not Resuscitate Order' (DNR).

Therapeutic privilege

Under certain circumstances, a physician's ethical obligation to avoid harm may conflict with legal obligations with regard to disclosure. Physicians have historically claimed a 'therapeutic privilege' of non-disclosure (from omission of information to outright falsehood) in cases where the standard of disclosure is a threat to the wellbeing of patients, deemed likely to produce extremely adverse reactions, or expected to make rational participation in medical decisions impossible. Court decisions have constrained the circumstances in which therapeutic privilege may operate and have specifically rejected non-disclosure which has as its object pre-empting refusals of potentially beneficial treatment. Studies indicate that physicians tend to underestimate the degree to which patients would like to be informed (Appelbaum & Grisso, 1995) and that patients desired more involvement in their treatment as they acquired more information about their condition (Meisel *et al.*, 1977).

Waiver

Patients are empowered by determining what information they desire as well as their desired level of participation in medical decision-making. Thus, under certain conditions, a competent patient may voluntarily relinquish the right to make decisions and/or to receive certain disclosures. In order for such a waiver to be valid, it must be 'informed, reasoned and voluntary' (Beauchamp & Childress, 2001). Moreover, the waiver may be partial: that is, pertaining to decision-making but not information, or concerning certain types of information, e.g. decline prognosis, but not risk information. However, competent patients who have waived information that is highly relevant to decision-making cannot be regarded as having full capacity. In the case of waiver, the healthcare practitioner may not assume surrogate decision-making authority and should make every effort to obtain valid consent from an appropriate third party, as well as assent from the patient.

Compulsory treatment

Certain kinds of treatment may be legally mandated and, strictly speaking, do not require the individual's consent. Depending on the jurisdiction, compulsory treatment for infectious diseases, vaccinations for military personnel, involuntary commitment, AIDS screening for newborns, etc. may be justified by society's overriding interest in protecting public health and welfare. Nevertheless, despite the absence of choice, it is appropriate to disclose information and obtain assent wherever possible.

Incompetence

Strictly speaking, incompetence does not provide an exception to the requirements of informed consent. Disclosure and consent are properly obtained from designated healthcare surrogates, court-appointed guardians, or the courts themselves.

Special contexts

A number of special contexts pose compliance and other concerns in connection with informed consent. Two briefly addressed here are psychotherapy and clinical research.

Psychotherapy

Material risk disclosure in psychotherapeutic contexts may require more attention to the limits of confidentiality, especially legally mandated reporting requirements and the degree of patient-professional privilege accorded to different classifications of practitioners. Specific consent must be obtained from patients as well as research participants prior to recording their voices or images. In discussing alternative treatments, opinion divides on whether treatment modalities not within the expertise of the therapist should be presented. Finally, consent may need to be updated or revised in the light of information or direction developed as the therapeutic relationship proceeds.

Clinical research

While all healthcare decisions are subject to informed consent, decisions to participate in research are recognized as a special case since the beneficiaries of research are not necessarily the individuals who are assuming the burdens of participating in research (Siminoff *et al.*, 2004). Moreover, research subjects and participants confuse scientific experiments with treatment, known as the ‘therapeutic misconception’, often over-estimating the benefits of participating in clinical trials (Appelbaum *et al.*, 1982). In the Belmont report (United States) the ‘reasonable patient standard’ is replaced with a ‘reasonable *volunteer*’ standard of disclosure to ensure that the risks of harm and the likelihood of personal benefit (as distinguished from benefit to others or to the knowledge building enterprise) are properly distinguished.

Current debates

Rapid changes in clinical healthcare and scientific research will continue to challenge the sufficiency of consensus and codes governing informed consent.

Third party information

Medical treatment of individuals often involves personal information that implicates third parties: genetic information, family history, information about exposure to infectious disease, community information about behaviour, criminal actions, etc. The information is disclosed or collected without the knowledge or informed consent of family members and social contacts, both living and departed. Research on human tissues and genetic materials may likewise reveal information about past, present and future family members; about one’s ethnic group or tribe; about one’s residential community or fellow employees, without their having agreed to the risks such information poses – employment and insurance discrimination; paternity disclosure; unwanted information about future health; diminished property values, etc. While it is impractical and probably impossible to obtain the informed consent of all who are/will be adversely affected by information disclosed during clinical care or collected for research, protection against harmful or unnecessary revelation of information must be a priority.

Genetics

Informed consent applies equally to decisions about predictive genetic testing (see ‘Screening: genetic’). In addition to standard disclosure elements, the consequences of having such information on the individual’s record, confidentiality issues and information about the accuracy of tests and the limits of their predictive capacity should be thoroughly understood. In situations where testing for more than one condition is combined in a single testing session, commentators disagree on whether consent ought to be obtained separately for each test in the panel, or whether the requirements of disclosure and consent are satisfied by addressing ‘common denominator issues’ (New York State Task Force, 2004). Where tests may reveal unsolicited and perhaps unwanted information about conditions other than those for which testing is proposed,

the disclosure should cover all conditions not just the intended use of the test.

Computing

The Internet has become a research site in which the health behaviours of users are observed or analyzed, and through which subsequent public health outreach may take place. Typical disclosure and consent protocols are likely to change the behaviour of those being observed and to render research less useful (Goodman, 2003). Goodman argues that health data is regularly collected and studied without giving citizens the ability to opt out – e.g. disease registries, death records – and that citizens permit this because of presumed offsetting public health benefits. However, we have yet to reach consensus on how ‘public’ Internet chats and blogs are and what expectations of privacy ought to prevail in this area.

Conflicts of interest

In both clinical care and clinical research, healthcare providers and investigators may have interests – financial incentives or non-financial but self-serving interests – that conflict with their primary professional duty to advocate for patients and avoid harm. In clinical care, providers may be under contract to health-care delivery systems that provide disincentives for certain types of care, or providers may be in a position to recommend and to channel services to facilities in which he or she has a proprietary interest is held (self-referral). Disclosure of financial interests that a patient would be unlikely to know about, or be able to judge the significance of, ought to be disclosed and properly framed in terms of community standards, alternatives in which the provider does not have a conflicting interest, and available research regarding the health implications of such conflicting interest.

In research contexts, the dominant conflict of interest concern relates to equity interests in pharmaceuticals and devices under study (Fiore, 2003). Few research institutions currently require investigators to disclose ‘significant financial interests’ to Institutional Review Boards (IRB’s) and/or subjects/participants (McCrary *et al.*, 2000). Critics argue that the failure to disclose financial conflicts of interest violates the ethical obligation to provide subjects and potential participants with information that is relevant to the choice to participate. Further, some argue that failure to disclose is fundamentally deceptive and that without complete information about the risks of participation, including the possibility that financial arrangements of the investigator might influence their judgement, consent is invalid. Others have argued that disclosure merely confuses or disturbs subjects/participants and does nothing to fundamentally eliminate or reduce conflicts of interest (Shimm & Spence, 1996). It is worth noting that the World Medical Association’s 2000 revision of the *Declaration of Helsinki* now lists ‘sources of funding’ as information that should be provided to subjects.

Cultural diversity

The doctrine of informed consent, grounded in ideals of individual rights and self-determination, assumes a view of persons as moral

agents, of physician–patient interactions and of personal relationships that is peculiarly Western. How is the autonomous decision-making model to be reconciled with divergent cultural values and customs? The argument from human rights asserts that local custom is not sufficiently weighty to override fundamental rights, specifically, the right of self-determination on which informed consent is based (Angell, 1988). Advocates of cultural sensitivity respond that the emphasis on patient autonomy arose in reaction to physician paternalism, not with the intention of alienating patients from family influences or indoctrinating liberal values. On this view, a patient's right to full participation in medical care decisions is consistent with an important role for family members. Thus the healthcare provider's obligation to disclose information and obtain

voluntary consent may need to be 'relativized' to permit fuller participation by families than the standard autonomous decision-making model anticipates (Macklin, 1999) (see also 'Medical decision-making').

Conclusion

The prospect of momentous scientific advances in medicine, information and biotechnology and associated social and cultural changes suggests that informed consent and other bioethical norms will be subject to continuing reflection, debate and adaptation. The ethical doctrine of informed consent can provide a 'moral counterweight' to practical necessity.

Interprofessional education in essence

Hugh Barr

University of Westminster

Interprofessional education is taking root in increasing numbers of countries and fields of practice. Encouraging though that is, its essence becomes correspondingly harder to capture. Different health and social care policies, priorities and practices carry different implications for objectives, content and learning methods compounded by lack of a unifying rationale, a fragmented (some may say fragile) evidence base and a seemingly perverse insistence on employing terminology in bewildering disarray.

Much, however, is being done to establish interprofessional education as a coherent and cohesive movement worldwide as this chapter explains. Terminology is being clarified. Principles are being enunciated. Types of interprofessional education are being distinguished. Theoretical perspectives are being compared. Evidence is being assembled. Communications channels are being opened and mutual support networks established.

Setting the agenda

Credit for promoting interprofessional education globally goes to a World Health Organization Working Group meeting in Geneva (World Health Organization, 1988), which advocated shared learning to complement profession-specific programmes. Students, said its members, should learn together during certain periods of their education, to acquire the skills necessary to solve the priority problems of individuals and communities known to be particularly amenable to teamwork. Emphasis should be put on learning how to interact with one another, on community orientation to ensure relevance to the health needs of people and team competence.

The WHO Group was influenced by a previous WHO European Regional Working Group which had met in Copenhagen. At that meeting delegates had argued that students from health professions with complementary roles in teams should share learning in order to discover the value of working together as they defined and solved problems within a common frame of reference. Such learning should employ participatory learning methods to modify reciprocal attitudes, foster team spirit and identify and value respective roles, while effecting change in both practice and the professions. This approach would support the development of integrated health care, based on common values, knowledge and skills (d'Ivernois & Vadoratski, 1988).

With hindsight, the lead given by the WHO can be seen to have had more impact in developing countries than so-called developed countries with the exception of some smaller European states. Developments in, for example, the United States, and for the most

part the United Kingdom, responded to local and national, not international, 'drivers'.

Blazing the trail

Interprofessional education had, however, already been pioneered in many countries during the preceding twenty years (Meads *et al.*, 2005) providing a fund of experience and examples on which both WHO groups drew.

The advent of interprofessional education in some countries was associated with a shift of emphasis from hospital-based to community-based healthcare as long-stay hospitals closed and community mental health and learning disabilities services developed. Charged with responsibility for long institutionalized and highly dependent ex-patients, members of multidisciplinary teams joined forces to respond flexibly to growing demands. Primary care was also developing, bringing together hitherto separate services and taking over responsibilities from hospitals. Here too multidisciplinary teams were being convened.

To attribute the rise of interprofessional education solely to the development of community-based services would, however, be less than the whole truth. In the United States much of the pioneering work was in hospitals, notably those of the Veterans' Administration. In community or hospital, the unifying factor was the need to respond to complex conditions which exceeded the capacity of any one profession acting alone. Mental illness and learning disabilities were two of these; others were physical disabilities and chronic or terminal illnesses for all age groups, but especially older people.

Emphasis on adults and older people was, however, soon redressed in countries such as the UK, where abuse of children, often leading to their death, was attributed time and again by Official Inquiries to failures in communication, collaboration and trust between professions and their respective agencies. Collaborative mechanisms were reinforced. The emphasis was further redressed as collaboration was strengthened in special needs education and juvenile justice.

Nor was collaboration limited to casework with individuals and families. It also included moves to combine energy and expertise across professions to promote health education and, in developing countries especially, public health strategies.

As the fields of collaboration multiplied so too did the number of professions participating. Different fields involved different configurations reaching beyond the health and care professions as commonly understood to include, for example, clergy, police officers, probation officers, psychologists and schoolteachers.

If most put education, health or social care at the centre, others focused, for example, on community development or the built environment.

Collaboration, which had long characterized good practice in these and other fields, was now required by policy-makers and service managers, enshrined in guidelines, included in performance appraisal and, not least, valued by practitioners themselves, but it could not be taken for granted. Miscommunication, misunderstanding and sometimes rivalry and territorial disputes too easily frustrated best laid plans, reinforcing the case for interprofessional education to cultivate collaboration in general and teamwork in particular.

Finding the focus

Given the stress put in the literature on teamwork, readers might reasonably expect it to feature strongly in objectives and content for interprofessional education. Many of the early interprofessional 'initiatives' were indeed team-based. Most, however, went unrecorded, still less evaluated, to be lost in the mists of time, although the early literature includes reports of initiatives where members of different teams were released to attend workshops where they could compare perspectives as they planned collaborative projects to implement in their teams (Spratley, 1990a; 1990b).

The notion of the learning team was, however, taking root and has since gained ground. Ways were being found to mobilize the resources of the team to respond to the learning needs of its members individually and collectively within and across professional and non-professional groupings (see, for example, Bateman *et al.*, 2003).

But teaching teamwork in pre-qualifying interprofessional education in college, at least in the UK, remained the exception (Miller *et al.*, 1999). Early examples reported of such education focused on modifying reciprocal attitudes or perceptions (e.g. Carpenter, 1995). Recent commentaries on interprofessional education put more emphasis on the reinforcement of competence (e.g. Barr, 1996; Whittington, 2004) for collaborative practice, although this has yet to be reported in evaluations of programmes (Barr *et al.*, 2005).

Furthermore, many policy-makers and service managers now look to interprofessional education to generate a multi-skilled and flexible workforce within which professions have the ability to substitute for each other and the opportunity to progress from one occupation to another without beginning their specialist professional education again from scratch. Only then, the argument runs, can the professionals be deployed optimally in the spirit of the modernization agenda set for health and social care by governments around the world and become agents of change (e.g. Meads *et al.*, 2005).

The implications for interprofessional education are far-reaching. Collaboration may still head the agenda, but it is an agenda which is growing longer and now includes items with quite different implications for objectives, content and learning methods.

Defining terms

The more diverse the fields of practice and the more varied the expectations, the greater the need for clarity of definition.

In response, the UK Centre for the Advancement of Interprofessional Education (CAIPE, 1997) defined interprofessional education as: 'Occasions when two or more professions learn from and about each other to improve collaboration and the quality of care'. It saw interprofessional education as a subset of multiprofessional education, which it defined as: 'Occasions when two or more professions learn side by side for whatever reason'.

Distinguished thus, interprofessional education is multiprofessional education with value added resulting from the methods that it employs and the ends for which it strives.

Enunciating principles

CAIPE (1996) has also published a set of principles for interprofessional education from which we select two in this context.

Alive to the dangers that interprofessional education can threaten the identity, integrity and territory of professions, CAIPE emphasized mutual respect, but went further. It asserted the need to enhance satisfaction for each of the participant professions in its own right and as a means to improve quality of care for individuals, families and communities.

In addition CAIPE asserted that effective interprofessional education will not only focus on the needs of service users and carers, but also engage them actively in planning, teaching and mentoring and as co-participants. This is easily said but less easily and less often done.

Building models

Numerous models can be devised to establish the organizational relationship between uniprofessional and interprofessional education. Each has its strengths and weaknesses. The following list is not exhaustive. Nor are the types mutually exclusive.

The marginal model

Early interprofessional education 'initiatives' were often freestanding, i.e. outside the mainstream of uniprofessional education associated with practice learning or part of continuing professional development. Either way, teachers were free to innovate unfettered by the need to win the support of profession-specific teachers for each of the professions involved or to jump through regulatory 'hoops'. Students or workers were, however, left to relate such learning as best they might to their uniprofessional education. Impact on mainstream uniprofessional education was minimal and initiatives vulnerable and short-lived when 'funny money' ran out or the champion of the cause moved on.

An early example of the marginal model organized lunchtime debates and case discussions for students concurrently on placement in Thamesmead during the 1980s (Jaques, 1986), whilst a more recent one in Vancouver organized extra-curricular team-building sessions on Saturday mornings (Gilbert *et al.*, 2000).

The block model

Early moves in Linköping in Sweden to integrate interprofessional education into the mainstream took the form of a ten-week block

before students embarked upon their uniprofessional courses. Albeit positively evaluated by its champion (Areskog, 1995), lasting benefits were harder to establish and depended on continuing opportunities for students to learn together during the remainder of their pre-qualifying studies which Linköping subsequently added.

The cross-bar model

A more familiar model in the UK and other countries where interprofessional is being 'mainstreamed' is the cross-bar model, where specified subjects, e.g. ethics and communication studies, are ceded from two or more uniprofessional programmes to be taught across them. Such studies are, however, no more than multiprofessional unless and until their objectives and learning methods are modified to become interprofessional. This model sets limits on the degree of intrusion on profession-specific curricula, but again leaves students to integrate inter- and uniprofessional studies as best they may.

The composite model

The nature and extent of integration is often governed by 'the art of the possible'; planners looking for a number of opportunity to introduce interprofessional education. King's College London, for example, provides combined (cross-bar) studies in communications and ethics in college during the first year, complemented later by patient mapping exercises for students concurrently on placement and learning at any time on the web about a virtual extended family with multiple health and social needs (Norman, 2004).

The comprehensive model

A more radical model exemplified by the New Generation Project in Southampton and Portsmouth (<http://www.mhbs.soton.ac.uk/newgeneration>) devises an overall multiprofessional curriculum from the outset within which uniprofessional and interprofessional sequences of study are embedded. Logistical constraints have, however, precluded initial plans for the different professions to share their multiprofessional education at the same time and place, which prompts questions about how similar the learning will be even though the outcomes prescribed are the same.

Each of these models has advantages and disadvantages at different stages in evolution of interprofessional education, depending on the resources available and the degree of support forthcoming from teachers, colleges, employers and regulatory bodies.

Comparing theoretical perspectives

Interprofessional education applies and augments principles of adult learning (Barr, 2002). It capitalizes on the widespread application of those principles in uniprofessional education, but goes further. To take two examples, building on Knowles' (1990) argument that adult learners are intrinsically motivated by the problems they identify and seek to resolve for themselves, interprofessional learning engages participants from different professions collectively in

problem-solving. Building on Lave Wenger's (1991) argument that adult learners enter into communities of practice where learning is participative, embedded and situated, interprofessional educators agrees with Strauss and Corbin (1990) that such learning involves shared commitments, shared resources, shared ideologies and shared meaning.

None of this is enough to change reciprocal attitudes for the better without also ensuring that conditions enshrined in contact theory are met, according to its exponents in interprofessional education (see, for example, Carpenter, 1995; McMichael & Gilloran, 1984). According to Allport (1979), who originated the theory, three conditions had to be met before such prejudice could be reduced: equality of status between the groups; group members working towards common goals; and cooperation during the contact. For Hewstone and Brown (1986), there were three more: positive expectations by participants; successful experience of joint working; and a focus on understanding differences as well as similarities between themselves.

Helpful though contact theory can be in formulating and testing favourable conditions necessary to effect attitudinal change during interprofessional education, it does not hypothesize conditions necessary to change behaviour.

Changing attitudes and behaviour are indeed required, but also action to improve services needs to be instigated if interprofessional education is to measure up to all the expectations now demanded. At this point it calls upon organizational learning theory (Argyris and Schon, 1978) whereby individuals work and learn collectively to improve the quality of their environment and the products or services they deliver. This theoretical perspective ties in with the notion of the learning organization which fosters a culture of questioning and enquiry, reframing information as learning and adopting a cyclical process of change given practical expression in work-based interprofessional education by the application of continuous quality improvement (Wilcock *et al.*, 2003).

Numerous other theoretical perspectives have been introduced (see Barr *et al.*, 2005) of which systems theory (Von Bertalanffy, 1971) is perhaps the most pertinent, applying as it does expressly to interprofessional learning and working as an antidote to the limitations of specialist disciplines in addressing complex problems, seeing wholes as more than the sum of their parts, interactions between parties as purposeful, boundaries between them as permeable and cause and effect as interdependent not linear. It is associated in interprofessional learning and working with the biopsychosocial model to counter the perceived limitations of a narrowly medical model (Engel, 1977).

Systems theory has multiple applications in interprofessional education and practice. It offers a unifying and dynamic framework within which all the participant professions can relate – person, family, community and environment – one or more of which may be points of intervention interacting with the whole. It can also be used to understand relationships within and between professions, between service agencies, between education and practice and between stakeholders planning and managing programmes.

The development of a systems theory in interprofessional education and practice which has the most potential may be activity theory (Engestrom, 1999). This offers a systemic approach to the understanding of, and intervention in, relations at

micro- and macro-levels to effect change in interpersonal, interprofessional and inter-agency relations. However, much remains to be done to express its analytical model in operational terms and language with which practitioners and their managers can readily engage.

Like all education, interprofessional education is grounded in an admixture of theories. It calls on academic disciplines which contribute to the uniprofessional education systems to which it relates. It would therefore be neither appropriate nor helpful to discriminate in favour of theories from one discipline or school of thought, or to press prematurely for a unifying theoretical frame of reference, to the exclusion of the many new and creative perspectives being brought to bear.

Assembling evidence

The World Health Organization stressed that claims that interprofessional education could improve collaboration, to which it subscribed, should be subject to critical evaluation (WHO, 1976, 1978, 1988).

That argument grew stronger as evidence-based practice gained ground in the healthcare sector during the 1990s. The case for the evaluation of interprofessional education became more compelling as it became more widespread. Furthermore, investment in small group interactive learning, to which many teachers were committed on the basis of their experience, was open to challenge in cost conscious times in the absence of evidence that it was needed.

Against this backdrop a Cochrane Review was undertaken (Zwarenstein *et al.*, 2000).¹ Criteria for inclusion were one of three experimental designs for evaluation (randomized controlled trials, controlled before and after studies and interrupted time series studies) and one or both of two outcomes (organizational changes and benefit to patients). Searches were carried out in Medline (1966–98) and CINAHL (1982–98) and the grey literature, but no studies met both methodological and outcome criteria (Zwarenstein *et al.*, 2000).

That review would be repeated. Meanwhile, some members of the team saw merit in conducting a review applying less constrained criteria (Barr *et al.*, 2005). The team therefore re-formed to become the Interprofessional Education Joint Evaluation Team (JET). Two members left and one joined at this stage.²

No longer simply concerned with whether interprofessional education 'worked', the research question was re-framed as follows: 'In what ways can interprofessional education contribute to improvements in collaboration between health and social care professions and in what circumstances?'

The team agreed to include a wider range of research methodologies – qualitative and quantitative – and the following continuum of outcomes adapted from the work of Kirkpatrick (1967):

- Learners' reactions
- Modification of attitudes or perceptions
- Acquisition of knowledge/skills
- Behavioural change

- Organizational change
- Benefit to patients

Medline (1966–2003) and CINAHL (1982–2001) were searched afresh plus the British Education Index (1964–2001) and the Allied Social Sciences Index and Abstracts (1990–2003).

Over 10 000 abstracts were scanned from which some 800 papers were selected for critical appraisal. Of these, 353 qualified for inclusion in the review, but power, rigour and presentation were uneven prompting a further selection of 107 higher quality studies to be made (Barr *et al.*, 2005).

Seventy-six (71%) of the reports had been published since 1996 and the number was continuing to increase year on year. Fifty-eight (54%) originated in the United States and 35 (33%) in the United Kingdom with the remainder spread thinly. Only one was from a developing country. The most commonly involved professions were nurses followed by doctors, allied health professionals and social workers. The most common research design was before and after measurement found in 58 (55%) of the sample, but only 12 (11%) of these included controls. Five (5%) were randomized controlled trials.

Outcomes reported were overwhelmingly positive, almost certainly reflecting bias in the publishing process. Employing multiple coding to the modified Kirkpatrick classification, positive responses most frequently reported were students' satisfaction with their interprofessional learning experience (45, 42%) followed by the acquisition of knowledge and skills relating to interprofessional working (38, 36%) and changes in organizational practice (37, 35%). The other three outcomes were similar: changing attitudes or perceptions (21, 20%), changing individual behaviour (21, 20%) and benefiting patients (20, 19%).

Further analyses indicated that reporting student satisfaction, acquiring knowledge and skills and modifying attitudes were more often associated with college-led interprofessional education and changing behaviour, changing organizational practice and benefiting patients with work-led interprofessional education. In other words, the college-led initiatives can meet intermediate objectives that may be taken further by work-led ones at a later stage. Much remains to be done to formulate the continuum of interprofessional education led by college and agency over time.

Opening channels for communication

Interprofessional education is reported more and more often in journals, books and conference proceedings and on websites. The *Journal of Interprofessional Care* (see www.caipe.org.uk) is wholly dedicated to the exchange of experience about collaboration in education, practice and research throughout health and social care worldwide. Books on matters interprofessional, including two derived from the work of JET (Barr *et al.*, 2005 and Freeth *et al.*, 2005) in a new series by Blackwell, are growing in number, while relevant websites multiply (e.g. www.caipe.org.uk, www.heALTH.ac.uk, www.commonlearning.net and www.nipnet.org).

¹ The Cochrane Team comprised Jo Atkins, Hugh Barr, Marilyn Hammick, Ivan Koppel, Scott Reeves and Merrick Zwarenstein.

² JET comprised Hugh Barr, Marilyn Hammick, Della Freeth, Ivan Koppel and Scott Reeves.

Building mutual support

International conferences, wholly or partly dedicated to matters interprofessional, inform, challenge, stimulate and extend mutual support as partnerships are forged between nations. They are backed up by national and regional networks such as CAIPE, the Nordic Interprofessional Network (NIPNET) and, the International Association for Interprofessional Education as Collaborative Practice (Inter Ed).

Building on the basics

Much remains to be done in interprofessional education to:

- encourage consistent use of concepts and terminology
- refine, apply and test principles
- discriminate between learning methods and test their efficacy
- develop a coherent but multifaceted rationale

- weave college-led and work-led uni- multi- and interprofessional education into a mutually reinforcing and progressive continuum of learning
- raise the general standard of evaluation to that of the best
- improve update and elaborate the evidence base
- strengthen channels for communication and mutual support

Gone are the days, however, when interprofessional education could be dismissed as a passing whim, comprising assorted, ephemeral and marginal activities. More complex and perhaps more confusing and more controversial than it once seemed, interprofessional education is responding to the agenda set internationally by the World Health Organization and nationally by reformist governments (Meads *et al.*, 2005) to become a force for change in education, health and social care policies. It remains, however, in essence a collective response by practitioners from increasing numbers of professions to the complexity of the human condition.

Medical decision-making

Clare Harries¹ and Peter Ayton²

¹University College London

²City University, London

Introduction

Doctors constantly make decisions that affect the health and lives of other people. They gather evidence by interpreting the signs and symptoms of the patient, conducting examinations and determining appropriate tests. All of these actions imply the use of judgement and decision-making. Using such evidence they may form a diagnosis and conclude what, if anything, is to be done. In the current healthcare climate, patients are also encouraged to participate in decision-making, either by sharing in it, or by making their own informed decisions, on the basis of the evidence presented to them by doctors (Charles *et al.*, 1997). Many of these decisions will be based on clear evidence from the patient and tried and tested methods drawn from the doctor's medical knowledge and may seem quite straightforward. However, very often, simple medical principles and rules will not be available. From the perspective of formal Decision Analysis, in order to make an optimal decision, a doctor and patient must identify all the options available, work out their potential outcomes and the probability that these outcomes will occur. They also need to assess how good or bad that outcome occurring would be. Such a process is often difficult for several reasons. Firstly, it is difficult to identify the options and outcomes and their associated probabilities. As the evidence base of medicine develops this may become easier, but where clear evidence about options, or actuarial statistics about their outcomes, are not available doctors have to rely on their judgement. Secondly, people find it difficult to understand and clearly communicate probabilities. Thirdly, we find it difficult to assess the utility, or the potential good or bad, of outcomes. Beyond these three aspects of decision-making, the combination of this information is hampered by the fact that the number of components in even relatively straightforward decisions soon expands beyond human information processing capacities (estimated at 7+/-2 pieces of information, or 4 chunks; Simon, 1979). This capacity may be reduced given the unpleasant emotions and stress associated with considerations of potentially

negative outcomes. In this chapter we shall review the evidence that these aspects of decision-making are difficult, discuss the psychological processes underlying them and briefly review the techniques that have emerged which seem to make good medical decision-making easier.

Clinical judgement

Although identification of the options and outcomes and their associated probabilities is partly the role of evidence-based medicine, the evidence may be uncertain: signs and symptoms can be ambiguous and tests results are rarely 100% accurate. Tests and treatments can involve adverse side effects or a risk of permanent damage or even death. In the absence of a clear rule for such situations doctors will be obliged to apply their own judgement.

Research investigating the topic of medical judgement has a fairly short, but intense, history. The first significant development was Meehl's (1954) book which evaluated clinical judgement. Meehl compared the intuitive clinical judgements made by experts (e.g. 'is this patient schizophrenic?') with those that could be made by a statistical formula using the same information. The statistical decisions were based on a 'linear model'. A linear model summarizes the relationship between a set of predictor variables and some criterion value – the outcome to be predicted. For example, if predicting the chances of survival from major surgery, relevant predictor variables may be the age, weight and general fitness of the patient. The linear model is constructed in such a way as to maximize the statistical relationship between the predictor variables and the criterion to be predicted. The value of each of the predictor variables is differentially weighted according to the strength of its diagnostic relationship to the criterion and then all the variables are summed.

In approximately 20 studies which compared clinical decisions with statistical decisions, Meehl found that the statistical model provided more accurate predictions or the two models were equally

accurate. Over the years since there have been many more studies comparing clinical and statistical judgement in an enormous range of areas of judgement. The superiority of the statistical method over clinical judgement has been replicated in all of these studies. Meehl (1986) commented: 'There is no controversy in social science which shows such a large body of qualitatively diverse studies coming out so uniformly in the same direction as this one'.

Despite this claim, the effect of the research on the practice of clinical judgement has been limited; according to Dawes (1988) it is 'almost zilch'. Dawes argues that this is because the findings are a challenge to the self-perceptions of experts. It is difficult for highly trained clinicians to accept that they cannot outperform a procedure which simply adds up the cues in favour of each judgement and picks the one with the highest score. This resistance may well be stiffened by the knowledge that the statistical method will not be perfect. There is evidence that resistance to the use of simple decision rules, which (given present knowledge) cannot be outperformed, increases with expertise and the importance of the decision. Doctors may find it unacceptable to settle for the given number of errors implied by the statistical approach when they feel that their judgement might do better. Moreover, when the statistical decision conflicts with the doctor's decision, the statistical decision may be seen as risky while their own judgement is seen as safe, quite opposite to the conclusion drawn from research.

So why is statistical judgement superior? Of course the statistical approach relies on all the relevant evidence being coded in a quantitative fashion, something which may itself require considerable clinical skill but which would not ordinarily be performed in clinical situations. The statistical model will, moreover, utilize this evidence in an entirely consistent fashion. The statistical model will not be influenced by fatigue and boredom or distracted by spurious factors as human judgement is. A large number of studies have discovered inconsistency in medical judgements. Studies reviewed by Schwartz and Griffin (1986) have shown that doctors will show substantial disagreement with each other when interpreting chest X-rays, electrocardiograms and electroencephalograms, as well as more global quantities such as severity of depression. They will also sometimes disagree with their own previous judgements. One study that asked pathologists to examine the same tissue sample on two different occasions found that the conclusions (malign or benign) differed 28% of the time.

The statistical modelling approach of Meehl and others makes no claims to investigate how medical judgements are actually made. However, other studies of medical judgement have sought to examine the extent to which descriptive theories of human judgement, developed in the psychological laboratory, apply in medical contexts. One theoretical approach to judgement assumes that, because human information processing capacity is limited, people do not judge under uncertainty using systematic strategies. Instead they use mental heuristics (rules of thumb) to judge uncertainties (Kahneman *et al.*, 1982). One such heuristic is representativeness. This heuristic determines how likely it is that an event is a member of a category according to how similar or typical the event is to the category. In a medical situation this may seem a reasonable strategy: a doctor might judge how likely a person is to have a disease on the basis of the similarity between their symptoms and those typical of the disease. For example, if a person walks in with all the symptoms of a cold it seems reasonable to judge it highly probable that they

have a cold. However, this strategy neglects consideration of the relative prevalence of cold symptoms in the presence or absence of a cold: such judgements need to be made on the basis of diagnostic, rather than typical information. When base-rates of different categories vary, judgements may be correspondingly biased.

Another heuristic used for probabilistic judgement is availability. This heuristic is invoked when people estimate likelihood or relative frequency by the ease with which instances can be brought to mind. Instances of frequent events are typically easier to recall than instances of less frequent events so availability will often be a valid cue for estimates of likelihood. However, availability is affected by factors other than likelihood. For example, recent events and emotionally salient events are more easy to recollect. Dawson and Arkes (1987) report the following anecdote to illustrate this point. An older practising physician had non-specific abdominal discomfort and had not been feeling well for several days. Chronic appendicitis was diagnosed and treated surgically. After having this experience he began diagnosing 'chronic appendicitis' in many of his older patients who presented with new-onset, non-specific abdominal discomfort and referred them for surgery.

Christensen-Szalanski *et al.* (1983) discovered an availability bias in physicians' estimates of the risk (mortality rate) of various diseases. They studied physicians and students and found that both groups over-estimated the risks. In general, physicians were more accurate than the students but the estimates of both groups were found to be biased by actual encounters with people with the disease. Judgements made on the basis of availability then are vulnerable to bias (see also 'Risk perception').

The literature reporting investigations of expert medical judgements provides several instances of poor judgement attributable to heuristic processing, some of which may have serious potential consequences. Eddy (1982) set a sample of physicians the task of estimating the likelihood that a patient had cancer given that, prior to the X-ray, their examination of the patient indicated a 99% probability that the lesion was benign but that the X-ray test was positive and had indicated it was malignant. They were told that research into the accuracy of the test showed that 79.2% of malignant lesions were correctly diagnosed and 90.4% of benign lesions were correctly diagnosed by the test. Applying a probability rule known as Bayes' theorem to this evidence allows us to consider the diagnosis as a statistical inference and calculate that the probability of cancer, in the light of the positive test, is nearly 8%.

However, most of the physicians misinterpreted the information about the reliability of the test and estimated the likelihood of cancer to be about 75%. When asked about their reasoning the physicians report that they assumed that the probability of cancer given a positive test result [$p(\text{cancer}/\text{positive})$] is equal to the probability of a positive test result in a patient with cancer [$p(\text{positive}/\text{cancer})$]. They seem to have used a representativeness heuristic in that they judged the likelihood of cancer in patients with a positive test in terms of how typical (or representative) they were of patients with cancer. They failed to properly consider the impact on the outcome of the very low incidence of the disease together with the tendency of the test to (falsely) show positive test results.

Confirmation that, in fact, real decisions are taken on the basis of such misunderstandings is provided by Dawes (1988). He cites a case of a doctor performing mastectomy operations on women judged to have high risk of breast cancer. The surgery was justified

on the basis of the supposition that 'one in two or three DY (highest-risk) women will develop breast cancer between the ages of 40 and 59'. However, it turns out that this conclusion was based on the probability that a woman with cancer will have DY breasts [$p(\text{DY}/\text{cancer})$], not on the relevant probability that a woman with DY breasts will develop cancer [$p(\text{cancer}/\text{DY})$]. The relevant probability, that a woman with DY breasts will develop cancer [$p(\text{cancer}/\text{DY})$], is approximately one in eight.

In order to make a clinical diagnosis the doctor must make an inference that involves assessing the probability that a patient has the disease given some pattern of symptoms [$p(\text{disease}/\text{symptoms})$]. However, according to Eddy and Clanton (1982), medical knowledge is not organized to assist this process. Most medical texts discuss the probability that patients will present a certain pattern of symptoms given that they have the disease [$p(\text{symptoms}/\text{disease})$]. This information is not sufficient for making a diagnosis and the focus on it may well encourage the false notion that $p(\text{disease}/\text{symptoms})$ is the same as $p(\text{symptoms}/\text{disease})$. The confusion between the two probabilities may be further engendered by the type of instruction that trainee physicians receive. On ward rounds patients with certain diseases are examined and the co-occurrence of symptoms is noted. However, people with the same symptoms but without the disease (healthy people not in hospital and patients with similar symptoms and different diseases) will not be subject to the same scrutiny. As a result the diagnostic significance of a given set of symptoms may be over-estimated.

Communication and understanding of probabilities

We have already seen an indication that physicians' judgements may be influenced by their use of rules of thumb. But there are several other notable features of the judgement and perception of probability. When people communicate about risk, they may be communicating one of several different things (Gigerenzer, 2003). Gigerenzer illustrates the potential for confusion in risk communications with an anecdote from a physician colleague whose patients were interpreting his advice that they had a 30–50% chance of a developing a sexual problem from taking a particular antidepressant as indicative of the fact that they had a propensity to have sexual problems – on 30–50% of all occasions. In fact such problems occurred for only 30–50% of people.

Whilst risk communication in medicine is often in verbal terms, these do not map clearly onto numerical terms, their mapping is context-specific and verbal terms contain additional directional information. For example, an event with a probability of 0.3 of occurring may be 'doubtful', or 'possible'. Doctors communicating in numerical terms are trusted more, and seen as less likely to distort the probability. But such numerical terms are subject to classical psychophysical phenomena (Lloyd, 2001). They are perceived categorically (e.g. no risk, low risk, medium risk, high risk). Their meaning is context specific. And perception of changes in risk will depend upon the risk levels involved. For example, we find it hard to distinguish between small probabilities (such as 1 in 20 000 and 1 in 200 000), and we tend to perceive situations as dangerous or safe, rather than integrating different risks. Such effects can be exacerbated when information is presented in terms of relative risk.

A treatment that reduces fatalities by 50% (a relative risk statement) sounds better than one that reduces fatalities by 5%, nonetheless the latter treatment might be more valuable than the former; reducing a tiny risk by 50% might be trivial relative to reducing a large risk by 5%. For example, media reports on the association between the contraceptive pill and thrombosis in 1995 were followed by a 16% increase in abortions in the first quarter of 1996. Arguably, the reports of the doubling of the risk of thrombosis with the pill led to its reclassification by the public as dangerous even though the risk that was doubled was still very small (Lloyd, 2001).

Even numerical probabilities are understood context-specifically: for example the difference between a 0% chance of dying and a 10% chance of dying is more salient than a 90% chance of survival and a 100% chance of survival. Such framing effects are largest when relative risk rather than absolute risk is presented. The strong effect of context is also seen in the contrast between people's perception of risk to themselves, and to other people, known as 'unrealistic optimism'. A striking example of this is seen in a study, cited in Lloyd (2001), in which 80% of cancer patients told there was no chance of cure, thought that there was some chance.

Two methods are currently being promoted to improve risk communications. Firstly, there is evidence to suggest that numerical probabilities can be communicated more clearly in terms of frequencies than probabilities, percentages etc. For example, when test information is presented as frequencies, the majority of physicians and other people reason correctly about conditional probability. Gigerenzer (1994) reviews a number of studies that show a dramatic improvement in reasoning with probabilities if they are converted into frequencies. For instance, we can change the mammography example above as follows:

Imagine 100 people (think of a 10 x 10 grid). We expect that one woman has cancer and a positive mammography. Also we expect that there are 10 more women with positive mammographies but no cancer. Thus we expect 11 people with positive mammographies. How many women with positive mammographies will actually have breast cancer?

With frequencies you immediately 'see' that only about 1 out of 11 women who test positive will have cancer. Although Harvard medical school staff have difficulties with the probability version (the majority give wrong answers) most undergraduates readily provide the correct answer to similar problems constructed with frequencies. Gigerenzer's physician colleague could also more clearly explain the risks involved with the antidepressant by talking in terms of the number of people taking the medication who would experience sexual problems.

A second method adopted to improve communication of risk is to present the information pictorially. A range of pictorial types can be used: bar charts, pie charts, sets of happy and sad faces, or different coloured human figures. Relatively little research has been carried out on the impact of such pictures though it is clear that they influence risk perceptions. Whilst one study found that the improvements with frequency formats were amplified when pictorial information was also available (Cosmides & Tooby, 1996), other studies have found that graphical information leads to greater risk aversion compared with numerical information. Presenting mortality risks in icons is associated with higher perceived risk and results in a lower number of participants choosing what may be the optimal

choice (Timmermans *et al.*, 2004). Risks represented as pictorial figures are perceived as riskier than risks presented as numbers (Stone *et al.*, 1997). This reiterates the findings of a review which suggests that providing more information which is understandable is associated with improved patient knowledge but greater wariness to take treatments or participate in trials (Edwards *et al.*, 2001) (see 'Communicating risk').

Ascertaining utilities

The third component of decision-making is the identification of the utility of potential outcomes. A distinction can be made between experienced utilities, or the pleasure and pain experienced during a particular moment; and decision utilities, the underlying valuation of outcomes that drive decision-making. Such utilities are often inferred from people's preferences and used to explain people's preferences. Psychologists have long realized that such valuations are not simply waiting to be uncovered, but rather are constructed by decision-makers (patients and physicians) as they consider the options and outcomes available. What is preferred depends upon what's on offer, how it's evaluated or assessed, how it's presented and when it's offered.

The effect of what's on offer can be seen both in patients' and in physicians' preferences. For example, preferences can be affected by whether options are evaluated one at a time, or side by side. In a study by Zikmund-Fisher *et al.* (2004), participants rated two eye surgeons. The two surgeons available were similar but one was Harvard-educated and had completed 80 successful operations; the other was Iowa educated and had completed 300 successful operations. Evaluated independently, the Harvard-educated surgeon was given a higher rating. However, when both surgeons were evaluated side-by-side, the Iowa surgeon was given the higher rating. The psychological explanation for this effect focuses on the evaluability of certain criteria. In this example, 80 successful operations indicates a reasonable performance, until a participant realizes that there are surgeons out there with 300 successful operations under their belt. Such contrast effects can be reduced by providing patients with reference points such as the minimum, maximum or average performance, when evaluating just one option.

But the ability to evaluate is not the only phenomenon underlying changes in preference with changes in options. In a study by Redelmeier and Shafir (1995), physicians were asked to prioritize for surgery someone from a choice of either a 52-year-old woman or a 72-year-old man; or prioritize someone from a choice of these two plus a 55-year-old woman. With a choice of two people most physicians prioritized the woman. With the choice of three, most prioritized the older man. This behaviour can be understood as an example of the effects of reason-based choice: decision-making is driven by identifiable reasons or arguments. But in choice the reasons that are used are affected by contrasts between the options available. Since any reason that led to a priority of the 52-year-old woman over the 72-year-old man also applied to the 55-year-old woman, they were not useful as a basis for decision-making. Those that become useful are those which prioritized the 72-year-old man. Plainly, the reasons that are salient and influential depend on the alternatives confronting the decision-maker.

Preferences are also affected by the method we use to make them. For example we could judge how much one would have to adjust an attribute of one option to make it as good as another, or we could simply choose between them. In a study by Sumner and Nease (2001), participants choosing between living for 30 years with migraines for 10 days per month, and living for 20 years with migraines for 4 days per month, tended to prefer to live for longer. But participants who were asked to state how many days of migraine during 30 years would make that option equivalent to living for 20 with migraine for 4 days per month gave a figure indicating that had they had the choice, they would prefer to live for a shorter period. There are several explanations of this pattern of results. It may be that asking for a judgement of one attribute led to an increase in salience (and therefore influence) of the attribute being judged (in this case days of migraine) or any attribute on a similar dimension. This effect has been labelled 'scale compatibility'. But there are also arguments that, in changing from judgement to choice, people change the way they process information. In judgement, the attributes or outcomes of an option must be traded off or compensate for each other, but in a choice people might just refer to prominent attributes (such as years of life) to resolve the dilemma.

In addition there is clear evidence that choosing an option encourages decision-makers to focus on positive attributes, while rejecting an option encourages a focus on negative attributes. The resulting inconsistency in attention to features can result in people both preferring *and* rejecting the same option depending on whether they are asked which option they want or which option they don't want (Shafir, 1993).

The effects of framing of information can be seen when preferences change depending on whether the probability of outcomes in surgery are presented as death or survival. But outcomes can also be framed as resulting from your action, or from inaction. People are reluctant to make choices in which harm is the result of their action. For example, most people will not accept a risk of 9 in 10 000 of death from a vaccine that eliminates a 10 in 10 000 probability of fatal flu, even though the result would be a reduction in risk (Ritov & Baron, 1990). However, what is seen as an action, or seen as leading to potential regret, depends upon what is seen as the status quo, or the norm in that situation.

Finally, people's preferences, and therefore their apparent utilities, change depending upon how soon the outcome will occur. In a study by Christensen-Szalanski (1984), one month before labour women expressed a preference to avoid anaesthesia during labour. During labour most chose to have anaesthesia, but one month later they again preferred the idea of avoiding anaesthesia during labour. Arguably, such preference differences result from our inability to predict how we will feel in a different emotional state (an intrapersonal empathy gap). We are over-influenced by our current emotional state in decision-making, and are particularly poor at making predictions across 'hot-cold' gaps. Which decision is the optimal one in the labour situation might be a matter of debate, but the attractiveness of vices over virtues (immediately fun but ultimately health-depreciating activities over steady health-promoting activities) has been explained in terms of these temporal and emotional effects (Loewenstein *et al.*, 2003).

Assisting medical decision-making

The prescriptive approach to decision-making seeks to identify the ideal method by which decisions should be made. We have already suggested that choice of actions should reflect both probabilities and utilities. Expected Utility theory, the major theory defining rational decisions, also prescribes evaluation of different courses of action in order to choose the best. Each option is evaluated in terms of the probabilities of achieving all of the possible outcomes that may ensue from it and their relative value. For each option these two quantities are multiplied together to determine the expected utility. Accordingly, the option which has the highest expected utility is chosen. At an individual decision-making level, Decision Analysis (the term given to the application of Expected Utility theory) encourages the expression of values that reflect individual patient's utilities for the outcomes. The method can thereby be used as a means for involving patients in decisions about their own treatment (important when informed consent is required) and it has been developed as a counselling technique to help pregnant women make decisions about risky tests for foetal abnormalities. The approach can also accommodate problems of allocation of limited resources and decisions about administering tests given that costs and risks are involved.

The strategy of Decision Analysis is to decompose what may be very complex decisions involving many considerations into basic components. Using a decision tree the components are then evaluated so that the attractiveness of each option can be determined. The appeal of the procedure is that it represents a systematic attempt to analyze all relevant considerations and give them their appropriate weight. Studies of decision analysis used in real clinical settings indicate that the procedure results in different decisions being made from those that would have been made intuitively; doctors are sometimes surprised by the recommendations of the analysis (Sonnenberg & Pauker, 1986) which is one reason why they may be reluctant to accept the result. To this extent then the procedure is clearly not redundant, but does it produce *better* decisions? Many patient decision aids aim to help reduce decision conflict, and to encourage decisions that are consistent with patients' values (in other words help patients work out how they value different attributes or goals and how to trade these off against each other), but there is evidence that decision aids without an explicit utility

assessment procedure facilitate decision-making. The decomposition rationale (break the decision down and consider each element separately) suggests that it prevents information overload and permits consideration of more factors than unaided intuition would allow.

Elstein *et al.* (1986) studied decisions regarding oestrogen replacement therapy, a treatment for osteoporosis which entails an increased risk of cancer, for a sample of women with varying levels of cancer risk, fracture risk and symptom severity. They compared intuitive decisions made by the doctors with those made by decision analysis where the same doctors provided their own estimates of all the relevant probabilities and utilities for all the possible outcomes. The decision analysis recommended the treatment far more often than the clinicians' intuitions. Intuitively the clinicians appeared to give far too much weight to the risk of cancer. Calculations indicated that as very poor outcomes are so rare the increased risk was heavily outweighed by the powerful benefits of the therapy. The idea that the doctors' component probabilities and utilities were somehow in error was rejected. In general the component estimates of likelihood were accurate and sensitivity analysis on the values used showed that any reasonable set of values entered in the decision analysis recommended treatment. Decisions therefore appeared to hinge on the sub-optimal way different bits of information were combined, not on (un)awareness of specific risks and benefits.

Conclusion

Traditionally, medical training has been largely concerned with the biomedical sciences. Increasingly however, competence in the decision sciences is being seen as vital to good medical practice. The methods for making a decision become crucial when the physician is uncertain through incomplete or ambiguous information, when risks are involved, and when the patient is participating in the decision. The growing mass of psychological research investigating medical decision-making presents a strong argument for the view that these decisions may not always be ideal and that, with the application of developing methods, they can be improved.

Medical interviewing

Jonathan Silverman

School of Clinical Medicine, University of Cambridge

Introduction

The medical interview is central to clinical practice. It is the essential unit of medical time, a critical few minutes for the doctor to help the patient with his or her problems. To achieve an effective interview, doctors need to be able to integrate four aspects of their work which together determine their overall clinical competence:

- knowledge
- communication skills
- problem solving
- physical examination

These four essential components of clinical competence are inextricably linked: outstanding expertise in any one alone is not sufficient.

Strangely then, traditionally the medical interview has been described only in terms of its output, the information that needs to be gathered from the patient in order to make a diagnosis. Until recently, very little attention has been paid to how to go about the process of such information gathering, or to what skills or techniques would aid the retrieval of the data required by the doctor.

Of course, data gathering is only one of the goals of medical interviewing. Even less attention has been traditionally paid to how to build a relationship with the patient, how to organize and structure an interview, how to explain and make plans with the patient or indeed to how the patient feels about the process.

There is also a strong argument to be made that the traditional data set required by doctors has been too restrictive, focusing only on the symptoms and signs of disease that help the clinician to

make a diagnosis, at the expense of gathering information about the patient's perspective of the illness and in particular his or her ideas, concerns, expectations and feelings.

This chapter looks at the medical interview more widely and attempts to bring together two different approaches to the medical interview; traditional history taking and the study of communication process skills, so that they form a seamless whole, indeed a 'comprehensive clinical method'.

Historical perspective

Generations of doctors have learnt a system of medical interviewing known as the traditional medical history which lists the data required by the clinician from the patient that could then be applied to solving the diagnostic puzzle. These are shown in Fig. 1.

This traditional method of history-taking is so firmly established in medical practice that it is easy to assume that it is the correct approach. Yet often in medicine we make such assumptions without considering the origins of what we do and their relevance to modern-day practice (McWhinney, 1989).

It was at the beginning of the nineteenth century that a new method of clinical medicine emerged. Prior to this, medicine had lacked any scientific basis: patients' symptoms had been the focus of doctors' attention and there had been little understanding of underlying disease processes. Innovations such as the stethoscope now revealed a whole new range of clinical information. At the same time, physicians began to correlate physical signs in life with post mortem findings in death. From this time onwards, the physical expression of the patient's illness became central to the profession's approach: it became the aim of the diagnostician to interpret the patient's symptoms in terms of specific diseases and to provide a scientific explanation.

By 1880, a fully defined clinical method had become established. This is apparent from hospital clinical records where the structured method of recording the history and examination that we are all so familiar with today had taken root (Tait, 1979; Roter, 2000). The history of present complaint, history of past illness, medication and allergy history, family history, personal and social history and functional enquiry provided a standard method of recording clinical enquiries and forged an ordered approach to history taking (see Fig. 1).

This method is still in use today, almost unchanged. Its greatest strength is that it provides physicians with a clear method of taking and recording the clinical history, supplying a carefully structured template with which to arrive at a diagnosis or to exclude physical disease. It simplified and unified a very complex process

TRADITIONAL MEDICAL HISTORY

- Chief complaint
- History of the present complaint
- Past medical history
- Family history
- Personal and social history
- Drug and allergy history
- Functional enquiry/systems review

Fig 1 Traditional medical history.

and enabled the data extracted from the patient to appear in a standard form.

A new approach

So what is missing from the traditional clinical method? First we will look at what vital elements of content are not represented in the framework of the traditional clinical interview. Then our attention is turned to the process of the interview.

Content

Content is what healthcare professionals communicate; the substance of their questions, the information they gather and give, the treatments they discuss. Content is the information that clinicians obtain when taking a clinical history, that they consider when formulating a diagnosis and that they discuss with their patients. It is *what* is written down in clinical records and discussed with other health professionals and with patients and relatives.

The patient's perspective

The strength of the traditional clinical method is also its weakness. As the profession embraced the objectivity required to diagnose disease in terms of underlying pathology, it increasingly concentrated on the individual parts of the body that are malfunctioning and honed this process down to a cellular or molecular level. Yet this very detached objectivity so easily misses the patient as a whole: as Cassell says 'the patient's individual concerns are brushed aside to support the function of their organs' (Cassell, 1985).

The scientific approach does not aim to understand the meaning of the illness for the patient or place it in the context of his life and family. Subjective matters such as beliefs, anxieties and concerns are not the remit of the traditional approach: science deals with the objective, that which can be measured, whereas the patient's feelings, thoughts and concerns are unquantifiable and subjective and therefore are deemed less worthy of consideration.

The traditional medical history concentrates on pathological disease at the expense of understanding the highly individual needs and perspectives of each patient. As a consequence, much of the information required to understand and deal with patients' problems is never elicited. Studies of patient satisfaction, adherence, recall and physiological outcome validate the need for a broader view of history-taking that encompasses patients' life world as well as doctors' more limited biological perspective (The Headache Study Group of The University of Western Ontario, 1986; Roter *et al.*, 1995; Stevenson *et al.*, 2000; Joos *et al.*, 1993; Bell *et al.*, 2002; Dowell *et al.*, 2002; Little *et al.*, 1997; Abdel-Tawab & Roter, 2002; Tuckett *et al.*, 1985). We need to move the concept of history-taking as diagnostic problem-solving to a much wider view of patient care in the real world. For this to be effective, doctors need not only to be good diagnosticians but also to care for their patients, understand their needs and negotiate effective plans.

McWhinney and his colleagues at the University of Western Ontario (McWhinney, 1989) therefore proposed a new approach

‘patient-centred clinical interviewing’ which encouraged doctors to consider *both* the doctor’s and patient’s perspectives in each interview (Mishler, 1984; Campion *et al.*, 1992; Epstein, 2000; Stewart *et al.*, 2003). The disease–illness model (Fig. 2) attempts to provide a practical way of using these ideas in everyday clinical practice:

The beauty of this analysis of gathering information is the clarity with which it demonstrates how we need to explore both ‘disease’ and ‘illness’ to fulfil our unique role as medical practitioners. ‘Disease’ is the biomedical cause of sickness in terms of pathophysiology. Clearly it is the doctor’s role to search for symptoms and signs of underlying disease. Discovering a diagnosis for the patient’s disease is the doctor’s traditional and central agenda. ‘Illness’, in contrast, is the individual patient’s unique experience of sickness, how each patient perceives, experiences and copes with their illness. The patient’s perspective is not as narrow as the doctor’s and includes the feelings, thoughts, concerns and effect on life that any episode of sickness induces. It represents the patient’s response to events around him, his understanding of what is happening to him and his expectations of help.

The disease–illness model does not in any way negate the scientific disease approach but adds a patient-centred arm as well. Doctors are not counsellors whose sole aim is to help patients to become aware of how their thoughts and feelings are influencing their lives and their illness: they have the extra responsibility and burden of diagnosing and treating disease. But if doctors consider their role as purely that of discovering disease, they will not fully help their patients’ very individual needs. The patient-centred approach enlarges the doctor’s agenda to take account of both disease and illness.

Other changes to the content of the medical interview

As well as the patient’s perspective, there are other omissions of content in the traditional medical history:

- (a) *A list of the problems that the patient wishes to address* The traditional medical history starts with a chief complaint and

the history of that complaint. Yet we know from research that patients present with more than one symptom or problem and that the serial order in which they are presented is not related to their clinical importance: the first concern presented is no more likely than the second or third to be the most important as judged by either the patient or the doctor (Starfield *et al.*, 1981; Beckman & Frankel, 1984; Barry *et al.*, 2000; Greenfield *et al.*, 1985). A list of problems rather than a single complaint helps prevent a biased and blinkered approach to history taking.

- (b) *Progression of events* Discovering a temporal sequence of events is essential to effective clinical reasoning, yet is not explicitly requested in the traditional clinical method.
- (c) *A record of what the patient has been told* Increasingly modern medicine is conducted in teams with shift work and hand-overs becoming more and more important. Yet nowhere in the clinical method is a record of the information provided to the patient.
- (d) *Plan of action that has been negotiated* Similarly no record is made of the plan of action negotiated despite modern approaches towards a collaborative shared decision-making model of practice.

An alternative template for the content of the medical interview

The disease–illness model provides the foundation for an alternative template for the content of information gathering which retains all the elements of the traditional medical history but in addition includes the ‘new’ content of the patient’s perspective (Kurtz *et al.*, 2003). This template forms the backbone of how physicians can record information in the medical records and present their findings to others.

This template, as shown in Fig. 3, explicitly demonstrates how the discrete elements of the traditional medical history and the components of the disease–illness model can seamlessly work together in clinical practice.

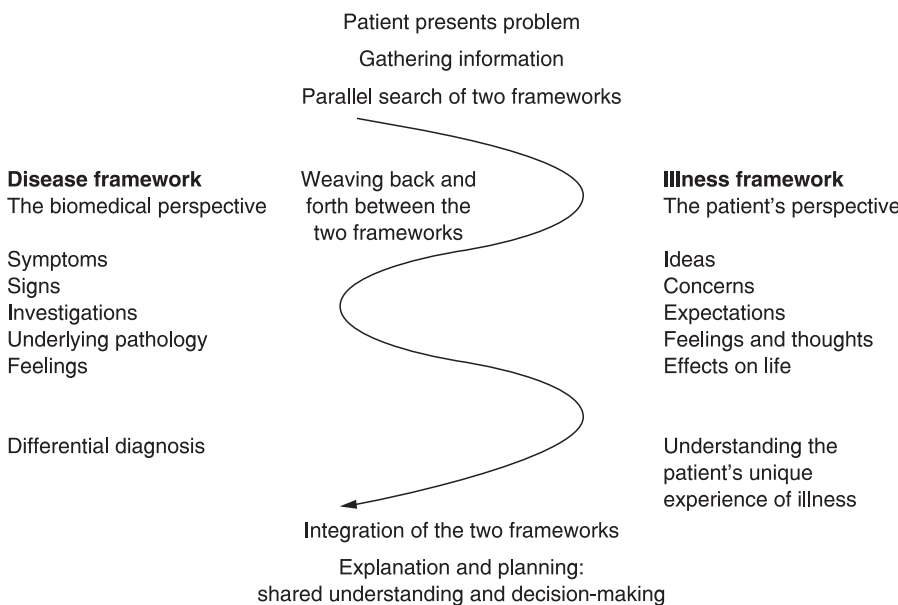

Fig 2 The disease–illness model (Levenstein *et al.*, 1998, Stewart *et al.*, 2003).

REVISED CONTENT OF THE MEDICAL INTERVIEW	
PATIENT'S PROBLEM LIST:	
1.	
2.	
3.	
4.	
5.	
BIOMEDICAL PERSPECTIVE:	(DISEASE)
<i>sequence of events</i>	
<i>symptom analysis</i>	
<i>relevant systems review</i>	
PATIENT'S PERSPECTIVE:	(ILLNESS)
<i>ideas</i>	
<i>concerns</i>	
<i>expectations</i>	
<i>effects on life</i>	
<i>feelings</i>	
BACKGROUND INFORMATION—CONTEXT	
<i>past medical history</i>	
<i>drug and allergy</i>	
<i>family history</i>	
<i>personal and social history</i>	
<i>review of systems</i>	
PHYSICAL EXAMINATION	
DIFFERENTIAL DIAGNOSIS—HYPOTHESES	
<i>including both disease and illness issues</i>	
PHYSICIAN'S PLAN OF MANAGEMENT	
<i>investigations; treatment alternatives</i>	
EXPLANATION AND PLANNING	
<i>what the patient has been told;</i>	
<i>plan of action negotiated</i>	

Fig 3 Revised content of the medical history.

This new template fits with what happens in real life clinical practice: clinicians can readily see how the new and traditional content fit together. It is important that this template makes intuitive sense to both practising physicians and teachers in communication courses (see 'Teaching communication skills'). Both these groups need to be able to embrace the same template with enthusiasm so that students, whether in the formal communication course or on the wards, can receive a consistent message about the content of the medical interview.

Process

There is a further even more fundamental problem with the classical method of history-taking. Students often erroneously perceive that the format in which they present their findings or record information in the case records is that in which they should obtain the information. They mistake the *content* of the traditional medical history for the *process* of medical interviewing. The way that doctors

have been taught about the symptoms that we need to explore in order to make a diagnosis suggests that if we ask the 15 questions we have learned about the functioning of a particular organ system, we will gather all the information that we need. But this closed approach to questioning actually encourages an inefficient and inaccurate method of history-taking (Evans *et al.*, 1991). In fact, it is the premature search for scientific facts that stops us from listening, that prevents us from both taking an accurate history and picking up the cues to our patient's problems and concerns (see 'Healthcare professional-patient communication' and 'Patient-centred healthcare').

Above we have described the changes required to the recording of the content of the medical history. Now we need to turn our attention to the process of the medical interview, how we go about communicating with our patients so that we obtain the above information and achieve so much more. Paying attention to the process of communication within the medical interview is essential if we are to make the most of our time with patients and enable both doctors and patients to achieve their goals.

But what exactly are the specific process skills of doctor-patient communication? How can we define the individual skills that together make up the medical interview?

Here we describe the Calgary-Cambridge Guides, an example of a process guide to the medical interview (Kurtz & Silverman, 1996; Kurtz *et al.*, 2003, 2005; Silverman *et al.*, 2005). Although numerous guides and checklists have been available in the past (Stillman *et al.*, 1976; Cassata, 1978; Carroll & Monroe, 1979; Riccardi & Kurtz, 1983; Tuckett *et al.*, 1985; Maguire *et al.*, 1986; Cohen-Cole, 1991; Sanson-Fisher R.W. *et al.*, 1991; van Thiel *et al.*, 1991; Novack *et al.*, 1992; van Thiel & van Dalen, 1995; Towle & Godolphin, 1999; Edwards & Elwyn, 2001) the Calgary-Cambridge Guides make significant advances by:

- providing a comprehensive repertoire of skills that is validated by research and theoretical evidence
- referencing the skills to current evidence
- taking into account the move to a more patient-centred and collaborative style
- increasing the emphasis on the highly important area of explanation and planning (see Carroll & Monroe, 1979; Tuckett *et al.*, 1985; Maguire *et al.*, 1986; Sanson-Fisher R.W. *et al.*, 1991; Towle & Godolphin, 1999; Edwards & Elwyn, 2001)

Firstly, the guides provide a set of three diagrams which outline the framework of the process of the medical interview and place it in the context of a comprehensive clinical method. The three diagrams depict this framework graphically in increasing detail and provide a logical organizational schema for both doctor-patient interactions and communication skills education. Secondly, the guides provide a comprehensive list of communication process skills that fit explicitly into this framework.

Three diagrams: the framework of the enhanced Calgary-Cambridge Guides

The three diagrams depicting the Calgary-Cambridge Guides make it easier to conceptualize firstly what is happening in a medical interview and secondly how the skills of communication and physical examination work together in an integrated way.

The basic framework

Figure 4a is a diagrammatic representation of the medical interview. This ‘bare bones’ map introduces five key tasks that physicians tend to carry out in temporal sequence during a full medical interview (initiating the session, gathering information, physical examination, explanation and planning and closing the session) and two that occur as continuous threads throughout the interview, building the relationship and structuring the interview. These tasks made intuitive sense and provided a logical organizational schema for both physician–patient interactions and communication skill education. This structure was first proposed by Riccardi and Kurtz (Riccardi & Kurtz, 1983) and is similar to that adopted by Cohen-Cole (Cohen-Cole, 1991).

The expanded framework

Figure 4b expands the basic framework by identifying the key objectives to be achieved within each of its six communication tasks.

An example of the inter-relationship between content and process

Figure 5 takes one task, i.e. gathering information, as an example and shows an expanded view of how content and process specifically inter-relate in the medical interview.

Together the diagrams in Figures 4a, 4b and 5 form a framework for conceptualizing the tasks of a physician–patient encounter and

the way they flow in real time. This framework helps us to visualize the relationships between the discrete elements of communication content and process.

Calgary–Cambridge Guides: communication process skills

More detail is then needed to move from merely thinking about the objectives of physician–patient interaction to actually identifying the communication process skills involved in the medical interview. The more complex Calgary–Cambridge process guide, as shown in Table 1, spells out the specific, evidence-based skills needed to accomplish each objective in the expanded framework of Fig. 4b.

Conclusion

This chapter makes the case that traditional ways of describing clinical interviewing have favoured the biomedical approach, limited doctors’ understanding of the patient as a person and over-emphasized content over process issues in medical interviewing. Here we have described how both content and process need equal attention and how marrying process and content into a comprehensive clinical method carries considerable benefits. Doctors need to understand that *how* they approach the patient, and *what* information they are gathering and explaining, are inextricably linked and that they need to very deliberately focus on both.

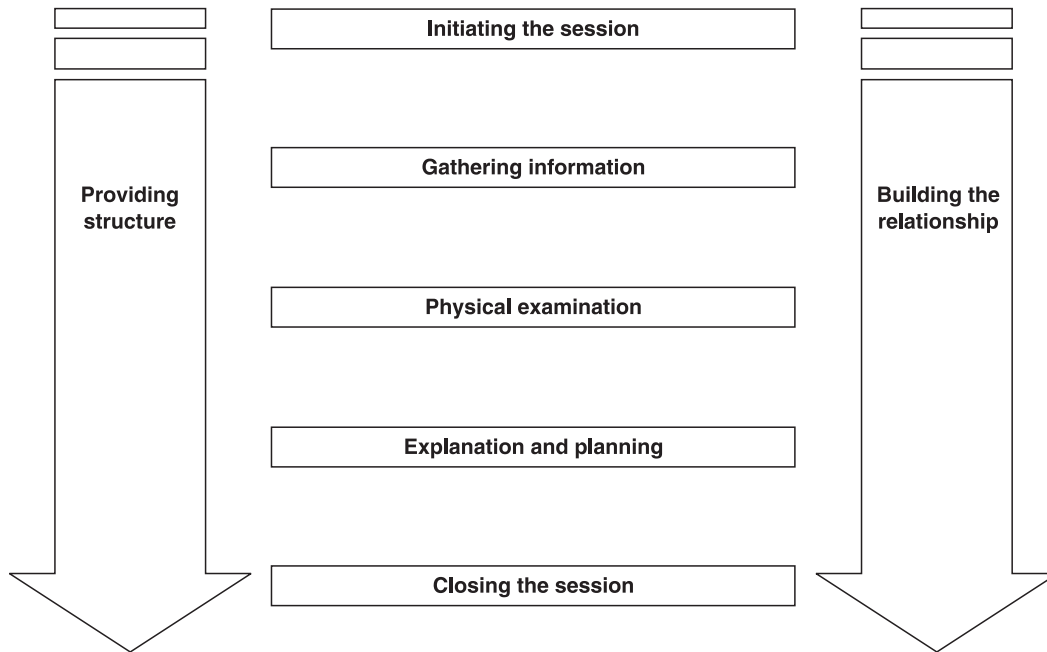

Fig 4a Basic framework of the Calgary–Cambridge guides.

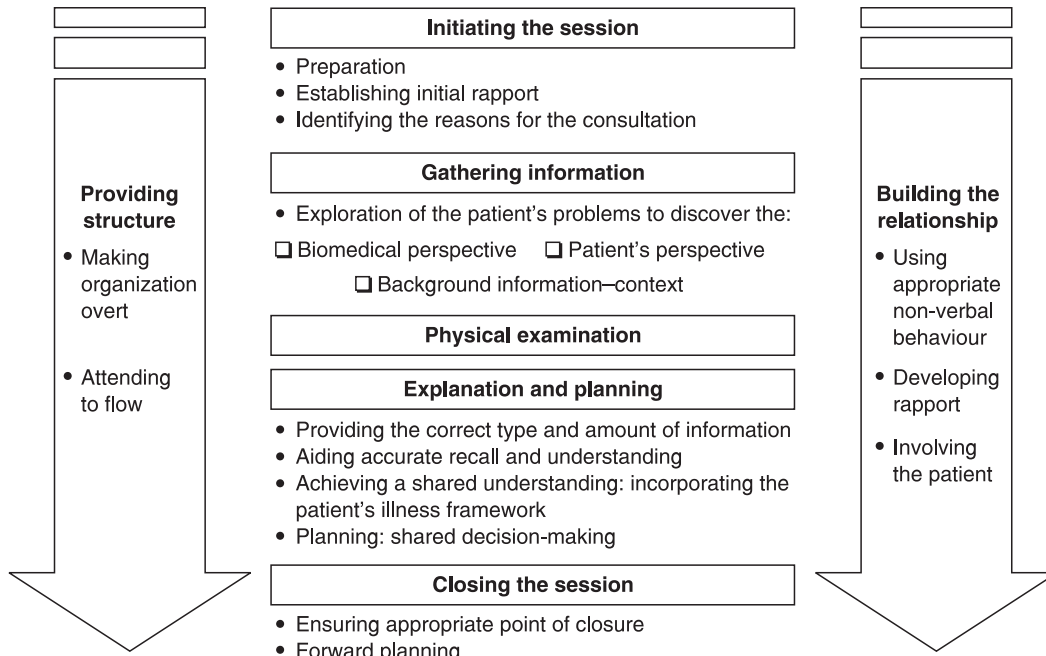

Fig 4b Expanded framework of the Calgary-Cambridge guides.

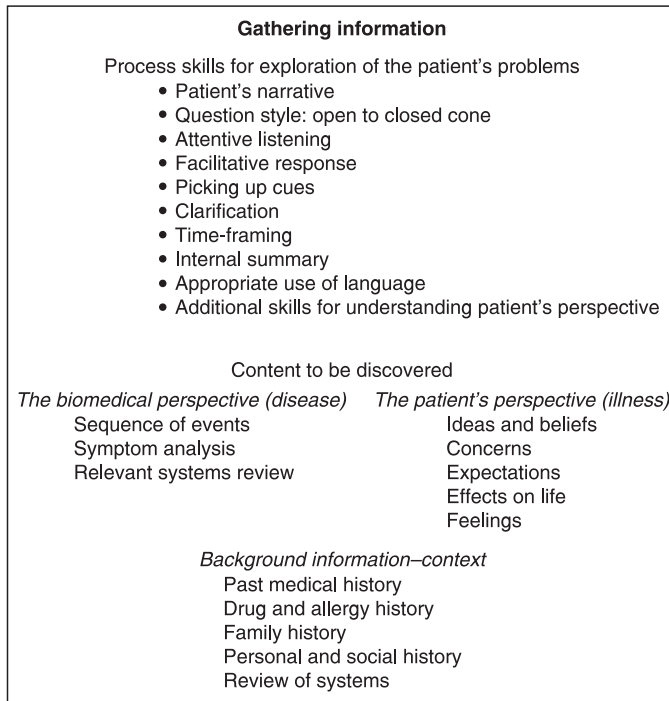

Fig 5 An example of the interrelationship between content and process.

Table 1. Calgary–Cambridge Guides: communication process skills**INITIATING THE SESSION****Establishing initial rapport**

1. **Greets** patient and obtains patient's name
2. **Introduces** self, role and nature of interview; obtains consent if necessary
3. **Demonstrates respect** and interest, attends to patient's physical comfort

Identifying the reason(s) for the consultation

4. **Identifies** the **patient's problems** or the issues that the patient wishes to address with appropriate **opening question** (e.g. 'What problems brought you to the hospital?' or 'What would you like to discuss today?' or 'What questions did you hope to get answered today?')
5. **Listens** attentively to the patient's opening statement, without interrupting or directing patient's response
6. **Confirms list and screens** for further problems (e.g. 'So that's headaches and tiredness, anything else?')
7. **Negotiates agenda** taking both patient's and physician's needs into account

GATHERING INFORMATION**Exploration of patient's problems**

8. **Encourages patient to tell the story** of the problem(s) from when first started to the present in own words (clarifying reason for presenting now)
9. **Uses open and closed questioning techniques**, appropriately moving from open to closed
10. **Listens** attentively, allowing patient to complete statements without interruption and leaving space for patient to think before answering or go on after pausing
11. **Facilitates** patient's responses verbally and non-verbally e.g. use of encouragement, silence, repetition, paraphrasing, interpretation
12. **Picks up** verbal and non-verbal **cues** (body language, speech, facial expression, affect); **checks out and acknowledges** as appropriate
13. **Clarifies** patient's statements that are unclear or need amplification (e.g. 'Could you explain what you mean by light headed')
14. Periodically **summarizes** to verify own understanding of what the patient has said; invites patient to correct interpretation or provide further information.
15. **Uses** concise, **easily understood questions and comments**, avoids or adequately explains jargon
16. **Establishes dates and sequence** of events

Additional skills for understanding the patient's perspective

17. **Actively determines and appropriately explores:**
 - patient's **ideas** (i.e. beliefs re cause)
 - patient's **concerns** (i.e. worries) regarding each problem
 - patient's **expectations:** (i.e. goals, what help the patient had expected for each problem)
 - **effects:** how each problem affects the patient's life
18. **Encourages patient to express feelings**

PROVIDING STRUCTURE TO THE CONSULTATION**Making organization overt**

19. **Summarizes** at the end of a specific line of inquiry to confirm understanding before moving on to the next section
20. Progresses from one section to another using **signposting, transitional statements**; includes rationale for next section

Attending to flow

21. Structures interview in logical **sequence**
22. Attends to **timing** and keeping interview on task

BUILDING RELATIONSHIP**Using appropriate non-verbal behaviour**

23. **Demonstrates appropriate non-verbal behaviour**
 - eye contact, facial expression
 - posture, position and movement
 - vocal cues, e.g. rate, volume, intonation
24. If reads, writes notes or uses computer, does so in a **manner that does not interfere with dialogue or rapport**
25. **Demonstrates appropriate confidence**

Developing rapport

26. **Accepts legitimacy** of patient's views and feelings; is **not judgmental**
27. **Uses empathy** to communicate understanding and appreciation of the patient's feelings or predicament, overtly **acknowledges patient's views and feelings**
28. **Provides support:** expresses concern, understanding, willingness to help; acknowledges coping efforts and appropriate self-care; offers partnership
29. **Deals sensitively** with embarrassing and disturbing topics and physical pain, including when associated with physical examination

Involving the patient

30. **Shares thinking** with patient to encourage patient's involvement (e.g. 'What I'm thinking now is')
31. **Explains rationale** for questions or parts of physical examination that could appear to be non sequiturs
32. During **physical examination**, explains process, asks permission

Table 1. (cont.)

EXPLANATION AND PLANNING

Providing the correct amount and type of information

*Aims: to give comprehensive and appropriate information
to assess each individual patient's information needs
to neither restrict or overload*

- 33. **Chunks and checks:** gives information in easily assimilated chunks, checks for understanding, uses patient's response as a guide to how to proceed
- 34. **Assesses patient's starting point:** asks for patient's prior knowledge early on when giving information, discovers extent of patient's wish for information
- 35. **Asks patients what other information would be helpful** e.g. aetiology, prognosis
- 36. **Gives explanation at appropriate times:** avoids giving advice, information or reassurance prematurely

Aiding accurate recall and understanding

Aims: to make information easier for the patient to remember and understand

- 37. **Organizes explanation:** divides into discrete sections, develops a logical sequence
- 38. **Uses explicit categorization or signposting** (e.g. 'There are three important things that I would like to discuss. 1st ...' 'Now, shall we move on to...')
- 39. **Uses repetition and summarizing** to reinforce information
- 40. **Uses concise, easily understood language,** avoids or explains jargon
- 41. **Uses visual methods of conveying information:** diagrams, models, written information and instructions
- 42. **Checks patient's understanding** of information given (or plans made): e.g. by asking patient to restate in own words; clarifies as necessary

Achieving a shared understanding: incorporating the patient's perspective

*Aims: to provide explanations and plans that relate to the patient's perspective
to discover the patient's thoughts and feelings about information given
to encourage an interaction rather than one-way transmission*

- 43. **Relates explanations to patient's perspective:** to previously elicited ideas, concerns and expectations
- 44. **Provides opportunities and encourages patient to contribute:** to ask questions, seek clarification or express doubts; responds appropriately
- 45. **Picks up and responds to verbal and non-verbal cues** e.g. patient's need to contribute information or ask questions, information overload, distress
- 46. **Elicits patient's beliefs, reactions and feelings** re information given, terms used; acknowledges and addresses where necessary

Planning: shared decision making

*Aims: to allow patients to understand the decision-making process
to involve patients in decision-making to the level they wish
in order to increase patients' commitment to plans made*

- 47. **Shares own thinking as appropriate:** ideas, thought processes and dilemmas
- 48. **Involves patient:**
 - offers suggestions and choices rather than directives
 - encourages patient to contribute their own ideas, suggestions
- 49. **Explores management options**
- 50. **Ascertains level of involvement patient wishes in making the decision at hand**
- 51. **Negotiates a mutually acceptable plan**
 - signposts own position of equipoise or preference regarding available options
 - determines patient's preferences
- 52. **Checks with patient**
 - if accepts plans
 - if concerns have been addressed

CLOSING THE SESSION

Forward planning

- 53. **Contracts** with patient re next steps for patient and physician
- 54. **Safety nets,** explaining possible unexpected outcomes, what to do if plan is not working, when and how to seek help

Ensuring appropriate point of closure

- 55. **Summarizes** session briefly and clarifies plan of care
 - 56. **Final check** that patient agrees and is comfortable with plan and asks if any corrections, questions or other issues
-

Patient-centred healthcare

Peter Bower and Nicki Mead

University of Manchester

Introduction

The delivery of healthcare is increasingly influenced by two fundamental philosophies. The first is evidence-based healthcare, which is defined as the 'the conscientious, explicit, and judicious use of current best evidence in making decisions about the care of individual patients' (Kleijnen *et al.*, 1997; Sackett *et al.*, 1996). However, in the past 30 years, an extensive body of literature has emerged advocating another key philosophy, which is described as patient-centred healthcare. This notion is commonly discussed in both the professional and health policy literature. This chapter will consider the nature of patient-centred healthcare, and review current research of relevance to this complex concept.

The definition of patient-centred healthcare

Despite the increasing popularity of the concept of patient-centred healthcare in the literature, there is little consensus as to its exact meaning. In fact, patient-centred healthcare has been most commonly understood in terms of its opposition to the philosophy of evidence-based healthcare (Bensing, 2000; Stewart, 2001). Evidence-based healthcare is generally based on rigorous outcomes research, characterized by the randomized controlled trial, which is itself concerned with the response of the 'average' patient receiving defined, conventional treatment for distinct, biomedical disorders. Evidence-based healthcare has a focus on treatments and technologies, often provided in specialist hospital settings. The style of healthcare practice engendered by this philosophy has been described as 'doctor-centred'¹. This means that evidence derived from controlled outcomes research on populations is to be interpreted and applied by the professional to the care of individual patients. This in turn means that healthcare consultations are driven by the agenda of the professional; the professional's need to know (i.e. to make an accurate diagnosis) and to control (i.e. to ensure that the prescribed treatments are delivered and adhered to by the patient, in line with the research evidence) (Byrne & Long, 1976). Patient-centred health care is often viewed as simply the antithesis of this style of practice.

Fortunately, more specific definitions have also been proposed. Patient-centred healthcare has been described as 'understanding the patient as a unique human being' (Balint, 1969) (p. 269) or as an approach whereby 'the physician tries to enter the patient's world, to see the illness through the patient's eyes' (McWhinney, 1985) (p. 35)

Other authors have highlighted sharing information and decision-making (Grol *et al.*, 1990; Verhaak, 1988; Winefield *et al.*, 1996) and providing care which is 'closely congruent with, and responsive to patients' wants, needs and preferences' (Laine & Davidoff, 1996). It is increasingly accepted that patient-centred healthcare is a multi-dimensional construct, and more comprehensive descriptions have identified a number of interconnecting components from a theoretical perspective (Mead & Bower, 2000b; Stewart *et al.*, 1995):

1. *The biopsychosocial perspective*: patient-centred healthcare involves exploring both the disease and the illness experience. This means that the professional needs to respond to any biomedical disorder, *and* to the patient's understanding of, and reaction to the problem they have brought to the consultation (Engel, 1977, 1980).
2. *The patient as person*: as noted above, evidence-based healthcare is concerned with the application of clinical data derived from groups of patients to the individual, whereas patient-centred healthcare is concerned with understanding the individual patient in his or her unique context (Bower, 1998).
3. *Sharing power and responsibility*: patient-centred healthcare involves a shift in the traditional dynamic of the doctor-patient relationship. The traditional dynamic has been described as the 'co-operation-guidance' model (analogous to a parent-adolescent relationship), whereas in patient-centred healthcare, the dynamic is one of 'mutual participation' (analogous to a relationship between adults), where power and responsibility are shared with the patient (Szasz & Hollender, 1956).
4. *The therapeutic alliance*: in patient-centred healthcare, the professional is expected to attend to the therapeutic nature of the professional-patient relationship (Browne & Freeling, 1976). This was described as 'the doctor as drug' (Balint, 1964), and relates to what is described as the 'therapeutic alliance' in the psychological therapy literature (Horvath *et al.*, 1993; Roth & Fonagy, 1996).
5. *The doctor as person*: this involves taking account of the subjectivity of the doctor as an influence on, or possible aid to diagnosis and treatment (Balint, 1964; Balint *et al.*, 1993). This is in contrast to evidence-based healthcare, where the subjectivity of the doctor is seen largely as a source of bias.

Although developed from within medicine, the concept of patient-centred healthcare has many roots in the psychological therapy research literature, and one of the first uses of the term related it to work conducted by psychoanalytic practitioners working with

¹ The term 'doctor-centred' is that commonly found in the literature, but here the term 'doctor' should be understood as referring to the broader notion of the healthcare professional

general practitioners in the United Kingdom (Balint, 1964; Balint, 1969). For example, understanding the perspective of clients in psychotherapy has been traditionally highlighted in discussions of empathy within client-centred therapy (Rogers, 1967), and it has long been suggested that the therapeutic alliance is a fundamental driver of change in psychological therapy (Roth & Fonagy, 1996).

However, the development of patient-centred healthcare also has its roots in the evolution of particular disciplines within healthcare. Many of the attributes of patient-centred healthcare have been championed by general practitioners as part of their professional differentiation from specialist, hospital-based medicine. Sensitivity to the ongoing doctor–patient relationship, respect for the patient as an individual and a belief in the intrinsic therapeutic potential of the consultation are all core themes in the academic literature of general practice. Lacking the complex diagnostic technologies of hospital medicine, general practice has instead defined for itself a model of care focused on the ‘whole person’ in his or her wider psychological and social context (May & Mead, 1999).

Patient-centred healthcare in the consultation

Given its origins within the disciplines of psychological therapy and general practice, it is no surprise that much of the development of the concept of patient-centred healthcare has been in relation to the individual consultation between professional and patient, and the content and quality of the actual process of care between doctor and patient. That is, patient-centred healthcare is conceptualized as a clinical method. This perspective is best exemplified by the literature concerning the role and function of patient-centred healthcare in the clinical setting, and the training and educational issues associated with it (Stewart *et al.*, 1995). Table 1 details examples of types of doctor behaviours indicative of the different dimensions of patient-centred healthcare described above.

It should be noted that the concept of patient-centred healthcare can also be applied at another level, that of health policy, where it concerns the organization of healthcare systems at a local, national or international level. For example, the blueprint for the National Health Service in the United Kingdom, the NHS Plan, states that ‘The NHS must be redesigned to be patient-centred – to offer a personalised service’ (Secretary of State for Health, 2000), (p. 20).

When used in this fashion, the concept is less concerned with the specific behaviours of health professionals, and more with broader values such as empowerment of patients and the need to design health services to fit in with their preferences and needs, as opposed to the convenience of professionals.

Research on patient-centred healthcare

Just as some critics have questioned the degree to which evidence-based medicine is patient-centred, it is possible to ask the degree to which the provision of patient-centred medicine is supported by the available evidence (Bensing, 2000). One of the first issues concerning research on patient-centred healthcare regards its measurement. Given the complex definition of patient-centred healthcare described above, it is clear that this is a significant challenge.

A plethora of different measurements of patient-centred healthcare have been used in the research and training literature (Mead & Bower, 2000*b*). These can involve measurements of the attitudes of professionals, global ratings of the quality of consultations, or microanalyses of actual behaviours demonstrated in the consultation which are hypothesized to correspond to patient-centred healthcare (Table 1) (see also ‘Healthcare professional–patient communication’).

However, attempts to measure this complex construct have highlighted significant problems. For example, there is some evidence that measurement tools which are ostensibly measuring the same concept are not always in agreement (Mead & Bower, 2000*a*). Furthermore, there is also evidence that measures of professional behaviour which are theoretically related to patient-centred healthcare are not in close agreement with ratings of the same consultations made by patients (Cape, 1996; McKinstry *et al.*, 2004; Mead *et al.*, 2002; Stewart *et al.*, 2000). This might suggest that professional and patient concepts of quality in healthcare consultations differ significantly (Burkitt Wright *et al.*, 2004). Alternatively, this may reflect the fact that a concept such as patient-centred healthcare is difficult to quantify. Patients judgements as to what appears to them to be ‘patient-centred’ may be highly idiosyncratic and variable: indeed, such variability may be highly appropriate, given the nature of the patient-centred philosophy and its focus on the subjectivity of the patient.

Table 1. Examples of patient-centred behaviours

Dimension of patient-centred healthcare	Examples of patient-centred healthcare
The biopsychosocial perspective	Discussion of psychosocial/lifestyle issues (Ford <i>et al.</i> , 1996), counselling about prevention (Roter <i>et al.</i> , 1987)
The patient-as-person	Eliciting patient’s assumptions about diagnosis and treatment (Langewitz <i>et al.</i> , 1998), responding to patient’s ‘offers’ of thoughts, feelings, symptoms, expectations or prompts (Henbest & Stewart, 1989)
Sharing power and responsibility	Giving information (Ford <i>et al.</i> , 1996; Roter <i>et al.</i> , 1987; Wissow <i>et al.</i> , 1998), assisting patients to participate in decision-making about diagnosis and therapy (Verhaak, 1988); soliciting and encouraging patient questions, opinions and suggestions (Stewart, 1984; Street, 1992)
The therapeutic alliance	Responding to patients with empathy and assurance (Ockene <i>et al.</i> , 1988); partnership-building statements (Ford <i>et al.</i> , 1996; Wissow <i>et al.</i> , 1998); statements of reassurance, support, empathy and inter-personal sensitivity (Street, 1992); talking about non-medical matters (Butow <i>et al.</i> , 1995)
The doctor-as-person	Self-awareness of limitations and personal response to stress; acceptance of risk of exposing own weakness and vulnerability; understanding of transference/counter-transference (Stewart <i>et al.</i> , 1995)

Notwithstanding difficulties in measurement, it is probably true that the 'gold standard' test of the utility of patient-centred healthcare is whether it has an impact on outcomes: that is, does practising in a patient-centred manner make any difference to the end result of the consultation? A number of studies have examined this issue, and a systematic overview of their results is beyond the scope of the current discussion. However, some relevant reviews will be discussed in detail.

The first examined the relationship between doctor behaviours within the consultation and patient outcomes such as satisfaction with healthcare, adherence with medical advice and health status. In this review, 16 out of 21 studies reported improvement in various outcomes, including distress, functioning, physiological measures (e.g. blood pressure) and health service utilization (Stewart, 1995). However, the reviewed studies covered a wide variety of clinical settings and patient populations and, importantly, none measured aspects of doctor-patient communication explicitly defined as 'patient-centred' by the respective investigators (Graugaard & Finset, 2004). A second review was restricted to primary care settings, and used a more clearly specified definition of patient-centred healthcare. Although there were some positive relationships, generally the pattern of results was much more inconsistent (Mead & Bower, 2002). There are a number of possible reasons for the differences in the results of these reviews, such as the types of professionals and patients included, and the study designs deemed eligible. However, the somewhat inconsistent results do suggest that an uncritical acceptance of the benefits of patient-centred healthcare may be inappropriate. A recent review of the effect of patient-centred healthcare in chronic illness has thrown some light on this inconsistency, suggesting that taking the patient's perspective (i.e. the patient as person) may have a different pattern of effect on outcomes than 'activating' the patient (i.e. sharing power and responsibility) (Michie *et al.*, 2003). Even then, there is also some evidence from diabetes research that improving patient outcomes through self-care may be more easily achieved by intervening directly with patients, rather than attempting to modify patients by teaching patient-centred skills to clinicians (van Dam *et al.*, 2003).

A related question concerns whether patient-centred skills can be taught, or whether they reflect more fundamental personality attributes that may not be amenable to change. At least one author has suggested that some aspects of patient-centred healthcare require 'a limited though considerable change in personality' (Balint, 1964) (p. 121)

However, others suggest that patient-centred skills can be learned without such profound psychological change (Gask & McGrath, 1989). A systematic review published in the Cochrane Library has examined the effects of interventions for health professionals who aim to promote patient-centred approaches in consultations (Lewin *et al.*, 2001). All the interventions involved training of professionals, but some included other interventions, such as materials for patients. Generally, interventions were successful in increasing the patient-centred nature of consultations in terms of the process of those consultations, and there was some support for the hypothesis that the interventions improved patient satisfaction with care. However, there was generally less evidence that the interventions impacted on patient health behaviours such as adherence to treatment, or on health outcomes. Again, this suggests that the benefits of patient-centred healthcare cannot be assumed.

Discussion

The question 'is patient-centred medicine evidence-based?' is difficult to answer definitively. Although it might seem self-evident that the behaviours described in Table 1 would lead to more satisfied patients and improvement in other health outcomes, current evidence is far from unequivocal. This last section will discuss some reasons for this, and consider implications for the future development of patient-centred healthcare.

It is a legitimate question whether patient-centred healthcare should be evaluated using the same standards of evidence-based healthcare that are applied to treatments and technologies. Firstly, the available measurement methodologies may be insufficiently sensitive to the complex nature of the concept. For example, in the psychological therapy literature, it has been suggested that research examining the relationship between certain behaviours (such as empathy) and patient outcomes are unwittingly applying what is called the 'drug metaphor' (Stiles *et al.*, 1995; Stiles & Shapiro, 1989), whereby the content of the consultation can be seen as analogous to drug ingredients and analyzable in terms of 'strength' and 'dosage'. Thus there may be an expectation that greater amounts of 'sharing of information' will be associated with greater patient satisfaction, irrespective of the appropriateness of the behaviour, the particular requirements of individual patients or the responsiveness of the professional to the patient and to the context of the consultation. This argument would suggest the need for more complex and sensitive research methodologies involving in-depth qualitative and quantitative research.

Issues of appropriateness and responsiveness relate to the question of whether patients actually want 'patient-centred healthcare', as currently defined. There are aspects of patient-centred healthcare that are generally considered relevant for *all* patients (e.g. developing a positive therapeutic alliance, understanding the patient experience), but patients may differ in their preferences for other aspects. For example, in terms of the issue of sharing power and control, it is possible some patients will prefer the doctor to make decisions, and have no great interest or desire to become more actively involved in the process of their medical care and clinical decision-making. Therefore, studies that attempt to increase involvement with all patients may actually worsen outcomes for some patients (Roter, 1977; Savage & Armstrong, 1990). Indeed, it is increasingly recognized that one of the key aspects of patient-centred healthcare is the ability of the professional to recognise or negotiate with the patient as to their preferred level of involvement in decision-making, so as to overcome this problem (Guadagnoli & Ward, 1998; Winefield *et al.*, 1996).

On a more fundamental level, patient-centred healthcare reflects value judgements concerning the way patients should be treated within healthcare (Laine & Davidoff, 1996; McWhinney, 1989), as well as being a way of encouraging 'instrumental' benefits such as improvements in health behaviours and outcomes (Lewin *et al.*, 2001). Even if there is no direct evidence that sharing control improves patient outcomes, there is an argument that such an approach is morally and ethically appropriate in the context of providing healthcare in societies which increasingly value individual rights.

Finally, it is important to consider the potential tension between the philosophies of evidence-based and patient-centred healthcare. Although in principle it should be possible to provide both, and that is still seen as the gold standard for healthcare delivery, it is equally possible that there are trade-offs to be made in terms of the benefits of the two different approaches. This was neatly demonstrated by a randomized controlled trial of the delivery of patient-centred diabetes advice in primary care (Kinmonth *et al.*, 1998). Practice teams received training in the provision of patient-centred healthcare, and the study found that increased patient-centred healthcare (as reported by patients) was associated with a reduction in quality of care as defined by objective biomedical indicators.

Summary

Patient-centred healthcare is a complex construct that defines a number of important processes in healthcare provision, focussing on the subjectivity of individual patients and their particular perspectives, needs and preferences. There is a growing literature on the methods by which this approach can be demonstrated in consultations between patient and professionals, and suggestive evidence that providing healthcare that is patient-centred improves outcomes, especially patient satisfaction. However, there are also emerging controversies concerning patient-centred healthcare that have important implications for research, clinical practice and health policy.

Patient safety and iatrogenesis

Maria Woloshynowych and Charles Vincent

Imperial College School of Medicine

Treatment for disease or ill-health is not without its risks. These risks may be inherent to the treatment, such as known side effects of medication, or due to the actions or omissions of healthcare professionals, such as accidentally cutting an adjacent organ during surgery or failing to give the patient prophylactic antibiotics to prevent post-operative infection. Terms used to describe treatment complications and injury to patients include the following: iatrogenic injury or iatrogenic disease; medical accidents; medical mishaps; adverse events; negligence; adverse events; medical mistakes; medical error and critical incidents. Some of these terms have specific definitions while others are general terms that are often used interchangeably. The definition, use and development of these terms are described

below. This is followed by an outline of methods used to help our understanding of medical harm, the impact on patients, families and staff, and concludes with a section on how harm to patients can be prevented.

Iatrogenic disease and patient harm

The term 'iatrogenic' comes from the Greek word for physician 'iatros' and from 'genesis', meaning origin; iatrogenic disease therefore is illness which is induced, in some way, by a physician. With the advances of medical science in the mid-twentieth century, particularly the development of penicillin and other antibiotics, the term

iatrogenic disease broadened in scope. By the mid-1950s some doctors were beginning to realize that there were potential hazards associated with the enormous increase in drug use and availability (Sharpe & Faden, 1998).

In the 1960s Schimmel (1964) instituted one of the first systematic studies of harm that resulted from 'acceptable diagnostic or therapeutic measures deliberately instituted in the hospital'. Reactions due to error or from previous treatment, and situations that were only potentially harmful were excluded. Even without errors more than 20% of patients experienced one or more episodes of harm and 16 fatalities resulted partly from diagnosis and treatment. In 1981, Steel and colleagues set out to reassess Schimmel's findings, noting that since his time the number and complexity of diagnostic procedures and the number of drugs used had increased and the patient population had aged. Of 815 patients surveyed, 36% suffered a iatrogenic illness, with 9% being major in that they threatened life or produced a major disability. Exposure to drugs was the main factor leading to adverse effects, with nitrates, digoxin, lidocaine, aminophylline and heparin being the most dangerous. Cardiac catheterization, urinary catheterization and intravenous therapy were the principal procedures leading to problems. Falls were also a serious issue.

Steel *et al.* (1981) were willing to admit that some of these episodes might have been preventable, but did not discuss error and were at pains to point out that there was no suggestion of culpability. Gradually however, there has been a greater willingness to examine the problem of patient harm and to speak explicitly of medical error; in the last 10 years the numbers of studies of medical error have increased dramatically. A particular terminology has also developed:

- *adverse events* refer to injury or complication caused by healthcare management (and not due to the disease process) which have resulted in extended hospital stay or disability at the time of discharge from hospital. These events may or may not be preventable
- *critical incidents* generally include harm due to treatment which have *not* resulted in extended stay or disability
- *near misses* refer to errors or circumstances, which if not averted might have resulted in an adverse event or critical incident
- *negligence* is a legal term, which refers to care clearly below the accepted standard of care and resulting in definite harm. In practice events that might be termed negligent are a sub-set of adverse events and critical incidents.

As well as a change in the terms used to describe harm to patients, there has also been a change in emphasis in the phrase used to describe the attempts to reduce harm to patients. Risk management is sometimes, for instance in the United States, oriented more towards resolving legal problems and protecting the organization. In Britain however, the term clinical risk management included attempts to make care safer and prevent harm. Increasingly the reduction of error and harm are encapsulated in the more positive term 'patient safety'. Patient safety activities and initiatives are described in the next two sections.

The nature and frequency of adverse events and critical incidents

In the last 20 years a number of factors combined to bring medical error and the associated harm to the attention of both patients

and professionals. These factors include rising rates of litigation, the emergence of risk management, the influence of safety theories and practices from high-risk industries, high profile cases, major government reports and increasing research activity. Perhaps the most powerful driver of all however has been epidemiological studies of harm to patients, defined as adverse events.

The definition for adverse events originated from a study in the United States, the Harvard Medical Practice Study (Brennan *et al.*, 1991), carried out in New York in the mid-1980s, sought to examine the scale of harm to patients in hospital. The researchers needed a measurable definition of adverse events and chose extended stay and disability at the time of discharge as these could be identified with retrospective record review of medical records. The initial findings were substantiated in further retrospective studies in the United States (Thomas *et al.*, 1999), Australia (Wilson *et al.*, 1995), the UK (Vincent *et al.*, 2000), New Zealand (Davis *et al.*, 2001), Denmark (Schiolar *et al.*, 2001), France (Michel *et al.*, 2004) and Canada (Baker *et al.*, 2004).

The incidence of adverse events in these studies vary, with rates ranging from 2.9% in the USA to 16.6% in Australia. However, subsequent analysis has revealed that this can be explained to some extent by differences in definitions, exclusion/inclusion criteria and purpose of the studies (Thomas *et al.*, 2000; Runciman *et al.*, 2000). Studies which have focused on quality of care have reported that 37–60% of adverse events were judged to be preventable (Wilson *et al.*, 1995; Vincent *et al.*, 2000; Davis *et al.*, 2003; Michel *et al.*, 2004; Baker *et al.*, 2004) and have attempted to identify the underlying causes for the adverse events and how to address these. For example, the Australian study recommended better implementation of policies and protocols, better formal quality monitoring, better education and training and more consultation (Wilson *et al.*, 1995); and subsequent US studies have shown how information and decision support systems can reduce medication events (Bates *et al.*, 1993).

Michel *et al.* (2004) have shown that prospective record review is comparable to retrospective record review and in fact identified more preventable adverse events. Prospective review studies are also being carried out in the UK (Chapman *et al.*, 2003). These review studies differ from the earlier, traditional adverse event studies in that they have widened the definition of adverse events to include critical incidents and potential harm. Preliminary results show that on six medical and surgical units 15% of patients experienced an adverse event and a further 14% experienced a critical incident. 72% of adverse events, and 90% of critical incidents, were judged to be preventable. Most adverse events caused little harm but had a negative impact on hospital resources (S. Olsen & G. Neale, personal communication).

Examination of cases identified in the preliminary feasibility study suggested that a significant proportion of critical incidents may be specific to a particular hospital, ward or unit (Chapman *et al.*, 2003). As such it is amenable to local action and this is a good starting point for strategies to improve patient safety. This could be included as part of the ongoing process of clinical risk management or quality improvement. For example, contributory factors may be difficult to assess in retrospective reviews, but prospective methods would enable the staff to further explore causes for particular types of adverse events or critical incidents.

Table 1. Framework of factors influencing clinical practice

Factor types	Influencing Contributory factors	Examples
Institutional Context	Economic and regulatory context; National Health Service Executive; Clinical negligence scheme for NHS trusts	Inconsistent policies; funding problems
Organizational and management factors	Financial resources & constraints; Organizational structure; Policy standards and goals; Safety culture and priorities	Lack of senior management procedure for risk reduction
Work environment factors	Staffing levels and skills mix; Workload and shift patterns; Design, availability and maintenance of equipment; Administrative and managerial support	High workload, inadequate staffing or limited access to essential equipment
Team factors	Verbal communication; Written communication; Supervision and seeking help; Team structure (consistency, leadership, etc.)	Poor supervision of junior staff, poor communication between staff
Individual (staff) factors	Knowledge and skills; Competence; Physical and mental health	Lack of knowledge or experience of specific staff
Task factors	Task design and clarity of structure; Availability and use of protocols; Availability and accuracy of test results	Non-availability of test results or protocols
Patient factors	Condition (complexity & seriousness); Language and communication; Personality and social factors	Distressed patient or language problem

Understanding adverse events

When the first edition of this book was published, very few studies focused directly on the causes of harm to patients. Confidential enquiries into maternal and postoperative deaths had revealed problems with supervision of junior staff and a higher mortality from surgeons operating outside their own speciality. Critical incident studies, which analyze potentially dangerous incidents reported by staff, have identified other common themes. Cooper *et al.* (1984) examined anaesthetic incidents such as breathing circuit disconnections, drug-syringe swaps and losses of gas supply. Failure to check equipment, unfamiliarity with the equipment, inattention and haste were frequently implicated. Closed claims analyses had also been instructive. For instance Ennis and Vincent (1990) summarized the findings of expert obstetricians in claims involving a stillbirth, perinatal or neonatal death, severe handicap or maternal death. Three major areas of concern were identified: inadequate fetal monitoring; mismanagement of forceps; and lack of involvement of senior staff – inexperienced doctors were left alone for long periods and could not get help when difficulties arose.

The complexity and nature of the factors that combine to cause harm to patients has been illuminated by studies of single cases and case series. In most high-risk industries learning from accidents and near misses is a long-established practice and a cornerstone of safety analysis and improvement. Aviation accidents for instance are exhaustively investigated and the lessons learnt disseminated widely, with important changes made mandatory by the regulatory authorities. In contrast learning within healthcare, with some notable exceptions, has generally been fragmentary and uncertain. Studies of accidents in industry, transport and military spheres have led to a much broader understanding of accident causation, with less focus on the individual who makes the error and more on pre-existing organizational factors.

There are a number of methods of investigation and analysis available in healthcare, though these tend to be under-developed compared with methods available in industry. In the USA the most familiar is the root cause analysis approach of the Joint Commission, an intensive process with its origins in Total Quality

Management approaches to healthcare improvement (Spath, 2000). The Veterans Hospital Administration has developed a highly structured system of triage questions which is being disseminated throughout their system (see the National Center for Patient Safety (NCPS) website). In Britain we have developed a method based on Reason's model and on the framework of contributory factors developed by Vincent *et al.* (Vincent *et al.*, 2000*b*; see Clinical Safety Research Unit website). Reason's essential insights are as follows: incidents and accidents are usually preceded by some kind of unsafe act, in which a person makes an error or mistake. However to understand how this occurred it is necessary to look further back to the 'error producing conditions' which led to the unsafe act and also to 'latent failures', decisions taken by management and others which may have had a bearing on the outcome. Reason's model has been extended and adapted for use in healthcare by developing a broad framework of 'contributory factors' which can impact on clinical practice (Vincent *et al.*, 1998; Table 1).

Information is gleaned from a variety of sources. Case records, statements and any other relevant documentation are reviewed. Structured interviews with key members of staff are undertaken to establish the chronology of events, the main care management problems and their respective contributory factors. The key questions are: 'What happened?' (the outcome and chronology); 'How did it happen?' (the care management problems); and 'Why did it happen?' (the contributory factors).

Analyses using this method have been conducted in hospitals, primary care settings and mental health units. The protocol may be used in a variety of formats, by individual clinicians, researchers, risk managers or clinical teams. For serious incidents a team of individuals with different skills and backgrounds may be assembled for a major incident. A clinical team may use the method to guide and structure reflection on an incident, to ensure that the analysis is full and comprehensive. The group approach is also useful for teaching, both as an aid to understanding the protocol itself and as a vehicle for introducing systems thinking.

The contributory factors that reflect more general problems in a unit are the targets for change and systems improvement. When obvious problems are identified, action may be taken after a single

incident, but when more substantial changes are being considered other incident analyses and sources of data (routine audits and outcome data) should also be taken into account. Recommendations may be made in a formal report but it is essential to follow these up with monitoring of action and outcome and to specify who is responsible for implementation.

After the event: the impact on patients, families and staff

Patients are often in a vulnerable psychological state, even when diagnosis is clear and treatment goes according to plan. Even routine procedures and normal childbirth may produce post-traumatic symptoms (Clarke *et al.*, 1997; Czarnocka & Slade, 2000). When patients experience harm or misadventure therefore, their reaction is likely to be particularly severe. Patients and relatives may suffer in two distinct ways after an adverse outcome, firstly from the incident itself and secondly from the manner in which the incident is handled. Many people harmed by their treatment suffer further trauma through the incident being insensitively and inadequately handled. Conversely when staff come forward, acknowledge the damage and take the necessary action, the overall impact can be greatly reduced.

The impact of a medical injury differs from most other accidents in two important respects. Firstly, patients have been harmed, unintentionally, by people in whom they placed considerable trust, so their reaction may be especially powerful and complex. Secondly, they are often cared for by the same professions, and perhaps the same people, as those involved in the original injury. They may have been very frightened by what happened to them and have a range of conflicting feelings about those involved. This can be very difficult, even when staff are sympathetic and supportive (Vincent *et al.*, 1993; Vincent, 2001).

The initial reaction to a medical injury is likely to be one of fear, loss of trust and feelings of isolation. Traumatic and life-threatening events produce a variety of symptoms, over and above any physical injury. Anxiety, intrusive memories, emotional numbing and flashbacks are all common sequelae and are important components of post-traumatic stress disorder (Brewin *et al.*, 1996) (see 'Post-traumatic stress disorder'). The full impact of most incidents only becomes apparent in the longer term. A perforated bowel, for example, may require a series of further operations and time in hospital. The long-term consequences may include chronic pain, disability and depression, with a deleterious effect on family relationships and ability to work. When a patient dies the trauma is obviously severe, especially after a potentially avoidable death (Lundin, 1984), when relatives may face an unusually traumatic and prolonged bereavement (see 'Coping with bereavement').

The aftermath of an adverse event can also have profound consequences for the staff involved, particularly if an individual is perceived as primarily responsible for the outcome. Staff may experience shame, guilt and depression after making a mistake, with litigation and complaints imposing an additional burden. In some cases doctors or nurses may become very nervous of clinical medicine, seek out a specialty with less direct patient contact or abandon medicine entirely. The reaction of the patient and their family may be especially hard to bear, especially when the outcome

is severe and if there has been a close involvement over a long period. The reaction of colleagues, whether supportive or defensive and critical, may be equally powerful. Guidelines and practical advice on caring for injured patients and supporting staff can be found elsewhere (Vincent, 2001).

Preventing harm to patients

With the proliferation of studies on medical error and patient harm, it is becoming clear that making healthcare safer is a massive and extremely difficult task. There are clear examples of rapid and obvious safety improvements, such as taking Potassium Chloride and other dangerous drugs off wards to avoid erroneous use. However, while incident reports and basic risk management programmes provide a starting point, fundamental changes are required to many healthcare processes and systems.

Compared with other hazardous enterprises like aviation and nuclear power, healthcare is extraordinarily diverse in nature and highly reliant on human beings, rather than technology, to ensure safety. Solutions required to ensure high reliability in, for instance, blood transfusion services, will obviously differ from those aimed at reducing suicides in mental health. Some factors, perhaps leadership and attitudes to safety, will be important in all environments. Improving safety is likely to require some generic, cross-organizational action, coupled with specialty and process specific changes. The way in which the specific and generic might combine (or interfere) has not yet been established. In this chapter we can only highlight some areas which are held to be of particular importance.

Culture and leadership

Almost everyone involved in patient safety is agreed that progress will depend to some extent on a change in attitudes to error, with more reflection and analysis and less blame and disciplinary action. The development of a 'safety culture' is often held up as the foundation of all approaches to improving patient safety. This term is not well defined, but tends to include an open and fair response to error, a more general awareness of the potential for error and harm, and a willingness to report and discuss error. Crucially, a strong organizational and management commitment is implied. Safety is taken seriously at every level of the organization: the cleaner on the wards is conscious of infection risks, the nurse is alert for potential equipment problems and drug hazards, and managers are monitoring incident reports. The hospital's chief executive should be setting the pace with clear and committed leadership that gives the safety of patients and staff a priority.

Reporting and learning systems

At the heart of most programmes are methods for early identification of adverse events, using staff reports or a systematic screening of records. Similar systems are already in operation in respect of the safety of medicines and medical devices. The reports are used to create a database to identify common patterns and prevent future incidents. The development of clinical risk management in the United Kingdom and elsewhere led to the establishment of local

incident reporting systems in hospitals, usually run centrally. Typically there is a standard incident form, asking for basic clinical details and a brief narrative describing the incident. Sometimes staff are asked to report any incident which concerns them or might endanger a patient; in more sophisticated systems, where staff within a unit may be trying to routinely monitor and address specific problems, there may be a designated list of incidents, although staff are free to report other issues that do not fall into these categories. Local systems are ideally used as part of an overall quality improvement strategy but in practice are often dominated by managing claims and complaints. The NHS has a well developed clinical incidents reporting system and this system should be seen as a tool by which patient safety issues can be identified and addressed to reduce the occurrence of clinical incidents and to improve both patient and staff experience. However, there still exist a number of barriers to reporting, such as fear of reprisals or poor understanding of the process of investigation of an incident.

Training, supervision and working conditions

Many senior doctors, and probably hospital management, may be unaware of the extent to which junior doctors are called upon to act beyond their competence. Poor communication between professions is another source of errors and lost information. Linked to the need for better training and supervision is the question of error-producing working conditions, particularly the excessive hours or long shifts that junior staff are required to work in Britain and many other countries. It is a curious paradox that it is illegal to drive a coachload of healthy passengers without regular rest, yet until August 2004, with the introduction of European directives on doctors' working hours, it was considered acceptable to care for a ward of desperately sick patients when close to exhaustion (Vincent *et al.*, 1993). There is still however, in all healthcare systems, serious concern about the impact of workload and fatigue on liability to error (Gaba & Howard, 2002).

Information technology

Bates and Gawande (2003) identify a number of ways in which information technology can reduce error: improving communication; making knowledge more readily accessible; prompting for key information (such as the dose of a drug); assisting with calculations, monitoring and checking in real time; and providing decision support. The use of information technology is accompanied by some degree of standardization and reduction in the variability of provision provided by human beings. Such standardization, when in the form of guidelines and protocols, can be criticized as being overly prescriptive and not taking a patient's particular constellation of

symptoms into account. Computers however, when provided with the appropriate information, can completely tailor their guidance or output to the individual patient. Thus technology potentially provides a marriage between the need for standardization and less reliance on human memory and decision-making, with the clinician's necessary insistence that treatment is tailored to the individual patient. Bates *et al.* (1998) have shown that the introduction of a computerized order entry system resulted in a 55% reduction in medication errors. With the addition of higher levels of decision support, in the form of more comprehensive checking for allergies and drug interactions, there was an overall reduction of 83% in medication errors.

Patient empowerment

A further initiative which is becoming more widespread is to involve the patient in reducing risks and promoting safety. Patients are usually thought of as passive receivers of treatment once they are admitted to hospital, but there is considerable scope for them to contribute to their own safety without placing an too much of a burden of responsibility on them (Vincent & Coulter, 2002). Some patients and relatives already do this, particularly when they suffer from a chronic condition and often may understand their treatment requirements better than a junior doctor. The ways in which patients can be involved in promoting safety are by helping to reach an accurate diagnosis; deciding on appropriate treatment or management strategy; choosing a suitably experienced and safe provider; ensuring that treatment is appropriately administered, monitored and adhered to; and identifying side effects or adverse events quickly and taking appropriate action (Vincent & Coulter, 2002).

In summary, we have shown that a growing awareness of iatrogenic injury led to the development of clinical risk management and then patient safety. Patient safety initiatives were driven and influenced by rising rates of litigation, the emergence of risk management, safety theories and practices from high-risk industries, high profile cases, major government reports and research activity, including epidemiological studies of harm to patients. Earlier initiatives such as confidential enquiries, critical incident studies, analyses of closed claims and case analyses also created a climate in which the systematic study of harm to patients became possible. We have described subsequent impact of critical incidents or adverse events, and stressed the importance of how incidents are handled, both for patients and staff. Improving safety for patients is likely to require some general as well as specific interventions and will include exploration of the following areas: culture and leadership; reporting and learning systems; training, supervision and working conditions; information technology and patient empowerment.

Patient satisfaction

Raymond Fitzpatrick

University of Oxford

The concept of satisfaction

There are three distinct reasons why we are interested in patient satisfaction. Firstly, the concept of patient satisfaction enables us

to view healthcare services from the patient’s point of view. Secondly, patient satisfaction provides a practical means of identifying problems in the processes of care, that is, how care is provided, so that such problems can be addressed and services

improved. In this applied use of the term, patient satisfaction is normally listed alongside five other dimensions whereby quality of health services should be assessed: access; relevance to need; effectiveness; equity; and efficiency. A third purpose, related to the second, is to contribute to the formal evaluation of health services (Sitzia & Wood, 1997). Although the theoretical and conceptual clarity of the term 'satisfaction' is generally agreed to be poor, the general emphasis of approaches is upon some form of discrepancy between the patient's expectations and actual experience. The concept of patient satisfaction reflects increasing emphasis upon the patient as 'customer', concerned to judge the value of a service. However it can be argued that the idea of patient as customer has some limitations: patients often do not feel like customers when seeking solutions to problems concerning their own bodies and wellbeing, being rather more intimately concerned in the product than the metaphor of customer implies (Hudak *et al.*, 2003).

There is a tension in the vast array of evidence regarding patient satisfaction. Many studies have focused upon patients' evaluations of their care, ultimately focusing on whether they were 'satisfied' or some related subjective appraisal. By contrast a distinct body of evidence prefers to focus upon patients' reported experiences; whether they have experienced particular problems or shortcomings of health services. Advocates of the former approach argue that the key issue is how patients feel about their healthcare. Advocates for the latter approach are less worried about whether patients accept or tolerate shortcomings; the value of the patient is in reporting experiences that in principle are capable of remedy. The two approaches can provide different assessments of the quality of a service. Patients frequently report themselves as satisfied with a service despite identifying one or more important problems (Jenkinson *et al.*, 2002). The two approaches are probably complementary rather than in contradiction. Inviting patients to say whether they have experienced any of a list of specific problems is a way of identifying specific components of services that we can remedy. Identifying which specific problems are most related to patients' judgements of satisfaction helps us to target and prioritize amongst perceived problems (Fitzpatrick, 2002).

Despite being of importance to our understanding of the behaviour of patients, it is remarkable how neglected patient satisfaction is in terms of theoretical discussion in psychology. A number of models have been proposed to explain available evidence regarding patient satisfaction. Thus satisfaction may be seen as the product of the discrepancies between patients' expectations of care and their perceptions of actual care received (see 'Expectations and health'). Other approaches emphasize the anxiety and uncertainty that attends illness, and argue that satisfaction is determined by the extent of emotional support and reassurance that patients receive. However, to date, no model or theory has emerged that fully encompasses the range of available evidence and more effort has gone into refining measures of satisfaction and applying them in the context of pragmatic evaluations of the quality of care (Fitzpatrick, 1993). It is useful to consider patient satisfaction as an evaluation by the patient of a received service, where the evaluation contains both cognitive and emotional reactions.

A multidimensional construct

Patient satisfaction is best considered as a multidimensional construct. Patients may hold quite distinct views in relation to different aspects of their healthcare. Cleary and McNeil (1988) distinguish nine different dimensions of health care on which patients' views can be obtained: 'the art of care' (i.e. health professionals' interpersonal skills); technical quality; accessibility; convenience; finance; physical environment; availability; continuity; and outcome. As will be evidenced below, the first category of influences, 'the art of care', contains elements of healthcare, such as health professionals' communication skills and sensitivity to patients' concerns, that have a particularly strong influence on patient satisfaction. Some evidence suggests that, so influential are such factors, patients are unable to distinguish between interpersonal skills on the one hand and technical competence on the other hand (Ware & Snyder, 1975). It may be argued that such 'halo effects' reduce the value of patient satisfaction surveys, at least in assessing the quality of healthcare. However, there is sufficient evidence that, in response to well designed questionnaires, patients are capable of distinguishing between technical and interpersonal aspects of the care that they receive (Fitzpatrick, 1993). It remains true that patients place great value on health professionals' empathic and communication skills and value them as least as highly as technical proficiency. Moreover, patients are best convinced that the health professional's technical skills have been appropriately applied when they feel that effort has been made by the doctor personally to understand the patient.

Relationship to other outcomes

As well as being of primary importance as an objective of health care, patient satisfaction is also of importance because its relationship to other outcomes of healthcare. In the first place it has been related to whether patients comply with their treatment regimen. In a study of a paediatric clinic in Los Angeles, mothers were interviewed by researchers immediately after their consultation and then visited at home a fortnight later (Korsch *et al.*, 1968). Three-quarters of mothers had been satisfied with the consultation, the rest were dissatisfied. The satisfied group were three times more likely eventually to have complied with the paediatrician's advice. The observation of a relationship between satisfaction and compliance has been noted in several other studies; for example, in a longitudinal study of patients attending a variety of neurological clinics in South-east England, dissatisfaction with consultations was found to be a significant predictor of non-compliance with drug regimes one year later (Fitzpatrick & Hopkins, 1981) (see 'Adherence to treatment').

A number of studies have also noted that satisfied patients are more likely to continue with their current healthcare provider. Thus, Baker and Whitfield (1992) sent two patient satisfaction questionnaires to the patients of two primary care practices and also to patients who had recently changed surgeries without changing their home addresses. The two instruments assessed satisfaction with different aspects of the general practice and with consultations. Patients who had changed their doctor produced poorer satisfaction scores on all dimensions of the two satisfaction instruments. A number of other studies have shown similar

relationships to related variables such as re-attendance at a given healthcare facility, change to alternative provider or health plan, or resort to unorthodox medicine (Fitzpatrick, 1993).

Patient satisfaction and health status

The most intriguing evidence is of a relationship between patient satisfaction and health status: more positively satisfied patients report better health. Thus Cleary and colleagues (1991) carried out a telephone interview survey of 6455 adult patients recently discharged from medical or surgical services of 62 hospitals around the United States. Patients who reported their health as poor reported twice as many problems with regard to satisfaction with care as did those who rated their health as excellent. The same pattern was found when other indicators of health were used such as number of days in bed with ill-health. This relationship between satisfaction and poorer health status and dissatisfaction has now been reported for a wide range of inpatient, outpatient and primary care settings (Fitzpatrick, 1993). A number of quite different explanations are possible. Patients may express greater dissatisfaction because of their failure to make progress in response to treatment. Both satisfaction and health outcomes could be produced by higher quality care. Dissatisfied patients may comply less with treatment regimens, as a result of which they make less progress in terms of health. General psychological wellbeing could influence responses to both health status and satisfaction questionnaires. In addition, there are a number of intervening non-specific or psychosomatic mechanisms that make it plausible that dissatisfaction may directly lead to poorer health. Longitudinal research designs are more likely to throw light on such processes. One such study examined the relationship between immediate satisfaction with consultations with a neurologist for headache and symptomatic change one year later (Fitzpatrick *et al.*, 1983). Patients who had expressed satisfaction with the neurological consultation were significantly more likely to report improvements in headaches one year later. Possible confounding variables such as severity of initial symptoms did not explain the relationship; nor were relationships due to intervening processes such as compliance. At present, it is not clear why relationships are consistently observed between satisfaction and health status. It is clear that satisfaction is positively related to a wide range of other desirable outcomes of healthcare.

Factors that influence patient satisfaction

A number of aspects of healthcare have been shown to influence patient satisfaction. Research evidence for such influences is most convincing when patient satisfaction has been measured by means of some standardized quantifiable instrument and measures have been obtained of the relevant component of healthcare independently of patients' reports. Roter (1989) carried out a meta-analysis of 41 such studies reporting aspects of doctor's behaviour and patient satisfaction. By far the most consistent influence upon patient satisfaction was found to be the doctor's information-giving. This overview confirms what is commonly assumed to be the case, that patients particularly appreciate receiving more information about their health problems and treatment. The importance of information-giving for patient satisfaction is

confirmed by experimental as well as observational studies. Information needs to be appropriate and comprehensible to be fully appreciated by patients (see 'Healthcare professional-patient communication').

Evidence from surveys of patients' experiences suggests poor communication is an organizational feature of hospital care across healthcare systems. Large independent surveys of patients discharged from hospitals in the USA, the UK and Canada all found similar problems of communication. Patients were not told what to expect in terms of daily hospital routines, were not told about side effects of medicines and received no information and advice about resuming normal activities after hospital discharge to their homes (Coulter & Fitzpatrick, 2000).

Effective communication between health professionals and patients is bidirectional; doctors need to be able to obtain medical histories and identify patients' main concerns as well as to give information. Aspects of how doctors obtain information can also influence patient satisfaction. Thus Stiles *et al.* (1979) recorded the consultations of 19 doctors providing general medical care, and then interviewed their patients subsequently to assess satisfaction with consultations. The consultations were analyzed by investigators rating the supposed intention of either the patient or doctor. Patients' satisfaction with the doctor was highest amongst those patients who had experienced consultations in which the doctor used a style of asking questions which invited patients to tell their stories in their own terms, what is often termed a 'patient-centred' rather than 'doctor-centred' form of history-taking (see 'Patient-centred healthcare'). Patients were more likely to feel, in response to this form of questioning, that the doctor had listened to them and understood their problem. In the meta-analysis of studies referred to above (Roter, 1989), a broad category of 'partnership building' processes had the biggest effect on patient satisfaction after information-giving. Roter includes in this category a wide range of behaviours by the doctor, including asking the patient's opinion, facilitating the patient's response or reflecting on statements by the patient. These may all be considered aspects of patient-centred communication and it is clear that such approaches have positive relationships with patient satisfaction. However, such effects are rarely large and not consistently found. Thus Henbest and Stewart (1990) studied the consultations of a sample of patients with six experienced family practitioners in Ontario. Consultations were recorded and rated in patients' views obtained by a follow-up questionnaire and interview. Some positive relationships were obtained in the predicted direction. Patient-centred consultations were more likely to result in the patient feeling that the doctor knew why they had consulted him or her. However, no significant effect could be found upon satisfaction scores. It may be that patient-centred forms of communication are only appropriate to certain presenting problems or patient's concerns and beneficial effects of this approach are less visible where all consultations are included in the analysis. Above all, it is of importance that patients and professionals may value different skills when rating consultations between doctors and patients. There were no correlations when professional examiners' ratings of communication skills of doctors in training were assessed in relation to patients' ratings of the same consultations via a satisfaction questionnaire (McKinstry *et al.*, 2004). The authors suggest that practices such as exploring the patient's reason for consulting or challenging patients' requests for a

prescription may be considered up-to-date practice in professional opinion but be considered invasive or unfriendly by the patients.

A number of other factors measured independently of patients' opinions have been shown to influence patient satisfaction. Thus, DiMatteo and colleagues (1980) assessed 71 doctors in a New York hospital for their sensitivity to human emotions by rating their performance in interpreting non-verbal emotions expressed in films and also by their own ability to demonstrate a range of emotions in experimental tasks. Patients consulting at the hospital were asked to assess the doctors via a patient satisfaction questionnaire. Patients' ratings of the doctors' interpersonal skills, but not of their technical skills, were found to correlate with the independently derived measures of doctors' interpersonal sensitivity. Such results are consistent with a wide range of evidence that patients are particularly aware of health professionals' interpersonal skills (Fitzpatrick, 1993). The study is also an example of how patient satisfaction questionnaires can be tested for discriminant validity. Other factors that have been independently measured and shown to influence patient satisfaction include length of time of consultations, continuity in the doctor-patient relationship and accessibility and availability of doctors (Baker & Whitfield, 1992; Fitzpatrick, 1993).

Several studies have shown that one of the main consequences of patient dissatisfaction with the consultation is a reduction of trust. In a study of patients attending primary care services in several cities in the United States, the more that patients experienced problems of communication with the doctor in consultations, the greater the likelihood that they reported themselves not trusting the doctor and also considering changing healthcare provider (Keating *et al.*, 2002). Similarly in a large survey of patients discharged from 51 hospitals in Massachusetts, trust and confidence in hospital staff was strongly associated with willingness to recommend the hospital to others (Joffe *et al.*, 2003).

Patients' views are of enormous value in evaluating the impact of organizational and delivery aspects of the health service and in the highly diverse and constantly changing pattern of services found in the United States especially, patient satisfaction surveys are used to assess such changes. Thus Landon and colleagues (2004) surveyed nearly half a million Medicare patients receiving care under different organizational arrangements. Patients receiving traditional fee-for-service care were more generally satisfied with their care than were patients under managed care. Managed care, by contrast appeared to be better in delivering preventative services. Another study experimented with different primary care providers in the managed care environment (Roblin *et al.*, 2004). Overall, patients receiving primary care from a physician assistant or nurse practitioner were as satisfied as those who received care from traditional medical practitioners. These examples illustrate the central role of patients' views and experiences to evaluate innovation in how healthcare is provided.

The measurement of patient satisfaction

There remain a number of measurement problems in the field of patient satisfaction. One difficulty is that several sociodemographic variables appear to exert consistent influence on patterns of response. In a meta-analysis of published patient satisfaction surveys Hall and Dornan (1990) found that the largest and most

consistent variable to influence results was age, with older patients reporting more positive satisfaction. A weaker but significant influence was that of education with less well-educated respondents expressing more favourable responses. Other sociodemographic variables were less consistent in effects. It is not clear why such influences occur, although it seems more likely that age effects are due to normative influences than to real differences in the quality of healthcare received. Other influences already cited, such as health status and psychological wellbeing, are more difficult to interpret. It is at least clear that studies that fail to control for sociodemographic and other known influences should be interpreted with great caution. In particular, variations in satisfaction levels between different healthcare providers may be due to other factors than the quality of care.

Results from satisfaction surveys tend to be positively skewed, with small minorities expressing dissatisfaction. Hall and Dornan (1988) carried out a meta-analysis of 68 published studies and found a median of 84% satisfied across surveys (range 43%–99%). It is not clear to what extent such skewness is due to methodological problems arising either from normative influences, which inhibit patients from expressing criticism of healthcare providers and services, or from limitations inherent in structured questionnaires. It is clear that the modest variability in satisfaction levels in some surveys makes identifying explanatory factors from modelling of results implausible (Hall & Dornan, 1988).

Considerable effort has been put into improving measurement properties of some satisfaction instruments. Increasingly, views are assessed via scales rather than single items in order to improve reliability. Ware and Hays (1988) review a number of scales from patient satisfaction instruments that have internal reliability coefficients which exceed 0.90. Test-retest reliability of instruments is less commonly examined, but results are often very satisfactory (Fitzpatrick, 1993). Ware and Hays (1988) report a study to examine effects of alternative wording of questionnaires. Patients attending outpatient clinics were randomly assigned to receive satisfaction questionnaires after their visit that either involved six point ('very satisfied' to 'very dissatisfied') or five point response options ('excellent' to 'poor'). The five-point format consistently produced more variability and greater construct validity in that answers were more strongly related to other variables such as readiness to comply with medical regimen and whether respondents would recommend the doctor just visited to a friend.

Because there is enormous diversity of healthcare settings and issues may be specific to particular settings, few questionnaires have become 'standard' in the sense of being widely and regularly used. Nevertheless there are a few instruments that have been quite widely applied and found to be of particular use. Thus, the consultation satisfaction questionnaire, comprising 18 items, is a well validated and extensively applied instrument assessing three key aspects of patients' experiences of primary care: the professional aspects of the consultation, the depth of the patient's relationship with the doctor, and the perceived length of the consultation (Baker, 1996). Similarly, the Picker Patient Experience Questionnaire is a 40-item instrument addressing seven core issues: information and education; coordination of care; physical comfort; emotional support; respect for patient preferences; involvement of family/friends; and continuity of care (Jenkinson *et al.*, 2003).

It has been widely employed to assess patients' views of hospital care.

Alternatives to the standardized questionnaire

Investigators remain concerned however that fixed-choice format questionnaires may not elicit patients' concerns fully or may not supply healthcare providers with the kinds of feedback from patients that lead to improvements in services. An increasingly wide range of alternative forms of obtaining patients' views about their healthcare is available (Fitzpatrick & Hopkins, 1993). On the one hand, a number of standardized instruments which have reasonably well-established psychometric properties are available. On the other hand, a variety of more in-depth methodologies have also been developed. Critical incident analysis requires trained interviewers to obtain detailed narratives of their healthcare encounters from which incidents which attract respondents' positive or negative reactions are abstracted for (largely) qualitative analysis.

In a similar vein, non-schedule standardized interviews have been used to obtain detailed qualitatively rich accounts of medical encounters on which conventional quantitative analysis can be performed. Finally, focus groups are increasingly used as a technique for eliciting patients' concerns and views in a way that is least contaminated by investigators' preconceptions. Examples of systematic approaches to these different methods exist but, to date, studies in which comparative advantages are directly compared are lacking (Fitzpatrick & Hopkins, 1993).

Ultimately, a large part of the purpose in assessing patient satisfaction is to provide evidence to healthcare providers of the scope for improvement revealed by patients' views. It is not yet clear that the increasing sophistication observed in measurement systems is matched by practical arrangements within healthcare organizations to respond constructively to evidence obtained from surveys. Increasingly, it will be necessary to examine the practical utility of alternative approaches to the assessment of patient satisfaction.

Psychological support for healthcare professionals

Valerie Sutherland

Sutherland Bradley Associates

The importance of psychological support in the health and wellbeing of patients and clients is well documented and acknowledged by healthcare professionals. However, it is suggested that healthcare systems and the professionals employed as carers do not optimize the benefits associated with psychological support as a stress reduction strategy. This article explores the concept and impact of psychological support as a mediator and moderator of the stress response and suggests ways in which social support systems for healthcare professionals might be improved.

Empirical evidence continues to highlight the negative impact and high costs associated with mismanaged stress in the workplace. It remains a significant problem associated with poor performance, high levels of sickness absence and increasing violence in the healthcare work environment. Jobs in human services share many of the sources of stress present in other occupations in addition to the potential strains associated with intense involvement in the lives of others. This requires a caring commitment and the ability to respond with empathy usually in high demand situations where staff shortages are a common feature of the healthcare environment. A negative spiral of stress can develop when staff shortages, caused by recruitment and retention problems, create high levels of job demand and work stress, leading to yet more strain, sickness absence, or withdrawal from the job because the employee cannot face further pressure. Verhaeghe *et al.* (2003) observed higher levels of 'job-demand' and lower levels of 'decision latitude' among Flemish healthcare workers (aged 35–59 years) compared with a control group. A clear association between high job demand, lack of social support and absenteeism was observed for this group of healthcare workers working under 'job strain' conditions (see also 'Healthcare work environments' and 'Patient safety and iatrogenesis').

Such conditions are optimal for psychological burnout and this has serious, deleterious consequences for both health professionals and patients. In addition, individuals working in healthcare occupations continually have their competence on trial in a highly visible way and in an environment where mistakes can be very costly. It is evident that the job of the healthcare professional is inherently

stressful and the recruitment and retention of healthcare professionals remains a key concern in several countries. It has been suggested (Sutherland & Cooper, 1990, 2000, 2003) that healthcare professionals will perform more effectively and suffer less negative effect or personal harm if they understand the role of stress and social support in their own lives and the impact that it could have on patients, clients, colleagues and staff.

A conceptual framework for social support

Dunkel-Schetter and Bennett (1990) provide a framework to guide our understanding of the concept of social support based on the following assumptions.

1. Social support is defined in functional terms as an interpersonal transaction. Therefore, a distinction is made between the existence of social relationships (social integration), the structure of social relationships (social networks) and the function of social interactions/relationships (see 'Social support and health'). Although some authors believe that the term 'social support' should be reserved for this latter interpretation, research evidence indicates the importance of social integration, i.e. the existence of social relationships. For example, Knox *et al.* (1985) found that the actual number of contacts and acquaintances was one of the significant factors inversely related to elevated blood pressure among young, male hypertensives. However, a six-month, longitudinal study of 350 nurses in the northwest of England concluded that perceived organizational support was also related to nurses' health and job satisfaction. This means that interventions designed to increase support, which typically operate at individual or group level, may be limited in their effectiveness unless nurses' perceptions of organizational support are taken into account (Bradley & Cartwright, 2002).
2. It is also necessary to differentiate between the availability of social support and the activation of it. The interactive model of stress defines a state of stress as an imbalance

between perceived demand and perceived ability to meet that demand (see 'Stress and health'). The processes that follow are the coping process and the consequences of the coping strategy applied. This means that stress is a subjective experience contingent upon the perception of a situation. Likewise, it is the belief about social support available, if needed, rather than the actual support available, which influences one's cognitive appraisal of the situation and is the determinant of effective coping and crucial to health protection. It is this assumption that provides a rationale for the interchangeable usage of the terms 'social support' and 'psychological support'.

- Individual differences in terms of needs, desires and social support seeking behaviour will have an impact on the activation of, receipt of, and perceived satisfaction with social support. Chay (1993) suggests that personality dispositions interact to influence the appraisal of a situation and supportive relationships; affect one's readiness to seek help from others; influence the need for sociable and intimate interaction; and influence one's response to feedback from others. Chay (1993) found that higher levels of perceived availability of support were associated with a combination of trait extraversion, internal locus of control and a high need for achievement among self-employed individuals and small business owners, suggesting that individual differences played a role in the utilization of support services (see also 'Personality and health').

Since the term 'healthcare professional' embraces a very wide range of employee groups working under quite different contractual arrangements, including both self-employed and employed status, it is important to include these factors in any operational model of social support for this occupational group. For example, in a survey of 882 consultants, Graham *et al.* (2001) observed that just 2% reported obtaining formal psychological support and only 12% coped with stress by formally talking to colleagues in a regular support group. However, the informal use of social support was a coping strategy used by more than two-thirds of this cohort. Consultants stated that talking to a partner, family or friends, or informally with colleagues helped as a stress-coping strategy. However, junior house doctors cite difficult relationships with senior doctors as a key source of stress (Firth-Cozens, 1993), indicating a lack of available social support from a boss or significant others at work. Powerful evidence indicates that a lack of psychological support from one's boss is associated with perceived job strain, job dissatisfaction and poor physical and psychological health.

Types of social support

It is also necessary to acknowledge that different types of social support exist which will have a variable impact on strains and pressures. These have been described in various ways, although it would seem that the four classifications proposed by House (1981) tend to include recent citations:

Emotional support

Emotional Support which involves providing love, caring, empathy and trust, is regarded by House as the most crucial because

individuals tend to think of 'being supportive' in terms of emotional support. Research evidence suggests that dentists tend to experience high levels of stress at work because of the nature of the job. However, it is the routine problems in dentistry associated with time pressures, high caseload and falling behind with schedules that cause most concern. These pressures are probably exacerbated because dentists tend to work in isolation from their peers and interact with clients who would, perhaps, rather not attend the surgery. The provision of effective emotional support would thus seem to be important for this occupational group. All branches of the nursing profession are subjected to high levels of stress and burnout and forensic nursing has been perceived as an area of high risk despite the paucity of research evidence. An in-depth study of 51 forensic psychiatric nurses (Happell *et al.*, 2003) found that relatively few suffered from 'high levels of burnout' and the least reported stressor appeared to be the lack of staff support for nursing activities. This work suggests that this form of emotional support may have accounted for the lower than expected levels of stress and burnout (see 'Burnout in health professionals').

Instrumental support

This involves actual assistance through an intervention. It refers to behaviour that directly helps the person in need. For example, to physically take over some aspect of a task for someone is instrumental support. It can also be described as 'material or tangible aid'. Many healthcare professionals have described work overload conditions and time pressures as the most stressful aspects of their job (Sutherland & Cooper, 1991, 1993; Tyler & Cushway, 1992). Having someone to physically provide help would alleviate these pressures but financial constraints do not permit this simple solution to a stressful situation. Usually the individual is required to cope with the strain and pressure of such overload conditions.

Informational support

This means providing a person with information that can be used in the coping process. The information itself is not viewed as instrumental support because it is usually aimed at helping the individual to help him- or herself. Tutoring or coaching a person to help that individual to reach a desired goal is an example of informational support. Beehr *et al.* (1990) found evidence for the supportive value of informational and emotional support from supervisors among occupational, registered nurses. Both positive job-related and non-job-related communications (versus negative job-related communications) were associated with the perception of the supervisor as supportive, and this had a positive, main effect on individual job strain. Evidence for a buffering effect (i.e. the interaction between social support and job stressors to reduce the strength of the stressor-strain relationship) was also found for non-job-related communication as a form of social support.

Appraisal support

This involves the transmission of self-evaluation information. Feedback from the environment, i.e. social comparison, is derived from information supplied directly and indirectly by the people around us. For example, we gauge our own work performance either from being told by significant others, or by interpreting what we see. At exam time, medical students all face the same challenge and potential threat. Knowing that everyone is in the same

circumstance has an impact on the way in which that situation is perceived. An increased understanding of the role of social support will enable an organization to maximize support networks in the workplace, especially during the times when strains and pressures are greatest (for example, threats to jobs, restructuring and during examinations etc.). Research evidence also suggests that there are psychological and physical health benefits, in terms of better immune function and blood pressure, associated with self-disclosure, including the sharing of personal secrets and disclosure of traumatic events (Kennedy *et al.*, 1990). Therefore, reciprocity in the transmission of appraisal and informational support would seem to be the most beneficial support strategy. However, many healthcare professionals tend to feel that they do not have other people around them to provide this form of support. Although general practitioners and dentists rarely operate in single-practice surgeries and tend to work as part of a multidisciplinary team with other autonomous professionals, the working structure and climate does not facilitate the supportive environment which is beneficial to the health and wellbeing of these carers.

Some authorities are attempting to overcome such problems by providing counselling services and/or employee assistance programmes for healthcare professionals. Nevertheless, there is also scope for improvement in the levels of social support within a group practice or team of health professionals, and the quality of interpersonal relationships at work is an area which would typically be addressed by a stress management intervention. Toloczko (1989) reports on the effectiveness of social support training on burnout and improving working relationships among nurses. Measures taken following a six week training programme (one two-and-a-half hour session per week) showed significant reductions in emotional exhaustion and depersonalization, compared with a no-training control group of nurses, even though measures of total life experiences remained consistent for both groups.

The importance of appraisal on stress-coping style was demonstrated in an evaluation study reported by Hirokawa *et al.* (2002). A 14-week stress management programme was provided for trainee social workers. They attended sessions on progressive muscle training, cognitive-behavioural skills training and assertion training. Pre- and post-measures of life events, stress symptoms and stress-coping skills (i.e. active and passive coping) were obtained. Compared with a control group, passive coping strategies had decreased and active coping skills had improved among the trainee social workers following the programme. An ability to identify a potentially stressful or negative situation, and actively seek social support would appear to be a crucial coping skill for healthcare workers (see 'Stress management').

Sources of social support

In addition to the existence of different types of social support it must also be acknowledged that sources of social support have a varying effect on outcomes, i.e. a specific source of support (e.g. a nurse manager) may buffer the effects of a specific source of stress (e.g. work overload) on a job-related strain (e.g. job dissatisfaction) and/or mental or physical health outcomes for a student nurse. Investigating these relationships is complex. For example, Tyler and Cushway (1992) found that having a friend, a partner,

or a member of the family to whom nurses could talk about problems at work had a small but beneficial effect on mental wellbeing. However, levels of anxiety and insomnia were higher in single/unpartnered people if they could talk to a partner, but higher in married/partnered people if they could not. This highlights the need to consider:

1. Perceptions held about the skill of the support givers (i.e. a partner may be there to help but is unable to engage in any clinically oriented discussion about a stressful experience at work, or understand the situation).
2. Stress experiences may be more acute when expectations of support are too high and therefore, are not realized. Support providers may feel unable to help or to meet the continual demands made which might elicit emotional reactions such as fear, embarrassment, discomfort or helplessness (Dunkel-Schetter & Bennett, 1990). Indeed, it is suggested that informal support providers may experience the same burnout and emotional exhaustion that occurs when professional care providers are over-extended. The outcome tends to be physical and/or psychological withdrawal, i.e. avoidance and detachment.

These results highlight the importance of having supportive work colleagues (or perceiving them to be supportive), because they share similar experiences and can help each other in a reciprocal manner. A formal way to maximize this form of social support is the introduction of co-counselling in the workplace. However, it is likely that much of this is already available informally. For example, Fletcher *et al.* (1991) found that 87% of health visitors screened ($N = 124$) believed that support and encouragement from work colleagues made the job easier most or all of the time. Performance feedback from colleagues and the ability to talk to colleagues during breaks were perceived as supportive in the work environment, and were ranked higher than support from the spouse and family. Nevertheless, for individuals who work in isolation from other healthcare workers, social support from a spouse/partner, or family or friends is clearly desirable. In a prospective study of case managers hired to work with seriously and persistently mentally ill clients, Koeske *et al.* (1993) found control coping strategies (which included talking to spouse, family and friends about the problems) facilitated the workers' ability to deal with a difficult and challenging work obligation. Workers who relied on avoidance coping strategies showed significantly poorer outcomes three months after starting the job (e.g. this included, 'keeping my feelings to myself', 'avoided being with people in general', 'drinking more' etc). Also, the study reported by Graham *et al.* (2001) indicates that a high percentage of consultants report talking to colleagues and family as a stress-coping strategy. However, we still need research evidence to evaluate the efficacy of informal versus formal sources of psychological support as a stress-coping strategy.

Developing psychological support systems

Social support as a stress management strategy could be developed for healthcare professionals in the following ways:

- Emphasize the importance of supportive relationships and networks during the selection, recruitment and training of healthcare

professionals in order to promote a supportive work climate and culture. As workload pressures among healthcare professionals continue to create strains and pressures, the importance of coping style is an important variable in the stress management process. In a large scale study of consultants, Graham *et al.* (2001) observed consultants who reported using alcohol or non-prescriptive drugs in response to stress were more than twice as likely to experience psychiatric morbidity as those who maintained a balanced, healthy lifestyle while experiencing stress at work. For example, out of a sample of 882 consultants, 70% coped by talking to a partner, family or friends and 67% coped by talking informally to a colleague. However, only 12% coped by talking formally to colleagues in a regular support group, suggesting that the role of social support among these healthcare professionals is acknowledged but not formalized.

- Social support from the boss appears to be very important. Lack of support is associated with perceived job strain, job dissatisfaction and poor wellbeing. Bennett *et al.* (2001) examined the relationship between stress within work and managerial support available, the strategies used to cope with work stress and levels of anxiety, depression and work satisfaction among one hundred and six ward-based nurses. Consistent relationships between work stress and each of these outcomes were observed. They also found that lack of managerial support was associated both with negative mood states and low levels of work satisfaction. The key predictors of negative affect were lack of management support, job overspill, having to make decisions under time pressure and lack of recognition by the organization.

Therefore it is necessary that healthcare professionals as managers of other people are trained to understand the role and importance of managerial support and reflect this in their style of leadership and supervision.

The support derived from a mentoring relationship can also provide a strong psychological support structure for the healthcare professional. Some Health Care Trusts in the UK have introduced mentoring as a professional development technique and this type of mentoring relationship can be found outside of the normal chain of reporting. In fact, there may be greater benefit in having a significant other as a mentor rather than one's manager (Young & Perrewe, 2000; Vance & Olsen, 2002).

- Coherent teamwork is crucial for the delivery of good quality patient care both directly in terms of efficient and effective services and indirectly via the impact on stress reduction (Firth-Cozens, 1998). Teamworking provides opportunity for support especially among multiprofessional clinical teams. Self-managed work teams and action groups help to develop support networks and provide opportunity for strong bonding. This is useful for healthcare professionals who spend much of their day working in relative isolation. For example, community nurses and doctors in the practice surgery lack opportunity to meet and socialize with peers and colleagues for much of the working day.
- Develop and provide psychological support services, such as employee assistance programmes, occupational health and counselling services for healthcare professionals. The need to ensure that a culture and climate exists that actively and overtly encourages the use of such services cannot be over-estimated. Staff will not seek help if they fear blame, or perceive that their

actions might jeopardize future employment or career opportunities.

- Each practice, ward, surgery or department should be encouraged to develop social networks, both at work and socially. Self-help groups such as health circles also provide a psychological support structure and forum (Kuhn, cited ILO, 1993).
- Education about the beneficial effects of social support between work-and home-life is necessary so that healthcare professionals and their significant others can build strong support networks as a buffer against the stress that is an inevitable part of working and living in the healthcare service.

Effects of social support

Much of the literature on the effectiveness of social support has focused on two sorts of health effects; main effects and buffer effects. The way in which social support works has generated considerable disagreement, but many of the differences in the findings appear to arise from the variation in the conceptual definition of the concept, the way in which it is operationalized, and the reliance on cross-sectional research designs (Thoits, 1986). However, evidence exists to support the various hypotheses proposed, but the findings may be affected by the actual source and type of support studied, and the stressor(s), outcome measure(s) and the person variables measured (e.g. gender, age and socioeconomic status). For example, Sutherland and Cooper (1993) found that reported use of social support, as a stress-coping strategy, was a significant predictor of job satisfaction among general practitioners. Low use of social support was a predictor of depression among this occupational group, and female general practitioners were significantly more likely to use this as a coping strategy than the males, who also evidenced a poorer level of psychological wellbeing than their female counterparts.

It is suggested that social support works in the following ways. Perceived social support can have a main effect on perceived job stress, job-related strain and/or mental and physical health. It can lessen the effect of perceived job stress on job-related strain, moderates job stress on mental and physical health, and it can ameliorate the effects of job-related strain on mental and physical health. Some authors have suggested that a 'coping' hypothesis best explains their findings, believing that social support is a coping mechanism that individuals use under stressful conditions. Thoits (1986) described similarities between social support and coping with stress:

1. Instrumental support was identified with problem focused coping strategies. This implies direct action on the environment or self to remove or alter the circumstances perceived of as a threat.
2. Emotional support was identified with emotion focused coping in that cognitive appraisal is used to control the undesirable feelings that result from a stressful situation.
3. Informational support is identified with perception-focused coping, which consists of cognitive attempts to alter the meaning of a situation so it is perceived as less threatening.

Therefore, both support and coping act to change the situation, the emotional reaction to the situation and/or the meaning of the

situation. Indeed, it has been suggested that knowing help is available, but coping with one's problems without using outside assistance leads to the best outcomes in terms of confidence in one's own capabilities (i.e. self-confidence, a sense of mastery and high self-esteem) (see 'Self-efficacy and health').

Conclusion

The individual who chooses to become a healthcare professional seeks a satisfying and challenging occupation. By definition it involves close contact and responsibility for the good health and life of another person. Mastery of sometimes difficult and demanding situations can provide stimulation and tremendous job satisfaction and it is likely that this protects healthcare professionals from some of the negative and stressful aspects of the job. However, there are greater perceived burdens that exist outside of the actual role of

caring. Change seems to be a constant theme in health practice and this is a potent source of stress. It includes changes to systems and practice as medical research advances, changes brought by legislation and government that bring new roles for health carers, and the changes in society that alter demands and the structure of support networks in our environment. The presence of psychological support can buffer against the negative impact of strain and job demand and an increased understanding of the role of psychological support as a stress coping strategy will help healthcare professionals to adapt to inevitable change. It is essential if they are to remain in the job, stay fit, healthy and happy, and deliver a quality service to patients and clients. Organizations who endorse the maxim, 'healthy workforce – healthy business' will achieve these objectives by the provision of systems and structures for the development and maintenance of psychological support for healthcare professionals.

Reassurance

Patricia Loft, Geraldine Meechan and Keith J. Petrie

The University of Auckland

What is reassurance?

Patients with physical symptoms attend medical consultations expecting a clear and valid explanation for their health complaints. Patient reassurance is a central component of the medical consultation and is the most commonly occurring and important aspect of patient care. After being reassured by their doctor, many patients are unconvinced that their symptoms do not relate to physical disease and continue to experience ongoing health-related distress. Whether in primary care or following a diagnostic test, effective patient reassurance is essential to promote wellbeing and prevent future unnecessary medical visits and investigations.

In most cases reassurance is offered following the history taking and physical examination, although often the process may occur after further diagnostic or laboratory testing. Reassurance can be defined as communication between doctor and patient that is intended to allay the patient's health related fears and anxieties. Typically, the process involves the doctor providing an explanation of the patient's symptoms and confirmation that the patient has no serious illness. To be effective reassurance needs to adequately address the patient's worries about the health threat.

Reassurance following investigative tests

Patient reassurance has received only minimal attention in current empirical research, with much of this research focusing on the effectiveness of reassurance following diagnostic medical tests. Evidence shows that many patients are not reassured following a negative test result and in some patients diagnostic tests may cause more harm than good by increasing patient perceptions of disease vulnerability. For example, women undergoing diagnostic laparoscopy for chronic pelvic pain experienced more pain and disturbed daily activities following the procedure even though no pathology was found, compared with a comparison group who underwent solely psychological and physiotherapy treatment (Peters *et al.*, 1991).

Ambiguous test results can elevate health concerns, particularly in patients who already have high health anxiety (Howard & Wessely, 1996; Verrilli & Welch, 1996). Lucock *et al.* (1997) found patients who reported high health anxiety prior to a gastroscopic investigation reported a decline in feelings of reassurance 24 hours later and continued to be concerned about their health when followed up a year after the test (Lucock *et al.*, 1997).

The process of diagnostic testing can in itself, make feelings of vulnerability to illness more salient and reinforce the patient's belief that there is something wrong with their health. Several studies have found evidence that cardiac investigations may not always be useful

in reassuring patients, but rather they may cause harm by creating anxiety and encouraging the patient's illness beliefs (Howard & Wessely, 1996; Mayou *et al.*, 1999). The process of cardiac investigation typically involves a hospital visit, patient consent for a procedure that is not without risk and the investigation itself, all of which may also encourage focusing on symptoms and reinforce the belief that the complaints are serious.

Research suggests that the more invasive the investigation, the more likely it is that illness concerns are activated. For example, more serious and frequent pain symptoms were reported by patients six weeks after receiving a negative test result following angiography, compared with patients who underwent a non-invasive assessment for chest pain symptoms. In addition, these individuals continued to use anti-anginal medication and had more hospital emergency admissions compared with those undergoing non-invasive assessment (Mayou *et al.*, 1999). A similar pattern of failed reassurance was reported in patients with normal coronary arteries as confirmed by angiography, with patients reporting continuing incapacity, distressing symptoms and ongoing medical visits two years following the procedure (Potts & Bass, 1993).

Why does reassurance fail?

Both doctor and patient factors contribute to successful reassurance and influence misunderstandings during doctor-patient communication. The doctor may assume the patient clearly understands that there is no physical pathology following a negative investigative result. However, the patient may come to the medical consultation with specific illness beliefs and ideas which significantly affect the interpretation of the reassurance offered by the doctor. Poor medical knowledge and previous experience of medical misdiagnosis can all undermine successful reassurance. For example, minimal reassurance was found in patients undergoing echocardiography for chest pain symptoms or a benign heart murmur even though heart disease was ruled out by a normal test result (McDonald *et al.*, 1996). Later interviews with the patients revealed that many lacked the important understanding that a murmur or symptoms could continue even though there was no heart pathology, whilst patients with a better understanding had reduced anxiety about their symptoms.

Individual differences also play a role in reducing reassurance. Some individuals have a high focus on their internal bodily state, making them sensitive to symptom detection and leading to misinterpretation of symptoms and subsequent failure of reassurance by a medical professional (Barsky & Borus, 1995) (see 'Symptom perception'). Other patients may be prone to catastrophic thinking following symptom discovery (Howard & Wessely, 1996). In such cases, the doctor may be unaware of the extent of the 'worst case

scenario' thinking which the patient has engaged in and the level of reassurance offered by the doctor may not be enough to overcome the patient's level of concern. Alternatively, the level of emotional distress developed from the patient's fear of a life-threatening condition may interfere with effective reception of the information provided by the doctor.

Even though reassurance may appear successful during the medical consultation, once the patient leaves the medical environment they may be influenced by a number of social factors that present obstacles to reassurance (McDonald *et al.*, 1996). For example, a patient may watch a graphic portrayal of death from heart disease on television, or a family member may develop cancer despite an earlier negative diagnostic scan, both of these being scenarios that may encourage fear and undermine reassurance. Stories concerning health threats have become commonplace in all areas of the media. This has the effect of undermining individuals' perception of their own health, heightening vigilance for symptoms and increasing the likelihood that symptoms will be interpreted negatively (Barsky & Borus, 1995).

Ambiguous behaviour on the part of the doctor may also impede patient reassurance. For example, many negative cardiac investigations fail to reassure patients simply because the doctor continues to prescribe anti-anginal or other cardiac medication. This communicates an ambiguous message to the patient regarding cardiac health (Mayou *et al.*, 2000). Additionally, a long delay before the diagnostic test is undertaken allows more time for negative illness beliefs to become established. This may include lifestyle changes geared to a different illness outcome, such as a reduction in work hours or leisure activities, which will make subsequent reassurance considerably more difficult (Nijher *et al.*, 2001).

Psychological morbidity

Patients who frequently attend medical clinics seeking reassurance for benign symptoms often suffer psychological morbidity and research suggests that these patients are more difficult to reassure. A study of women undergoing bone screening for osteoporosis found that women with high health anxiety were only temporarily reassured following a high bone density result. Long-term follow-up showed a return to baseline levels of worry and perceived likelihood of developing osteoporosis (Rimes & Salkovskis, 2002). Similarly, patients with high levels of both anxiety and depression continued to experience chest pain symptoms after a negative exercise test ruled out cardiac problems, compared with those low in psychological morbidity who became pain-free following a negative result (Channer *et al.*, 1987). Again, individuals with severe headaches who also suffered from anxiety and depression did not feel reassured following a neurological consultation (Fitzpatrick & Hopkins, 1981).

High trait anxiety has been found to be associated with an increased focus on internal bodily states, which leads to more symptoms being detected and reported (Watson & Pennebaker, 1989). A heightened sensitivity to the frequency and intensity of physical symptoms can make anxious or depressed patients extremely resistant to medical reassurance. Many patients who do not have significant medical illness but consistently seek medical care for reassurance about their symptoms tend to be high in trait anxiety

(Banks *et al.*, 1975) and tend to be less likely to make normalizing attributions for common somatic symptoms than other people are (Sensky *et al.*, 1996) (see 'Psychosomatics').

Patients with medically unexplained symptoms are a common occurrence in medical practice and much time and effort is devoted to patients where no medical diagnosis can account for persistent and disabling symptoms. Often these patients have multiple symptoms, experience considerable distress and are high users of medical resources. A number of syndromes have evolved from clusters of unexplained physical symptoms, such as irritable bowel syndrome and chronic fatigue syndrome. Reassurance is often extremely challenging with these patients as there is uncertainty as to why symptoms persist even though serious illness has been ruled out. Also, patient support groups may provide information that inadvertently validates symptoms, encourages further investigations and undermines reassurance provided during the medical consultation (Page & Wessely, 2003).

Improving reassurance

Poor communication is frequently the most significant cause of unsuccessful reassurance and both verbal and non-verbal cues contribute to this problem. Reassurance is improved when the provision of information is clear and unambiguous. If a clinician offers reassurance in an unsure manner this may encourage the patient's resolve that the condition is incurable or life threatening. Similarly, the patient may be left with ambiguities if vague words are used, such as 'probably' – a word that embodies some doubt and may encourage catastrophic thoughts and speculation (Coia & Morley, 1998). A recent study of patients with minor to severe arthritis found that although patients were given reassurance that the condition was 'low' in seriousness, at an 'early stage' or the prognosis was 'mild', many patients misinterpreted this information to mean that their condition would change in the future and would eventually progress to more intense pain and disability (Donovan & Blake, 2000).

Building rapport with the patient and adopting a patient-centred communication style is a useful method for alleviating illness concerns and increasing reassurance (Kessel, 1979). This can be achieved by ensuring that the patient's thoughts and fears have been adequately addressed, thereby conveying to the patient that they have been heard and understood. Patient-centred consultation styles significantly increased patient reassurance in a study of Ontario family doctors, where patients who were encouraged to express their thoughts and feelings felt significantly more reassured following the consultation (Henbest & Stewart, 1990) (see 'Patient-centred healthcare' and 'healthcare professional-patient communication').

Reassurance following invasive diagnostic tests can also be improved if medical professionals prepare patients for the possibility of normal findings. Additionally, structured interventions that address patient's maladaptive cognitions following a negative investigative result may also enhance patient reassurance. Klimes *et al.* (1990) employed a psychological intervention to enhance reassurance in patients who continued to experience chest pain symptoms following negative cardiac investigation. The cognitive behavioural therapy challenged incapacitating beliefs and behaviours and

provided patients with training in relaxation, distraction and breathing. Significant reductions in chest pain were reported by patients as well as better mood and less disruption in daily life compared with a control group, suggesting that this type of programme may be very effective in patients where initial reassurance has failed (Klimes *et al.*, 1990). Moreover, in order to prevent the development of negative illness cognitions in patients waiting for medical investigations, shorter waiting times prior to the diagnostic test may also improve patient reassurance (Nijher *et al.*, 2001).

The challenges involved in reassuring patients with medically unexplained symptoms, have led to the development of a number of interventions to improve the management and treatment of these patients. A meta-analysis of studies utilizing cognitive behavioural therapy for patients with somatoform disorders has revealed significant success for this type of treatment option (Looper & Kirmayer, 2002). These interventions typically include methods such as exploring the patient's illness beliefs and behaviours, developing normalizing cognitive strategies, reducing body scanning for symptoms and enhancing physical activity (Rief & Nanke, 2004) (see 'Cognitive behaviour therapy').

Recent research has also found that training primary care physicians to effectively manage frequent medical attenders was helpful in reducing subsequent medical visits (Rief *et al.*, 2006).

The general practitioners received training in patient communication, in managing the patient's organic health beliefs and avoidance of physical activity, beginning and stopping medical examinations and patient reassurance. Subsequent patient visits to the trained doctors declined, whereas patient visits to the untrained doctors did not, which suggests that this type of training programme is a useful and effective tool in assisting doctors to manage these patients.

Conclusions

Reassurance is at the heart of many medical consultations. To provide effective reassurance the clinician needs to provide an explanation for symptoms that fits into the patient's knowledge of the condition and addresses the patient's concerns about the health threat. Patients with high health anxiety and fixed negative health cognitions provide a particular challenge for clinicians. More research needs to be completed to identify effective strategies for clinicians working with such patients to improve levels of reassurance and resist pressure for inappropriate investigations. Cognitive behavioural approaches have the potential to reduce illness concerns in patients following failed reassurance but need to be based on a more detailed theoretical understanding of the reassurance process.

Screening in healthcare: general issues

Anne Miles

University College London

People are offered screening tests throughout their lifetime, from birth through to old age. But although screening for certain diseases/disorders is widely accepted, screening for other types remains controversial. The aim of this chapter is to provide a general outline of the current debates and developments within screening, and it draws principally on examples from the field of cancer screening. More detailed discussion of the issues surrounding cardiac, genetic and antenatal screening and further discussion of cancer screening, can be found in other chapters in this book (see ‘Screening: antenatal’, ‘Screening: cancer’, ‘Screening: cardiac’ and ‘Screening: genetic’).

The aims of screening

The term ‘screening’ is usually reserved to describe the testing of all people within a specific sector of the population (e.g. people within a particular age range) who have no symptoms, and who appear to be at ‘average risk’ of getting the target disease. Although, in the case of neonates, screening might be used to enhance the medical management of the future date (i.e. once the child has been born) or to give parents the opportunity to terminate a pregnancy if they do not wish to have a child who has a particular disability or condition, the main purpose of screening is often to reduce disease-related morbidity and mortality by detecting disease at an early stage, when treatment is more likely to be successful.

Early detection can lead to fewer disease-related complications, because simpler, less toxic treatment is required. It can also dramatically enhance a person’s chance of survival. For example, five-year survival rates for colorectal cancer are 90% if the disease is detected whilst still localized, but drop to 10% if the disease is detected after it has spread to vital organs, such as the liver. Screening for colorectal cancer can reduce mortality from the disease by as much as 33%, but the benefits of screening can be even greater if the

pre-disease stage is identified. Most colorectal cancers develop from pre-malignant adenomatous polyps. If polyps are removed, this type of cancer can be prevented altogether, sparing people both the trauma of a cancer diagnosis and obviating the need for major interventions such as surgery and chemotherapy.

Many types of screening aim to detect signs of disease; as a result, screening is usually classified as a type of secondary prevention. Increasingly, though, tests have become available that identify individuals at ‘enhanced susceptibility’ to developing a disease at some point in the future, which means that screening has begun to play a role in primary prevention.

Identifying people who are susceptible to developing future disease, or who have pre-disease states, is clearly preferable to finding active disease because it can lead to a reduction in disease incidence as well as mortality. However, this is not always possible. In the case of cancer, whilst some types of the disease, such as cervical cancer and colorectal cancer, have an identifiable ‘pre-malignant’ stage, other types do not. So whether a particular screening test aims to detect enhanced susceptibility towards developing a disease, pre-disease states, or early-stage disease, depends on what is known about how a particular disease progresses and whether an appropriate test is available.

Although screening is widespread, it provokes a number of debates. How should screening be offered? Should it be tightly controlled or should people be free to choose which screening tests they have? How can people be encouraged to have screening and how do motivational efforts square with the move towards greater informed choice? What are the psychological and behavioural consequences of screening and how can these be minimized?

Offering screening

There is little doubt that screening can help to prevent or cure a number of diseases, but it does not always lead to an improvement

in health outcomes. Detecting a disease at an earlier stage may fail to improve a person's prognosis, it may only increase the length of time that they are aware they have the disease. For example, there is no evidence at the moment that screening for cancers of the prostate and lung increases survival, although research into the efficacy of screening for these types of cancer is continuing (Prorok *et al.*, 2000). In addition, screening tests, and the treatment of any screen-detected abnormalities, may have adverse consequences that offset any health gains. So how do people decide which types of screening should be encouraged and which should not?

The guidelines issued by the World Health Organization specify that screening should only be offered if the disease is common; has high levels of associated morbidity or mortality; effective treatment is available that can reduce morbidity and mortality; and screening and treatment for the disease are acceptable, safe and relatively inexpensive (Wilson, 1968). In short, screening should do more good than harm at reasonable cost.

The benefits, harms and costs of screening can all be established through Health Technology Assessment (HTA). Randomized controlled trials can demonstrate whether screening is effective in reducing disease morbidity/mortality and what the harmful effects of screening might be. However, although such studies may show how effective screening is in theory, in practice things may turn out rather differently. High levels of population coverage, good quality screening and the effective follow-up and treatment of any screen-detected abnormalities are all needed if screening is to be effective in reducing disease incidence/mortality. Simply offering screening is not enough. In Mexico, cervical screening has been available since 1974, but mortality rates have failed to decline, because of low uptake rates and poor quality screening (Lazcano-Ponce *et al.*, 1999).

Screening is more likely to be effective in reducing disease morbidity and mortality if it is offered as part of an organized programme. This is because targets for screening uptake, quality and follow-up, are set and monitored within organized settings as part of a coordinated system of care; and if standards are not met, coordinated efforts are made to attain them. In contrast, where screening is 'opportunistic' there are fewer opportunities for recording screening uptake and monitoring the effectiveness of treatment and follow-up (Lurie & Welch, 1999) and hence failings in the screening service may remain undetected.

The greater potential for organized programmes to reduce disease related morbidity/mortality is reflected in the WHO guidelines, which state that screening should be offered as part of an organized system. Despite this recommendation, countries differ in their screening provision. Such inter-country differences are determined partly by financial resources. Certain types of screening can be expensive to set up and co-ordinate, for example mammography screening for breast cancer, and they may be too costly for poorer countries to provide. In countries with similar wealth status, the price of introducing organized screening will depend on how much of the necessary infrastructure is already in place. In countries where opportunistic screening is already widespread, many of the required services, e.g. trained staff and equipment, will already exist, making the introduction of an organized programme less expensive. But the way screening is offered is also determined by the political values which underlie healthcare provision. Countries that value equality of access are likely to offer centralized, publicly-funded

healthcare where screening is offered as part of an organized programme. In contrast, those countries that value individual choice will promote the use of private healthcare services, and screening will tend to be more opportunistic, with individuals deciding when to be screened and what to be screened for.

Decisions about how to offer screening have important consequences for the individual. Organized programmes focus on benefits, harms and costs at a population level. As a result, the individual may not be offered maximum protection from a particular disease: rare disorders may not be screened for, screening may be less frequent than optimal, and those most at risk of getting the disease may not be screened due to insufficient gain in terms of life-years saved. Whilst screening done in less regulated settings may afford greater protection to the individual, people are less likely to be protected from the harms of screening: they are more likely to be over-screened, have poor quality screening and have access to screening of unproven benefit.

Because screening in opportunistic settings is not as tightly regulated, there is less attention to Health Technology Assessment (HTA). This can result in screening activity which conflicts with the available evidence. For example, in the United States, prostate screening is more common than colorectal cancer screening, despite the fact that the efficacy data for the latter is much stronger (Sirovich *et al.*, 2003). However, a plus-side to this more flexible attitude towards HTA is that new screening technologies will be available to the general population more quickly and, if beneficial, may mean much earlier adoption of a successful screening test. This can be seen in colorectal cancer screening which has been offered in the USA for the last 10 years, but is only now becoming available in the UK through the introduction of a nationwide screening programme (see Miles *et al.* (2004) for a more detailed comparison of organized and opportunistic screening).

Adherence to screening

Screening uptake

In order to reduce disease prevalence or mortality, a high proportion of the population needs to be screened so that enough cases can be detected and treated for prevalence/mortality rates to drop. Achieving high population coverage is therefore an essential part of delivering an effective screening service.

The particular strategies used by healthcare providers depend to some extent on how screening is offered. In places where invitations are issued to all those within the target population, methods to increase uptake may focus on the content and source of invitation letters, and the number of reminders that are sent. For example, research has shown that adherence is increased if the invitation letter comes from a primary care provider (King *et al.*, 1992) and a timed, dated appointment is offered rather than an open invitation (Stead *et al.*, 1998). Where there is no call-recall service, healthcare providers may themselves need reminders to ensure that they offer screening tests to those eligible (Zapka & Lemon, 2004).

Despite the success of such approaches, a substantial proportion of the population still under-use screening services. In particular, there is evidence across countries and screening modalities that socioeconomically deprived and ethnic minority groups are less likely to receive screening than more affluent groups and members

of the ethnic majority (Streetly *et al.*, 1994; Kim *et al.*, 2004). This is the case even in countries where screening is heavily reimbursed or offered for free, and so cannot be attributed simply to lack of access to screening.

A number of theories have been forwarded to understand why people use screening services and hence how they might be persuaded to adhere. One of the most widely used is the Health Belief Model (HBM). This model was initially developed to understand why people took up the offer of X-ray screening for tuberculosis. It proposes that six factors determine whether someone will accept an offer of screening. Two relate to 'threat perception': (i) the likelihood of experiencing the health problem, and (ii) the perceived severity of the health problem were it to develop; and another two relate to 'behavioural evaluation': (iii) the benefits of doing something to prevent the health problem from occurring, and (iv) the costs (or barriers) to taking preventive action. A fifth factor, 'cues to action' (e.g. noticing a symptom or seeing a health education campaign), promotes health behaviour if the appropriate positive beliefs about the particular behaviour are held. A further factor, added to the model at a later date, is 'health motivation' or 'readiness to be concerned' about a particular health issue (see 'Health belief model').

Consistent with this model, threat evaluation and behavioural evaluation variables have been found to significantly predict adherence to screening. Believing oneself to be at risk from the disease has been associated with higher participation at screening (Vernon, 1999) and a variety of barriers to screening have predicted lower screening adherence, including concerns about the procedure, such as anticipated embarrassment or discomfort, refusal to believe the test can help decrease cancer morbidity or mortality, and fear of a cancer diagnosis (Wender, 2002; UK CRC Screening Pilot Evaluation Team, 2003). Conversely, screening rates are consistently higher among those who have a preventive orientation and participate in other preventive activities (Sutton *et al.*, 1994). Cues to action, such as the presence of symptoms, have also been associated with screening, but the role of health motivation has rarely been examined.

Other theories of behaviour have also been used to predict participation in screening, such as the Theory of Planned Behaviour (TPB) and Protection Motivation Theory (PMT). Like the Health Belief Model, PMT proposes that perceived susceptibility and disease severity will predict adherence to screening. Where it differs from the HBM is in its claim that efficacy beliefs also play a role. According to PMT, beliefs that one can perform the recommended behaviour (self-efficacy) and beliefs in the effectiveness of the recommended behaviour in reducing the health threat (response-efficacy) are considered important. Perceived control is also identified as a predictor of behaviour by the TPB, along with perceived social norms, attitudes and behavioural intentions, and there is evidence of the predictive value of both PMT and TPB in understanding screening uptake (see Connor & Norman, (1995) for an overview of these theories and Weinstein, (1993) for a discussion of the conceptual overlap between them) (see also 'Theory of planned behaviour').

Strategies to target people's beliefs and thereby enhance adherence to screening have included sending leaflets aimed at reducing perceived barriers to screening, informing people of the benefits, modifying threat and efficacy beliefs and enhancing perceived social norms. However, some of the erroneous and negative beliefs

about screening appear to be attributable to low levels of 'health literacy', either due to illiteracy or a failure to understand commonly used medical terms (Lindau *et al.*, 2002). Hence, non-written methods of persuasion may be required to reach this group (see Meissner *et al.* (2004) for a review of methods to promote adherence).

In addition to ensuring adherence to screening, people also need to be persuaded to attend for any treatment or make any lifestyle changes recommended as a result of their screening test. For example, individuals identified as susceptible to future disease may need to adopt one of a number of different primary prevention strategies to prevent pathological changes from developing. These strategies may involve the use of drugs or dietary change to reduce risk factors such as raised cholesterol levels, or more invasive methods, such as the removal of tissue that may develop cancer in the future (e.g. prophylactic surgery to remove ovaries/breasts following the detection of genes such as BrCa1 and BrCa2). If such interventions are not adhered to, then screening will fail to reduce incidence/mortality rates.

Informed consent, and informed and shared decision making

Previously, where screening was endorsed by the government/healthcare provider, the main aim was to achieve high population coverage. As a result, people were encouraged to go for screening, and were often poorly informed of its limitations and potential to cause harm. However this is no longer the case. Now, the main goal is to ensure that individuals are fully informed of the benefits and harms of screening, and people are encouraged to make a decision about whether or not to be screened based on their own values.

This move towards informed consent, and informed and shared decision-making, has been attributed to concerns among healthcare bodies about litigation; pressure from patient advocacy organizations; and the increased availability of health information, notably via the World Wide Web (Wilson, 2000; Rimer *et al.*, 2004). Litigation is particularly likely following false negative results whereby a screening test fails to detect a disease, leading to delay in diagnosis and treatment (Brenner, 2004). Unfortunately, such outcomes are an inevitable part of screening, because many screening tests are not 100% sensitive (Wilson, 2000). The hope is that, by raising awareness of the inherent limitations of screening, litigation surrounding missed disease might reduce.

Whilst the move towards informed consent is to be welcomed, it has its disadvantages. The additional burden it places on staff time is one (Laing & McIntosh, 2004). Informed consent may also raise anxiety by drawing attention to the limitations of screening, for example, that it offers no guarantee of prevention or cure, although relatively little work has examined this possibility (see Goldberger *et al.*, 1997). A further problem is the impact that informed consent might have on the perceived benefits of screening. Fully informing people of the benefits and harms of screening has the potential to put people off. At the very least, it conflicts with strategies that have been successful in promoting uptake, such as payment incentives to primary care providers. At present, though, little research has examined the impact of informed consent and decision-aids on screening uptake. The limited research done in the area of cancer screening has shown informed decision-making leads to small changes in uptake with decreases in prostate

screening and increases in breast and cervical screening. Hence the observed shifts have been in line with screening recommendations, where there is stronger evidence to support the efficacy of breast and cervical screening than prostate (see Rimer *et al.* (2004) for a review).

It has been suggested that, where the evidence clearly points to the benefits of screening, efforts should be made to fully inform people of associated harms, but minimal physician time should be expended on discussing the pros and cons. Rather, an explicit recommendation to be screened should be issued (Rimer *et al.*, 2004). This view is in agreement with the general proposal that informed consent should be used where there is only one sensible course of action, whilst shared decision-making (where the patient is involved in the decision process) should be reserved for situations that involve at least two sensible alternative routes to medical care which the patient must decide between (Whitney *et al.*, 2004). However, this approach conflicts with the idea that the patient's values, rather than scientific evidence, should guide screening decisions.

Advocates of informed consent often propose that individual-level benefits should be made explicit (Marshall & Adab, 2003) and that this should be done using absolute risk information rather than relative risk information because the former is easier to understand (Gigerenzer & Edwards, 2003). However, people may attend screening out of a sense of social obligation, that is, people may value actions that benefit society. This suggests that people should be informed about both the population-level and individual-level benefits that screening confers (see also 'Communicating risk', 'Informed consent' and 'Risk perception').

Psychological and behavioural consequences of screening

Screening involves testing asymptomatic 'healthy' people for a disease they are unlikely to have. There is therefore understandable concern that any adverse effects are kept to a minimum. One of four outcomes can arise as a result of screening: true positives, where disease is correctly identified; false positives, where people have a suspicious result which, on further investigation, turns out to be normal; true negatives, where disease is correctly judged to be absent; and false negative, where disease is missed. All have the potential to cause adverse effects.

Very little research has examined the impact of false negative results, and the work that has been done is almost exclusively in the realm of antenatal screening (Petticrew *et al.*, 2000). This is because it is easier to identify false negatives in tests for antenatal disorders, as they often become apparent with the birth of the baby. In adult diseases, however, false negative results are harder to establish. They may only become evident if there is further screening (which correctly identifies the disease) or the disease becomes symptomatic. However, it is hard to determine whether the disease was missed by the previous screening or developed subsequently. Some diseases may remain asymptomatic and never be diagnosed.

Based on the limited evidence available it appears that, in the field of antenatal screening, a false negative result may lead to poorer acceptance of a child with chromosomal abnormalities (Down's

Syndrome) than if no screening had taken place (Hall *et al.*, 2000). And one of few studies on the impact of false negatives in cancer screening showed that such error led to reduced confidence in the screening programme, but did not alter people's intention to be screened in the future (Houston *et al.*, 2001).

Research into the psychological impact of false positive results is more extensive. False positives usually involve further medical investigations and a period of waiting before a 'normal' result is verified. In breast cancer screening there is strong evidence that the psychological distress arising from false positives is relatively short-lived (Rimer & Bluman, 1997). Although anxiety is raised when people are recalled for further investigation of suspicious findings, this returns to baseline levels once people have been informed their result is normal (Lampic *et al.*, 2001). However a number of studies have shown that cancer-specific worries may persist for months and even years after screening, e.g. Aro *et al.* (2000).

True positive results may also lead to further investigations or treatment, for example cervical screening can detect pre-cancerous cells which may require minor surgery to be removed. As with false positives, there is anxiety related to the duration of medical surveillance and treatment, and evidence that cancer-specific worry, though not anxiety, may persist for months afterwards (Wardle *et al.*, 1995). Evidence for the adverse effects of 'susceptibility' testing, though is mixed. Some research into the impact of familial hypercholesterolaemia in children has shown little effect on anxiety and quality of life but heightened disease-specific concerns (de Jongh *et al.*, 2003). Behavioural problems in children identified as at high risk for hyperlipidemia in routine screening have also been observed (Rosenberg *et al.*, 1997), but other studies, albeit on adults, have shown no such effects. For example, no indication of adverse effects on psychological wellbeing and absenteeism from work has been observed among a community sample of people attending blood cholesterol screening (Havas *et al.*, 1991). However, the way in which information about enhanced susceptibility is communicated is a key factor in determining its impact. For example, men identified as being at increased risk of cardiovascular disease were less likely to view this information as threatening if they were provided with individually-tailored and supportive information about risk factors for cardiovascular disease (Troein *et al.*, 2002).

Although true positive results are the main aim of screening, screening can detect disease states or abnormalities that the individual may never have become aware of. The increased detection of so-called 'pseudo-disease' is a problem for many types of screening, but relatively little research has been conducted into the psychological consequences of over-diagnosis. This is mainly because it is currently impossible to identify those individuals who have pseudo- rather than true disease.

The majority of people screened will receive a clear (or true negative) screening result. Whilst this might be seen as the best outcome of screening, concerns have been raised that clear results may promote complacency about health. People may believe that any poor health habits to date, such as smoking, have had no ill effects and may be continued (Hoff *et al.*, 2001). Equally, a clear result may lead people to conclude that they do not need to look out for symptoms or attend for screening in the future, a phenomenon known as 'false reassurance'. Relatively little research has been done in this area although some work has shown that screening results

may stimulate positive changes in health behaviours (Bankhead *et al.*, 2003).

A number of strategies may reduce the impact of screening. Anxiety tends to be raised until testing and investigations are complete, and waiting is often seen as an unpleasant aspect of screening. Speeding up the investigation of screen-detected abnormalities will therefore help to reduce any unnecessary anxiety. Further issues, such as false reassurance, complacency about health and the adverse effects of false positives can potentially be attenuated through careful provision of information. For example, informing women undergoing breast cancer screening of the possibility of further investigations, and the fact that such investigations rarely lead to a diagnosis of cancer, has successfully reduced anxiety associated with recall for the follow-up of suspicious findings (Austoker & Ong, 1994).

Conclusion

Screening technologies are proliferating. Efficacy trials for prostate, ovarian and lung cancer screening are taking place; the search for genes that place people at above average risk of developing diseases, such as coronary heart disease and cancer, is continuing; and a variety of tests for antenatal, neonatal and adult testing are currently being considered for introduction into routine care. All these factors mean an increasing proportion of the population will find themselves eligible for one form of screening or another. The ethical, social and psychological implications of this increase in health surveillance need to be carefully monitored. It is important to ensure, for example, that such information is not used to discriminate unfairly against people.

Shiftwork and health

Katharine R. Parkes

University of Oxford

Current trends in shiftwork

Industrial and commercial activities that operate outside normal work hours have become widespread in recent years; services such as banking, communications, transport, catering and retailing are routinely available during evening hours, and often round-the-clock. Consequently, the work patterns of a substantial proportion of the population now extend beyond regular daytime working hours; variable schedules (often including evening or night work) and rotating shifts are both widespread. In a recent European survey, 28% of the workforce had variable work patterns, 10% had evening or night schedules, while 17% worked two-shift or three-shift rotating schedules (Boisard *et al.*, 2003). Further analyses showed that the proportion of shift workers remained relatively constant up to age 45 years, but fell sharply at higher ages, particularly over 55 years (European Foundation for the Improvement of Living and Working Conditions, 2003), reflecting older workers' difficulties in adjusting to shiftwork.

Similarly, analyses of US survey data showed that, in 1997, 27.6% of the workforce had flexible work schedules, while 16.8% of full-time employees had 'alternative' schedules involving work outside normal daytime hours (06.00–18.00 hrs), 6.4% of whom worked night or rotating shifts (Beers, 2000). These proportions varied by occupation; rotating shifts were particularly common in security services (16.3%), mining (12.5%) and catering (8.7%), but infrequent among professionals and managers (1.7%). Night work was prevalent in healthcare, manufacturing and manual occupations. Global trends towards a '24-hour society' suggest that these proportions are likely to rise; thus, the implications of shiftwork for physical and mental health are not only a matter of current concern but are also likely to become increasingly important in the future (Costa, 2001; Rajaratnam & Arendt, 2001).

Mechanisms underlying the health effects of shiftwork

Shiftwork has been empirically linked to a variety of diseases although evidence does not suggest an effect on all-cause mortality (Knutsson, 2003). Three pathways have been implicated in associations between shiftwork and disease (Boggild & Knutsson, 1999; Knutsson, 1989; Knutsson & Boggild, 2000): disruption of circadian rhythms (leading to sleep/wake disturbances, desynchronisation of internal processes, and increased susceptibility to disease); disturbed socio-temporal patterns (resulting from atypical work hours leading to family problems, reduced social support and stress); and unfavourable changes in health behaviours (increased smoking, poor diet and irregular meals). Moreover, there is evidence

that biomarkers, such as cholesterol and other lipids, plasminogen, blood pressure and cardiac activity show changes related to shiftwork, and may act as mediators of disease processes (Boggild & Knutsson, 1999).

The general pattern of findings is that shift workers, as compared with day workers, exhibit less favourable profiles of lifestyle, behavioural and biological risk factors (e.g. Lac & Chamoux, 2004; Morikawa *et al.*, 1999; Parkes, 2002). Psychosocial factors are also relevant; for instance, Smith *et al.* (1999) found that chronic fatigue and ineffective coping behaviour acted to mediate the process by which sleep loss and social disruption led to disease endpoints. Shiftwork may also interact with individual and environmental factors (e.g. age, personality, poor physical work conditions) to increase the risk of health problems (Smith *et al.*, 2003).

Shiftwork in relation to particular health outcomes

Findings relating shiftwork to particular health problems and diseases are summarized in the sections below. In interpreting the findings reviewed, several methodological problems of shiftwork research should be noted. Specifically, shiftworkers tend to differ from day workers in factors such as age, socioeconomic status, job demands and physical/psychosocial work environment characteristics, all of which may contribute to disease outcomes. Moreover, those who are selected (either by self or employer) into, and survive in, shiftwork may differ from day workers in age, personality and initial health status. Comparisons of shiftworkers and day workers may therefore be confounded by pre-existing differences between the groups and by environmental factors. Whilst statistical methods potentially allow control of these effects, stronger evidence of the causal role of shiftwork in relation to disease risk can be derived from prospective studies which assess baseline data prior to exposure (e.g. van Amelsvoort *et al.*, 2004).

Sleep, fatigue and mental health

Disturbed sleep is an almost inevitable outcome of the disruption to normal circadian rhythms associated with shiftwork, particularly night work. The fundamental problem is the mismatch between the need for wakefulness and work activity during night hours when circadian rhythms are conducive to sleep, and for sleep during daylight hours, normally the time of wakefulness and activity (Akerstedt, 1998; 2003; Smith *et al.*, 1999). This reversal of the usual diurnal pattern underlies many of the sleep problems experienced by shiftworkers; environmental conditions (e.g. domestic and traffic noise, presence of children and normal social activities) may also disturb shiftworkers' daytime sleep.

Consistent with the empirical evidence (e.g. Harma *et al.*, 2002; Ohayon *et al.*, 2002), delayed onset of sleep, reduced sleep duration and sleepiness and fatigue during working hours are seen as characteristic sleep disturbances among night shiftworkers (Akerstedt, 1990). Adaptation to a new sleep/wake pattern occurs at a rate of ~1 hr per day (Akerstedt, 2003). Thus, for rotating schedules, adaptation to one shift may not be complete before a further shift change occurs; sleep disturbances and fatigue may also continue into rest days. The nature and magnitude of shiftwork effects depend on the type of schedule, particularly the direction and speed of rotation (Akerstedt, 2003). These factors combine to influence sleep, fatigue and performance differently during morning, afternoon and night shifts, but productivity tends to be most adversely affected during night work (Folkard & Tucker, 2003) (see 'Sleep and health')

The combination of chronic fatigue resulting from sleep disturbances and the disruption of family life and leisure activities associated with shiftwork, may give rise to social stress and work-family conflict, and to psychological distress, particularly anxiety and depression (e.g. Gordon *et al.*, 1986; Jamal, 2004; Jansen *et al.*, 2004; Parkes, 1999; Pisarski *et al.*, 2002). Impairment of psychological health often leads shift workers to change to day-work jobs; Costa (1996) estimates that 20% of workers leave shiftwork after a relatively short time because of its adverse effects, that only 10% do not complain about shiftwork, and that the remaining 70% withstand shiftwork with varying degrees of tolerance.

Gastrointestinal disorders

Gastrointestinal complaints are among the most frequently reported health problems of shift workers; these problems are estimated to be two to five times more common among night-shift workers as compared with those not working nights (Costa, 1996). Circadian disturbance affecting the intake, digestion and absorption of food are thought to play a major aetiological role, but sleep loss, fatigue and the social stress of shiftwork may also be implicated. Typically, shiftworkers have higher levels of gastric symptoms (e.g. indigestion, heartburn, constipation, loss of appetite and nausea) than day-workers, even with control for demographic, job and lifestyle variables (e.g. Caruso *et al.*, 2004; Costa *et al.*, 2001; Parkes, 1999). Evidence also links shiftwork to peptic ulcers (Knutsson, 2003). In particular, in a study based on endoscopic examination of suspected cases, the prevalence of gastric ulcers among Japanese workers was 2.38% among current shiftworkers, 1.52% among past shiftworkers, and 1.03% in day-workers (Segawa *et al.*, 1987). Duodenal ulcers also showed higher prevalence among shiftworkers in this study.

Cardiovascular disease

Evidence accumulated over the past two decades suggests that shiftwork is a significant risk factor for cardiovascular disease. Thus, a recent review by Knutsson (2003) concluded 'there is rather strong evidence in favour of an association between shiftwork and coronary heart disease' (p. 105). Findings from a meta-analysis of 17 studies of cardiovascular disease in relation to shiftwork (Boggild & Knutsson, 1999) support this view. Overall, shift workers were found to have a 40% excess risk for cardiovascular disease relative to day-workers, although there was wide variation across studies.

Findings of two major studies included in this analysis are outlined below.

In a six-year prospective study of cardiovascular (CHD) risk, Tenkanen *et al.* (1997) followed up 1806 industrial workers, assessing lifestyle factors, blood pressure and serum lipid levels, and identifying CHD cases from official health records. Overall, the relative risk of CHD among shiftworkers as compared with day-workers was 1.5 (CI 1.1–2.1), decreasing to 1.4 (CI 1.0–1.9) with control for physiological and lifestyle variables. Among blue-collar employees, day-workers, 2-shift and 3-shift workers had relative risks of 1.3 (CI 0.8–2.0), 1.9 (CI 1.1–3.4) and 1.7 (CI 1.1–2.7) respectively. Shiftwork was also found to interact with smoking and obesity to increase CHD risk (Tenkanen *et al.*, 1998).

Kawachi *et al.* (1995) examined the incidence of CHD over a four-year period among 79 109 female nurses in relation to the total years of rotating night shiftwork. The age-adjusted relative risk was 1.38 (95% CI, 1.08–1.76) in women who reported ever doing shiftwork compared with those who had never done so. This excess risk remained significant after adjustment for cigarette smoking and other cardiovascular risk factors. The analyses also demonstrated a dose-response relationship between CHD risk and duration of shiftwork (greater risk being associated with longer durations), consistent with earlier findings (Knutsson *et al.*, 1986).

Cancer

Empirical studies demonstrate associations between night work and elevated risk of breast cancer (e.g. Hansen, 2001; Tynes *et al.*, 1996). In each of these studies, shiftwork was associated with an overall risk ratio for breast cancer of 1.5, but the risk increased with age and length of exposure to night work. Similarly, in a prospective study of nurses, positive associations were found between breast cancer and extended periods (>30 years) of intermittent night work (Schernhammer *et al.*, 2001); among postmenopausal women, the risk ratio also increased for 1–14 years and 15–29 years of rotating night work. One mechanism by which shiftwork may lead to breast cancer is that the normal production of melatonin during hours of darkness is disrupted by working at night; suppression of melatonin is thought to lead to an increase in reproductive hormones (particularly oestrogen), acting to increase hormone-sensitive cells in the breast (Schernhammer & Schulmeister, 2004). However, other pathways may also exist; for instance, Bovbjerg (2003) suggests that alterations in immune function associated with circadian disruption may be implicated.

Evidence linking night work and cancer is largely specific to breast cancer; little is known about other types of cancer in this context, or about the possible mechanisms involved. Although Taylor and Pocock (1972) reported an increased incidence of cancer among shiftworkers, Tynes *et al.* (1996) found that cancer incidence among female shiftworkers was not different from that of the general female population. However, increased risk of colorectal cancer among female nurses working rotating night shifts for >15 years has recently been reported (Schernhammer *et al.*, 2003).

Pregnancy and reproductive disorders

Two review articles (Costa, 1996; Scott, 2000) summarize evidence linking shiftwork to adverse pregnancy outcomes (e.g. premature

births, miscarriages and low birth weight). For instance, a meta-analysis of 29 studies identified shiftwork as a significant risk factor (OR 1.24) for pre-term birth (Mozurkewich *et al.*, 2000). In the light of the evidence, Knutsson (2003) recommended that women should avoid shiftwork during pregnancy. Recent studies (using data from the Danish National Birth Cohort) also indicate that shiftwork, especially fixed night work, is associated with adverse pregnancy outcomes (e.g. Zhu *et al.*, 2004).

Other aspects of reproductive dysfunction (e.g. irregular menstruation) have also been linked to shiftwork (e.g. Hatch *et al.*, 1999; Labyak *et al.*, 2002). Disruption of circadian rhythms, and the resulting desynchronization of cyclic physiological functions (including hormonal activity), is thought to be the most likely cause of menstrual problems among shiftworkers (Costa, 1996; Smith *et al.*, 2003).

Accidents and injuries

Sleep loss and fatigue associated with circadian disruption impairs cognitive performance, particularly in tasks requiring vigilance, concentration and decision-making (e.g. Meijman *et al.*, 1993); this impairment potentially increases the risk of accident and injury incidents. However, in many work situations, the number of personnel exposed, the nature of the work done, the level of supervision and the likelihood of an accident being reported, differ across the 24-hour workday; thus, incident rates cannot be directly compared across shifts (Folkard & Tucker, 2003). Nonetheless, a few studies in which confounding factors are adequately controlled do allow such comparisons.

Thus, Smith *et al.* (1994) found that, relative to the morning shift, the overall risk of an injury incident during the night shift was 1.23 (CI 1.14–1.31), with a higher risk for self-paced work at night, 1.82 (CI 1.30–2.34). Folkard & Tucker (2003), combining five data sets, found that risk increased approximately linearly across the three shifts. Relative to the morning shift, the increase was 18.3% for afternoon shifts, and 30.4% for night shifts. More generally, Smith *et al.* (2003) note that the disasters of Three Mile Island, Chernobyl and the Challenger space shuttle all occurred during the night.

Use of statistical methods to estimate risk from large-scale exposure data provides an alternative (although less precise) method of studying accidents in relation to shift patterns. For instance, Williamson and Feyer (1995) analyzed a total of 1020 work-related fatalities occurring over a two-year period in Australia. To estimate exposure rates, they used national survey data to determine the proportion of the employed population engaged in night work as compared with day work. Taking into account the difference in exposure rates between night hours and day hours, the risk of fatality was found to be more than twice as high for night work (19.00–07.00 hours) as compared with day work (07.00–19.00 hours). However, Laundry and Lees (1991) found no evidence of elevated rates of minor accidents during night work, although they did find a circadian pattern of accident frequency with morning (0800–1000 hrs) and afternoon (1400–1600 hrs) peak periods. Using more complex statistical methods, Hanecke *et al.* (1998) found that, beyond the eighth or ninth hour of work, there was a marked increase in relative risk particularly for afternoon and night shifts.

Tolerance to shiftwork and intervention strategies

Shiftwork tolerance

Individual variation in the ability to adjust to shiftwork has been widely noted (e.g. Costa, 2003; Smith *et al.*, 2003). Age is a particularly important factor. Individuals older than 45 years experience increasing difficulty in adjusting to altered sleep–wake cycles; reduced fitness, decreased restorative powers of sleep and greater proneness to internal desynchronization of circadian rhythms, all contribute to decreased shiftwork tolerance. However, other individual factors, including circadian type ('morningness' versus 'eveningness'), and personality traits (e.g. extraversion) also affect shiftwork adaptation. These traits are related to circadian cycle characteristics that influence preferences for morning or evening activities (Tankova *et al.*, 1994); however, in the absence of validation data, Smith *et al.* (2003) caution against the use of such measures for selection purposes.

Interventions to facilitate shiftwork adaptation

Several types of interventions can be effective in facilitating shiftwork adaptation (for reviews, see Knauth & Hornberger, 2003; Smith *et al.*, 2003). At the organizational level, shift schedule design is particularly important; although there are no ideal shift patterns, factors such as shift duration, direction of rotation, changeover times and work/rest sequences all affect adaptation. Other recommended strategies include worker participation in the design and implementation of shift schedules and attention to work conditions (e.g. staffing levels, workload, rest breaks and the physical environment, especially lighting levels) that may accentuate or mitigate the effects of shiftwork.

At the individual level, recommendations for favourable adaptation include 'sleep hygiene' (e.g. regular sleep routine, quiet bedroom, curtains or blinds to eliminate sunlight during sleep hours, avoidance of caffeine or alcohol prior to sleep); healthy diet and fixed meal times; active coping; and ensuring a balance between sleep and family time (Knauth & Hornberger, 2003). Exposure to bright light during specific circadian phases has also been found to speed adaptation (e.g. Bjorvatn *et al.*, 1999), but use of melatonin as a sleep medication to aid adjustment to shift changes, whilst potentially effective, is subject to some safety concerns (Smith *et al.*, 2003).

Conclusions

The material reviewed in this chapter suggests that shiftwork significantly increases risks of cardiovascular disease, cancer and several other major illnesses: shiftwork is also implicated in psychosomatic problems, particularly sleep disturbance and fatigue, in psychological distress and in the occurrence of accidents. However, the mechanisms by which shiftwork impacts on physical and psychological health are still not fully understood. Whilst evidence suggests that each of the three pathways identified earlier in this chapter (circadian disruption, behavioural change and disturbed socio-temporal patterns) are involved, it is likely that their relative importance varies across different health outcomes,

and in relation to individual and environmental characteristics, including the particular shift hours and rotation patterns worked. Nonetheless, the desynchronization of normal psychophysiological functions associated with circadian disruption (particularly during night work) is generally thought to play a key role (Costa, 2003;

Knutsson & Boggild, 2000). It is therefore unlikely that the health impact of shiftwork can be entirely eliminated, although identifying individuals with greater tolerance to shift changes, and implementing organizational and individual strategies to facilitate adaptation, can help to alleviate some adverse outcomes.

Stress in health professionals

Chris McManus

University College London

Stress and burnout are inevitable problems for the highly committed, highly involved individuals who work in healthcare services, as they deal with the physical and emotional problems of seriously ill and sometimes emotionally disturbed patients, while also having to cope with running effective teams, dealing with complex management structures and conflicting demands at all hours of the day and night. Anyone working in such conditions will inevitably become stressed if enough such pressures are placed upon them. Having said that, not everyone in practice does become stressed, and that raises a host of questions about who becomes stressed, why people become stressed, what are the precipitating and protective factors and what are the causal processes underlying the separate but related conditions of stress and burnout. A brief review such as this can inevitably only present a personal view of a large

research area. Several recent edited volumes are recommended as good starting places for studying the field further (Dollard *et al.*, 2003; Cooper, 2005).

Defining and measuring stress and burnout

Stress

As p. 1 of Cox (1978) pointed out long ago, 'the concept of stress is elusive... It is a concept which familiar to both layman and professional alike; it is understood by all when used in a general context but by very few when a more precise account is required...'. Stress suffers from the conceptual confusion of both referring to the external event and to the internal response (just as in engineering,

a stress is a force upon an object such as an aircraft wing, and the damage that results from that force, as in metal fatigue). It also suffers from the problems that beset technical terms within psychology which are also used in everyday language, so that hardly a person nowadays describes their work as anything other than 'stressful', or describes themselves as anything other than 'stressed out'. Amongst the various definitions of stress and stress responses, perhaps a common denominator is a failure of normal, effective functioning, which can manifest in disordered, ineffective behaviour, of which perhaps the symptoms of anxiety-related and depressive disorders are the first and commonest signs (see 'Stress and health').

For research purposes, many empirical studies have resorted to defining stress in terms of conventional measuring instruments, typically questionnaires, of which the General Health Questionnaire (GHQ) has become the most popular, not least because of its conceptual and research links to the diagnosis of anxiety and depressive disorder. The GHQ was originally introduced by Goldberg (1972), as an instrument to be used in general medical practice for detecting undiagnosed psychiatric disorders in general medical and surgical patients. The original 140-item scale was also presented as a more popular 60-item scale (GHQ-60) which had several sub-scales. Subsequently, shorter versions of the instrument have been used, including the 28-item scale (GHQ-28), and the very popular 12-item questionnaire (GHQ-12), which conventionally is regarded as having only a single scale, but probably assesses two correlated factors, i.e. anxiety/depression and social dysfunction (Kalliath *et al.*, 2004). An important feature of the original GHQ was that a scoring method was devised which was validated against independent, psychiatric assessments of the individuals using standardized clinical interviews. A score of four or more on the GHQ-12 has been shown, in its proper context, to have about an 80% sensitivity and 80% specificity for detecting psychiatric illness, with good comparability even when used cross-culturally in a range of countries, and after translation into ten different languages (Goldberg *et al.*, 1997), and a positive predictive value of about 65% (Schmitz *et al.*, 1999).

Because of its success as a screening instrument for detecting psychiatric illness ('caseness'), the GHQ began to be seen as a useful instrument for assessing psychiatric morbidity which could then be used as a proxy for stress and stress-related illnesses. There are many such studies in the literature, and a recent review summarized the result in these terms: "Although stress is common in most professions, the figures for doctors suggest that 28–30% of them suffer above the threshold level of stress as measured by the General Health Questionnaire" (Maxwell & Squire, 2000). Such studies typically do not include a population control, but where such data are available, as in the Health and Lifestyle Survey in the UK, the rate of caseness was about 14% (McManus *et al.*, 1999), seeming to support the idea that doctors and health professionals may indeed be particularly stressed.

An important problem in using the GHQ for assessing stress is that it is typically not used in the context for which it was originally devised. The rubric for the GHQ very carefully does not make any mention of stress (and indeed the term is not even found in the index to Goldberg's 1972 monograph). Instead it asks, 'how your health has been in general, over the past few weeks'. However many of the studies, which have used versions of the GHQ for estimating stress rates in health professionals, present the

questionnaire in an explicit context of stress, often with a covering letter with a title such as, 'Stress in doctors'. Such phraseology potentially primes respondents to answer in particular ways if they feel that they are indeed 'stressed' in the everyday sense of the term, but the risk is that the validity of the instrument is threatened. Almost no studies using the GHQ to assess stress in health professionals have cross-validated GHQ-detected cases against formal psychiatric diagnosis; it is just assumed implicitly that the measure is as valid as in its original context. An important exception used the GHQ-12 to identify cases in a population of healthcare professionals and hospital staff in a hospital setting in the north of England. The proportion of cases was 27% (Weinberg & Creed, 1999). However formal psychiatric assessment found that only 52% met the criteria for a psychiatric diagnosis (Weinberg & Creed, 1999). It seems likely, therefore, that a proportion of GHQ-based studies of the absolute rate of stress in health professionals over-estimate rates of stress, a risk that will of course be exacerbated if there is response bias, with the most stressed seeing an opportunity to express their discontent. Great care should therefore be taken in interpreting such surveys, particularly when they form the basis for headlines used by medical politicians. A study in which GHQ-assessed stress rates in doctors could be assessed properly was a stratified, representatively sampled study of attitudes of 1013 UK doctors to the General Medical Council's Performance Procedures, in which we included the GHQ-12 amongst a range of questions unrelated to stress, and with its proper rubric which does not mention stress. The overall rate of caseness was 16.9%, which was similar to rates of 14.1% and 17.8% in large-scale population studies (McManus *et al.*, 1999). Interestingly there was evidence of a relationship of stress to age, doctors in mid-career showing the highest rates of stress.

In summary, the measurement of stress is not straightforward, and absolute rates should be treated with care when assessed by instruments such as the GHQ. Whether doctors and other health professionals are more stressed than the public as a whole is at best controversial. What is clear however, is that *some* doctors are more stressed than others, and it seems likely that those with high stress, as assessed by the GHQ, are neither happy nor effective doctors, often wanting to leave medicine for other careers.

Burnout

The concept of 'burnout' is less conceptually confused than that of stress, not least because of a clear articulation of the different components, and their ready measurement in a single, well-accepted measuring instrument, the Maslach Burnout Inventory (MBI) (Maslach & Jackson, 1986). Maslach has defined burnout as, "a psychological syndrome in response to chronic interpersonal stressors on the job" (Maslach *et al.*, 2001). The three separate components, measured by the MBI are:

- Emotional Exhaustion (EE; a sense of being emotionally over-extended and exhausted by one's work)
- Depersonalization (DP: an unfeeling, impersonal response towards patients; cynicism)
- Personal Accomplishment (PA: a feeling of achievement and competence in working with patients; efficacy)

These are differentiated by EE and DP being positively correlated with each other and with burnout overall, whereas PA is negatively correlated with burnout overall and with EE and DP. In more recent work Maslach has extended the conceptualization and in particular has emphasized ‘engagement’, the positive antithesis of burnout, which is the starting point from which ‘What started out as important, meaningful and challenging work becomes unpleasant, unfulfilling and meaningless. Energy turns into exhaustion, involvement turns into cynicism, and efficacy turns into ineffectiveness’ (Maslach *et al.*, 2001) (see ‘Burnout in health professionals’).

An important and often misunderstood feature of the MBI is that there is no absolute scoring, and unlike the GHQ there is no validation against formal psychiatric assessment. The manual (Maslach & Jackson, 1986) does describe high, medium and low scores, but these in effect are simple tertiles, dividing the original normative groups into top, middle and bottom thirds. The claim, as is sometimes seen, that in a survey, ‘a third of the subjects showed high levels of burnout’, is not saying that there are high levels of burnout but that there are normal levels of burnout.

An important conceptual aspect of the definition of burnout is the clear distinction between burnout and depression. Although the two conditions can co-occur, Maslach emphasizes that while burnout is job-related and situation-specific, depression in contrast is a condition which pervades every aspects of a person’s life. Of course depression may cause burnout and burnout may cause depression, but their clear aetiological and diagnostic distinction must be maintained.

A similar conceptual distinction can also be made between stress and burnout, perhaps most clearly seen in the work of Pine, whose existential model clearly differentiates burnout from stress and strain (Pines & Keinan, 2005). In the existential perspective, people need their lives to be meaningful, and a sense of meaning is in part achieved by having jobs which are useful, important and of perceived significance. Burnout is the absence of such a sense of meaningfulness, and correlates principally with a lack of perceived job significance, whereas strain correlates particularly with work stressors such as workload. Pine also emphasises that the lack of significance is specific and situational, rather than generalized, so that individuals can, for instance, be burned out in one part of their life, such as at work but not in another part, such as their marriage.

The causal relationship between stress and burnout

Many studies measure levels of stress and burnout in health professionals, and the consistent finding is that doctors with higher stress levels also report more emotional exhaustion, more depersonalization and less personal accomplishment. The correlations are undisputed: much more problematic is the causal relationships between the measures, and these are much less studied. Particularly problematic is that the inference of causation from cross-sectional data is not straightforward, where stress is correlated with lowered personal accomplishment and increased depersonalization (Graham *et al.*, 2002). Proper longitudinal studies are rare, but in one study path modelling was used to interpret the relationships between stress and burnout measures in doctors assessed after a three-year interval (McManus *et al.*, 2002a). Figure 1 shows that the engine which drives the relation between stress and burnout is the causal cycle from stress to emotional exhaustion and from emotional exhaustion to stress. However the other effects are less intuitive. Longitudinally, personal accomplishment acts not to protect against stress but to increase it, whereas depersonalization acts to reduce subsequent stress. A metaphor may perhaps help in understanding the relationships; the oxygen of high personal accomplishment may initially help to ignite the fire of engagement, but just as a fire runs out of fuel, so burnout results when mental resources are consumed. To burnout one has firstly to have burned brightly and high personal accomplishment both makes the fire burn and also burn out (McManus, 2002).

Stress, personality and working conditions

A frequent assumption in the stress literature is that working conditions, and in particular in the case of doctors, a heavy workload and long working hours, including work at night and sleeplessness, are the major cause of stress (see ‘Healthcare work environments’ and ‘Shiftwork and health’). Certainly it is the case that if one interviews doctors who are highly stressed then they will attribute their stress to working conditions. The problem, however, is that non-stressed doctors also describe similar working conditions. Systematic surveys of working conditions find a very poor, almost non-existent correlation, between working hours, patient load and

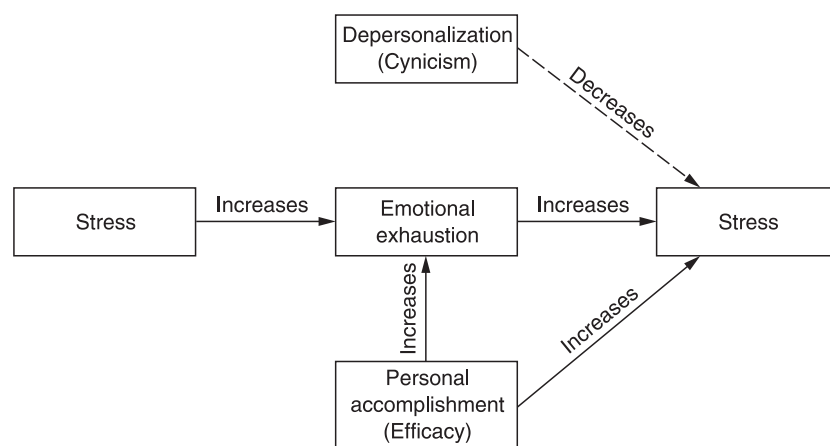

Fig 1 Causal relations between stress and burnout (for further details see text and McManus *et al.* (2002a)).

other variables describing working conditions, with stress levels (McManus *et al.*, 2002b; Bovier & Perneger, 2003) or with burnout (Pines, 2000). Two possibilities are therefore raised: one, is that, it is not workload per se which is stressful (and after all, many people find activation, exhilaration and excitement from working hard at a job they enjoy doing), but the imbalance between effort and reward (Tsutsumi & Kawakami, 2004): hard work for little reward, financial, psychological, social or professional, is stressful and results in burnout. The other possibility is that stress is as much a characteristic of the doctor or health professional as it is of the work environment.

Most studies are incapable methodologically of separating effects of the individual from effects of the environment, since they assess a single health professional in a single job, the person and the situation being completely confounded. A study which shows the separation of the two looked at a large group of British doctors in their pre-registration house officer (PRHO) posts, the first year after qualification (McManus *et al.*, 2002b). The study was large enough to mean that many doctors had worked in the same post (i.e. for the same consultant firm, in the same hospital, which was a part of the same trust, which was supervised by the same postgraduate deanery). Such data can be analyzed by multi-level modelling, which allocates variance to different levels of the hierarchy. The analysis showed that many measures, such as reported working hours, number of patients, perceived quality of the job, etc. did indeed involve variance at the level of the consultant firm, or the hospital or trust. However, the most striking result was that stress and burnout *only* showed variance at the level of the individual doctor. In other words, two doctors working in precisely the same post showed no greater similarity of their stress levels than did two doctors working for different consultants, in different hospitals under different trusts and academic deaneries (McManus *et al.*, 2002b). The strong implication is that stress is, to a large extent, an individual response of the health professional, rather than being directly driven by working conditions.

The clinical literature has long reported that the personality dimension of neuroticism is related to anxiety disorders (Matthews

et al., 2003; Tyssen & Vaglum, 2002) and an obvious personality correlate for stress and burnout in health professionals is neuroticism (see 'Personality and health'). Although personality is rarely measured in studies of stress, when it is there are clear correlations of neuroticism with stress levels (Deary *et al.*, 1996a, b; Tyssen *et al.*, 2002). Larger scale studies have found that other personality variables are also important in predicting stress, doctors with higher stress levels not only being more neurotic, but also being more introvert, and having lower levels of conscientiousness and agreeableness (McManus *et al.*, 2003, 2004). Intriguingly these are precisely the same personality variables which in meta-analyses predict low levels of job satisfaction, life satisfaction and marital satisfaction (Heller *et al.*, 2004). Particularly important is that in longitudinal studies, neuroticism measured at one time, when doctors are in a particular job, is predictive of stress and burnout levels five years later, when doctors are in an entirely different work environment (McManus *et al.*, 2004). The effects of stress on the working environment are manifold, particularly when interacting with personality and study habits and learning styles, causing a surface-disorganized approach (Kirby *et al.*, 2003) and a high sense of workload, but also a less supportive-receptive working environment, and less independence of choice in work (McManus *et al.*, 2004) (see Fig. 2).

The management of stress and burnout

Whatever the disputes about the causes of stress in health professionals, there is little doubt that many health professionals are stressed and burned out and interventions to reduce that stress would be beneficial to the professionals themselves and probably also to their patients and their colleagues. Several broad sets of intervention can be distinguished.

Stress-reduction techniques

Stress-reduction techniques for the workplace have been classified into six broad groups: relaxation; physical fitness; cognitive

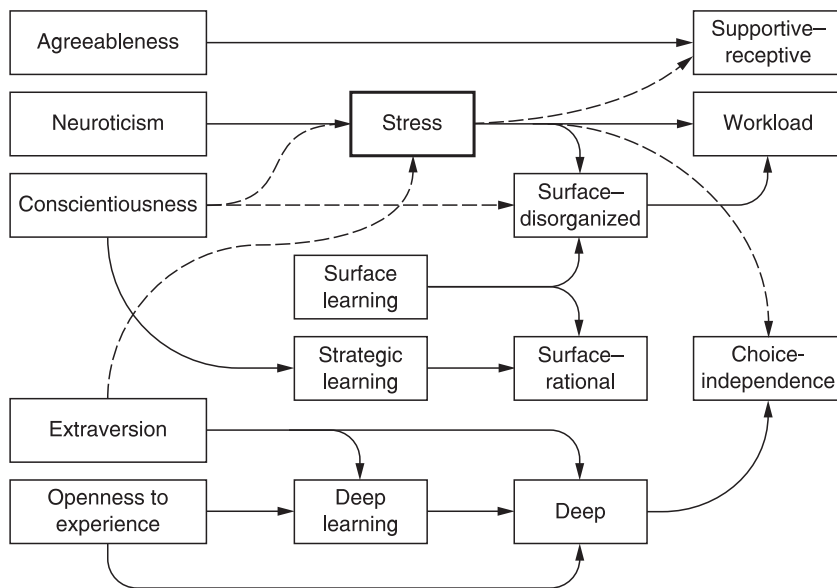

Fig 2 Summary of causal influences of personality and study habits (left-hand side) upon stress and of stress upon working styles and work environment (right-hand side). Solid lines indicate positive relationship, and dashed lines indicate negative relationships. For technical details see McManus *et al.* (2004).

restructuring; mediation; assertiveness training; and stress inoculation (Bellarosa & Chen, 1997) (see 'Cognitive behaviour therapy', 'Relaxation training' and 'Stress management'). Experts in such techniques were most familiar with relaxation, rated it as the most practical and cheapest of the methods and along with physical activity, the most effective of the methods although its effects were seen to be short-lived, with cognitive restructuring having the most long-lasting effects. Properly conducted empirical trials of the effectiveness of stress-reduction techniques are rare, one review of such interventions for mental health professionals finding only three well-evaluated studies, which found that stress reduced after attendance at workshops linked to sustained consultation, after participation in an intensive programme and after interdisciplinary education (Edwards *et al.*, 2002). A meta-analysis of stress-reduction methods, found that the most effective techniques are cognitive-behavioural (Cohen's $d=0.68$; 95% confidence interval $CI=0.54$ to 0.82), with relaxation techniques less effective ($d=0.35$; 95% $CI=0.22$ to 0.48), and organizational interventions without any significant effect ($d=0.08$; 95% $CI=-0.03$ to 0.19) (van der Klink *et al.*, 2001); the overall effects were described as 'small but significant' (van der Klink *et al.*, 2001). Large-scale randomized trials are unusual, not least because they are expensive, but an important exception is a study in which healthcare professionals in oncology received 105 hours of training on attitudes and communication skills, with significant reductions in stress being found three and six months later (Delvaux *et al.*, 2004).

Lifestyle

Healthcare professionals are not only healthcare professionals, but also have lives outside of hospitals and other workplace institutions. In some cases it is events in those outside lives which have an impact on stress and burnout. In one study, many cases of stress identified by the GHQ-12 had problems outside work, including substantial health difficulties in close relatives, a past psychiatric history, marital difficulty and the lack of a confidant. These were more predictive of stress than were work problems (Weinberg *et al.*, 1999). Family life can be a source of stress to doctors, particularly female doctors and those with children, with the problems of combining work and family being a common problem, which can result in continual compromises (Töyry *et al.*, 2004). Although having children was a source of stress for doctors, interestingly doctors with

children reported lower levels of depersonalization and higher levels of personal accomplishment than those without children (Töyry *et al.*, 2004). GHQ scores were systematically lower in doctors who responded to stress at work by maintaining a balanced, healthy life-style (Graham *et al.*, 2005).

Selection for hardiness

A recurrent suggestion, particularly from selectors for medical school, is that since neuroticism and other personality factors predict stress and burnout, then a sensible strategy is to select the hardest of students, who will be the stable, conscientious extraverts. Although superficially attractive, such an approach has several problems. Firstly, it assumes that the selection ratio is sufficiently high to allow selection on multiple factors, but with only about two applicants for every medical school place, that is unlikely to be the case (McManus & Vincent, 1993). Secondly, the approach assumes that neuroticism, introversion and low conscientiousness have only negative correlates. However, that is unlikely to be the case. In the dangerous world in which early humans evolved, with the ever-likely possibility of predation and indeed in the dangerous modern technological world which modern humans have subsequently created, the risk of death or injury is always present. To have no anxiety about such possibilities is to run the risk of being eaten or run over. However, to be excessively anxious is also to run the risk of being paralyzed into inactivity. Moderate levels of neuroticism are therefore beneficial (and it is always worth remembering that, by definition, we are all the descendants of individuals who were sufficiently anxious as to make sure that they were not eaten by sabretoothed tigers before they had reproduced). It is likely also that moderate, or even high, levels of neuroticism have their benefits in medicine: we want doctors and nurses who do sometimes go home and worry that they may have made a diagnosis wrongly, may have carried out an operation less well than they might have, or did not communicate properly with a patient or their relative. If we need such reflective individuals who worry about their jobs (and it seems likely we do) then we also need counselling and other career support systems which help them to continue coping at doing the thing at which they are good, and for which they have been so expensively trained, which is practising as health professionals.

Surgery

Claus Vögele

Roehampton University

Introduction into the healthcare system and hospitalization can be a stressful experience on its own. Among the aspects of hospitalization considered to be most stressful Koenig *et al.* (1995) identified the following in a sample of elderly medical inpatients: communication problems with healthcare professionals; diagnostic and therapeutic procedures; the hospital environment (noise, rigid routines etc.); worries about the home situation and the separation from home; insufficient information about diagnosis and prognosis; and fear of dependency, loss of autonomy and control.

In addition to uncertainties about their illnesses (because of unclear communication) and the unfamiliar surroundings of a hospital ward, therefore, patients encounter additional stress because they must undergo medical procedures and examinations (see 'Hospitalization in adults'). Even some outpatient procedures such as dental treatments or blood donation can be stressful. Normally patients would report increases in anxiety in anticipation of procedures such as surgery, endoscopy, cardiac catheterization, cancer screening or chemotherapy. In addition to the anticipatory anxiety

associated with the procedure itself, diagnostic procedures such as cancer screening are characterized by a prolonged period of anxiety between screening and receiving the result (Marteau *et al.*, 1993). The same is true for procedures such as HIV testing although the development of rapid testing procedures with the provision of same-day results and counselling has reduced the negative psychological consequences associated with a long wait (Kassler *et al.*, 1997) (see 'Coping with stressful medical procedures').

Of all medical procedures, surgery is perhaps the most threatening event as it contains many unpredictable and uncontrollable features such as losing consciousness due to the administration of a general anaesthetic, the anticipation of post-operative pain and the surgical trauma related to the incision. This chapter will concentrate on surgical procedures and describe the stressful characteristics associated with being hospitalized for surgery. The literature on psychological and physiological responses to the experience of surgery will be reviewed and findings from studies investigating psychological preparation for surgery will be summarized.

Stressful characteristics of the surgical situation

There are obvious potential threats for the surgical patient: anaesthesia; pain; physical restriction; life-threatening procedures; being away from home. Evidence suggests that the lack of predictability and control are significant contributors to the stressful experience of surgical patients (Slangen *et al.*, 1993). It is usually the case that we need to be able to predict an event in order to be able to control it. But the reverse does not follow: being able to predict an event does not necessarily mean we can control it. Such is the case for elective surgery, which accounts for the vast majority of surgical interventions.

This evidence confirms that there are common characteristics of the surgical situation which are identified by most patients as stressful. However, it seems likely that different types of surgical procedures produce different types of stress. Weinman and Johnston (1988) suggest that a useful way of distinguishing between the various procedures would be by considering the function of the procedure (diagnostic, treatment or both) and the timeline and nature of stress associated with the procedure. Weinman and Johnston (1988) further distinguish between procedural stress (i.e. the stress associated with the negative aspects of the actual procedure itself) and outcome stress (i.e. longer term fears and concerns related to the results of the treatment or procedure). To illustrate the latter point, some operations, for example, may have more positive characteristics in terms of their expected outcome than others, e.g. restoration (hip replacement) versus removal of physical function (leg amputation).

Responses of surgical patients at emotional, cognitive and physiological levels

Emotional responses

Most studies investigating emotional responses to surgery have shown elevated levels of anxiety both before and after surgery. In some groups of patients postoperative anxiety levels may be even higher than those measured preoperatively and this may reflect

different sources of worry (procedural versus outcome). Vögele and Steptoe (1986) and Vögele (1992) found moderate levels of anxiety on the day before the operation and a significant increase on the days immediately following surgery in patients undergoing total hip replacement. As this particular type of surgery involved the patients to get out of bed on the second or third day after the operation it seems likely that the observed postoperative increase in anxiety was due to the anticipatory anxiety about the outcome of the operation. Interestingly, a similar pattern of responses could be observed in another patient group undergoing a much more minor orthopaedic surgical procedure (knee arthroscopy; Vögele & Steptoe, 1986).

Although anxiety has been the most frequently assessed emotional response for obvious reasons, it has been shown that surgical patients may also experience high levels of nervousness, depression, anger and boredom (Vögele, 1992).

These results indicate that emotional responses to the surgical situation may vary as a function of the type of operation, and therefore, outcome concerns. They also point to the possibility of effective interventions not only before but also after surgery.

Cognitive responses

Several studies have examined surgical patients' worries and it has been suggested that patients' main worries are more related to the outcome of the operation rather than the operation itself (Weinman & Johnston, 1988). Patients also worry significantly about normal everyday matters such as family and home, perhaps exacerbated by hospitalization and the impending surgery. As in the treatment of depression, the cognitive elements of surgical patients' stress response may be critical in indicating the most promising intervention approach to alleviate distress.

Physiological responses

The most thorough research on physiological responses to surgery has been carried out on indices of sympathetic-adrenomedullary activity. The most consistent finding is that of a reduction in palmar sweat gland activity prior to surgery followed by recovery to normal levels postoperatively (e.g. Vögele & Steptoe, 1986). Palmar sweat gland activity closely follows the pattern of subjective distress and pain, indicating that sweat gland activity is reduced by the stress of surgery. Some authors, however, have argued that the palmar sweating pattern of surgical patients is related to the effort rather than the distress aspect of stress, i.e. changes in palmar sweating are due to changes in activity levels. Indices of cardiovascular activity may be even more complicated to interpret. Goldstein *et al.* (1982) suggested that the cardiovascular responses to the stress of surgery have multiple determinants and may not be mediated by sympathetic influences. They found preoperative increases in heart rate, systolic blood pressure and cardiac output, but these persisted when noradrenaline responses were eliminated by diazepam sedation. In studies by Vögele & Steptoe (1986) and Vögele (1992), elevated heart rates before and after the operation that could not be accounted for by blood loss were consistently found.

A more recent line of research has investigated neuroendocrine and immune changes in response to surgery (Kiecolt-Glaser

et al., 1998) and wound healing (Ebrecht *et al.*, 2004). Postoperative elevations in plasma levels of adrenaline, cortisol and beta-endorphin reflect sympathetic nervous system and hypothalamic–pituitary–adrenal axis activation (Salomaki *et al.*, 1993). Evidence for immune suppression during surgery comes from studies showing suppression of natural killer cell activity (Pollock *et al.*, 1991), lymphocyte proliferative responses to mitogens and changes in lymphocyte populations (Tonnessen *et al.*, 1987).

In order to interpret these physiological responses to surgery as psychophysiological phenomena (including the experience of pain), it is necessary to disentangle the effects that are due to the experience of stress from those that are caused by the surgical trauma and other medical interventions (e.g. anaesthesia). Surgery represents in most cases a major trauma with a relatively stereotyped physiological response pattern (Salmon & Hall, 1997). This response pattern involves physiological changes reminiscent of Selye's 'General Adaptation Syndrome' (GAS) (Selye, 1980), and includes the release of catecholamines, glucocorticoids, growth hormone and glucagon, the suppression of insulin secretion and changes in other endocrine systems. These hormonal responses are assumed to trigger a cascade of metabolic adjustments leading to catabolism (a metabolic state of breakdown of the body's own protein) and substrate mobilization in the postoperative period.

This pattern of responses is sometimes described in the medical literature under the term 'La maladie post-opératoire' or 'Post aggression syndrome' (Moore, 1976). The implication of a unifying concept of postoperative physiological changes as suggested by this term has, however, been criticized in favour of a more differentiated view (Anand, 1986; Moore, 1976) taking into account the site and extent of the surgical trauma. In the simple uninfected elective surgical trauma, which usually forms the basis for psychological research reported in this chapter, there is little to note other than the mild tissue injury, with prompt healing, transient starvation and trivial fluid volume reduction. It could be argued, therefore, that any differences between patients in physiological responses to surgery may be attributable to psychological and behavioural factors, and this (despite all caveats) makes physiological indices of stress an attractive paradigm for the study of the impact of the surgical situation on postoperative recovery. As we will see in the following section such differences in physiological responses (including immunological and neuroendocrine changes) may have an effect on indices of postoperative recovery such as speed of wound healing.

Surgical stress and postoperative recovery

Despite a strong effect of physical factors such as extent of tissue damage caused by the surgical trauma on postoperative recovery, there is variability across patients who have undergone the same procedure. It is unclear what accounts for this variability, and this has led to the suggestion that psychological factors such as anxiety and depression may play some part in determining the duration or quality of postoperative recovery.

There is considerable theoretical and empirical support for the relevance of psychosocial factors to postoperative recovery. These include demographic variables such as age, gender and

socioeconomic status, and also personality variables such as anxiety, neuroticism, coping style and social support. Most of the available literature today suggests a linear association between preoperative anxiety and success of recovery, in that the more anxious the patient before the operation the less favourable the postoperative recovery. There is even evidence that preoperative anxiety is related to intra-operative adjustment (Abbott & Abbott, 1995; de Bruin *et al.*, 2001), however with equivocal results: while in the former study highly anxious patients required more anaesthetic, the latter reports an inverse relationship: the higher the preoperative anxiety levels, the less anaesthetic was required during the operation.

In a review of studies relating anxiety and postoperative recovery, Munafò & Stevenson (2001) conclude that there is consistency across studies in finding a linear relationship between preoperative state anxiety and postoperative mood. A somewhat smaller degree of consistency is reported for the association between preoperative anxiety and other recovery variables. The authors use this finding to highlight methodological problems of these studies that prevent any firm conclusions to be drawn as yet.

Although the number of studies employing physiological recovery indices is relatively small, there is some compelling evidence for a positive relationship between preoperative self-report measures and postoperative immune function. Linn *et al.* (1988) assessed the relevance of differences in preoperative pain tolerance and stress to postoperative immune function. Physiological responses to a cold pressor test were measured the day before surgery in 24 men undergoing hernia repair. After controlling for preoperative immunological values (as well as age and social support) lymphocytes from men who reported more recent stressful life events had lower proliferative responses to an antigen (Phytohemagglutinin, PHA). In addition, high responders to the cold pressor test (i.e. a lower pain threshold) had significantly lower proliferative responses to a pokeweed mitogen after surgery (i.e. impaired immune function). They also required more pain medication and had more complications.

Across a number of studies, greater self-reported anxiety is typically related to more severe postoperative pain. In addition to direct effects on endocrine and immune function, the greater pain sensitivity of more anxious patients can have further consequences for recovery through altered behaviour. Breathing exercises, for example, can reduce the risk of pneumonia, and ambulation decreases the risk of phlebitis and may improve wound healing (Kehlet, 1997). Highly anxious patients may be more reluctant to follow recommendations for coughing, deep breathing or walking.

Personality variables may moderate post-surgical outcomes via their influence on stress, mood and coping (Mathews & Ridgeway, 1981). For example neuroticism as assessed by the Eysenck scales, has been shown in many studies to be associated with poorer surgical outcomes, such as increased postoperative pain and medical complications. Scheier *et al.* (1989) assessed the effect of dispositional optimism on recovery from coronary artery bypass surgery. After controlling for a number of confounds (extensiveness of surgery, severity of disease, smoking, hypertension, high cholesterol) the authors found that compared with pessimistic men, optimistic men fared better on perioperative physiological variables; they also began walking faster after surgery, and rehabilitation staff rated them as showing a more favourable physical recovery.

In summary, there is increasing evidence from psychoneuroimmunological work that stress and pain have a negative effect on endocrine and immune function and may thereby lead to delays in wound healing and other clinical complications. Although wound healing is only one postoperative outcome among a whole range, it is certainly a central parameter for short-term outcome in recovery from surgery. Kiecolt-Glaser *et al.* (1998) offer a bio-behavioural model suggesting a number of routes through which psychological and behavioural responses can influence surgery and postoperative recovery (See 'Psychoneuroimmunology').

Psychological preparation for surgery

Most patients cope with preparations for stressful and potentially painful medical procedures as well as they can. However, the evidence reported in the previous sections of this chapter suggests that this coping ability might be compromised by a range of factors such as preceding life events, personality characteristics, demographic variables such as age and gender and previous unfavourable experiences with such procedures.

Efforts to design interventions to help surgical patients with their coping can be traced back more than four decades. Studies have investigated a diverse range of intervention techniques on equally diverse outcome measures.

Types of pre-surgical interventions

The provision of information of some kind concerning the surgical experience has perhaps been the most frequently employed. There are two types of information provision that can be distinguished; procedural information and sensory information. While the former describes the procedure and sequence of events in more detail, the latter places the emphasis on informing the patient about the sensations which they are likely to experience, e.g. nature, site and duration of pain after surgery etc. Another related intervention gives patients instructions on the behaviours they should engage in order to promote recovery (e.g. breathing, coughing, walking, eating etc.). This group of interventions is usually referred to as behavioural instructions. Although both information provision interventions are thought to act through the same mechanism of anxiety reduction, there is evidence that sensory information may be more effective by creating a 'cognitive map' within which to locate subjective (pain) experiences. It is difficult, however, to prove these claims in the context of preparation for surgery as many researchers in this area have designed interventions that contain mixtures of these three treatments.

Other, less frequently used interventions include cognitive techniques to help the patient re-appraise the surgical situation in a more positive (adaptive) way, relaxation techniques (progressive muscle relaxation, breathing techniques), hypnosis and emotion focused/psychotherapeutic interventions.

There is not only heterogeneity in interventions used but also in the way they have been delivered. Some studies use a group format, whereas others rely on low cost alternatives such as booklets, manuals, audiotapes and videotapes (e.g. Doering *et al.*, 2000). It may be worth noting, at this point, that most interventions are

remarkably brief: the majority of studies employ a single session with an average duration of 30 minutes (Devine, 1992).

While being critical of the methodology of some of the studies included, several major literature reviews (e.g. Mathews & Ridgeway, 1984) and meta-analyses (e.g. Mumford *et al.*, 1982; Johnston & Vögele, 1993) are in broad agreement that prepared patients have better postoperative outcomes. In most cases 'better outcome' would relate to statistically significant differences between the group of patients receiving the preparation and an unprepared control group. Contrada *et al.* (1994), however, argue on the basis of several meta-analyses that these differences are not only statistically but also clinically meaningful. Depending on the meta-analysis, 60–75% of prepared patients had better outcomes than untreated controls, and the size of the improvement was in the order of 20–28%.

As to the question how psychological preparation for surgery promotes recovery two classes of explanations can be distinguished. The first set of assumptions stipulates that the physiological changes accompanying stress reduction resulting from psychological preparation (e.g. reduction in sympathetic arousal) improve patients' immunological responses (Kiecolt-Glaser *et al.*, 1998). There is evidence that interventions that alter appraisal, coping and/or mood may modulate immune and endocrine function (Kiecolt-Glaser & Glaser, 1992; Manyande *et al.*, 1995). An alternative explanation suggests that preparations exert their effects by reducing the frequency and extent of maladaptive behaviours that an unprepared patient might engage in (Mathews & Ridgeway, 1984). These two explanations are not mutually exclusive and can be subsumed under the biobehavioural model described by Kiecolt-Glaser *et al.* (1998).

Individual differences and psychological preparation for surgery

As discussed in the previous section, personality variables have been shown to moderate postoperative recovery via their influence on stress, mood and coping. Such individual differences may also be important in moderating the effects of psychological preparation for surgery, in particular in the area of preferred styles of coping with threat. For example, patients with a vigilant coping style (monitors) scan for threat-relevant cues, whereas those with a more avoidant coping style (blunters) try to distract themselves from threat cues. The two types of patients appear to show better adjustment in clinical settings when interventions are tailored to their coping style (Miller, 1992). Monitors fare better with voluminous sensory and procedural information, whereas the opposite is true for blunters (Prokop *et al.*, 1991).

Outcomes

In view of the heterogeneity of interventions, intervention formats, surgical procedures and the potential of individual differences to interact with treatment outcomes, the results achieved by psychological preparation for surgery are surprising and speak for the robustness of the effect.

The question remains, however: effective in gaining which benefits? It would also seem important to establish if all forms of

preparation are equally effective. There are different reasons for an outcome to be valued. In a meta-analysis of the literature on preparing adult patients for surgery (Johnston & Vögele, 1993) the authors examined which benefits were sought, whether they were achieved and whether all benefits were equally likely to be gained by psychological preparation. They grouped outcomes in eight categories: negative affect; pain; pain medication; length of stay; behavioural and clinical indices of recovery; physiological indices; and satisfaction. The most important conclusion to be drawn from this analysis is that prepared patients show significant improvements in all outcomes analyzed. Given the heterogeneity in the data analyzed, the consistency of these results seems impressive. They are certainly sufficient to offer useful guidance to the medical or nursing staff or managers of a surgical unit attempting to improve outcomes for patients having routine, elective surgery under general anaesthesia.

In relation to interventions used, procedural information and behavioural instructions were found to be clearly effective in improving all eight outcomes. Relaxation is also highly effective, showing benefit on all outcomes except behavioural recovery, although this has been investigated in a number of studies. The results for cognitive interventions suggest that this type of preparation may have a specific effect on negative affect, pain, pain medication and clinical recovery, but not on length of stay in hospital, behavioural recovery, or physiological indices (see 'Cognitive behaviour therapy'). It is plausible to assume that these interventions affect a negative affect/symptom complaint dimension, but do not affect physiological or behavioural measures. Finally, it was found that sensory information, hypnotic and

emotion-focused approaches to be rather less effective in improving outcome. However, these interventions have been explored in fewer studies and the procedures may be less well developed. In a more recent study comparing the effects of structured attention, self-hypnotic relaxation and standard care in a group of patients undergoing percutaneous vascular and renal procedures (angiographies) hypnosis had more pronounced effects on pain and anxiety reduction (Lang *et al.*, 2000) (see 'Hypnosis').

Implications for research and practice in the future

As a consequence of technical advances in medicine and surgery, many operations are less invasive than in the past. They are, therefore, increasingly performed on an outpatient basis, or with a greatly reduced hospital stay. Kehlet and Wilmore (2002) estimate that in the future most elective surgical procedures will become day surgical procedures or require only one to two days of postoperative hospitalization. In addition to this development, the introduction of managed care in the healthcare systems of many countries has led to a further shortening of length of hospitalization. With any extended convalescence at home, family members or carers play a more important role. The additional demands that are placed on carers of surgical patients recovering at home should not be overlooked. Future developments should address these issues in research and in the design of flexible interventions that take into account the psychosocial context in which they take place.

Teaching communication skills

Angela Hall¹ and Jane Kidd²

¹University of London

²University of Warwick

Background

The prevailing view in medicine that communication skills improve with practice and experience was challenged by the seminal studies published by Maguire and colleagues between 1976 and 1986. The traditional apprenticeship model of learning how to elicit information from patients was shown to have serious deficiencies. Few students managed to discover the patient's main problem or clarify its exact nature, let alone explore ambiguous statements, respond to cues or cover personal topics. Students who then underwent a

training programme reported almost three times as much accurate and relevant information as the control group. A sub-sample of these students was followed up five years later to see whether their skills had persisted: both control and trained groups had improved, but the superiority in the skills associated with accurate diagnosis in the group given feedback was maintained. Both groups were poor at giving information, although this was something that these doctors were doing on a daily basis. Skills associated with information-giving had not in fact been taught to these doctors while they were undergraduates.

During the same period of time evidence was accumulating for the importance of effective communication, not only for participants in the consultation but also for the health service (see 'Healthcare professional-patient communication'). For patients, effective communication was associated with enhanced satisfaction (see 'Patient satisfaction'), enhanced adherence (see 'Adherence to treatment'), and improved health outcomes. For doctors, effective communication was associated with reduced burnout, enhanced functioning and fewer complaints and litigation. Finally, for the health service, effective communication was associated with shorter stays in hospital and less waste of drugs.

In acknowledgement of these sorts of finding, the General Medical Council in the UK has encouraged all medical schools to include the teaching of clinical communication in undergraduate curricula (1993; 2002). With the impact of modernizing medical careers and the development of new roles for junior doctors with competency-based assessment, communication skills teaching and learning continues in the postgraduate years as well (www.mmc.nhs.uk; Department of Health, 2004).

A literature review conducted by Aspergren (1999) confirmed that communication skills in medicine can be both taught and learned. Eighty-one of 180 studies fulfilled the criteria for having a high or medium methodological standard; only one study failed to show positive changes in skill following a teaching intervention. Not only did these studies demonstrate that communication skills can be learned, they also illuminate our understanding about appropriate learning methods. Learners require a framework that explicitly identifies what areas should be covered and what skills they should use. Effective learning also requires opportunities for students to be given systematic feedback on how effectively they communicate with their patients. Evans *et al.* (1989) demonstrated that didactic methods alone are not sufficient to bring about change in learners' skills. There is a place for didactic or cognitive methods, in particular, introducing conceptual frameworks through which to view the medical interview and to stimulate interest and expand the understanding of learners. There is overwhelming evidence however, that it is experiential methods of teaching that bring about lasting behavioural changes in the clinical setting. These include direct observation of the learners interviewing each other, simulated or real patients, the provision of appropriate and constructive feedback, and the facilitation of practice and rehearsal in a safe and supportive environment.

Introduction

Effective doctor-patient communication contains three categories of skills (Silverman *et al.*, 2005): those that reflect the content of a consultation (what to ask and what to provide information about), those that reflect the process (how to do it); and those that reflect the perceptual skills (awareness of the impact of certain skills and how they affect self and patient). All three sets of skills are essential in enabling a consultation to be effective for both the doctor and the patient (see 'Medical interviewing'). This chapter is going to focus primarily on the teaching and learning of the process skills.

We will start by identifying challenges for tutors as students enter medical school, looking at the effect of their prior learning. The chapter will continue by exploring the needs of undergraduate

and postgraduate learners and then consider curriculum development with these needs in mind. Some models of the doctor-patient consultation will be identified as well as teaching approaches that have been shown to be effective. The chapter will close with an overview of assessment and draw some conclusions.

Challenges

There are particular challenges for students starting medical school which need to be recognized and understood by tutors. There can be few medical schools that do not consider students' ability to communicate as a key element of the selection procedure. Students are aware of this, yet when they arrive, they are required to reflect and analyse how they communicate. What is more, they are being asked to do this in what for most is a completely new context, i.e. medicine. Importantly, they are required to communicate in a professional manner which may be rather different to the way in which they normally interact with people. Even something as basic as explaining to a patient the reason why they wish to carry out a clinical interview is potentially fraught. 'A quick chat' is something that students may have with their friends, but employed in a clinical setting as an explanation, hardly conveys the purpose of the interview. It is small wonder that students may feel awkward and uncomfortable during sessions early on in the curriculum and need explicit acknowledgement of the expertise they already possess and the context in which that expertise is valued, in order not to feel de-skilled.

Needs of undergraduate and postgraduate learners

Students enter medical school with certain ideas and perceptions of themselves that may need to be reviewed in terms of effective doctor-patient communication. People who are learning skills can be working at one of four levels which are shown in Box 1.

Whether in the undergraduate or postgraduate arena, it is important not to make assumptions about the level at which a learner is

Box 1. Competence Learning Model

Unconscious incompetence	The person is not aware of the existence or relevance of the skill area. The person does not know what s/he does not know. The learner is in a state of 'blissful ignorance'. Confidence exceeds ability.
Conscious incompetence	The person becomes aware of the existence and relevance of the skills and also aware of their deficiency in this area. Confidence reduces with the realization that ability is limited. Practice is essential to learning.
Conscious competence	The person achieves 'conscious competence' in a skill when they can perform it reliably at will. The person needs to concentrate and think, in order to perform the skills.
Unconscious competence	The person can perform the skills but does not necessarily know how s/he does it – it becomes second nature.

www.businessballs.com/consciouscompetencelearningmodel.htm

functioning. These stages are not age-dependent and not all qualified doctors are working at the level of unconscious competence. There is a wide variation in knowledge and competence across the spectrum from initial entry to medical school through to consultant. The learning styles of learners need to be taken into account as well as where they sit on the spectrum between pedagogy (where learners are perceived to be dependent) and andragogy (where learners are perceived to be self-directed) (Knowles, 1990; Grow, 1996). For both undergraduates and postgraduates, it is necessary on occasion to revisit basic skills in order to identify that these are still in place and then to allow the learner to move forward by building on these in a helical type of model.

We need to ensure that for all learners there is a clear link to application: for junior medical students who spend most of their time in medical school, this is often more difficult to achieve than for more senior students and practising doctors. However postgraduate learners who are attempting to gain technical competence in dealing with disease, to develop their professional identity and to learn how to heal, can also at times find this difficult.

Undergraduate and postgraduate learners may differ in terms of having experienced different models of feedback and having experienced a wider range of consultations with patients. Initially a more prescriptive type of feedback may be beneficial to the learner, using guidelines such as those developed by Pendleton *et al.* (1984). With more experience of patients and particularly of challenges faced on a daily basis, postgraduate learners are often more able to identify where their own strengths and difficulties lie in terms of effective doctor-patient communication. They are thus more able to state what it is they would like feedback on and work with the more appropriate agenda-led outcome-based analysis (ALOMA) model of feedback described by Silverman *et al.* (1996).

Curriculum development

Many medical schools have now adopted a helical approach to the learning of communication skills referred to earlier and first described by Dance (1967). The helix conceptualized an important theoretical principle underpinning how we communicate, namely that effective communication depends on interaction between sender and receiver and, crucially, depends on both the giving and receiving of feedback about the impact of the message. Communication gradually evolves in a spiral fashion and demands both reiteration and repetition to become effective. The concept of the helix has been widely used by medical educators, as well as those working in the field of communication. Simply put, the communication curriculum should allow learners to 'review, refine and build on existing skills while at the same time adding in new skills and increasing complexity' (Kurtz *et al.*, 2005). The model emphasizes that people learn in a spiral rather than a linear form. The curriculum should be delivered not as a series of isolated sessions or modules, but as opportunities for learning, review and challenge as learners move to higher levels on the helix.

Educators themselves face considerable challenges when developing a communication curriculum. In a thoughtful editorial, Cushing (1996) makes the point that the relationship between the components of the curriculum, and when and how they are taught, is crucial. The worst message that can be given to students is that

communication skills are a soft add-on to the 'real' curriculum. To avoid this, teaching needs to be integrated into the curriculum as a whole and made relevant to what students are learning elsewhere in their course.

There are many creative ways in which integrated teaching and learning can be achieved. With the change in many schools from traditional, didactic, lecture-based courses towards problem-based learning, the clinical content of communication sessions can be determined by the paper problem of the week or the system being learned. Communication issues can be flagged up for discussion in tutor notes. Content can also be determined by what is expected of students on their general practice, community and hospital placements. Thus, some sessions can specifically prepare students for visits or for clinical attachments. Explicit integration with other specialisms, such as medical statistics, helps students appreciate the relevance of aspects of their curriculum to clinical practice (Sedgewick & Hall, 2003). Finally, the active involvement of practising doctors in the teaching of process skills gives a powerful message to students about the importance of communication and how it fits into medical practice.

There are other aspects of effective communication that need to be included in the medical curriculum. Written communication is one of the principal ways in which healthcare professionals communicate with each other and at the very least students need to know how to write notes, discharge summaries and referral letters (Nestel & Kidd, 2004) (see 'Written communication'). They also need to know how to present their patients to senior colleagues with a clear, succinct and relevant summary. The value of integrating teaching communication and clinical skills is also beginning to be addressed (Kidd *et al.*, 2005).

Models of the medical interview

In teaching and learning about communication, two types of model are important. There are models (or frameworks) for the consultation and there are role models, the current practitioners of doctor-patient communication.

Models of the consultation are important as they provide a structure that can help the learner to understand that the medical interview has an internal logic with a beginning, a middle and an end. Different phases or stages of the interview have different functions and there is a range of skills that can be utilized to achieve these functions. Many models of the consultation have been proposed over the past 30 years (Stewart & Jones, 1991; Stott & Davis, 1979; Byrne & Long, 1976; Heron, 1975; Helman's 'Folk Model', 1981).

Since 1984, models have been developed that describe specific stages, functions or tasks in a consultation. Each of the models listed in Box 2 divides the consultation into stages, tasks, or areas to be explored. They identify objectives for each stage and the skills that can help the doctor to meet those objectives.

Even a quick glance at these models shows the reader that there is a lot of similarity in terms of the stages and functions identified as elements of an effective consultation. When the authors begin to describe the skills associated with effective communication for each stage or task, there is again a high degree of consistency between models.

Box 2. Models of the Medical Interview*Pendleton et al. (1984)*

1. Define the reason for the patient's attendance
2. Consider other problems
3. With the patient, choose an appropriate action for each problem
4. Achieve a shared understanding of the problems with the patient
5. Involve the patient in the management and encourage him or her to accept appropriate responsibility
6. Use time and resources appropriately
7. Establish and maintain a relationship with the patient which helps to achieve other tasks

Neighbour (1987)

1. Connect – establish rapport with the patient
2. Summarize – discover why the pt has attended and summarize back
3. Hand over – agree agenda for consultation
4. Safety net – explore options for each item on agenda
5. Housekeep – Check on 'self' before seeing next patient

Disease-Illness Model (McWhinney, 1989)

This model concentrates on the task of gathering information and suggests that doctors need to explore two parallel frameworks: the disease framework of the doctor and the illness framework of the patient. In this way this model introduces new content to information-gathering from the patient's perspective

The Three-Function approach to the medical interview (Cole & Bird, 2000)

1. Develop rapport
2. Gather data
3. Educate and motivate

The Calgary-Cambridge Approach to Communication Skills Teaching (Kurtz et al., 2005)

This model identifies five sequential tasks to a consultation:

1. Initiating the session
2. Gathering information
3. Physical examination
4. Explanation and planning
5. Closing the session

and two continuous tasks:

1. Providing structure to the consultation
2. Building the relationship

However, it is perhaps the models who the learners see in action, i.e. the current practitioners, who have the most influence on the skills that the learners perceive to be important and put effort into learning. This modelling works at three levels. First, learners observe their more senior colleagues communicating with their patients and can pick up on the skills that they see being used. At the second level, they are also learning what their role models consider

important, through the topics that are chosen for discussion related to the consultation. Is the discussion always on the content of the history, physical examination and problem solving or are the process skills and the patient's perspective included in the discussion? At the third level medical students learn from observing how their role models interact with all the people around them and how they themselves are treated. If learners feel valued, they are far more able to reflect that in their relationship with patients (see also 'Medical interviewing').

Teaching methods/approaches

An effective communicator needs at the very least to have a body of knowledge, a set of skills and an appropriate attitude. To be an effective communication skills tutor one needs a parallel set of knowledge, skills and attitudes related to education, coupled with a set of tools to move learners from the level of unconscious incompetent practitioner to that of unconscious competent practitioner. Good tutors are genuinely facilitative and behave towards their students as they would in turn wish the students to behave towards their patients. There are many parallels in the relationship between teachers and learners and between doctors and patients. Characteristics of competent trainers are listed in Box 3.

Moving learners from the stage of unconscious incompetence to conscious incompetence requires introduction to cognitive material in terms of a framework, identification of skills (naming skills) and evidence of effectiveness on which learners can reflect. Such material can be delivered effectively in interactive lectures or during

Box 3. Characteristics of a competent trainer**Knowledge**

Understands basic teaching methods
Understands effective communication skills (why they work, what impact they have)

Skills: ability to

use a range of teaching tools
use effective communication skills
observe keenly
analyze effectively
provide constructive feedback
foster reflection in the trainee

Attitudes

Has respect for the trainee
Has an interest in the trainee
Gives latitude to the trainee
Is available for consultation
Flexibility
Enthusiasm
Self-insight

(Amended from Boendermakers *et al.*, 2000)

group work. However, as identified earlier in the chapter, the evidence points to the need to work with experiential learning methods to enhance the skills of learners. Most communication skills learning takes place in small groups or on a one-to-one basis, which greatly enhances a feeling of safety for learners when they are in the hands of a competent trainer. Hutchinson (2003) has written an excellent and sympathetic chapter on creating an optimal context or climate for learning.

Kolb's learning cycle (Kolb, 1984) describes one way of conceptualizing how people learn skills. It has four main components: concrete experience, followed by reflective observation, abstract conceptualization and finally active experimentation. Learners carry out an interview (the concrete experience) before having the opportunity to comment on it (reflective observation) prior to considering what it might mean for them and their patient (abstract conceptualization) and deciding what it is they might do differently the next time (active experimentation).

The theory of reflective practice developed by Schon (1983) throws useful light on the reflective process in learning and its relationship to the acquisition of competence. He identifies 'reflection *in action*' as the ability to learn and develop by applying past experience to unfamiliar events as they are occurring. Observing reflection in action is one of the most rewarding experiences for tutors, as students actively demonstrate what they have learned. 'Reflection *on action*' takes place after the event and corresponds to Kolb's 'reflective observation'. Building in the opportunity to reflect is a crucial part of becoming an effective communicator, in particular because it encourages reflection on both the attitudes and the feelings of the learner.

How can we reflect the learning cycle in terms of education about effective communication? What tools do we have to work with and what are their benefits and drawbacks? There are three main experiential approaches: role-play with colleagues; working with simulated patients; and working with patients. We describe each briefly.

Role-play between peers

This process may well be one of the most misused approaches in health professional education. There is an assumption that learners can take on a role with minimal or no preparation and learn from it but this is far from the case. For such an experience to be successful with inexperienced learners, detailed attention has to be given to the questions in Box 4.

With this level of preparation learners are less likely to have difficulty in getting into role because they know their 'patient' too well and all they can do is giggle or feel so embarrassed that their performance is inhibited.

Role-play with simulated patients

Simulated (standardized) patients have been used successfully in learning and assessment settings since the early 1960s (Barrows & Abrahamson, 1964). Simulated patients are a valuable resource in the teaching of communication skills. They work with the facilitator and the learner or learning group, playing live simulations of both a clinical problem and communication challenges appropriate and

Box 4. Questions about using role-play in teaching sessions

How role-play fits into a teaching session

- which learning outcome is it designed to meet?
- what is the objective of the interview?
- what is the precise role of the interviewer? (is s/he playing him/herself, or a different role?)
- what is the precise role of the 'patient' (both in terms of the presenting problem and the character of the patient)?
- how much time is allocated to the exercise?
- how is that time divided between role play and feedback?
- how will the learner be given feedback on his/her performance (verbal, written, checklist, global)?
- will the learners work in trios so that there is an observer for every interview?
- will every learner have the opportunity to play the interviewer, the patient and the observer in turn? (if learning about receiving and proving feedback is a session outcome then designing a session with an observer is essential)
- will the learners work with the same role for each interview or will new roles be provided?

relevant to learners' needs. Simulated patients are members of the public who have an interest in medical education. They may come from different backgrounds: many are professional actors but some are members of the local community who are able to portray roles that do not reflect their own real-life experience.

Much has been written about the benefits of working with simulated patients (e.g. Kaufman *et al.*, 2000; Madan *et al.*, 1998; Stillman *et al.*, 1990). One of the major benefits for learners is that it does not matter if they make mistakes, as there are no adverse consequences for the patient. Working with simulated patients allows the learner to rehearse skills time and time again, to try new skills and approaches, to receive constructive feedback, to explore feelings associated with the behaviour of the simulator and its impact on the learners and vice versa. At the same time the simulated patient can improvise (be learner-centred) to the level of the challenge that the learners want, which may be in terms of skills they wish to practise (e.g. empathy, reflection, picking up cues), a difficult situation (e.g. breaking bad news, working with an interpreter) or the type of character they would like to practise interviewing (e.g. angry, distressed, talkative).

For simulated patients to be of maximum benefit to the teaching of clinical communication, a selection and training programme needs to be in place. Not everyone who wants to participate in sessions as a simulated patient has the necessary qualities: the ability to play a role, reflect on it while it is happening in order to identify why they are reacting to the 'doctor' in the way that they are, and then phrase that feedback constructively to the learner. It is essential that during feedback, the simulated patient reinforces the tutor's teaching messages. Some learners have difficulty with simulated patients in that they perceive them as 'not real' or that they are 'being set up'. With appropriate introduction and honesty between trainer and trainee these perceptions can be minimized and overcome. Guidelines for introducing and setting up a simulated patient role-play are given in Box 5.

Box 5. Introducing simulated patient role-play

- Discuss the scenario and interviewer task with the group
- Brainstorm any clinical information that might be needed
- Ask for a volunteer (or more than one and share the interview)
- Discuss objectives – ask the learner what they want to achieve
- Any challenges? Any strategies? (these can be discussed with the group)
- Ask the learner to decide on a few things they would like feedback on
- Allocate specific feedback to each group member – ask them to write comments down and be able to give verbatim quotes
- Flag up to the learner that they can stop at any time during the scenario and take time out to discuss what they would like to do next
- Negotiate how long the interview will be (make it clear that they should only get as far as they can in the time, not necessarily get to the end)
- Flag up that at the end of the interview, the learner comments first on how it went

Working with patients

There are several ways in which to gain access to this rich resource. Learners at both under- and postgraduate level can videotape their interviews with patients on the wards or in outpatient clinics, to review later with their tutor. They may also carry out the same exercise in general practice and video an entire surgery from which to select material for review. From the learner's perspective, the great advantage of working with a patient is that they are real. From the educator's perspective, the advantage is that learners can be observed at the performance level of Miller's 'pyramid of assessment' hierarchy (Miller, 1990).

Medical schools involve real patients through volunteer programmes and community programmes. These are patients who are willing to come into the medical school and be available for students to elicit their history, in full or in part. Patients can be selected for given sessions on the basis of having a particular condition or experience. Increasingly schools are setting up programmes to support and train patients to give feedback to learners, which enhances the experience for both sides. Patients can also help students' learning by allowing filming of their consultation with an experienced doctor, so that students can subsequently observe and give feedback about both the content and process skills of the interviewer. Capturing appropriate material can be time-consuming but is worthwhile, because students respond so positively to the real thing.

It is very important to pay attention to how patients have been invited to participate in teaching: taking care to elicit properly informed consent is crucial. Patients need to be very clear about the purpose of the exercise and not be constrained by power imbalance. Their concerns should be addressed about whether refusal might have an impact on their treatment and care. Tutors need to be aware of the possibility of patients feeling coerced and this also applies to opportunistic approaches for bedside or outpatient teaching.

Without training, patients are not usually in a position to give constructive feedback nor is it usually possible to rehearse skills or ask the patient 'could I try that again?'. However, the benefits of working with real, carefully selected patients, usually far outweigh these constraints.

Videotaping

All three of the above experiential learning opportunities can be enhanced if it is possible to video-record the consultations. Videotape is a powerful tool for self-observation and enables learners to make detailed and accurate assessments of themselves. Learners do not have to rely on reflection alone but can observe and hear themselves in action and identify their own strengths and weaknesses. Recordings can be looked at over time to review learning goals and track progress.

Some learners have difficulty with the idea of being video-recorded, and as with the use of role-play, this may be related to a previous poorly structured learning experience. In such cases the tutor needs to work with the individual to determine their barriers to working in this way. It can be helpful to discuss the benefits that such an experience can bring, identifying that feedback will be constructive (not humiliating), re-emphasizing the formative nature of the experience and who will see the video-recording.

As we have seen, reflection on performance is a key aspect of learning how to be an effective communicator in the clinical context. It is particularly useful to be able to revisit exact points in an interview and discuss them without disagreement about whether recall about what happened was accurate. Although more complicated to set up and manage, videotape is superior to audiotape because it provides an unparalleled opportunity to observe non-verbal communication.

Assessment

Care and thought should be given to the assessment of skills. Measurement of knowledge, skills and competencies has always been an essential part of medical education. However, both reliability and validity were frequently compromised in traditional long and short cases; to measure skills reliably, performance of candidates has to be sampled across a range of problems. The Objective Structured Clinical Examination (OSCE) was introduced more than 30 years ago as a flexible format to administer assessment (Harden, 1979) and is based on a circuit around which all candidates rotate. In this way all students can be tested on a number of patient-based problems and all carry out the same tests. This assessment format is now used by many healthcare professionals at both under- and postgraduate level. For those who wish to know more about the OSCE, including its limitations, Smee (2003) has written a succinct introduction. From this chapter's perspective of teaching communication skills, it is essential that OSCE stations assess skills that have been taught to all students, reflected in the learning objectives for the curriculum.

Conclusion

There is much evidence that skills for effective communication in clinical practice can be taught, learned and will persist, given the

opportunity for practice, reflection and feedback. Understanding what the skills are and appreciating their effectiveness smoothes the path for learners as they make the transition to competent practitioner. The skills are the building blocks or tools. Students need to learn not only the skills themselves but also how to select those appropriate to the individual and for the task in front of them. In the same way that patients always bring the psychosocial dimension of their illness to the medical interview, so learners bring their own

attitudes, values, feelings and personal history, which play out in their behaviour. Attitudes influence skills and skills acquisition can lead to changes in attitude. Paying attention to both increases understanding, insight and job satisfaction for both learners and their teachers.

Written communication

Lorraine M. Noble

University College London

This chapter considers two domains of written communication in health care: (1) written information *for* patients, and (2) written information *about* patients.

Written information for patients

What is it for?

Written materials are used:

1. to provide information, for example, about investigations, screening, health promotion, diagnosis, prognosis, treatment and aftercare (e.g. discharge planning)
2. to aid decision-making, for example, about investigations, treatments or screening, or as part of a process to obtain a record of informed consent to treatment or a clinical trial
3. to encourage uptake of healthcare (e.g. investigations, screening, or treatment)
4. to train patients to communicate more effectively in consultations with healthcare professionals.

When is it needed?

Studies have consistently found that the majority of patients want to be kept informed about their condition and treatment, and that they want more information than they are typically provided (Audit Commission, 1993; Benbassat *et al.*, 1998). In addition, many studies have shown that patients have gaps in understanding and recall following face-to-face consultations (Ley, 1988). Investigators have concluded that written information plays an important role in routine care, either to provide a reminder of what has been discussed or more detailed information.

Supplementary written information is also useful when there are problems which create barriers to the effectiveness of face-to-face communication, for example:

- i. when there are high levels of emotion (such as fear) or 'high stakes' consultations (e.g. serious illness)
- ii. due to the complexity or quantity of information (e.g. presenting statistical information about treatment options, or lists of medication side effects)
- iii. when communication is affected by patient factors (e.g. age, disability, cognitive impairments, language or cultural issues).

Research has indicated that patients are more passive in consultations than they intend to be, and that improving patient participation leads to improved outcomes (Harrington *et al.*, 2004). The

evidence suggests that interventions to facilitate patients' communication with professionals could be beneficial in routine care. This complements current practice in the training of health professionals, who receive skills-based teaching on all aspects of their communication with patients (see 'Medical interviewing' and 'Teaching communication skills').

What form does it take?

Information is usually given in the form of leaflets (either prepared locally or by organizations such as charities, government departments or companies), notes written by the health professional for the patient, or copies of letters or reports. Interventions have included booklets, prompt sheets and guidance for patients to make their own notes either before or during a consultation.

Increasingly, information is available online. Recent developments such as interactive healthcare applications have made use of technological advances by providing electronic fora for peer information-exchange and decision-support (Eng *et al.*, 1999).

Do written materials address patients' needs?

Problems with the quality of information provided for patients has been noted for written materials and online resources (Audit Commission, 1993; Eysenbach *et al.*, 2002). Patient focus groups have reported a number of problems with written information, such as omission of topics of importance to them, over-optimism, avoidance of uncertainty and lack of detail (Coulter *et al.*, 1999). Feedback from patients is not commonly sought when written materials are being prepared, despite the use of techniques such as lists of 'frequently asked questions'.

The literature on patient leaflets was examined by Dixon-Woods (2001), who identified two discourses: a 'patient education' theme, where patients are perceived as passive recipients of information and healthcare in general; and a 'patient empowerment' theme, which takes into account patients' priorities and promotes active participation in decision-making. Dixon-Woods argued that the majority of patient leaflets serve a biomedical agenda, by aiming to save time in the consultation, reduce staff boredom and promote behaviour changes desired by professionals (such as compliance and a reduction in consulting rates). Other investigators have concluded that written materials may serve professional or commercial agendas, such as encouraging an uncritical approach to treatment (e.g. Kenny *et al.*, 1998).

The use of written materials in line with a biomedical approach tends to assume that the provision of information acts as an 'end-point' in communication. For example, it is assumed that after

reading the information given in a medication leaflet, the patient then proceeds to take the medication. In practice, written information forms part of a more dynamic process. For example, patients may seek out written information as a means of enabling them to prepare questions to ask healthcare providers (e.g. Ehrenberger, 2001).

Coulter *et al.* (1999) made a series of recommendations for the preparation of written materials, which included involving patients throughout the process, being honest about uncertainty and risks, and educating clinicians about techniques to promote shared decision-making.

Is written information effective?

Ley (1988) noted that, in order to be effective, written materials must be noticed, read, understood, believed and remembered. Much research has focused on determining whether materials are understandable and whether they aid recall. A number of tests have been developed to assess the understandability of leaflets, such as readability indices (e.g. the Flesch Reading Ease formula or the SMOG Index), word familiarity indices and tests of comprehension (such as the Cloze technique) (e.g. Beaver & Luker, 1997). In addition, controlled trials have considered the effectiveness of different formats and presentation styles (for example, verbal compared with pictorial or graphical presentation).

The unanimous conclusion from these studies has been that written materials for patients are not understandable by the majority of the population. Furthermore, there are concerns more generally about the level of functional health literacy, defined as the ability of people to read, understand and act on health information (Andrus & Roth, 2002). It has been noted that people with 'low functional health literacy' also have difficulty with oral communication, and are therefore doubly vulnerable to not getting the information they need from healthcare providers (Schillinger *et al.*, 2004).

The focus on readability, comprehension and recall has been criticized as a simplistic approach to assessing the quality and utility of written communications, as it implies that problems with effectiveness are due to 'patient incompetence' (e.g. low literacy and forgetfulness), rather than the appropriateness of the information for the individual (Dixon-Woods, 2001). Conclusions from surveys of written materials inevitably recommend that information is kept short and simple, but this contradicts the consistent finding that patients want more detailed information (e.g. Coulter *et al.*, 1999).

Indices of effectiveness have varied, depending on researchers' conceptions of the purpose of written materials. Investigators have examined the effects of written information on outcomes including knowledge and recall; uptake of screening; anxiety; satisfaction; intensity of pain; appropriate prescription of medication; compliance with treatment plans; and promotion of an active role in decision-making (e.g. Johnson *et al.*, 2003; Miaskowski *et al.*, 2004; Davison *et al.*, 1999). The consistent finding from this literature is that written information in addition to normal care is superior to normal care. In addition, in studies where no positive effect on observable outcomes was reported (e.g. on knowledge or recall), investigators have noted that patients still appreciated being given written information.

Written materials used to facilitate patients' communication with professionals have mainly been used to encourage patients to

identify and verbalize their requests, problems and concerns. Whilst benefits in outcomes, such as patient question-asking, have been reported, generally the evidence indicates that written interventions are not as effective as interventions based on face-to-face coaching (Harrington *et al.*, 2004). This concurs with findings suggesting that other media can be equally or more effective in providing information. For example, studies have indicated that giving patients an audiotape of their consultation improves recall and decreases the need for repetition of information in subsequent consultations (e.g. Bruera *et al.*, 1999).

Do patients want written communication?

The consensus from the literature is that patients do want written information, but that they prefer information to be given by a person (e.g. Maly *et al.*, 2003; Wald *et al.*, 2003). Written information is perceived as a helpful addition to, but not as a substitute for, a face-to-face consultation with a health professional. This is partly explainable from the point of view of information flow: consultations are interactive, thus increasing the likelihood that information can be tailored to patients' needs. However, a consultation provides not only information, but a whole package of care, including a sense of reassurance and trust in a professional-patient relationship. That said, a recent initiative in Sweden giving free access to online consultations with a doctor was also found to be popular, with patients valuing the convenience and anonymity afforded (Umefjord *et al.*, 2003).

Individual differences have been noted in whether people actively seek written information (for example, on the Internet) or only access sources when specifically directed by health professionals. Overall, the literature suggests that there is no 'one-size-fits-all' model, i.e. that it is naïve to assume that a leaflet can be designed which meets the needs of all patients in a target population. Rather, written information should be given as part of a package which is tailored to the individual. Ideally, the health professional should go through written materials with the patient (Kenny *et al.*, 1998). Note that this approach does not assume that the aim of providing written information is to save time.

Is written communication based on psychological theories?

Much research has focussed on developing pamphlets, which are not theoretically driven, but rather created in response to a perceived clinical need to provide information and improve compliance. Although an underlying approach to the professional-patient relationship (e.g. biomedical, biopsychosocial, patient-centred) may be inferred from their content, these materials tend not to be tested for effectiveness using a psychological model.

However, some investigators have produced written materials (which include computer- and Web-based materials), specifically based on theories such as the Health Belief Model, the Transtheoretical Model, or message-framing (such as the use of 'threat appeals') (e.g. McKay *et al.*, 2004). Written materials which form part of an intervention package, such as self-management programmes, are more likely to be theoretically-driven, as such interventions have been routinely based on models such as

Social Cognitive Theory or Self-Regulation Theory (see 'Self-management' and 'Self-efficacy and health behaviour').

Written information about patients

What form does it take?

Letters, reports, medical notes, medication charts, as well as informal notes (known as 'scraps') which do not form a part of the patient's record, all have a significant role in the communication of information and delivery of care.

Is it good enough?

Problems with written communications result from:

- poor quality of information, for example, incomplete or inaccurate information
- systems failures in the transmission of information
- differences of opinion among professional groups about what is important to include in the communication
- alternative channels of communication being used.

Quality of care is affected by problems with written communication. Considerable attention has focused on medication errors (e.g. Benjamin, 2003), probably due to the salience of the written record in this aspect of care and ease of comparison with prescribing standards. However, close examination of any situation involving written communication can reveal deficiencies with implications for quality of care. For example, one study found that surgeons misunderstood pathologists' reports 30% of the time (Powsner *et al.*, 2000).

Increasingly, written communication skills are being taught and assessed in undergraduate and postgraduate medicine. However, this component of training curricula is relatively new and needs to include information about systems issues and multi-disciplinary communication in addition to training in medical record-keeping.

Do health professionals want written communication?

Whilst written communication is required in many aspects of service delivery, in practice it may be superseded by other forms of communication, or may play a smaller role than intended. Many studies have shown that professionals prefer oral communication (either face-to-face or by telephone), supplemented by written communication (e.g. Forrest *et al.*, 2000; Blankenship *et al.*, 1999). Furthermore, there is evidence that oral inter-professional communication can be more effective in achieving a result (Martin *et al.*, 2003).

As perceptions of the nature of the doctor-patient relationship have changed, there has been a corresponding attitudinal shift regarding medical record-keeping. Until relatively recently, there was an accepted stereotype of a 'heartsink' patient, who typically had a 'fat file' or who brought a list of questions. It is now more accepted for patients to keep a diary or record of symptoms to bring to a consultation, although there remains a variable response to

patients who bring written information to discuss or a list of questions.

How much are patients involved?

The increasing involvement of patients in their own care has been supported by a number of government initiatives regarding written communication, particularly changes to the law regarding patients' access to their own medical records. The right of access of persons to data about themselves has been established in the UK in the Access to Health Records Act 1990 and Data Protection Act 1998. Furthermore, the recent National Health Service Plan (Department of Health, 2000) directed that from April 2004, patients should routinely be offered copies of letters about themselves. However, professional reservations regarding patients' access to their own records have been repeated in the more recent debate about access to letters (White, 2004).

There have been many trials of patient-held records, particularly in services for cancer, antenatal and mental health care. However, it is likely that technological advances will supersede these initiatives. Current developments in electronic patient records (EPR) are expected in time to allow patients to access information held about themselves by all healthcare providers. This technology may include patient-held 'smart cards'.

Patients have the right, protected by law, to decide whether or not to have any given medical intervention, which includes investigations, treatment, screening or research. A written record of informed consent is expected in certain situations, for example, when the intervention is complex, involves significant risks, or is part of a research programme (Department of Health, 2002) (see 'Informed consent'). The 'consent form' documents the discussion with the patient. Professional guidelines note that obtaining consent is not an isolated event, but involves a continuing dialogue, and that a signed consent form is not sufficient evidence that a patient has given informed consent. However, problems with the process of obtaining informed consent have been reported. For example, studies have found that a third of patients do not understand the purpose of the consent form, and that the majority of patients sign the form without reading it (Lavelle-Jones *et al.*, 1993; Olver *et al.*, 1995).

A further area in which patients have been involved in preparing written documentation is advanced care planning. This takes place when a patient is expected at some future point to become incapacitated to the extent of being unable to express their wishes regarding treatment. In preparation for this, a patient's wishes may be documented in an advance directive (also known as a 'living will'). However, as with informed consent, there is a common misconception that the purpose of advanced care planning is to make a written document. In addition, differences of opinion between professionals and patients about the purpose of advanced care planning have been identified. Investigators have found that patients view it as more of a social process, involving their relatives, and with a wider remit than choosing among treatment options (e.g. preparing for death) (Singer *et al.*, 1998). Often patients regard the completion of a written document as unnecessary. Furthermore, there is evidence that increasing documentation of advance directives has not resulted in an increase in care which is consistent with patients' preferences (Covinsky *et al.*, 2000).

A specific aspect of advanced care planning which has caused much controversy is the documentation of 'do not resuscitate' (DNR) orders. A DNR order is written into the patient's medical notes to record the decision that interventions to attempt to sustain life should not be conducted (e.g. cardio-pulmonary resuscitation, CPR, in the event of heart failure). Traditionally, there has been considerable variability in whether DNR orders have been discussed with patients at all, and there remains considerable debate about the involvement of patients in this process (Biegler, 2003; Cantor *et al.*, 2003).

Conclusions

Written communication plays an important role in many aspects of health care, but it is best viewed as one part of a dynamic process involving other channels of information flow. The future of written information is electronic (e.g. online resources, electronic patient records) which should enable easier access to information and is intended to improve patients' involvement in their own care. However, it is important to remember that both patients and professionals prefer information to be given by a person.

Part II

Medical topics

Abortion

Pauline Slade

University of Sheffield

Abortion

Although induced and spontaneous abortion both involve the death of a fetus there are important differences in these experiences. In the former, pregnancy ends through an individual's choice while the latter is not because of, but often in spite of, the woman's and professionals' best efforts to save the baby. Women who have miscarried are often distressed by staff usage of the term 'spontaneous' abortion as this carries an unpleasant connotation and so this will be referred to as 'miscarriage' in this chapter.

Miscarriage

Up to 20% of recognized pregnancies end in miscarriage, defined as a pregnancy loss up to 24 weeks of gestation. Studies suggest that anxiety symptoms may be elevated for many months afterwards and a proportion of women may show depressive symptoms (Geller *et al.*, 2004). Miscarriage has been compared to bereavement but the process of coping may be complicated by the abstract nature of the loss and the absence of memories of an individual. The loss is often hidden as many women will not have shared the news of their pregnancy at such an early stage and the support that unpleasant events often generates, may be absent. Our society lacks ritual acknowledgement of miscarriage and the prevailing view is often exemplified by the phrase 'it was for the best'. A further aspect that is increasingly recognized is that miscarriage can be considered as a potentially traumatic experience. It clearly involves loss of life, and often fear, pain and loss of blood (Lee & Slade, 1996). Many women do report elements of involuntary reliving of aspects of the experience and attempts to avoid reminders. The woman may also subsequently have fears about her future fertility and there is evidence that anxiety symptoms are elevated in subsequent pregnancies even though the risk of miscarriage is not itself increased (Geller *et al.*, 2004). The impact on the relationship between the expectant parents is increasingly recognized (Swanson *et al.*, 2003). The evidence is generally that impact on the male partner is less significant than for the woman although this is disputed by Conway and Russell (2000). There is a need, however to consider the partner's loss in its own right. Earlier work has tended to consider only the potential support he could provide to the woman.

Whilst demographic factors or aspects of the event have been suggested as being linked to the impact of miscarriage it is recognized that it is the personal meaning to the individual that is primarily important. Viewing this in a stress and coping framework (Lazarus & Folkman, 1994) is probably most useful. In this context, emotional responses are influenced by the appraisal of the event in terms of its meaning, which is potentially balanced by the

appraisal of coping in terms of factors such as individual resources and social support from others (see 'Stress and health').

Coping is also likely to be influenced by the quality of care provided. For medical and nursing staff, miscarriage can be viewed as a routine and/or trivial event. Such a mismatch of perceptions between the staff and patients can lead to care being experienced as insensitive (Evans *et al.*, 2002). One aspect of care that seems to be particularly important is that women should be given the news about viability or non-viability of their pregnancy as soon as this is available, that is at the scan, rather than after a protracted wait. They should be given the news in circumstances of privacy, in a sensitive manner and also provided with an opportunity to talk with appropriately trained staff about their feelings and concerns (see 'Breaking bad news'). In addition, women express a need for information about potential physical and emotional consequences together with an opportunity to discuss these issues at a follow-up appointment two to three weeks after the event. There is evidence that psychological counselling in combination with medical follow-up is potentially beneficial: the value of such services is now established (Nickevic, 2003) although unfortunately not routinely available.

It is also important to recognize that miscarriage should not just be considered as 'a pathway to pathology'. Qualitative studies have identified positive growth experiences in terms of impact on the couple's relationship, and reevaluation of life values and goals that may facilitate wellbeing (Maker & Ogden, 2003).

Whilst there is no evidence to suggest that low mood contributes to the occurrence of first miscarriage (Nelson *et al.*, 2003), there are tentative suggestions that this may increase risk in those with recurrent abortion (Sugiura-Ogasawara *et al.*, 2002). High emotional distress in the 1% of women who may experience three or more miscarriages has been linked to cognitive processes such as degree of investment in the parenting role and low levels of non-child-related positive thoughts (McGee *et al.*, 2003). These factors lead to the potential for cognition-focused interventions should the impact be severe, although few intervention studies are available.

Induced abortions

Countries differ in the legal limit for induced abortion. The legal situation in Britain is now governed by the 1990 amendment of the 1967 Abortion Act. This provides an upper time limit of 24 weeks gestation for most abortions, but there is no time limit if there is a risk to the life of the mother, risk of grave permanent injury or serious fetal handicap. Termination takes place within an evolving socio-political context. The rate of termination of pregnancy in the UK has been rising and there is particular concern about the number of women

undergoing repeat terminations. There is also debate about the capacities of the fetus, its ability to feel pain and consequent unease about the paradox of babies born within the window for termination surviving through technological developments in neonatal intensive care. Alongside these factors within the UK there is evidence that social attitudes towards abortion in general have become more liberal between 1990 and 2000, possibly as its use has become more commonplace (Scott, 1998). The social acceptability and indeed the legality of abortion varies considerably within different societies. It is likely that the emotional consequences of the process may be significantly influenced by cultural values.

In terms of the processes involved, pregnancies of less than 13 weeks (the first trimester of pregnancy) may be terminated via surgical or medical means. The former typically involves a general anaesthetic and evacuation of the contents of the womb by suction. The latter involves the administration of prostaglandins to trigger contractions of the uterus. In medical abortion, the woman is conscious throughout, may see the fetus and the process may be protracted.

At later stages of pregnancy the woman is also likely to involve a hormonally induced labour. Many of the later induced abortions occur because of detection of abnormality in the fetus through the use of blood tests and amniocentesis. As the motivation is different this may be an important sub-group in terms of psychological issues raised.

The literature suggests that the emotional consequences of induced abortion in the first trimester in general are unremarkable, with many women, at least initially, showing a sense of relief. Bradshaw and Slade (2003) in a review of the area suggest that after recognition of the pregnancy and prior to the termination, distress, particularly in the form of anxiety, is high. However, there is a dramatic reduction of distress post termination and this seems to be maintained in the longer term. It is perhaps important to note that follow-ups beyond a year are rare and participation rates rather poor. Whilst follow-ups of cohorts have not indicated evidence of

emotional distress, there have been criticisms that the more distressed may absent themselves from studies, thereby biasing findings. It appears to be important that the woman should feel that she has made the decision herself and that she has not been coerced by partner or parent. Although it has been hypothesized that medical terminations may be experienced as more traumatic because of conscious awareness, the level of exposure to blood and pain and the longer duration of the process, there is little evidence to support this notion (Slade *et al.*, 1998). It does seem that there may be a sub-sample of women who react to the experience of termination of pregnancy with more adverse consequences and there is an indication that the rate of psychiatric admission which is recognized to be high in the postnatal period is much higher post termination. (Reardon *et al.*, 2003)

As with miscarriage, there are issues about the quality of care for women undergoing induced abortions. Censorious attitudes or insensitive care from staff may enhance guilt and may negatively affect emotional outcome. It is important that staff involved in such care provision examine their own attitudes and values and are aware of their own potential for influencing adjustment in a positive or negative way (Slade *et al.*, 2001). As with the miscarriage literature, the body of published work has been criticized for being negative in focus and failing to investigate potential benefits (Boyle, 1997).

In summary, whilst the physical processes of miscarriage and induced abortion have some similarities, the psychological experience and implications may be very different. Other commonalities concern the need to consider not just the implications for the woman but also her partner, the key role of staff attitudes in promoting positive adjustment and possible impact in future pregnancy. Finally, such experiences should not just be considered as pathways to pathology and the potential for positive effect has perhaps received less attention than required.

Accidents and unintentional injuries

Robert G. Frank and Andrea M. Lee

University of Florida

Injury is a leading cause of death and disability for America's young adults and children. It is the leading cause of death for those from ages 1 to 44 (Mokdad *et al.*, 2004) and is the fifth leading cause of death for all Americans (Centers for Disease Control and Prevention, 2001). Injuries are associated with higher treatment costs than the other three leading causes of death. Traffic accidents are the leading cause of severe brain injury, as well as most paraplegic and quadriplegic cases (Spielberger & Frank, 1992).

For many years, injuries were viewed as 'accidents' that were inevitable and not responsive to prevention efforts. Injury events tended to be attributed to human error or misaction; individuals died or were injured due to driving while intoxicated or a leg was broken when someone failed to watch their step. This psychological model of injury was related to the emergence of the concept of 'accident-proneness' during the 1930s and 1940s. In this approach, accidents occurred to individuals as a function of unconscious wishes or desires (Waller, 1994).

Injury events were also attributed to human error or misaction because they often involved relatively rare events that were perceived as unpredictable. Many data systems tended to record only 'single' causes of injury, negating the idea that a crash may occur both because the driver is impaired by alcohol and because the roadway geometry at the crash location is inadequate (Waller, 1994). Rarely did anyone examine the overall frequency of injuries to determine if higher risk existed under certain circumstances. For example, lacking statistics, the crash risk at a particular bend in a roadway may go unrecognized. Only when examined will the 1 per 250 000 vehicle risk achievable with improved roadway design, compared with the existing crash risk of 1 per 50 000, be recognized (Waller, 1994).

Models of injury control

In 1959, James J. Gibson, an experimental psychologist, recognized that injury was caused by energy interchange which occurred at the moment of, and subsequent to, the incident. Gibson suggested the most effective method of classifying sources of energy is the form of the physical energy involved (Rosenberg & Fenley, 1992). Gibson's observation became the lifework of Dr William Haddon, Jr, an

engineer and public health physician. Haddon narrowed the potential agents to five forms of physical energy: kinetic, chemical, thermo, electrical and radiation. Haddon also recognized 'negative agents' for injuries produced by the absence of critical elements such as oxygen or heat. Haddon labelled these agents as vectors and the vehicles as energy forms. He divided injuries into three phases: (i) a preinjury; (ii) a very brief injury phase; and (iii) a post-injury phase.

During the preinjury phase, the control of the energy source is lost. The preinjury phase includes everything that determines whether a crash will occur (e.g. driver ability, vehicle functioning, seat belt usage). The injury phase typically lasts less than a second and transfers energy to the individual, thereby causing damage. The postinjury phase determines whether the injuries and consequences could be reduced with subsequent prevention of further disability (e.g. speed, inefficiency of first responders). During the postinjury phase, attempts are made to retain physiological homeostasis and repair damage. Haddon also observed that injuries can often be prevented by attending to the vector (Rosenberg & Fenley, 1992; Waller, 1994).

Using this model, Haddon developed an innovative plan to intervene upon injury events by: (i) preventing or limiting energy build-up; (ii) controlling the circumstances of energy to prevent unlimited release; (iii) modifying the energy in transfer phase to limit damage; and (iv) improving emergency, acute and rehabilitative care to affect recovery (Waller, 1994).

Haddon's model led to the development of the Haddon Matrix. Haddon's 'phase-factor matrix' is actually a series of matrices developed for different purposes. The Haddon Matrix emphasizes the preventive value of the epidemiological approach to injury control. In the matrix, the host, agent (vector) and environment are seen as factors that interact over time to cause injury.

Haddon's work led to the recognition that, during each of the three phases, preinjury, injury and postinjury, injury likelihood can be reduced by changes in the driver (in the case of vehicular injury), the agent (or vehicle), or the environment. Previous models of injury prevention have emphasized psychological factors, thereby allowing only one intervention point. In contrast, the Haddon Matrix creates nine cells, each of which offers an opportunity for

intervention. While behaviour is undeniably an important factor in injury causation, the Haddon Matrix demonstrates that it is only one of several areas where intervention may be effective. In determining the appropriate intervention, it is important to recognize that injury prevention is not necessarily based upon the most obvious cause of contributing factors. Interventions may occur at a number of points in the chain of events that can lead to injury (Williams & Lund, 1992). Adoption of an energy control strategy to injury prevention led to discarding the term 'accident'. The connotation of chance, fate and unexpectedness has been replaced by descriptions of injuries and physical and chemical injuries involved (Williams & Lund, 1992).

Psychological factors and injury control

Human behaviour remains an important factor in injury control. This view has been reinforced in recent years as psychologists and others have begun to contribute to our understanding of the behavioural and social causes. Within the field of injury prevention, a dialectic has developed between proponents of individually directed interventions and those who support public health models (Frank *et al.*, 1992). These approaches to prevention have been characterized as active versus passive or individual versus population. Active individual injury prevention requires action by the individual to reduce risk (e.g. wearing a seat belt, using a motorcycle helmet, exercising or maintaining proper diet). Active or individual approaches reflect the legacy of health psychology, with its emphasis upon individuals assuming responsibility for their own behaviour (Frank *et al.*, 1992).

The passive intervention model, derived from public health approaches, emphasizes altering health behaviours at the population level (Frank *et al.*, 1992). In this approach, intervention is designed to automatically affect all individuals. Passive intervention models are viewed as most effective because they avoid difficulties associated with individuals making consecutive decisions regarding health and safety behaviours. Examples of the passive or population approach include automatic seat belts, mandatory air bags, locking systems to prevent drunken driving and air safety restraints.

Most often, active and passive approaches have been viewed as mutually exclusive. Others have suggested that active and passive approaches to injury reflect a continuum (Frank *et al.*, 1992). Models of health psychology have included a broader emphasis upon the health of communities (Winett *et al.*, 1989). Roberts (1987) has suggested that a multilevel approach is the most effective approach to injury control. In this approach, the active individual model congruent with health psychology is viewed as one end of a continuum, while the passive approach that matches public health models anchors the other end of the continuum.

Recently, a health promotion approach has been recognized as useful to injury prevention (Sleet *et al.*, 2004). Health promotion, by definition, involves targeting behaviours, environments and policies in the prevention of injury (see 'Health promotion'). The immediate goals of health promotion strategies with regard to injury prevention are to reduce individual risk factors, minimize exposure to hazards in the environment and remove unsafe products. These goals are achieved by individual and community efforts through education, social and organizational change, and public policy, legislation and enforcement (Sleet *et al.*, 2004).

In the area of health education, the PRECEDE model (Predisposing, Reinforcing, and Enabling Causes in Educational Diagnosis and Evaluation) was developed for planning education programmes (Fee *et al.*, 2000). In this model, prevention strategies are dictated by three sets of factors: predisposing factors (individual characteristics), enabling factors (aspects of the environment) and reinforcing factors (rewards or punishment of behaviour). Once prevention strategies are implemented, evaluation of the prescribed programme is an integral part of the PRECEDE model (Fee *et al.*, 2000).

Although many opportunities exist for psychologists to be involved in the community approach to prevention of injury, the traditional niche occupied by health psychologists with its emphasis upon the individual has most often been the focus of the profession. Because injury most often affects individuals under the age of 24, a disproportionate emphasis has been placed upon injury prevention among children and adolescents.

The prevention of childhood injuries continues to be a major research area (Peterson & Roberts, 1992). It is now clear that the parents whose children are most at risk (poor, under-educated, disturbed, or from single parent families) are least likely to utilize safety precautions. Children most at risk are preschoolers older than 2.5 years and children who display difficult behaviours are at higher risk than other children (Dal Santo *et al.*, 2004). Many parents do not appreciate, or are indifferent to, factors that may contribute to injury. Often, even middle-class parents lack a strong sense of risk factors for their children. Children are rarely taught safety behaviours (Peterson & Roberts, 1992). Too often, injury prevention is based upon single presentations of safety material in classrooms. Peterson and Roberts (1992) observed that educators would never consider teaching maths by working arithmetic problems before children for one hour, or teaching spelling by having the teacher discuss spelling. These methods often serve as a safety curriculum in schools. Parents greatly over-estimate their children's safety knowledge, and when asked where the child acquired these presumed skills, parents most frequently cite visits of police or fire officials to the class (Peterson & Roberts, 1992).

Injury prevention in children includes a wide variety of interventions. Injury prevention methods have been classified according to level: national and state level, community level, family level, caregiver and child level initiatives (Damashek & Peterson, 2002). As has been the case with adult and adolescent populations, the two predominant methods have been legislation and education. Legislative changes have often been directed at product manufacturers. In contrast, educational efforts are most often directed at children's caregivers and may be direct, utilizing weak contingencies (such as suggestion that a low probability negative event may be prevented) or immediate rewards (such as a lottery ticket or prize to a child). In general, the stronger the contingency, the more effective the intervention (Peterson & Roberts, 1992).

The most frequently cited legislative success, aimed directly at the injury vector, was a 1973 mandate requiring child-resistant packaging and limiting the amount of a drug contained in any one package (Peterson & Roberts, 1992). Although legislation can be very successful, the large number of products known to cause injury to children are inadequately controlled for a variety of reasons. Many known hazards to children, such as guns, have political connotations making legislation problematic in some countries. In other cases, items directly marketed to children are hazardous,

but have not been prohibited. For example, as many as 42% of accidental injuries to children under one year of age may be due to 'baby walkers' (Peterson & Roberts, 1992) which offer no developmental advantage to children. Similarly, under-inflated or uninflated balloons also pose a high risk to small children. Failure to regulate these items may stem from the perception that injury is as much a function of poor parental supervision as it is of the product alone. Thus, regulation may not be sufficient.

Persuasion to behave differently through mass media campaigns, enhanced product availability and social sanctions may rival legislative change. For example, the first child restraint law in Tennessee was accompanied by extensive publicity and media coverage. The eventual success of this legislation may reflect the publicity as much as the legislation (Peterson & Roberts, 1992).

Efforts to use education to prevent injury have yielded an uneven history. Most successful have been recent programmes that target caregivers with simple interventions requiring minimal consumer effort. When safety products are freely available, or available at a reduced cost in exchange for safety behaviour, education is effective. For example, smoke detectors, lightweight rails to guard windows, or programmes providing individualized attention rewards for decreasing hazards have all been shown to be highly effective (Peterson & Roberts, 1992). How mass media tends to influence children's safety has rarely been evaluated. Programmes aimed directly at children have had some success (Peterson, 1989). Young children can successfully learn a variety of skills ranging from bicycle safety, management of small emergencies like house fires and serious cuts, to the preparation of safe snacks, if provided with intensive modelling, rehearsal and explanation of clear, positive consequences (Peterson, 1989).

Because adolescence is a time of particular risk for injury, as well as the period when many patterns of behaviour are established, it has been a developmental epoch that has been the target of many intervention efforts (see 'Adolescent lifestyle'). Although it is a critical developmental period for the consolidation of cognitions, behaviour and learning, many common adolescent beliefs make intervention particularly problematic. Teens have strong beliefs of personal immortality and invulnerability. Adolescence is a period of increased testing of autonomy and growing identification with peers. Risky behaviours are common, and peer pressure may increase risk-taking activities. Even when the risk of injury is understood, avoiding danger may be less important than obtaining peer approval. Attempts by adults to minimize this behaviour may simply increase peer pressure to engage in such activities (Frank *et al.*, 1992).

The highest rate of fatalities and injuries in traffic crashes is among young men from ages 15 to 24 years (Centers for Disease Control and Prevention, 2001). Because young drivers are involved in the disproportionate number of traffic injuries and fatalities, many prevention programmes have focused on altering the behaviour of the driver. The most common example of these are driver education programmes which have been implemented throughout high schools in the United States. Unfortunately, these educational programmes, at best, have had limited success. There is no evidence that driver education programmes result in a reduction of the number of crashes (Robertson, 1986).

An alternative approach designed to increase safe behaviours among adolescents utilizes behavioural and/or mass media approaches to increase the use of seat belts. Behaviour approaches

have been criticized by authors such as Robertson (1986), who note that while contingencies are in effect, there is an increase in seat belt behaviour use. However, when rewards are withdrawn, seat belt use declines. What has often been ignored is that decline typically does not return to baseline, but nets a gain in overall belt usage. Similar improvements have been reported in other behavioural interventions to reduce injury risk, such as high noise environments and child restraint programmes (Frank *et al.*, 1992).

The high personal and emotional costs of catastrophic injuries, such as head and spinal cord injuries, have resulted in the proliferation of programmes designed to change behaviours associated with injury risk (see 'Head injuries' and 'Spinal cord injury'). Many hospitals have viewed these prevention programmes as an attractive way to provide a public service while marketing their name. Schools are particularly eager to endorse such programmes (Frank *et al.*, 1992). These programmes often utilize a 'shotgun' approach which includes education, modelling and persuasion. Evaluation of the efficacy of these programmes has been problematic for a number of reasons. First, the injuries the programmes are designed to prevent are low frequency events. The number of injuries occurring in any area covered by a prevention programme is likely to be small, thus complicating statistical inferences. Secondly, the proliferation of prevention programmes combined with public media efforts has resulted in a barrage of prevention type interventions. Adolescents are often exposed to a variety of such messages, making it virtually impossible to find an unexposed sample of teenagers.

As was discussed with regard to child injury prevention efforts, adolescent injury prevention programmes are often provided in a single presentation. There is little reason to believe that, regardless of the emotional or educational content of the programme, a single presentation will be sufficient to alter the complex and diverse behavioural factors involved in injury in adolescents. In general, evaluation of injury prevention programmes is demonstrated by increased knowledge and improved attitudes regarding safe behaviours in students who are exposed to the programme. Students exposed to prevention programmes show long-term maintenance of improved knowledge, better attitudes and more safe behaviours than children not exposed to programmes. However, specific analysis after exposure to a prevention programme does not demonstrate improved driving habits or increased perceived vulnerability to injury either immediately after exposure to the prevention programme or at a one-month follow-up (Bouman, 1992). Taken together, it appears that prevention programmes influence attitudes and knowledge, but may have little effect upon behavioural change. Again, expectations of behavioural changes after exposure to a single programme are naive.

In addition to modifying behaviours as a prevention strategy, it has been suggested that personalized interventions, such as mentoring programmes, would be effective in reducing injury risk (Sleet & Mercy, 2003). Furthermore, family therapy and the quality of parental involvement have been shown to reduce adolescent risk-taking behaviours (Sleet & Mercy, 2003).

In general, altering of adolescent injury risk is more complex than most studies have recognized. Evaluation of the multiple determinants, the gradual nature of behavioural change, assessment of the individual's current behaviour, beliefs, social support and alternative responses, as well as the maintenance of behaviour, are

all essential steps (Frank *et al.*, 1992). Most injury prevention programmes have addressed only one or two of these issues. Successful implementation of safe behaviours will require cognizance of the individual, the community and national health priorities. Interventions must recognize an altered perceived vulnerability to injury, as well as social support factors.

Conclusions

Injury is the leading cause of death in Americans under age 44. Narrow prevention interventions designed to assess or alter injury,

based on unidimensional concepts, whether psychological, behavioural, or environmental have been shown to rarely succeed. Successful prevention of injury is more likely to occur when injury is viewed from an epidemiological perspective with multiple causations. Recognition of the interaction between these causal factors and development of multiple interventions is critical to successful prevention of injury. Psychological factors comprise one element of the matrix leading to injury. Psychologists and other researchers interested in preventing injury have been most successful when they designed interventions targeting the individual, the community and state and national policy.

Acne

Stephen Kellett

Barnsley Primary Care NHS Trust

Introduction

Of all the skin diseases, acne is the most common with approximately 85% of people affected to some degree at some time in their lives (Rapp *et al.*, 2004). In males, acne typically presents in

early adolescence, with the greatest disturbance to skin being observed between the years of 16 to 19 (Hurwitz, 1993). In females, acne tends to present at an earlier age and then subsequently lasts longer than in males (Fallon, 1992). Acne therefore unfortunately tends to occur during adolescence, precisely at a time of

simultaneous and significant psychological, physical and social changes (Yazici *et al.*, 2004).

The biological model of acne points to the increased metabolism of androgens in the dermis, in combination with sebaceous gland sensitivity to androgens creating varying degrees of comedones, papules and pustules ('spots')(Cunliffe & Simpson, 1998). The most common form of acne is that of *acne vulgaris*. In about 20% of such cases, the disease necessitates contact with health services (Munro-Ashman, 1963). There are a number of less common variants of acne termed nodular and cystic acne, which have a far more serious prognosis for ongoing and distal physical appearance; *acne conglobata*, *acne fulminans* and Gram-negative folliculitis (Cunliffe & Simpson, 1998). The *raison d'être* of physical intervention with regard to treating all variants of acne, is the prevention of physical scarring, by limiting the number of skin lesions and thereby minimizing the potential psychological implications of the disease (Healy & Simpson, 1994). In psychological terms, it is possible to equate and locate the psychological effects of the skin disease of acne within an internal scarring metaphor (Layton *et al.*, 1997).

In recent years within dermatological research, biological models have been supplanted with more expansive and inclusive biopsychosocial approaches (Rapp *et al.*, 1998). Biopsychosocial disease models tend to emphasize the multifactorial nature of the aetiology of skin disease by highlighting the interaction of factors such as biological, environmental, psychoemotional and interpersonal factors. Kellett & Gilbert (2001) presented a biopsychosocial model of acne, which integrated previous psychological and biological models. This model emphasized the role of shame as a stressor that functioned to maintain the skin disease of acne, via increased arousal and associated lowered immune system functioning (Teshima *et al.*, 1982), which subsequently and reciprocally reinforced shame reactions and responses through the continuation of the skin disease.

Skin diseases such as acne tend to be unfortunately and short-sightedly dismissed as inconsequential, trivial and trifling in some medical quarters, when compared with diseases of other organ systems, simply because skin diseases do not directly cause death (Mallon *et al.*, 1999). Some evidence exists that 'skin failure' exerts such a degree of psycho-emotional strain on some sufferers, that acne indirectly causes death due to those sufferers eventually progressing to commit suicide (Cotterill & Cunliffe, 1997). The fact that acne is primarily active on the face (Cunliffe & Simpson, 1998) and hence the skin pathology is observable and visible at all times during social interactions, has been hypothesized as the key reason why acne is potentially psychologically potent and pathogenic (Kellett, 2002).

Research indicates the number of people suffering from acne in the adult years is on the increase (Cunliffe & Simpson, 1998) and has been attributed to a combination of an increase in environmental pathogens and the stress–diathesis model (Kellett & Gilbert, 2001). Cunliffe and Gould (1997) illustrated that 25% of patients attending a skin clinic suffering from acne had a mean age of 34 years. Individuals who develop acne in the adult years may be equated with burns victims in that the acne, as the burn, is unwanted and unexpected and therefore difficult to integrate into already well established self-perceptions regarding body image (Coughlan & Clarke, 2002). Although acne may obviously take longer to develop than a burn, the end result is identical in that the skin surface

is radically altered in comparison to previous appearance. Psychologically, such events can be linked by the theme of loss. The acne sufferers 'lose' their previous clear skin and therefore are presented with a body image at odds with previous body precepts. The burns victim may also earn the sympathy of others, a sympathy which may not be extended to acne sufferers, due to the presence of various 'acne myths' (Alderman, 1989). Such 'myths' regarding the aetiology of acne, include excessive masturbation, lack of hygiene and poor dietary control (Alderman, 1989). Such myths essentially represent the dual stigma of acne; the stigma of having the skin disease in the first place and the secondary stigma of the myths regarding acne causation. Unfortunately, community research regarding sufferer's knowledge concerning acne tends to mirror such acne myths, in that sufferers tend to primarily believe that a lack of general cleanliness represents the main cause of their acne (Smithard *et al.*, 2001).

The effects of dermatological difference

Once skin disease causes disruption to the presentation of the skin, three typical responses (Thompson & Kent, 2001) have been demonstrated; (a) stigma (b) psychological consequences and (c) the individual variability of such psychological responses. These issues will now be considered in relation to acne.

In terms of stigma, individuals with acne consistently report instances of discrimination, which has tended to be termed 'enacted stigma' (Scambler & Hopkins, 1986). Krowchuk *et al.* (1991) have shown that acne sufferers tend to believe that they are seen and treated by others as socially unattractive, repugnant beings. Such discrimination tends to be reported in terms of social rejections, with experimental studies illustrating that such rejections are a tangible reality, rather than a figment of the sufferer's imagination. Rumsey *et al.* (1982) illustrated that when actors are made up to appear dermatologically different from that of a control condition, then the public tended to try to ignore the presence of that person, found gaze difficult and tended to stand further apart. Marshall (1941) illustrated that, in relation to acne, prospective employers made consistent negative attributions concerning acne sufferers, regarding the degree to which potential customers would be 'repelled' by the person and hence tended not to employ acne sufferers. Interestingly, experimental evidence indicates that being dermatologically different, can also negatively influence and slant the sufferer's perceptions of social interaction. Strenta & Kleck (1985) illustrated that actors who believed that they were being made to appear dermatologically different, but then actually had any such differences removed, tended to report stronger reactions from the public in comparison with a control group. The everyday reality of coping with acne, probably represents an uncomfortable interaction of both of the aforementioned processes (see also 'Stigma').

In terms of psychological consequences of acne (point b), there is evidence that acne can exert significant negative effects upon wellbeing. Many studies have indicated that, as a group, people with acne tend to experience and report lower levels of self-esteem (Gupta & Gupta, 1998), increased depression (Cotterill & Cunliffe, 1997), heightened anxiety (Wu *et al.*, 1988) and generalized problems with socializing and social contact (Koo, 1995).

Thirdly, there is considerable individual variation between sufferers in terms of the manner in which they react and adapt to

being dermatologically different. There does not appear to be a manifest relationship between the severity of presenting acne and the degree of associated psychological distress. A collection of fairly minor blemishes can result in marked mental health problems in one person, whereas another can cope relatively well with more severe disruptions to the appearance of their skin (MacGregor, 1990). Interestingly, there is also a schism between the manner in which dermatology patients and dermatologists assess symptom severity and associated quality of life (Jemec, 1996).

The measurement of psychological distress in acne

Researchers have set out in the attempt to provide an objective index of the distress associated with acne, primarily through the development and usage of self-report questionnaires (Salek *et al.*, 1996). Although there are quantitative measures of psychodermatological quality of life and associated distress (Klassen *et al.*, 2000), such measures tend to tap broadbrush and generic psychodermatological issues. Acne-specific scales, as they are disease-specific scales, are more sensitive (Morgan *et al.*, 1997) and more responsive to change (Newton *et al.*, 1997), than the generic measures available.

The aim of the following section is to review the commonly used acne-specific measures in terms of their overall purpose, psychometric foundations and to inform measure selection in the clinical and research forums. Methods of measuring acne-related distress are necessary and important due to increasing the scope and range of assessment possible in the skin clinic, the psychological assessment of new physical management techniques in clinical research (Salek *et al.*, 1996) and the evaluation of innovative psychological interventions in dermatological settings (Fortune *et al.*, 2004). The measures developed to assess 'acne handicap' (Salek *et al.*, 1996) have tended to fall into two camps; (1) the assessment of quality of life issues in acne and (2) psychosocial issues in acne. The following sections structured accordingly.

Quality of life measures

Acne-QoL

The Acne-QoL scale (Martin *et al.*, 2001) was developed to assess quality of life issues specific to facial acne samples. The 19 item Acne-QoL purports to measure four aspects of quality of life: self-perception, role-social, role-emotional and acne symptoms. In terms of reliability, the Acne-QoL has acceptable internal consistency on individual scales, sufficient stability over time and displays sensitivity to intervention effects. In terms of validity, the Acne-QoL displays adequate convergent and discriminant validity (Martin *et al.*, 2001) (see also 'Quality of life' and 'Quality of life assessment').

Psychosocial measures

Acne disability index (ADI)

The ADI (Motley & Finley, 1989) is a 48-item questionnaire, which is completed using linear analogue procedures. The ADI is purported to measure eight categories: psychological (14 items), recreation (3 items), employment (3 items), self-awareness (3 items), social reaction (14 items), skin care (3 items) and financial (4 items). The internal consistency of the total scale is high, with sound test-retest reliabilities for the whole and sub-scales. The total scale score also displays satisfactory convergent and discriminant validities (Salek *et al.*, 1996). However, the lack of clarification regarding the construct validity of the ADI represents a major psychometric concern.

Cardiff acne disability index (CADI)

The CADI (Motley & Finley, 1992) is a shortened version of the ADI, consisting of 5 questions presented in a Likert format. The CADI is scored and treated as a unidimensional construct. The measure has been illustrated to have sound internal and test-retest reliabilities and demonstrated to be a valid measure with which to assess the degree of handicap and disability experienced by a patient in relation to their acne (Salek *et al.*, 1996). The CADI has been piloted in a New Zealand sample (Oakley, 1996) and found to be useful in identifying the functional disability caused by acne.

Conclusions

This chapter has illustrated that acne is likely to exert a considerable amount of psychosocial strain upon sufferers. The measures for assessing such acne disability have been reviewed. Although there is a growing body of literature regarding the psychological implications of acne, there are a number of concerns regarding the of evidence base: (a) the lack of psychological theory regarding the impact of acne guiding resultant research; (b) the lack of testing of biopsychosocial models; (c) the lack of qualitative evidence; (d) the lack of triangulated evidence; (e) the lack of evidence regarding how sufferers cope effectively with acne; and (f) broader investigations of psychological interventions for acne. Methodologies that attempt to address the aforementioned issues would provide a far greater understanding of the psychosocial impact of acne and provide further opportunities to increase the breadth of care offered to acne patients. (See also 'Eczema and skin disorders').

Alcohol abuse

Michael A. Sayette

University of Pittsburgh

Alcohol has been consumed by people in all parts of the world for thousands of years. Most people who routinely consume alcohol generally do not develop drinking problems. Nevertheless, the millions of people who do develop problems associated with alcohol create enormous social, economic and medical costs to society. Complications resulting from chronic alcohol problems include liver damage, strokes and memory loss, as well as a host of negative life events. Although the term 'alcoholism' is used widely in both the lay and professional communities, its lack of specificity and moralistic overtones have led to use of alternative terms such as 'alcohol abuse' and 'alcohol dependence' in recent diagnostic formulations.

In the most recent edition of the *Diagnostic and Statistical Manual of the Mental Disorders (DSM-IV-text revision: American Psychiatric Association, 2000)*, 'alcohol dependence' includes biological, psychological and social components. Most importantly, alcohol dependence involves difficulty controlling alcohol consumption and continued drinking despite aversive consequences. Edwards (1986) notes an increase in the salience of drinking, with alcohol taking on an increasingly dominant role in a drinker's life, as an important element in the alcohol dependence syndrome. Although none of the following is required for diagnosis, alcohol dependence symptoms include: tolerance (a diminished effect of alcohol, usually accompanied by increased consumption); withdrawal symptoms following reduced consumption; consumption of larger amounts or for a longer time period than was intended; persistent desire or unsuccessful efforts to cut down or control drinking; excessive time spent obtaining, consuming, or recovering from the effects of alcohol; reduction of important activities due to drinking; and continued drinking despite knowledge that it is causing or exacerbating a physical or psychological problem.

'Alcohol abuse' is conceptualized by DSM-IV-TR as a maladaptive drinking pattern (i.e. continued drinking despite knowledge that it is causing or exacerbating a problem). Individuals diagnosed with alcohol abuse must not meet the criteria for alcohol dependence and manifest at least one of the following: recurrent drinking despite its interference with the execution of major role obligations; continued drinking despite legal, social, or interpersonal problems related to its use; and recurrent drinking in situations where intoxication is dangerous. Data from the Epidemiological Catchment Area study (Robins & Reiger, 1991) indicated a lifetime prevalence rate for either alcohol abuse or dependence of 13.8%, with men being significantly more likely than women to develop drinking problems.

For heuristic purposes, this chapter will use the term 'alcoholism' to denote alcohol abuse or dependence. Alcoholism is a heterogeneous disorder that is multiply determined by both genetic and psychological factors. Support for a genetic aetiology for

alcoholism is derived from adoption, twin and family studies, as well as from animal studies in which rodents are bred for sensitivity to alcohol's effects and alcohol-seeking behaviour. Both twin studies and research identifying cultural and occupational differences in alcoholism rates reveal that environmental and psychological factors also contribute to the development of alcoholism. (See McGue (1999) for review of both genetic and environmental influences.) From a psychological perspective, alcoholism can be considered to be a disorder of behavioural excess, a maladaptive habit that has developed through powerful reinforcement contingencies, rather than a biomedical disease (Marlatt & Gordon, 1985).

A number of psychological theories have been developed to understand alcohol use and alcoholism (Leonard & Blane, 1999). Generally these theories state that people drink alcohol to increase pleasant feelings (positive reinforcement) or to decrease unpleasant feelings (negative reinforcement). Often these theories lead to predictions about which people will be most sensitive to these reinforcing effects, and thus will be at greatest risk for developing alcoholism.

Many people, including both those who treat and those who suffer from alcoholism, believe that alcohol is consumed because it reduces anxiety. This tension reduction hypothesis has spawned more than 50 years of experimental research. Although the data have been mixed, it appears that under certain conditions, alcohol does provide anxiolytic effects and that anxiety symptoms can sometimes precipitate drinking or relapse. Recent models have attempted to explore the mechanisms underlying these anxiolytic effects. These include models positing direct pharmacological effects of alcohol on the nervous system and the notion that anxiolytic effects are mediated by alcohol's effects on information processing (Sayette, 1999). This latter position is represented in a number of recent social-cognitive models.

Hull (1987) has proposed that alcohol's anxiolytic properties are cognitively mediated. By impairing the encoding of information in terms of self-relevance, intoxication decreases self-awareness. The inhibition of encoding processes reduces performance-based self-evaluation which, in situations where such evaluation is unpleasant, increases the probability of drinking. Alternatively, intoxication may interfere with self-evaluation rather than self-awareness of one's vulnerabilities. That is, we may know that we were judged unfavourably by another, but this information does not adversely affect the way that we view ourselves. Other cognitive mechanisms proposed to account for alcohol's anxiolytic effects include effects on attentional capacity, and initial appraisal of stressful information. (See Sayette (1999) for a review of the preceding theories.)

Although alcohol's effects on anxiety have received the most scrutiny, other negatively reinforcing effects have also been investigated. For example, alcohol has been consumed to cope with a variety of life events or situations. From this social learning perspective, alcoholism may result when one becomes overwhelmed by the demands of a situation (Maisto *et al.*, 1999). In addition to these negative reinforcing effects, alcohol often is consumed in order to produce positive effects such as enhanced arousal and positive mood. For instance, alcohol can enhance feelings of power. The euphoric effects of alcohol generally appear while blood alcohol concentrations are rising and are thought to be important in decisions concerning drinking, as people's beliefs about drinking will be most affected by the most immediate consequences of alcohol consumption (Marlatt, 1987).

Vulnerability to alcoholism

Children of alcoholics are at heightened risk to develop alcoholism compared with children without this background (Sher, 1991). Considerable research is underway to explore the genetic and environmental moderators and mediators of this relationship. Individuals at risk for alcoholism due to a family history of the disorder tend to show stronger effects of alcohol during the ascending limb of the blood alcohol curve yet weaker effects on the descending limb than those without familial risk (Newlin & Thomson, 1990). Although the evidence is mixed, some investigators have observed that alcohol's anxiolytic effects are enhanced among children of alcoholics (Sher, 1991). Research also has documented relationships between certain personality traits such as impulsivity and habituation to stimuli and the development of alcoholism. Because alcoholism is recognized to be a heterogeneous disorder, current personality theories of alcoholism have shifted away from identifying a unitary alcoholic personality and instead focus on specific personality dimensions, such as behavioural undercontrol or negative emotionality, that may place an individual at increased risk (Sher, Trull, Barthelow, & Vieth, 1999).

Psychological contributions to the treatment of alcoholism

Approaches to alcoholism treatment are becoming increasingly integrated with attempts to address biological, psychological and social aspects of the disorder. A number of pharmacological treatments continue to be developed to treat alcoholism (Fuller & Hiller-Sturmhöfel, 1999). Disulfiram (Antabuse) has long been used to deter persons from drinking. When alcohol is consumed, disulfiram produces an accumulation of the toxic metabolite acetaldehyde, causing nausea and hypotension. If disulfiram is reliably used, these extremely unpleasant sensations often can deter an individual from drinking. Other drugs, such as Acamprostate and Naltrexone, have been posited to reduce alcohol craving and drinking. In addition to these pharmacological agents, a number of psychosocial interventions have been developed, which are summarized below.

Relapse prevention

Because the majority of people with alcoholism who quit drinking relapse, a trend in alcoholism treatment has been on maintaining treatment gains rather than focusing entirely on initial cessation. Marlatt and his colleagues (e.g. Marlatt & Gordon, 1985; Witkiewitz & Marlatt, 2004) have developed a model of relapse prevention that focuses on factors that can promote relapse. This model posits that particular situations, and not just personality traits, can precipitate a return to drinking. Marlatt argues that initial drinking following attempted abstinence (a lapse) leads to full blown relapse due to the shame involved in violating abstinence. This abstinence violation effect is treated psychologically by helping patients recognize the situational precipitants of the lapse, rather than interpreting the lapse as indisputable evidence that they are treatment failures. Thus, treatment focuses on anticipating high-risk situations that might jeopardize abstinence and identifying coping strategies. Should a lapse occur, however, relapse prevention seeks to prevent it from developing into a full-blown relapse. In this case, treatment involves exploring the events and experiences that triggered the lapse. Interest in understanding the variables that can precipitate relapse has led to a number of psychological strategies that are used in treatment programmes.

Skills training

The ability to cope effectively with high risk situations is related to effective treatment and is believed to prevent relapse. Certain situations appear to pose a high risk for relapse, including interpersonal anger and frustration, social pressure, negative emotional states and stimulus-elicited craving (Marlatt & Gordon, 1985). Communication difficulties also have been implicated as a problem for many who battle alcoholism. Deficient areas that often are targeted in coping skills interventions include assertiveness, initiating conversations, listening skills, giving and receiving compliments and criticism and enhancing close relationships. Particular attention is paid to developing skills specific to drinking situations. For instance, drink refusal training permits modelling and practising of skills needed to cope with offers to drink by peers. In addition, receiving criticism about drinking and enhancing non-alcoholic support networks are targeted in skills treatment. These coping-skills training programmes have reduced alcohol consumption and increased work days after treatment (Rohsenow *et al.*, 2001).

Cue exposure

Both clinical observations and experimental research suggest that exposure to alcohol cues can precipitate relapse. For example, being in the vicinity of alcohol at a party may lead to a return to drinking. Individuals in this situation may become physiologically aroused, experience a craving for alcohol and ultimately act on their urge and drink. Treatments have been developed in which patients are repeatedly exposed to alcohol cues (e.g. sniffing their favourite drink) but are not permitted to drink the beverage. Initially, patients experience heightened reactions such as intense cravings for the drink, increased physiological arousal and increased salivation. With repeated exposure to the drink over several sessions, however, patients' responses to the cues diminish. In conditioning terms, cue

exposure attempts to extinguish or attenuate the strength of association between alcohol cues and drinking behaviour. From a social learning perspective, cue exposure permits modification of one's beliefs concerning both the reinforcing aspects of drinking (positive outcome expectancies) and the perceived ability to cope with, or resist, the urge to drink (self-efficacy judgments). Regardless of its underlying mechanisms, cue exposure treatment has shown promising results in conjunction with skills training in improving treatment success (e.g. Rohsenow *et al.*, 2001). Treatments that provide a richer presentation of the complex array of cues associated with relapse may enhance the efficacy of these interventions (Conklin & Tiffany, 2002).

Couples therapy/family therapy

The emphasis on determining triggers for drinking has led to increased focus on the patient's spouse or family members in understanding and treating alcoholism. Although family and relationship issues are generally not the primary cause of alcoholism, they often contribute to the maintenance of alcohol problems. Thus, among individuals with alcoholism, marital and family conflict can precipitate drinking. Further, the non-alcoholic spouse and family members may reinforce problem drinking by providing financial and emotional support during times of heavy consumption. These factors have led to the use of couples and family therapy as an adjunct to individual treatment (McCrary, 2001). Specifically, treatment has effectively improved (a) patients' initial motivation to quit; (b) treatment gains during the year following initiation of therapy; and (c) maintenance of treatment gains during long-term recovery (O' Farrell, 1992).

Alcohol expectancies

An individual's alcohol expectancies (i.e. beliefs about the effects of alcohol on affect, behaviour and cognition) predict drinking behaviour over time as well as treatment outcome (Goldman, 1994). Furthermore, it appears that individuals at increased risk for alcoholism, due to a personality marked by behavioural undercontrol or negative affectivity, or a family history of alcoholism, show differential patterns of alcohol expectancies relative to individuals who are not considered to be at risk. These expectancies may in turn predict drinking (Goldman, 1994; Sher, 1991). Expectancies about alcohol's effects may provide a common pathway that permits other factors such as personality variables or reactivity to alcohol's effects to influence the initiation and maintenance of alcohol use and alcoholism. Developments in the alcohol expectancy domain hold promise for providing a theoretical foundation for conceptualizing advances in the prevention of alcohol problems.

Motivation enhancement

Alcoholism treatment failure often has been attributed to poor motivation to recover on the part of individuals with alcoholism. Consequently, the ability to enhance one's motivation to quit has become a therapeutic goal (Miller, 1992). Simple interventions designed to improve motivation have produced significant changes in an individual's willingness to accept treatment. Data from a major multi-site study in the United States suggest that

Motivational Enhancement Therapy may be an especially cost effective intervention (Project MATCH, 1998)

Self-help groups

Many individuals with alcoholism have derived benefit from self-help groups such as Alcoholics Anonymous (AA) or Rational Recovery. Self-help group meetings involve discussion by members of their experiences abstaining from alcohol. These groups can serve a number of important functions. Members gain a non-drinking support network, discuss their fears and concerns about relapse, and perhaps most importantly, realize that their struggle with alcohol is shared by others. More than one million people throughout the world attend AA meetings annually. AA relies on a 12-step treatment approach that emphasizes a belief in a higher power to combat what is viewed as an incurable but arrestable illness. Despite its widespread appeal, there have been few systematic evaluations of AA's effectiveness (Fuller & Hiller-Sturmhöfel, 1999). Rational Recovery offers a non-spiritual treatment alternative that appeals to those who are uncomfortable with AA.

Patient/treatment matching

Traditionally, patients being treated for alcoholism would receive the particular treatment package implemented by that agency. The degree of individualization of treatment often has been minimal (Miller, 1992). The 'Project Match' randomized clinical trial compared responses to a 12-step, a cognitive-behavioural and a motivational enhancement approach to treatment. Results generally did not, however, identify which type of treatment works best for particular types of individuals (matching patients to treatments using characteristics such as social support and degree of dependence). Currently a major study is underway (Project COMBINE) which examines combinations of varying intensities of psychological treatment along with pharmacological interventions (placebo, Naltrexone, Acamprosite). Clients in this ambitious study will be treated for 4 months and then followed for a year, and the findings should prove valuable.

Alcoholism: contextual issues

Understanding the aetiology of alcoholism requires an appreciation for a host of other psychological disturbances that may face the patient. Two such issues are comorbid psychiatric disorders and polydrug use. Mood, anxiety and personality disorders are examples of psychiatric conditions often comorbid with alcoholism. Exploring the nature of these relationships is important for understanding risk factors as well as for developing effective treatment strategies for these individuals.

Polydrug use among those with alcoholism is increasingly becoming the rule rather than the exception. Because many alcohol treatment facilities and research projects have excluded polydrug users, important information regarding these subjects has until recently been lacking. Generally, polydrug patients present with more severe problems than those whose problems are exclusive to alcohol. The nature of these differences has just begun to be

explored. Research is needed to determine whether cessation is indicated for all drugs simultaneously or, if not, what the sequence of cessation ought to be. This concern typifies the current view of

alcoholism that recognizes the importance of understanding the disorder within a broader biopsychosocial context.

Allergies to drugs

Mary Gregerson

Family Therapy Institute of Alexandria

Features

As a well-accepted medical/scientific iatrogenic problem, allergies to drugs have high human and medical costs. Human costs include discomfort, dysfunction and, sometimes, death. Medical costs concern emergency care to reverse acute hypersensitivity effects,

expensive and semi-reliable diagnostic tests and the health risks of re-administration to definitively confirm the drug allergy.

These sensitivities are often termed 'side-effects' since they are epiphenomenal to the drug's intended effect. This minimization in the terminology does not reflect the medical reality either in terms of intensity or impact. These adverse reactions to drugs are real, and

can be life-threatening. The phrase ‘concurrent effects’ better describes these effects.

Three different types of drug allergies have been detailed (Pichler, 1993): (1) classic drug allergies are immune over-reactions to the medication itself; (2) an immune reaction occurs but is not mediated by other immune substances; (3) an autoimmune reaction can occur when the drug invokes an immune reaction to autologous structures.

The physical sequelae of an allergy to drugs can vary widely. Symptoms may be as benign as simple mild skin rashes, or as threatening as potentially fatal anaphylactic reactions. Anaphylaxis, a constriction of smooth muscles, results in a reddening and swelling of affected areas. If the breathing passages are swollen, suffocation can occur. Death from drug allergies emanates from anaphylactic shock is unabated by medical counter measures.

Particular aspects of antibiotics termed beta-lactams often cause allergic reactions. Allergy to penicillin is quite common, and the most extensively researched of the known drug allergies. For example, research before 1970 identified contaminants in penicillin mixtures which were responsible for a large portion, but not all, of the adverse reactions to this drug (Knudsen *et al.*, 1970). Subsequent penicillin compounds no longer contain these contaminant allergens.

Additionally, determination of which individuals experience drug allergies is influenced by a range of individual differences in genetics, metabolism and health. Major histocompatibility complex (MHC) class II pathways process drug allergens (Pieters, 1997). If a person has slow acetylation, which is genetically determined, metabolism of the pharmaceutical agent transforms toward reactivity (Clark, 1985; Rieder *et al.*, 1991). The inflammation of infectious states sometimes amplifies reactivity to produce an allergic response (Moseley & Sullivan, 1991; Uetrecht, 1999). A curious medical finding is that although atopy does not mean a higher probability of a positive penicillin skin test (Adkinson, 1984), atopy is a major risk factor for penicillin anaphylaxis that is severe and even fatal (Idsoe *et al.*, 1968).

Environmental factors also influence drug allergy reactions. Environmentally some trace antibiotics found in dairy and milk products will cross-react with a drug (Birnbaum & Vervloet, 1991), although current US regulations monitor carefully these trace elements. So, it is highly unlikely, but not impossible, for a sensitizing predisposition to evoke an allergic drug reaction (Division of Medical Science, 1980; Dewdney, 1984). Moreover, social engineering like the abolition of topical cream forms of penicillin avoid potential atopic dermatitis reactions sometimes resulting from these creams (Helton & Storrs, 1991; Holdiness, 2001).

Diagnosis

Diagnosis is challenging for drug allergies (Sabbah & Caradec, 1992). The natural history of most drug allergic reactions is complicated. First of all, the polypharmacoepia usual in hospitalization (usually more than 8 medications at any time) and outpatient management of many chronic diseases confound easy identification of the drug culprit producing the allergic reaction.

A scant number of definitive and universally accepted tests exist. Therefore, consultation for these multi-medication cases require six steps:

- 1) Assemble clinical data ...;
- 2) Narrow candidate list of drug allergen (by time frame of drug administration and symptom onset as well as the surge and abatement of symptoms) ...;
- 3) Consider pharmacoepidemiology of candidate list ...;
- 4) Stop and/or substitute all drug candidates known as allergens ...;
- 5) Consider skin testing ...;
- and 6) Readminister incriminated drugs as clinically indicated ... (Adkinson, 2001, p.1686)

Skin tests and lymphoblast transformation tests may imitate the drug-invoked allergic reaction or merely indicate sensitivity. A prevalent test to determine allergy to drugs is the leukocyte migration inhibition test. A simplification of this test proved 66% effective (Tarasov *et al.*, 1991). Another common test assesses basophil degranulation against the exposition. Some evidence exists that this latter test, although more risky, is quicker, simpler, more useful and has more specificity (Rangel *et al.*, 1991). The most definitive and highest risk test is a re-administration provocation test showing the drug’s elicitation of the allergic reaction.

Pseudoallergic reactions, though, can confound successful diagnosis and treatment (Adkinson, 2001). For instance, often after the administration of anesthetic, e.g. in dentistry, vasovagal syncope can masquerade as anaphylaxis. In vasovagal syncope IgE mediation is not involved. Furthermore, a pseudoallergy and idiosyncratic allergy to drugs share the same biologic function, but cross-reactivity of the drug allergen with other drugs demonstrates a common biologic structure (Adkinson, 2001). Pseudoallergic responses must be separated from true allergic reactions since stark differences exist in prognosis, counselling and treatment/management.

T-cell mediation is implicated in the most common drug allergy which is a late onset rash (Yawalkar & Pichler, 2001). This rash symptom associated with aminopenicillin appears related to class II MHC (Romano *et al.*, 1998). Thus, patch tests and delayed cutaneous intradermal tests appear reliably to predict responsiveness to readministration (Romano *et al.*, 1999), and may have usefulness for other drug allergies as well a clinical sequelae for treatment.

Medical treatment

Acute and long-term treatment protocols have been developed. The three step acute protocol includes: (1) identify and cease administration of drug allergen; (2) administer counteractive, supportive, or suppressive agents and; (3) determine whether and how substitution may be made for the drug allergen. Antihistamines, in particular, may attenuate an acute reaction.

For long-term care, at least a two- to four-week waiting period after the anaphylactic event is necessary to evade the refractory period. Of course, use of the drug causing the allergic reaction is contraindicated. Other related drugs in that same class may also need to be avoided. For instance, discontinuance of histamine-releasing drugs is usually advised, although some question exists concerning this practice (Moss, 1993).

Long-term treatment focuses upon prophylaxis. Prevention includes the avoidance of identified allergen and all cross-reactive drugs. A number of different ways, such as the wearing of ID jewelry

to identify those with drug allergies have been suggested to alert emergency and other medical personnel who might administer treatment to an unconscious person with a drug allergy. Consultation may also be sought on which of the three recommended alternatives would best suit a particular patient. These three approaches are: (1) using an unrelated alternative medication; (2) use of a non-identical but potentially cross-reactive drug; and (3) desensitization to the drug allergen. Each alternative has benefits and drawbacks (Adkinson, 2001).

Additional concern, based on clinical evidence, exists for indirect exposure from secondary trace sources, as mentioned earlier under environmental factors. Although injection is the most potent dosage method, oral ingestion can produce reactivity, especially if the allergen is undiluted. For instance, though, for trace form in antibiotic-treated animals' meat, researchers continue to examine the potential of the ingestion to contaminate further up the food chain. Investigations have scrutinized allergic reactions to residues in foods such as dairy products and meats (for a review see Dewdney *et al.*, 1991). Although no conclusion can be drawn at this point,

caution is warranted regarding ingestion or inhalation of the allergen or its derivatives in trace amounts. Those with a prior allergic history especially need to carefully monitor for traces of antibiotic residuals.

Of great interest to health psychologists is that presenting symptoms may seem psychological, at first glance, and treatment issues such as drug allergies can interfere with treatment adherence. At first, when no foreknowledge of medication use is available, allergic reactions may appear as a panic attack (Jasnoski *et al.*, 1994). Psychological sequelae may include hyper-arousal, hyperactivity, feelings of impending doom, scattered cognitions, uncontrollability and 'unreasonable' fear. Adverse reactions to medications need to be ruled out before diagnosing panic attack as the primary symptom rather than as a secondary response to an allergic reaction. Finally, when adherence becomes problematic, drug allergies should be ruled out before more psychological adherence facilitation can appropriately be implemented.

Allergies to food

Mary Gregerson

Family Therapy Institute of Alexandria

Features

Food allergies are immunologic hyper-reactions to ingested substances considered non-pharmacologic, for the most part. Either the failure to develop or a breakdown in oral tolerance may be at fault in Immunoglobulin E (IgE) mediated allergy while inflammatory mediators are implicated in non-IgE cell mediated food allergies. Some food allergies have a mix of IgE and non-IgE mediation (Sampson, 2003). Generally, food allergies engage multiple classic immune mechanisms found in allergies (see 'Allergies: general').

Irrespective of aetiology, food allergies are the number one cause of generalized anaphylaxis treated in hospital accident and emergency (A&E) departments, and cover one-third of the total emergency room/A&E visits in the USA and the UK (respectively, Yocum & Kahn, 1994; Pumphrey & Stanworth, 1996). Anaphylaxis is when the smooth muscles vasodilate and constrict causing vasculature collapse because there is no blood pressure. Unknown, though, is why different individuals respond with different symptoms to different foods.

Food allergies can produce a range of discomfort and disease. Allergic immune dysfunction may create gastrointestinal, respiratory, or dermatologic symptoms like migraine, gluten enteropathy, Crohn's disease, eczema, wheeze, urticaria, irritable bowel syndrome or abdominal pain, and, in extreme cases, systemic anaphylactic shock (Del Rio Navarro & Sienna-Monge, 1993) (see 'Inflammatory bowel disease' and 'Irritable bowel syndrome'). Besides producing discomfort and disease, these allergies can be fatal, and need serious consideration.

Food allergies are different from food intolerance and food aversions (Ferguson, 1992). Allergy requires an immune over-reaction, typically with elevated immunoglobulin E (IgE). On the other hand, food intolerance simply cannot absorb food by catabolism, resulting in sensitivity, and food aversion is a taste preference without physical problems. Allergy is certainly the most serious of these three food syndromes.

The morbidity of food allergic reactions depends upon the nature and amount of substance ingested as well as the patient's age (Esteban, 1992). Food allergens, or sensitizing substances, have been reported to various fruits, nuts, vegetables, dairy products, fish, grains and meats (Gluck, 1992). Fruit allergy usually centralizes in throat and mouth reactions like lip- or tongue-swelling, hoarseness and uncontrollable throat clearing. Nuts and vegetables, though, produce a more systemic acute attack with symptoms like laryngeal oedema, asthma, urticaria and even anaphylactic shock. Meat or fish reactions often result in asthma. Age is one component of incidence rate.

Incidence

Prevalence rate varies with age. Food allergy prevalence can only be considered estimates since no conceptual agreement and diagnostic procedures are consensually accepted (Esteban, 1992). Approximately 2% of adults may evidence food allergies while 8% of children under 3 years of age do (Bock, 1987). Between the 1970s and 1990s some allergies like peanut appeared to be increasing (Sampson, 1996).

Children (8%; Bock, 1987) compared with adults (2%; Novembre *et al.*, 1988), though, have a greater incidence, which diminishes with age. For children under 3, 8% have food allergies, which dissipate after reaching 1 to 3 years of age (Bock, 1987). Tolerance appears to grow with age and exposure, yet food allergies can also appear initially in adulthood.

Most recent epidemiological work has found similarities in incidence across countries. For instance, the incidence of peanut allergy in children seems similar in the United States (Sicherer *et al.*, 1999) and the United Kingdom (Tariq *et al.*, 1996). In the United States (Sampson, 1996) from the 1980s to the 1990s and on the Isle of Wight (Grundy *et al.*, 1994) from 1994 to 1996, children referred for atopic dermatitis had twice the incidence of peanut reactivity. Epidemiology studies have shown ~2% incidence rate of allergies in adults in the UK (Young *et al.*, 1994) and in the Netherlands (Niestijl Jansen *et al.*, 1994). Researchers can only extrapolate a similar incidence rate in the US since no large scale epidemiological work on food allergies has yet been conducted in that country.

Diagnosis

Allergies to food gained better clinical acceptance when diagnostic techniques improved in scientific rigour (Finn, 1992). Clinical skill, history taking and elimination diets have been the basis for many past diagnoses of food allergies. Tests for cutaneous (standardized skin pricks for immediate hypersensitivity) and for specific IgE antibodies (RAST, ELISA), for histamine (BHR, IMCHR), for intragastral provocation under endoscopy (IPEC), and for intestinal biopsy (after allergen elimination and subsequent feeding challenge) have proved useful.

A careful diagnostic evaluation would include medical history, a dietary diary, a physical examination and various in vitro and in vivo tests (Burks & Sampson, 1992). Standardized skin-prick tests and radioallergosorbent (RIA) assays may be used for screening, but their high rate of false positives require further confirmation with the 'gold standard', a double-blind, placebo-controlled food challenge (DBPCFC; May, 1976). Single-blind challenges, though,

can be used to narrow down the scope of potential allergens before confirming with the more expensive, labour- and time-intensive DBPCFC. This rigorous approach eliminates psychological confounds that continue to influence patients' dietary practices when they think they have food allergies (Wisocki & King, 1992). Differential diagnosis needs to consider gastrointestinal disorder, contaminants and additives, pharmacologic agents and psychological reactions.

A number of diseases are considered food hypersensitivity disorders. General categories are IgE-mediated, cell-mediated, Mixed IgE- and cell-mediated and unclassified (Sampson, 2003). IgE mediated disorders include cutaneous (morbilliform rashes and flushing, angioedema, and urticaria), gastrointestinal (gastrointestinal anaphylaxis and oral allergy syndrome), respiratory (bronchospasm or wheezing and acute rhinoconjunctivitis) and generalized (systemic anaphylaxis without or with shock). Mainly cell-mediated disorders span cutaneous (dermatitis herpetiformis and contact dermatitis), gastrointestinal (coeliac disease, food protein-induced enterocolitis, food protein-induced enteropathy syndromes and food protein-induced proctocolitis) and respiratory (food-induced pulmonary hemosiderosis or Heiner's syndrome). Mixed IgE and cell-mediated food allergies-related diseases include cutaneous (atopic dermatitis), gastrointestinal (allergic eosinophilic gastroenteritis and allergic eosinophilic esophagitis) and respiratory (asthma). Finally, the unclassified category includes migraine, arthritis and cow's milk-induced anaemia. Both IgE antigen-antibody complexes and cell-mediated mechanisms are implicated, at least partially, in these pathological conditions.

Treatment

Prevention controversy has existed since almost seventy years ago when exclusive breastfeeding of infants was first identified as prophylactic (Grulee & Sanford, 1936). Results have been mixed in terms of maternal and infant avoidance of suspect allergens, with success with cow's milk allergy but neither peanut nor egg allergy (Zeiger & Heller, 1995). Animal (Hanson, 1981) and human (Fergusson *et al.*, 1990) studies confirm that a varied diet early in life predicts later a higher likelihood of food sensitivities and atopic dermatitis, respectively, especially in high-risk infants (Kajosaari & Saarinen, 1983). High-risk children are those with a first order relative with atopy or food allergies. US allergists (Sampson, 2003) and the Department of Health (1998) in the United Kingdom advise avoidance or delay of introduction for suspect allergens, especially for high-risk children:

- children under 6 months of age should avoid solids
- children up to 12 months of age should avoid cow's milk
- children up to 18–24 months of age should avoid eggs and egg products
- children up to 3 years of age should avoid peanuts, tree nuts, shellfish and fish.
- mothers during pregnancy and lactation, should avoid peanuts.

Most young children acquire immune tolerance of their food (except peanuts, tree nuts and seafood) allergies by 3 years of age (Bock, 1982; Hill *et al.*, 1989; Host, 1994). Yet for 1-year-olds with milk hypersensitivity, 35% by 3 years of age (Host & Halcken, 1990)

and 25% by 20 years of age (Host *et al.*, 1997) evidence additional food allergies to other allergens. No formal studies have examined non-IgE-mediated skin and respiratory allergies.

For treatment of existing food allergies, subcutaneous injections have been ineffective (Evans, 1992). The primary standard treatment programme consists of elimination diets as well as challenge tests (Ferguson, 1992). Elimination simply requires systematic abstinence from the suspected allergen. Then, if signs and symptoms disappear, the allergen is re-introduced and confirmed in the most rigorous fashion with a double-blind placebo-controlled provocation test. If and when symptoms re-appear determines the subsequent treatment plan. Strict elimination of the allergen is the only proven treatment for food allergies. One third of children and adults lose reactivity after complete elimination (Sampson & Scanlon, 1989; Pastorello & Stocchi, 1989; Businco *et al.*, 1989; Hill *et al.*, 1986). However, those with peanut, tree nut, fish, or shellfish allergies rarely lose their sensitivity.

Although their scientific validation has only started quite recently, some alternative approaches have treated food allergies (Kay & Lessof, 1992). Treatments that have been used with clinical success are clinical ecology, acupuncture, homeopathy, hypnosis and herbalism. Again, even though case studies have verified effectiveness, the mechanisms of and limits to these treatments are little known. Caution is warranted since many of the evaluative findings are not currently available (see 'Complementary medicine').

Behavioural and psychological aspects

Psychologists need to concern themselves most with the proper diagnosis of a food allergy and subsequent adherence to a diet regime. Those reporting food allergies which objective physiological tests do not confirm have a hypochondriacal and hysteric profile compared with those with tests that do confirm food allergies (Parker *et al.*, 1991). Whether undiagnosed food allergies cause these problems or the reported 'allergies' stem from a psychological disturbance is unclear. Yet the unqualified acceptance of a double-blind procedure to definitively determine food allergies underlines the very potency of psychological aspects not only in the initial experience of food allergic symptoms but also in their maintenance into a disorder.

Furthermore, food allergies produce physical symptoms like migraine headaches which are perhaps misdiagnosed as psychological. Food allergies also need checking in psychological syndromes like attention deficit disorder (Burks & Sampson, 1992). Moreover, attention to other physical symptoms indicating allergies should assist in proper diagnosis. Biofeedback has actually been used to determine food-sensitive persons (Laird, 1986).

Adjunctive psychological interventions pertain to control, if not prevention, of food allergies. The psychological management skills from education focuses upon label reading, menu planning and food abstinence. Success of prevention and recovery efforts involving the strict avoidance of allergy-producing foods centrally concerns adherence, a medical challenge that is inherently psychological (Burks & Sampson, 1992). The final galvanizing news for the field of health psychology is that elimination diets work for about one-third of those with food allergies. Why?

So much is known about morbidity. Now is the time to pursue prevention, recovery and, ideally, cure. Certainly the thrust of inquiry now needs to determine aetiology ('how much is genetics?') and individual differences ('why don't all those at risk succumb?'). What will facilitate adherence to an allergen elimination diet? What else besides elimination might be used for control and cure?

To conclude, the health psychology field of food allergies is only just beginning to coalesce in scientific acceptance of its

existence. So, the next step is a rigorous application of the scientific method for diagnosis of risk and manifestation and motivation for prevention as well as for recovery and cure. The elimination diet is really not the final solution, but rather just a 'way station' or temporary stop-off point that delays the tough challenge of cure.

Allergies: general

Mary Gregerson

Family Therapy Institute of Alexandria

Features

Allergies are a T lymphocyte cell-mediated immunity (CMI) gone awry (Zweiman, 1999). Normal CMI development usually results in a synchronous, efficacious T-helper cell (Th1) mediated protection of the human from internal disruptions or against the invasion of disease provoking foreign agents. In allergies, an over-abundance of another specific type of T-helper cell named Th2 is the abnormality (Broide, 2001). After extensive research, whether the relationship between allergies and CMI is inverse remains an experimental question. For allergies, though, the elevated presence of Th2 results in an immediate hypersensitivity called Type I.

The genetic basis of allergies is commonly accepted. Even with similar genetic risk, some persons either never get allergic symptoms or theirs disappear while others continually experience allergies. Family transmission of allergy has been acknowledged since 1920. If two parents have Type I Hypersensitivity, offspring have a 50% chance to manifest atopy, and with one parent, almost a 30% chance. These individual differences in responsivity and the interruption of Mendelian genetic transmission make psychological and behavioural treatment factors important considerations in allergies.

The immune substrate of allergies is determined both by genetics (hardware) within the Type I major histocompatibility complex (MCI) and by learning (software), for example, histamine tissue priming (Peeke *et al.*, 1987). Both hardware and software regulate the individual's allergic immune responsivity. The Th2 pattern is related to elevated emission of a cascade of other sequela, specifically, Immunoglobulin E (IgE), interleukins (4, 13 and 10) as well as eosinophil-laden inflammation. These immunological changes manifest in numerous clinical symptoms and distinct disease states.

Clinical symptoms of atopy

These biological sequela result in distinct clinical features for a myriad of diseases such as asthma, eczema, rhinitis (perennial

and seasonal, which is commonly called hay fever) and urticaria. The umbrella term for these symptoms is atopy. The atopic disease allergy results from an immune over-reaction to a specific agent called an allergen or antigen. The former is from an outside source; the latter from an inner source.

Allergies cause physical and psychological discomfort, and, sometimes, death. In hay fever the mucous membranes in the nasal passages swell; in eczema the skin inflames with wheals and flares; in asthma the bronchial passages constrict severely; and in anaphylaxis the smooth muscles vasodilate and constrict causing vasculature collapse because there is no blood pressure (see 'Asthma' and 'Eczema'). Also, allergies are associated with a number of psychological symptoms (see Bell *et al.*, 1991; Jasnoski *et al.*, 1994). Specifically, depression, shyness, panic and anxiety have been connected to allergies. Recently in a large cross-sectional Norwegian twin study, allergies had a small inverse correlation with subjective wellbeing (Roysamb *et al.*, 2003). Concomitant allergies have been observed frequently in other diseases, e.g., eating disorders such as bulimia, schizophrenia and systemic lupus erythematosus.

Mechanisms

People with allergy usually, but not always, evidence higher levels of circulating IgE (up to 12 mg/ml) compared to normals (approximately 0.3 mg/ml). IgE's heat sensitivity could explain why rapid temperature or humidity changes and drafts often increase allergic nasal obstruction. IgE further degranulates histamine which produces positive immediate wheal and flare skin reactions. Sometimes independent of IgE elevation, inflammatory tissue priming itself can produce the clinical features of allergy (Peeke *et al.*, 1987).

After the activation of mast cells releasing vasoactive mediators, often a late phase reaction (LPR) follows within hours. At the LPR site, Th2 lymphocytes cause aggregation and activation of eosinophils and perhaps basophils. These Th2 are mainly memory T-lymphocytes and are often activated 6–8 hours after the allergen

challenge. At the challenge site, among the cascade of biologic responses, eosinophils release possible noxious cationic proteins, basophils activate histamine release, and chemokines aggregate and/or activate inflammatory cells.

In an example of classical conditioning, sometimes histamine itself can produce allergic reactions without the involvement of IgE. Total IgE levels are elevated in only 30% to 40% of those with allergic rhinitis. A residual histamine priming could, even in the absence of IgE elevation, conceivably result in an allergic response, thus accounting for those with allergic symptoms that do not evidence higher IgE levels. An important study (Rietveld *et al.*, 1997) demonstrated that the subjective reports of severity in children with asthma as well as their subsequent breathlessness were influenced by false feedback of high levels of wheezing after exercise.

In allergies, suggestion may be an important psychological consideration. Similar to the asthma study just cited (Rietveld *et al.*, 1997), in some instances, a 'placebo' allergic reaction has been evoked when the patient thought the allergen was present and it was not (see 'Placebos'). For instance, pictures of hayfields or misrepresented 'placebo' liquids have actually caused a full allergic attack (see Jemmott & Locke, 1984, for review). These psychological considerations figure into a real physiological picture of psychosomatic disease and distress.

In terms of physiology, some speculation exists that a depressed CMI (anergy) allows the allergic cellular substrate and subsequent symptomatology to develop. In essence, the CMI fails to activate in order to protect the individual. Whether absence of normal T cell function or the over-abundance of certain T cells with suppressive power underlies anergy is under study now. Perhaps both mechanisms play a role, interdependently or independently.

Also under scrutiny is whether anergy results in or results from particular diseases. Physical vulnerabilities like age, disease and pregnancy have been associated with immune vulnerability when stressed (Kiecolt-Glaser *et al.*, 2002; Segerstrom & Miller, 2004). For cancer patients, some in vitro evidence exists that stress interferes with normal anti-inflammatory responses to cease atopic symptoms (Miller *et al.*, 2002). Conceptually, the immune, neural and psychological systems are thought to be systemically interrelated (Lekander, 2002). In asthma, psychophysiological mediation is commonly accepted (Lehrer *et al.*, 2002).

Diagnosis

Double-blind, placebo-controlled provocation tests often discount IgE mediation for as many as 60% of those with a history of allergies (Jarvis, 1993). The question arises, though, as to what causes an allergic response to trigger histamine priming or other provocations of the allergic response. In the absence of physiological answers, psychological and behavioural factors are implicated. Even the methods to determine the existence of allergies implicate psychological factors.

Interestingly, one research study (for review see Jemmott & Locke, 1984) distinguished between clinical symptoms and cellular changes. A 'placebo' non-allergic mixture falsely represented as the allergic substance elicited symptoms and cellular changes, while the allergic mixture misrepresented as non-allergic also elicited cellular changes, but not symptoms. In other words if allergic participants

thought the substance was non-allergic, although their underlying physiology changed, they did not show symptoms. Other work has shown a conditioned allergic response elicited by the color of the vial and not the substance in the vial. This growing body of evidence heavily implicates psychological factors in allergic clinical manifestations.

Skin tests, radioallergosorbent tests (RASTs) and relevant provocation tests have been effective in diagnosing allergies. Skin-prick tests and the enzyme allergosorbent test usually screen for allergy specificity. Then the 'gold standard' DTH provocation test confirms the allergy (Rosenstreich, 1993).

Five major criteria need to be met for a successful DTH skin test (Zweiman, 2003, p. 974):

1. The use of stable, standardized and non-irritating antigens;
2. A precise intradermal antigen injection;
3. Well-defined area of induration (not just erythema), with reproducible measurements by experienced observers;
4. A sufficient sensitivity so that a negative reaction is strong evidence against prior sensitization; and
5. A reproducible degree of reactivity in repeat testing.

A small percentage of disagreement may exist between these tests. Both false positives and negatives are possible.

Furthermore, one study (Rietveld *et al.*, 1997) has shown that children reported more symptoms when simply misled by hearing sounds of excessive wheezing. Such sensitization has been identified as anxiety sensitivity (Jasnoski *et al.*, 1994). Psychological considerations like this may be important in the diagnosis of severity which, in turn, determines treatment.

Treatment

Treatments can be drugs or psychotherapy. Besides allergen avoidance, immunotherapy is the main pharmacological treatment available. This treatment desensitizes the person with allergies by creating a tolerance. A number of well-designed studies have corroborated immunotherapy's effectiveness to reduce symptoms for allergies like hay fever and allergic asthma (Nicassio *et al.*, 2004).

Antihistamines can be used to curtail the intensity of allergic symptoms. This treatment interferes with the late phase following the immediate allergic response. Often this late phase correlates with severity. This approach, though, controls symptoms without decreasing the basic hypersensitivity.

With time and with change, allergies can disappear without pharmacological treatment. A relevant, well-accepted aspect of allergies is their responsiveness to adaptive patterns and changes in life situations. Although the mechanism has not yet been found (Stone *et al.*, 2000), one experimental study (Smyth *et al.*, 1999) found that journal writing about stressful events actually improved symptoms in those with the atopic diseases of rheumatoid arthritis and asthma (see 'Emotional expression and health'). Therefore, psychological and behavioural treatments are sensible adjunctives to medical treatment for those experiencing allergic symptoms. Recommendations include a close dovetailing of research, treatments and public policy for a consummate health psychology approach (Nicassio *et al.*, 2004).

Psychological and behavioural treatments

Research on the efficacy of psychological and behavioural treatments now needs increased conceptual and methodological rigour. For instance, individual differences such as absorption ability can spuriously confound results if not appropriately controlled (Gregerson, 2000, 2003). Of the different types of health psychology interventions available, the strongest evidence for allergy management exists for hypnosis and conditioning treatments, with equivocal support for disclosure and stress management and no support for relaxation (Miller & Cohen, 2001) (see 'Hypnosis' and 'Behaviour therapy'). All allergy research and treatment with psychosocial variables aims at morbidity and mortality but not etiology.

For allergies per se, emotional treatment and behavioural medical approaches (Schmidt-Traub & Bamler, 1992) have proved effective in diminishing outbreaks. Other alternative approaches have included hypnosis (for review see Jemmott & Locke, 1984) and nutrition (Van Flandern, 1985). The ubiquitous issue of adherence/compliance with allergy treatments has responded to behavioural intervention (Finney *et al.*, 1990).

Allergies also have a strong body of research addressing the effects of the mother-child relationship and family environment upon symptom severity. For example, one study identified parent dyadic patterns which predicted allergy risk level in children (Faleide *et al.*, 1988). Other work found that higher support, independence and organization, as well as lower religiosity, predicted lesser atopic dermatitis symptom severity in children (Gil *et al.*, 1987). Significant relief of asthmatic symptoms has resulted from

family therapy compared with conventional medical treatment (Gustafsson *et al.*, 1986). One study pinpointed open extended discussion of conflict as the distinguishing characteristic of families without a member with asthma compared with those in which asthma was present (Northey *et al.*, 1998), although the direction of causality was neither established nor addressed.

More definitive research needs to identify, assess and treat family patterns, among other psychosocial variables, related to allergic symptoms. In addition to familial support, a review (Uchino *et al.*, 1996) has emphasized that emotional support appears as important as social support for its important psychoimmune influence (see 'Psychoneuroimmunology' and 'Social support and health'). Moreover, health-related behaviours appear superfluous to such psychoimmune associations like those found in allergies. Finally, stress buffering might be possible.

Conclusion

So, an array of psychological and behavioural factors appears to be implicated, at least, in allergy management. Personality characteristics such as absorption ability and anxiety sensitivity need consideration in research into and treatment of allergies. Furthermore, familial and other social support, emotional support and stress management appear worthwhile to pursue as morbidity and mortality factors. Again, no studies appear to definitively address the behavioural, psychological and social effects of allergy aetiology.

Amnesia

Barbara A. Wilson¹ and Narinder Kapur²

¹MRC Cognition and Brain Sciences Unit

²Addenbrooke's Hospital

Amnesia and organic memory impairment are commonly seen after many types of brain injury including degenerative disorders, head injury, anoxia and infections of the brain. If severe, amnesia is often more handicapping in everyday life than severe physical problems.

People with the classic amnesic syndrome show an anterograde amnesia (AA), i.e. they have great difficulty learning and remembering most kinds of new information. Immediate memory, however, is normal when this is assessed by forward digit span or the recency effect in free recall. There is usually a period of retrograde amnesia (RA), that is a loss of information acquired before the onset of the amnesia. This gap or period of RA is very variable in length and may range from a few minutes to decades. Previously acquired semantic knowledge about the world and implicit memory (remembering without awareness or conscious recollection) are typically intact in amnesic subjects. As the majority of patients with severe memory disorders present with additional cognitive problems such as attention deficits, word finding problems or slowed information processing, those with a classic amnesic syndrome are relatively rare.

Nevertheless, people with a 'pure' amnesic syndrome and people with more widespread cognitive deficits tend to share certain characteristics. In both cases, immediate memory is reasonably normal; there is difficulty in remembering after a delay or distraction; new

learning is difficult and there is a tendency to remember things that happened a long time before the accident or illness better than things that happened a short time before.

A number of conceptual frameworks have been proposed to help explain the pattern of memory loss that is seen in memory-impaired patients. The reader is referred to the *Oxford handbook of memory* (Craik & Tulving, 2000) for a detailed exposition of memory models and theoretical expositions that are available for helping to consider memory loss in neurological populations. There is a broad consensus that memory is best considered as a number of dissociable systems, rather than as a unitary system (Schacter & Tulving, 1994), though it is likely that there is considerable overlap in the brain mechanisms underlying some of these systems (Rajah & McIntosh, 2005).

The commonly agreed memory systems are:

- *Episodic memory*, which refers to the retention of personally-experienced events that can be related to specific spatial and temporal contexts (e.g. remembering a recent holiday).
- *Semantic memory*, which refers to the organized knowledge about words, concepts and culturally/educationally-acquired facts (e.g. knowing what certain words mean).

- *Working memory* (sometimes called short-term memory), which refers to processes for holding and manipulating material in a temporary store, usually for seconds or a few minutes (e.g. remembering a telephone number shortly after hearing it).
- *Procedural memory*, which usually refers to the ability to acquire new skills, or use previously acquired skills, be they motor or linguistic (e.g. learning to ride a bicycle).
- *Perceptual memory*, which usually refers to the ability to retain the perceptual features of a stimulus, and is thought to underlie learning that leads to the perceptual identification of stimuli (e.g. seeing a new model of a car and being able to identify it better the second time round).

In the case of memory processes, while it is generally accepted that encoding, consolidation and retrieval represent important stages of memory processing, there are divergent views as to the specific mechanisms that underlie such stages (Meeter & Murre, 2004). The 'standard consolidation' model (Squire *et al.*, 2004) takes the view that while the medial temporal lobe plays a part in the laying down of new memories, their stored representation is eventually subserved by cortical mechanisms, especially those in the neocortex. By contrast, the multiple-trace model (Nadel *et al.*, 2000) regards the medial temporal lobe as being critical for the retention and recollection of all episodic memories, no matter how long ago they have been stored.

Although precise figures are not available, there are considerable numbers of memory impaired people in society. Some 10% of people over 65 years of age have dementia and some 36% of people with severe head injury will have permanent memory impairments (see 'Dementias' and 'Head injury'). Add to these figures those whose memory deficits result from Korsakoff's syndrome, encephalitis, anoxia, AIDS and so forth, and one can begin to appreciate the enormity of the problem.

Assessment of memory should include both neuropsychological and behavioural measures as it is important to identify cognitive strengths and weaknesses and to identify the everyday problems arising from memory impairment. Neuropsychological tests should include general intellectual functioning, language, perception and executive functioning as well as detailed memory assessments. Immediate and delayed memory, nonverbal and verbal memory, recall and recognition, semantic and episodic memory,

implicit memory (remembering without awareness) and new learning will all need to be assessed (see Wilson, 2004 for further discussion). More functional and behavioural measures will identify everyday problems causing concern and distress. These measures include observations in real life settings, interviewing patients, their relatives and care staff and the collection of information from such self report measures as diaries, checklists, questionnaires and rating scales (see 'Neuropsychological assessment').

Restoration of memory functioning or retraining of memory following brain damage appear to be unachievable goals although some recovery may occur for a period of years (Kapur & Graham, 2002; Wilson, 2003). Consequently, rehabilitation for memory-impaired people focuses on environmental adaptations, compensatory strategies, improving learning and helping them to make better use of their residual skills. For those who are very severely intellectually impaired, structuring the environment, to reduce the need to remember, is probably the most effective method. Examples include labelling doors, cupboards and drawers, drawing coloured lines from one place to another and positioning material so it cannot be missed. External memory aids are probably the most beneficial of all therapeutic approaches, although many memory-impaired people find it difficult to use these aids efficiently and it requires considerable ingenuity to teach their use (Sohlberg & Mateer, 1989). Kapur *et al.* (2004) cover aspects of external and compensatory aids in some detail. One of the recent developments for improving learning in amnesic subjects is the errorless learning approach (Baddeley & Wilson, 1994; Wilson *et al.*, 1994) whereby it was shown that preventing errors during the learning process led to improved learning by amnesic subjects. Helping people to make better use of their residual, albeit damaged, memory skills can be achieved through the use of mnemonics and study or rehearsal strategies (see 'Neuropsychological rehabilitation').

Finally, many memory-impaired people are anxious and isolated; so too are their families. Rehabilitation should address these anxieties through anxiety management programmes, information and counselling and perhaps through groups for patients and/or their relatives. Tate (2004) addresses these issues and other aspects of rehabilitation for people with amnesia.

Amputation and phantom limb pain

Ronald Melzack¹ and Joel Katz²

¹McGill University

²York University

Phantom limbs occur in 95–100% of amputees who lose an arm or leg. The phantom limb is usually described as having a tingling feeling and a definite shape that resembles the somatosensory experience of the real limb before amputation. It is reported to move through space in much the same way as the normal limb would move when the person walks, sits down, or stretches out on a bed. At first, the phantom limb feels perfectly normal in size and shape, so much so that the amputee may reach out for objects with the phantom hand, or try to step on to the floor with the phantom leg. As time passes, however, the phantom limb begins to change shape. The arm or leg becomes less distinct and may fade away altogether, so that the phantom hand or foot seems to be hanging in mid-air. Sometimes, the limb is slowly ‘telescoped’ into the stump until only the hand or foot remain at the stump tip (Solonen, 1962). However, the neural basis of the phantom does not disappear. Injury of the stump years or decades after fading or telescoping may suddenly produce a phantom as vivid and full-sized as that felt immediately after amputation (Cohen, 1944).

Amputation is not essential for the occurrence of a phantom. After avulsion of the brachial plexus of the arm, without injury to the arm itself, most patients report a phantom arm (the ‘third arm’) which is usually extremely painful (Wynn-Parry, 1980). Even nerve destruction is not necessary. About 95% of patients who receive an anaesthetic block of the brachial plexus for surgery of the arm report a vivid phantom, usually at the side or over the chest, which is unrelated to the position of the real arm when the eyes are closed but ‘jumps’ into it when the patient looks at the arm (Melzack & Bromage, 1973). Similarly, a spinal anaesthetic block of the lower body produces reports of phantom legs in most patients (Bromage & Melzack, 1974), and a total section of the spinal cord at thoracic levels leads to reports of a phantom body including genitalia and many other body parts in virtually all patients (Bors, 1951; Conomy, 1973; Melzack & Loeser, 1978).

Phantom limb phenomena

The most astonishing feature of the phantom limb is its incredible reality to the amputee (Simmel, 1956), which is enhanced by wearing an artificial arm or leg; the prosthesis feels real, ‘fleshed out’. Amputees in whom the phantom leg has begun to ‘telescope’ into the stump, so that the foot is felt to be above floor level, report that the phantom fills the artificial leg when it is strapped on and the phantom foot now occupies the space of the artificial foot in its shoe (Riddoch, 1941). Patients who have undergone a cleavage of the forearm stump muscles, to permit them to hold objects, report that the phantom hand also has a cleavage and lies appropriately in the stump (Kallio, 1950).

The remarkable reality of the phantom is reinforced by the experience of details of the limb before amputation (Katz & Melzack, 1990, 2003). For example, the person may feel a painful bunion that had been on the foot or even a tight ring on a phantom finger. Still more astonishing is the fact that some amputees who receive drugs that produce the tremor of tardive dyskinesia report a tremor in the phantom (Jankovic & Glass, 1985).

Phantoms of other body parts feel just as real as limbs do. Heusner (1950) describes two men who underwent amputation of the penis. One of them, during a 4-year period, was intermittently aware of a painless but always erect phantom penis. The other man had severe pain of the phantom penis. Phantom bladders and rectums have the same quality of reality (Bors, 1951; Dorpat, 1971). The bladder may feel so real that patients, after a bladder removal, sometimes complain of a full bladder and even report that they are urinating. Patients with a phantom rectum may actually feel that they are passing gas or faeces. Menstrual cramps may continue to be felt after a hysterectomy. A painless phantom breast, in which the nipple is the most vivid part, is reported by about 25% of women after a mastectomy and 13% feel pain in the phantom (Kroner *et al.*, 1989).

The reality of the phantom body is evident in paraplegics who suffer a complete break of the spinal cord. Even though they have no somatic sensation or voluntary movement below the level of the break, they often report that they still feel their legs and lower body (Bors, 1951; Burke & Woodward, 1976). The phantom appears to inhabit the body when the person's eyes are open and usually moves co-ordinately with visually perceived movements of the body. Initially, the patient may realize the dissociation between the two when he sees his legs stretched out on the road after an accident yet feels them to be over his chest or head. Later, the phantom becomes coordinate with the body, and dissociation is rare.

Descriptions given by amputees and paraplegics indicate the range of the qualities of experience of phantom body parts (Bors, 1951; Katz & Melzack, 2003, 1990). Touch, pressure, warmth, cold and many kinds of pain are common. There are also feelings of itch, tickle, wetness, sweatiness and tactile texture. Even the experience of fatigue due to movement of the phantom limb is reported (Conomy, 1973). Furthermore, male paraplegics with total spinal sections report feeling erections and paraplegic women describe sexual sensations in the perineal area. Both describe feelings of pleasure, including orgasms (Bors, 1951; Money, 1964; Verkuyl, 1969).

One of the most striking features of the phantom limb or any other body part, including half of the body in many paraplegics, is that it is perceived as an integral part of one's self. Even when a phantom foot dangles 'in mid-air' (without a connecting leg) a few inches below the stump, it still moves appropriately with the other limbs and is unmistakable felt to be part of one's body-self. So, too, the multiple phantoms sometimes felt after an amputation are all part of the self (Lacroix *et al.*, 1992). The fact that the experience of 'self' is subserved by specific brain mechanisms is demonstrated by the converse of a phantom limb, the denial that a part of one's body belongs to one's self. Typically, the person, after a lesion of the right parietal lobe or any of several other brain areas (Mesulam, 1981) denies that a side of the body is part of him by or herself and even ignores the space on that side (Denny-Brown *et al.*, 1952). From these cases it is evident that the brain processes which underlie the experience of our bodies must impart a special signal that provides the basis for experience of the self. When these brain areas are lost, the person denies that a part of the body belongs to the self. Even when a hand, for example, is pinched hard so that the patient winces or cries out, s/he still denies that the hand is hers/his.

There is convincing evidence that a substantial number of people who are born without all or part of a limb (congenital limb deficiency) feel a vivid phantom pain of the missing part. These phantoms are reported by children (Poeck, 1964; Weinstein *et al.*, 1964; Melzack *et al.*, 1997) as well as by adults (Saadah & Melzack, 1994; Brugger & Regard, 1997), and possess all the properties of phantoms described by amputees. Furthermore, the phantom may sometimes not appear until maturity, usually after a minor injury or surgery of the deficient limb (Saadah & Melzack, 1994).

The innate neural substrate implied by these data does not mean that learning experience is irrelevant. Learning obviously underlies the fact that people's phantoms assume the shape of the prosthesis, and people with a deformed leg or a painful corn often report, after amputation, that the phantom is deformed or has a corn. That is, sensory inputs play an important role in the experience of the phantom limb. Heredity and environment clearly act together to produce the phenomena of phantom limbs.

These observations can be summarized in the form of four propositions (Melzack, 1989) which derive from the data:

1. The experience of a phantom limb has the quality of reality because it is produced by the same brain processes that underlie the experience of the body when it is intact.
2. Neural networks in the brain generate all the qualities of experience that are felt to originate in the body; inputs from the body may trigger or modulate the output of the networks but are not essential for any of the qualities of experience.
3. The experience of the body has a unitary, integrated quality which includes the quality of the 'self', that the body is uniquely one's own and not that of any other individual.
4. The neural network that underlies the experience of the body-self is genetically determined but can be modified by sensory experience.

A hypothesis for phantom limbs: the neuromatrix

The anatomical substrate of the body-self, Melzack (1989) proposes, is a network of neurons that extends throughout widespread areas of the brain (which has been demonstrated in imaging studies by Ingvar & Hsieh, 1999). He has labelled the network, whose spatial distribution and synaptic links are initially determined genetically, and are later sculpted by sensory inputs, as a 'neuromatrix'. Thalamocortical and limbic loops that comprise the neuromatrix diverge to permit parallel processing in different components of the neuromatrix and converge repeatedly to permit interactions between the output products of processing. The repeated cyclical processing and synthesis of nerve impulses in the neuromatrix imparts a characteristic pattern or 'neurosignature'.

The neurosignature of the neuromatrix is imparted on all nerve impulse patterns that flow through it; the neurosignature is produced by the patterns of synaptic connections, which are initially innate and then modified by experience, in the entire neuromatrix. All inputs from the body undergo cyclical processing and synthesis so that characteristic patterns are impressed on them in the neuromatrix. Portions of the neuromatrix are assumed to be specialized to process information related to major sensory events (such as injury) and may be labelled as neuromodules which impress subsignatures on the larger neurosignature.

Phantom limb pain

About 70% of amputees suffer burning, cramping and other qualities of pain in the first few weeks after amputation. Even seven years after amputation, 50% still continue to suffer phantom limb pain (Krebs *et al.*, 1985; Jensen & Nikolajsen, 1999). Why is there so much pain in phantom limbs? Melzack (1989) proposes that the active neuromatrix, when deprived of modulating inputs from the limbs or body, produces an abnormal signature pattern that subserves the psychological qualities of hot or burning, the most common qualities of phantom limb pain. Cramping pain, however, may be due to messages from the neuromatrix to produce movement. In the absence of the limbs, the messages to move the muscles may become more frequent and 'stronger' in the attempt to move a part of the limb. The end result of the output message may be felt as cramping muscle

pain. Shooting pains may have a similar origin, in which the neuromatrix attempts to move the whole limb and sends out abnormal patterns that are felt as pain shooting down from the groin to the foot. The origins of these pains, then, lie in the brain. Sensory inputs, however, clearly contribute to the phantom: stimulation of the stump or other body sites often produces sensations referred to the phantom limb (Katz & Melzack, 2003).

Surgical removal of the somatosensory areas of the cortex or thalamus generally fails to relieve phantom limb pain (White & Sweet, 1969). However, the new theory conceives of a neuromatrix that extends throughout selective areas of the whole brain, including the somatic, visual and limbic systems. Thus, to destroy the

neuromatrix for the body-self which generates the neurosignature pattern for pain is impossible. However, if the pattern for pain is generated by cyclical processing and synthesis, then it should be possible to block it by injection of a local anesthetic into appropriate discrete areas that are hypothesized to comprise the widespread neuromatrix. Data obtained in rats have shown that localized injections of lidocaine into diverse areas, such as the lateral hypothalamus and the dentate gyrus (McKenna & Melzack, 1992) produce striking decreases in experimentally produced pain, including the pain in an animal model of phantom limb pain (Vaccarino & Melzack, 1991).

Anaesthesia and psychology

Keith Millar

University of Glasgow

The introduction of anaesthesia using ether and chloroform in the mid-nineteenth century meant that patients were largely spared the horror of surgery whilst conscious or merely sedated. Oblivion and survival were not assured, however, when those volatile agents were administered by less skilled practitioners. Now, in the twenty-first century, anaesthesia is reassuringly safe. Although estimates show that some 0.1% of patients die during anaesthesia, mortality during this period is confounded with both the effects of surgery and the patient's state of health which may compromise survival during a procedure. Deaths caused by the anaesthetic are therefore very rare. Where deaths can be attributed to the anaesthetic, they may arise from equipment malfunction or human error, rather than the anaesthetic itself (Arnstein, 1997).

Concern does attach, however, to the effects of anaesthesia upon cognitive function. The increasing trend towards day-case surgery means that patients are admitted to hospital, anaesthetized and subjected to a surgical procedure or investigation and then discharged a few hours later. The critical issue is whether patients' cognitive functioning has recovered sufficiently at the time of discharge for them to be regarded as 'street-fit'. As many patients do not heed advice to be cautious in their post-anaesthetic activities, there is clearly a practical imperative to establish the degree and duration of impairment after anaesthesia.

The typical methodology of studies of recovery

Most clinical studies estimate the 'average' recovery profile of an anaesthetic agent (in other words, the group mean response to the anaesthetic) rather than whether an individual patient has recovered their normal level of functioning. Studies commonly use test batteries to assess the main domains of cognitive functioning, many tests being derived from research into factors known to affect arousal including sleep deprivation and alcohol sedation. Others have been adapted from neuropsychological assessments (see 'Neuropsychological assessment').

Prior to anaesthesia, patients practice the tasks in order to provide a baseline with which to compare post-anaesthetic performance. In a busy day-case unit, the conditions are rarely optimal, and patients are distracted by the impending procedure, so that the baseline assessment is not a stable measure. When well enough after recovering consciousness, patients repeat the tests at intervals until time for discharge. In the immediate recovery period, performance shows highly significant impairment relative to the preoperative baseline. Over a period of a few hours, however, performance will typically recover to the level seen at baseline.

Potential shortcomings in methodologies

The problem of group mean performance

The recovery profile described above is typical of studies where performance is averaged across a group of patients. The conclusion is that the recovery profile represents the duration of impairment for the 'average' patient. In the case of modern intravenous anaesthetics, such profiles often favour a conclusion that recovery is complete after some three to four hours. However, the standard deviation of the mean reveals that many patients do not enjoy 'average' recovery and that a significant proportion must remain impaired at discharge. The 'masking' of individual impairment is long recognized (Hickey *et al.*, 1991), and statistical solutions are readily available, but the issue continues to be neglected.

Practice effects and the omission of control groups

Few performance tasks are free of practice effects and, as noted above, day-case conditions rarely permit sufficient practice. Inclusion of a control group that does not undergo anaesthesia, but follows the same test schedule as the anaesthetized group, allows practice effects to be estimated. Regrettably, few studies employ control groups.

Insensitive assessments

Decades of human performance research have established key factors that determine whether a task will be sensitive to cognitive impairment. However, many of these factors are neglected in recovery research.

Task duration and short-term effort

Studies of sleep deprivation have shown that adverse effects on cognition are often detected only when tasks last for 20 minutes or more because, in the short-term, people can motivate themselves to perform well, even when fatigued. Similarly, even when still sedated after anaesthesia, patients can pull themselves together to perform effectively for a few minutes on a short task to give the misleading impression of normal functioning (Dijkstra *et al.*, 1999). Many post-anaesthetic assessments employ durations of 60 seconds or less, and hence bear no resemblance to conditions encountered when discharged. As the hospital environment constrains performance assessment, a pragmatic approach might concentrate upon the extended performance of one task. Pollard *et al.* (1994) have confirmed the benefits to detecting residual impairment where task duration is sufficient for performance to be examined as a function of time on task.

Task complexity

Just as brief tasks may be insensitive, so, too, are those which are simple and undemanding. Tasks which require sustained attention may provide a solution because they give no opportunity for respite. They may also permit the use of relatively shorter performance periods without loss of sensitivity to impairment: for example, a stimulus-matching task employing a very fast rate of information has been shown effective even at very short task durations.

Sampling and exclusions

Patients are often excluded from anaesthetic recovery studies if they suffer conditions including cardiovascular disease, cancer, hepatic and renal disease, diabetes and affective disorder. Whilst such exclusions still permit relatively homogeneous samples, they are not representative of the population at large. Older patients will often have one or more of the above conditions, any one of which will also affect cognition, so that to exclude them is to favour a benign outcome. Where the study is conducted to evaluate a new anaesthetic agent, the outcome may give a misleading impression of the true degree and duration of impairment. Given the power of statistical modelling to account for variables such as those above, there must be an argument for recovery studies to be broad ranging in their sampling in order to derive a reliable estimate of impairment.

Effect sizes, sample size and power

In the immediate recovery period, virtually all patients show very marked performance impairment relative to their preoperative performance. The effect size of the anaesthetic at this stage is very large and, consequently, only small samples are required to demonstrate highly significant impairment. As recovery continues, impairment reduces and differences from baseline become statistically non-significant. Whilst the conclusion is then that impairment has resolved, many studies simply do not have the power to detect subtle residual impairment. Sample sizes for such studies should be estimated from the much smaller effect sizes likely to be observed later in the recovery period where a relatively smaller proportion of patients continue to suffer residual impairment. The detection of residual impairment in such vulnerable patients is of critical clinical and applied importance.

Defining impairment and the issue of pre-existing deficits

Impairment

'Impairment' is often implicitly defined as a statistically significant difference between baseline and postoperative performance: the corollary is then that impairment has resolved when such differences are not significant. However, for reasons discussed above, such a definition of impairment is inadequate. Other definitions of impairment are arbitrary; for example, that performance is impaired when it differs from baseline performance by more than one standard deviation of the baseline mean. Collie *et al.* (2002) have reviewed alternatives to detecting cognitive change which include the familiar reliability-change index and its modifications, and simple and multiple regression procedures.

Tasks which have extensive age- and gender-based performance norms permit estimation of whether a given patient is impaired relative to the norm (Ancelin *et al.*, 2001). Many of the well-developed computerized test batteries provide such norms, as do the more traditional neuropsychological assessments. Such norms also afford the possibility of establishing whether a patient's performance is relatively impaired *before* anaesthesia.

Post-anaesthetic impairment can also be defined by comparing the effects of anaesthesia with the well-established effects of a sedative drug such as alcohol. Alcohol is a useful comparator because a specific blood-alcohol content (BAC) has been legally defined as the limit for driving safely. Given the importance that patients are 'street-fit' when discharged after anaesthesia, it has been shown that there is utility in defining their state according to the level of performance associated with the legal limit for alcohol (Grant *et al.*, 2000; Thapar *et al.*, 1995).

Pre-existing deficits

Pre-existing impairment is known to be a significant predictor of postoperative decline in patients having cardiac bypass surgery (Millar *et al.*, 2001; Rankin *et al.*, 2003). However, the role of pre-existing impairment in patients having non-cardiac procedures is little known. Ancelin *et al.* (2001) have, however, shown that pre-existing impairment, greater age, low educational exposure and depressive symptoms are predictive of greater postoperative impairment in patients aged over sixty-four years.

Vulnerable groups

Older adults

The vulnerability of older adults to post-anaesthetic impairment is of growing practical importance as the proportion of such patients in the population increases (see 'Ageing and health behaviour'). Moreover, advances in anaesthetic and surgical techniques mean that many more older patients can now be subjected safely to such procedures: more than half of those currently aged over 65 years will undergo anaesthesia and surgery in the years remaining to them.

A multi-centre study of 1218 patients aged greater than 60 years and having major non-cardiac surgery, reported 25.8% post-operative cognitive impairment at 1 week after surgery, and 9.9% at 3 months, in comparison with 3.4% and 2.8% respectively in a control group (Moller *et al.*, 1998). A 10% incidence of impairment is cause enough for concern, but is probably an under-estimate because the authors acknowledge that theirs was a relatively fit sample, and that attrition was more likely in those with cognitive impairment. Re-analysis of other recovery studies confirms that substantially more patients suffer cognitive deficits than first supposed (Kneebone *et al.*, 1998): indeed, a remarkable 56% of older patients may suffer persistent impairment at 3 months after anaesthesia (Ancelin *et al.*, *op. cit.*).

It is beyond the scope of this chapter to consider in detail the supposed mechanisms of post-anaesthetic cognitive impairment which are so well exemplified in older patients. Dodds and Allison (1998) provide an extensive review of physiological, neurological,

biochemical and genetic factors that may explain postoperative decline.

Children

Some 60% of children exhibit behavioural disturbance immediately after anaesthesia and 30% continue to show symptoms one month later (Kotiniemi *et al.*, 1996). Children who have pre-existing behavioural problems, and younger children, are at greater risk. Little is known of the effects of anaesthesia on children's cognition, probably because of the practical difficulties in assessing them peri-operatively. Anaesthetics have different pharmacokinetics and dynamics in children so that one cannot draw implications from the cognitive effects seen in adults. There is, however, evidence that reaction time, memory and psychomotor co-ordination may be impaired for up to three hours after day-case anaesthesia, and may not have resolved at the time of discharge (Millar *et al.*, 2006; Schröter *et al.*, 1996).

Patients who are 'aware' during anaesthesia

On awakening from general anaesthesia, some 0.2–0.7% of patients report awareness and memories, sometimes traumatic, of pain and

intra-operative events. The use of muscle-relaxant drugs to aid surgery prevents them from signalling their awareness at the time. Whilst some of these 'explicit' memories are explained by inadvertent or deliberate 'light' anaesthesia (for example in obstetric cases), enterprising research has employed sensitive tests of 'implicit memory' to provide variable evidence that patients can retain implicit (unconscious) memories for verbal stimuli presented whilst they are ostensibly adequately anaesthetised. The methodology has been employed in conjunction with electrophysiological measures of brain activity and other physical indicators of awareness in an attempt to establish the precise anaesthetic conditions under which explicit and implicit memories occur.

Concern also attaches to the potential emotional consequences of such memories which may, in turn, have legal consequences when patients seek compensation for suffering such a traumatic experience. There is evidence for emotional disturbance after episodes of frank awareness, and that in some circumstances psychological disorder also follows periods of wakefulness for which no explicit memory is retained (Wang, 2001). Comprehensive coverage of this enigmatic and highly significant research is found in the text by Ghoneim (2001).

Antenatal care

Kirstie McKenzie-McHarg and Rachel Rowe

University of Oxford

The provision and type of antenatal care varies across countries and continents, but its general aim is always to ensure that women and their unborn babies remain healthy during pregnancy and that any difficulties are diagnosed early and treated appropriately. Typical antenatal interventions include ultrasound screening, regular blood and urine tests, maternal weight checks, fetal heart monitoring and discussions relating to lifestyle changes such as diet and smoking. In addition, women are generally offered antenatal screening for chromosomal or structural fetal abnormalities and diagnostic testing if necessary (see 'Screening: antenatal'). Most women and their partners are given the opportunity to attend antenatal classes, aimed at providing information relating to labour and delivery, and some have access to parentcraft classes, aimed at teaching prospective parents about care of a newborn baby. There is also a wealth of educational material available, and women may access this via the Internet, directly from their care providers, in books or through friends and family.

In 1997, Clement *et al.* examined a range of methods of providing antenatal care, with the express aim of meeting women's psychological needs. They identified three strands of maternal antenatal psychological need, information and support and reassurance. They argue that the professional emphasis of routine antenatal appointments is often on medical issues, whereas women need time to ask questions, be reassured about symptoms and think through concerns. They propose a system of individualized care, where each pregnant woman and her healthcare providers work together to devise a mutually acceptable programme of antenatal care, including discussions relating to timing of antenatal visits, type and level of interventions and access to educational materials and groups. This group of researchers also recognized the need for flexibility within the antenatal system, suggesting an enhanced provision of care which could incorporate drop-in clinics, telephone counselling and targeted advice where necessary.

In the same year, the first edition of this title was published, and Hewison noted in this chapter (pp. 366–7) that the UK picture of antenatal care was changing (Hewison, 1997). At that time, the UK government's stated policy (*Changing Childbirth*, 1993) was to see maternity services become more woman-centred, giving more control of care and involvement in decision-making into each woman's hands. This sentiment has been mirrored in many parts of the world and there has been a significant increase in the level of research interested in ascertaining women's views and experiences of antenatal care generally and in relation to specific interventions. For example, Nigenda *et al.* (2003) undertook a study of women's opinions of antenatal care in four developing countries, while Ladfors *et al.* (2001) examined Swedish women's opinions of antenatal, delivery and postpartum care. In the UK, changes made as a

direct result of the government's new policy were evaluated by Spurgeon *et al.* (2001) and the DIPEX group has been formed, aimed at qualitatively evaluating individual experiences of health-care (www.dipex.org.uk).

Research such as this clarifies that women experience the varying types of intervention differently and that each woman will have an individual response. Inevitably, this means that the process of ensuring that all women receive personally satisfactory and appropriate antenatal care is a complex one. For example, Hildingsson *et al.* (2002) assessed women's preferences in terms of the number of antenatal visits, finding that around one-third of women wanted more or fewer than the standard number, highlighting the need for flexibility within the system. They also found that women who had previously experienced a stillbirth, miscarriage or negative birth experience were in need of 'special attention', emphasizing the importance of considering women's individual circumstances, personal resources and psychological responses within the antenatal care system. Even when a majority of women are positive about a specific intervention, there may be unforeseen repercussions. For example, Garcia *et al.* (2002) conducted a systematic review of women's views of pregnancy ultrasound, and found that although women were generally positive about having ultrasound offered and performed, there was a lack of clarity relating to the purpose of these scans, and women were often unprepared for adverse findings. A qualitative study examining women's experiences of screening and perceptions of risk of group B streptococcus, found that this intervention remained poorly understood despite the majority of women agreeing to undergo the test (Darbyshire *et al.*, 2003). Unnecessarily high levels of psychological distress may result if there is an initial lack of understanding or preparedness for an unwanted test outcome (see 'Screening: antenatal' and 'Screening: general issues').

The importance of psychological wellbeing during pregnancy is paramount. Antenatal psychological distress has been linked to postnatal psychological distress (Green, 1990) and antenatal depression and antenatal anxiety are both significant predictors of postnatal depression (e.g. O'Hara *et al.*, 1991; Ritter *et al.*, 2000). Women who have low self-confidence and poor support antenatally appear to be at increased risk of a range of postnatal psychological problems including depression and post-traumatic stress disorder (Czarnocka & Slade, 2000; Keogh *et al.*, 2002) and there is evidence that good antenatal psychosocial support may even have an impact on physical outcomes such as birthweight and fetal growth (Feldman *et al.*, 2000; Rini *et al.*, 1999). Many antenatal interventions can themselves create anxiety in women; Baillie *et al.* (2000) found that two-thirds of women identified via ultrasound screening as being 'high risk' continued to experience residual anxiety about their pregnancy even after being reassured by a negative diagnostic

test, with potential implications for secure attachment. Women experiencing antenatal psychological difficulties such as anxiety or depression are likely to have increased need in terms of support, information and reassurance.

Psychological difficulties can be compounded when associated with social disadvantage (see 'Socioeconomic status and health'). Brown and Harris (1978) studied pregnant women and women caring for children at home in the 1970s and found that working class women experienced a higher frequency of life events than more affluent women. Irrespective of severe life events, women in lower social classes are more likely to suffer from anxiety, depression and phobias than higher social class women (Goldberg, 1999). While social support may have a protective effect in terms of mental health, acting as a 'buffer' against stress and anxiety (see 'Social support and health'), the effects of poverty and area deprivation may combine so that disadvantaged women may have reduced access to a range of potential sources of advice and social support such as shops, health facilities, parks and friends.

A significant UK development since the first edition of this title is the recent publication of the *Antenatal care guideline* (National Collaborating Centre for Women's and Children's Health, 2003). This guideline sets out the standards of antenatal care expected for the healthy pregnant woman, and includes advice relating to woman-centred care, informed decision-making, lifestyle considerations, management of pregnancy symptoms, clinical examination, screening, fetal growth and wellbeing and management of specific clinical conditions. The publication of the guideline has implications for the psychological wellbeing of pregnant women: standards of care are now described based on the best quality evidence available and services are expected to move towards delivering the standards described. One challenge faced by care providers is to meet these standards of care while remaining flexible and responsive to the needs of women from different social and ethnic backgrounds in the context of substantial and persistent social

inequalities in the outcome of pregnancy. The move towards having more first trimester antenatal appointments is a good example here. The aim is to provide women with increased support and information at a time when the demands on them, in terms of learning about pregnancy and making decisions about antenatal care, are greatest. Women experiencing psychological difficulties or from particularly socially disadvantaged backgrounds may have increased needs at this time, but may also be least able to access these services in a timely way. Antenatal care providers need to consider how best to reach out to and engage those women so that they are able to take advantage of best quality care and make informed choices. It is at this point in time that services are faced with the challenge of providing best quality care, together with the range of flexibility needed to ensure that women and their families can have the level and type of care provision that is most appropriate for them medically and psychologically.

In summary, research that examines women's satisfaction with antenatal care, and their experiences of specific interventions, shows that most women do wish to be actively involved in making decisions about their own care. It also shows that there may be confusion about the purpose of interventions such as screening, and that more may need to be done to prepare women for the potentially negative findings of the tests, which can lead to psychological distress at a higher level than would be expected if women were better prepared. All women need to be given the opportunity to ask questions within an environment conducive to understanding. It is not enough to ask women to acquiesce in suggested care; the research suggests that while many women will agree to suggested interventions, additional explanation is required in order to achieve an appropriate level of understanding. Psychological distress can occur both antenatally and postnatally, but as antenatal distress is a significant risk factor for postnatal difficulties, appropriate antenatal care and support is of paramount importance.

Aphasia recovery, treatment and psychosocial adjustment

Chris Code

University of Exeter

'Aphasia' is the generic term used to describe the common range of language impairments that can follow mainly left hemisphere brain damage. Neurological damage can also cause a range of communication problems that do not directly affect such 'straight' linguistic aspects of language, such as right hemisphere language impairments, impairments to the planning component of speech production (apraxias of speech) and dysarthria (i.e. articulation impairment). To distinguish aphasia from other language impairments accompanying brain damage, aphasia can be described in terms of disorders of the core components of a linguistic model; features like lexical semantics, syntax, morphology and phonology. This chapter will outline what we know about the recovery from, psychosocial adjustment to and therapy for, aphasia.

Recovery

Most research into recovery from aphasia has been without reference to any theoretical model. Group studies have shown that most aphasic people make some recovery, yet most studies have used operational definitions, based on a group's improved performance on a test battery (Basso, 1992; Code, 2001) (see 'Neuropsychological assessment').

Such operational definitions, e.g. change in an overall score or aphasia quotient on a psychometric battery, are used widely but do not help to improve understanding of the cognitive processes underlying recovery. One hypothesis (e.g. Le Vere, 1980) is that recovery is best seen as neural sparing and distinguishes between 'losses' which simply cannot be recovered, and behavioural deficits

which are the result of attempts to shift control to undamaged neural systems. Real recovery requires the sparing of the underlying neural tissue. Behavioural deficits, the characteristics or symptoms of aphasia for instance, are compensatory. Recovery for an individual therefore may occur through a combination of restitution of lost cognitive functions or compensation for lost functions.

There have been three basic approaches to predicting recovery. A range of prognostic factors has been identified and significant relationships are often found between demographic variables and outcome (e.g. de Riesthal & Wertz, 2004) but reviews complain (Code, 2001; Basso, 1992) that on many of them there is disagreement. Such factors as severity, aphasia type, site and extent of lesion, presence of dysarthria and bilateral damage, are clearly inter-related and probably interdependent (Code, 1987). There is considerable controversy as to whether some are useful theoretical constructs (e.g. type of aphasia). For several, such as age, sex and handedness there is considerable disagreement between studies regarding their prognostic value (de Riesthal & Wertz, 2004; Basso, 1992).

A second approach involves classification into aphasia type. If type is known then some prognosis can be made. However, between 30–70% of aphasic speakers are not classifiable; many change type with recovery and many do not recover in predictable ways. Fundamentally, milder types ('Conduction', 'Transcortical', 'Anomia') have the best prognosis and severe types ('Global', 'Broca's', 'Wernicke's') have the least hopeful. However, 'type' correlates highly with severity.

Thirdly, Porch *et al.* (1980) developed a statistical approach to predict a likely recovery entailing detailed analysis of scores on

the *Porch Index of Communicative Abilities* (the PICA) (Porch, 1967), a standardized aphasia test. Using multiple regression, they demonstrated that PICA scores at 1 month post-onset could predict an overall PICA score at 3, 6 and 12 months post-onset with correlations ranging from 0.74 to 0.94. Code *et al.* (1994) have examined the application of neural networks to predicting recovery. Initial results suggest that this method is superior to standard statistical approaches and offers the possibility of comparing a range of possible models of aphasia through 'lesioning'.

Clinicians and aphasic people are not just interested in 'psychometric' recovery, but mainly in ability to cope and function and adjust, which is what really matters to the aphasic person and family. Recovery of these aspects of communication disability has hardly been researched at all.

Therapy

Treatment for aphasia is generally targeted at language impairments and/or communication disabilities, on how the impairments impact on using communication in the aphasic person's everyday community interactions with people. Treatment aims either for restoration (or restitution or re-establishment) of lost functions or compensation (or substitution) for lost functions (Code, 2001). Therapists may employ specific re-organizational methods to achieve restoration or compensation. Aphasia therapy utilizes aspects of education, learning theory, counselling, linguistics, neuro- and cognitive psychology. Following Howard and Hatfield (1987), we can classify most approaches into several main methodologies, although in practice many clinicians adopt a fairly eclectic approach. Didactic methods aim to re-teach language utilizing traditional and intuitive educational methods from child and foreign-language teaching. Overlapping didactic methods are essentially atheoretical behavioural methods like repetition, imitation, modelling, prompting and cuing (see 'Behaviour therapy'). They are utilized in some hierarchically organized therapy approaches for apraxia of speech and contemporary computer based methods use systematic behavioural methods. (See chapters in Code and Muller, 1989, 1995 and Helm-Estabrooks and Albert, 1991).

Language stimulation is also universally used. Here functions are seen to be inaccessible, rather than lost. Language performance is impaired but language competence has survived. Therapy involves facilitating and stimulating language use. If improvement occurs it is because the aphasic speaker does not re-learn lost vocabulary or syntactic forms, but facilitates and integrates what he or she already knows. Intense auditory stimulation, maximum response from the speaker and repetition, facilitation and various types of cuing are general features.

Luria's (1970) neuropsychological model forms the basis for an approach to the re-organization of function. Intact functional sub-systems can substitute for impaired sub-systems. For instance, 'articulograms', which are drawings of the lips producing particular combinations of speech sounds, have been developed for severe apraxia of speech. Here the speaker makes use of an intact visual route into the speech production system. A range of other approaches has been developed for the treatment of the apraxia of speech, which is common in non-fluent aphasia (McNeil *et al.*, 1997; Duffy, 2005).

Approaches exist based on surviving right hemisphere processing, which are mostly reorganizational and aim to compensate for lost functions (Code, 1987, 1994). Melodic Intonation Therapy (Helm-Estabrooks & Albert, 1991), for instance, tries to re-establish some speech in speakers with apraxic problems by reorganization of the speech production process using intoned speech.

There is a range of treatment studies using gesture and drawing (Helm-Estabrooks & Albert, 1991). Group therapy is often considered relevant for development of everyday functional communication (See chapters in Chapey, 1987, 1994; Code & Muller, 1989, 1994).

The progress of cognitive neuropsychology has strongly influenced development of an hypothesis-driven single case assessment process based on an information processing model. The contention is that standardized assessment can provide only inadequate information on the specific deficits underlying individual impairment. Hypotheses concerning impairments must be tested using psycholinguistically controlled tests, and such resources have been developed (Kay *et al.*, 1992). The alternative view is that standardized and reliable tests should provide a baseline against which to measure change (Shallice, 1979). Batteries may be best seen as standardized and reliable screens providing a basic profile and to pinpoint areas for detailed investigation. Contemporary approaches based on social models are developing as therapists begin to acknowledge more the psychosocial implications of aphasia. The aim is to attempt to improve the aphasic person's quality of communicative experience by adjusting the communicative and social environment of the aphasic person by educating and 'training' those who come into contact more with aphasic people (family, shop attendants, health professionals).

Howard and Patterson (1990) outline three strategies for impairment-based therapy inspired by the cognitive neuropsychological model: (1) re-teaching of the missing information, missing rules or procedures based on detailed testing; (2) teaching a different way to do the same task; (3) facilitating the use of impaired access routes. Research suggests that person- and deficit-specific treatment can improve performance in speakers that can not be accounted for in terms of spontaneous recovery or non-specific effects (Howard & Hatfield, 1987) (see 'Neuropsychological Rehabilitation').

Psychosocial and emotional adjustment

Research has shown that recovery and response to rehabilitation in aphasia are probably significantly influenced by emotional and psychosocial factors (Hemsley & Code, 1996; Code & Herrmann, 2003).

There are three broad factors to consider concerning the emotional and psychosocial effects of brain damage on the individual with aphasia. The direct effects of neurological damage on the neurophysical and neurochemical substrate of emotional processing; the indirect effects which we should see as natural reactions to catastrophic personal circumstances; and the pre-existing psychological balance, constitution and the ways of coping that the individual can harness. While our knowledge of the significance of the first two factors is improving, little is known about the interaction of the third factor.

'Psychosocial' refers to the social context of emotional experience. Most emotions are closely associated with our interactions with others and this is what produces most of our happiness, sadness, anxiety, etc. Psychosocial adjustment to aphasia entails coming to terms with a unique constellation of life events. Because the aphasia affects others too, it has implications for the individual's whole social network, especially the immediate family (Code & Muller, 1992; Code & Herrmann, 2003; Duchan & Byng, 2004). The disability as experienced by the aphasic person, rather than the impairment itself, is of particular importance. Studies investigating how psychosocial adjustment to aphasia is perceived have concluded that aphasic people and their families suffer from considerable stressful changes resulting from professional, social and familial role changes, reductions in social contact, depression, loneliness, frustration and aggression. The value dimensions of psychosocial factors in our lives, like health, sexuality, career, creativity, marriage, intelligence, money, family, etc. are markedly affected for aphasic peoples and their relatives (Herrmann & Wallesch, 1989).

There has been increased attention to direct emotional disorders recently as interest in the cerebral representation of emotion and its relationship to language impairment has grown (see Code, 1987; Starkstein & Robinson, 1988, for reviews of issues). Post-stroke depression correlates highly with anterior lesions but does not appear to correlate with aphasia type (see also 'Stroke'). However, research also shows that as time elapses since onset there is an increase in the interaction between extent of cognitive and physical impairment and depression (Robinson *et al.*, 1986).

But there has been little research that has sought to identify reactive emotional states following brain damage and to separate them from direct effects. Herrmann *et al.* (1993) found no differences in overall depression between acute and chronic aphasic groups, but acute speakers showed significantly higher ratings for physical signs of depression and disturbances of cyclic functions (e.g. sleep), generally considered direct effects, and an association between severity of depression and anterior lesions close to the frontal pole. Further, aphasic peoples with major depression (all acute) shared a common subcortical lesion. This suggests that the symptoms of depression in acute aphasic speakers may be caused more by the direct effects of the damage. At later times post-onset it is a more reactive depression which emerges.

One approach has been to view the depression accompanying aphasia within the grief model (Tanner & Gerstenberger, 1988) where individuals grieving for the loss of the ability to communicate move through stages of denial, anger, bargaining, depression and acceptance. The extent to which aphasic people work through the stages of the model has not been investigated. The psychological

processing of denial, bargaining, acceptance, are less amenable to more objective forms of measurement but have been investigated in aphasic persons through interpretive assessments, such as personal construct therapy techniques (PCT), by Brumfitt (1985, p. 93) who argues that the impact of becoming aphasic is seen as an event of such magnitude as to affect core-role construing and that the grief the aphasic individual feels concerns loss of the essential element of oneself as a speaker.

Studies of depression following brain damage have used factors considered symptomatic of depression, like diminished sleep and eating, restlessness and crying. These are the factors included in depression questionnaires, although these symptoms may be caused by physical illness and hospitalization directly unrelated to mood state (Starkstein & Robinson, 1988) (see 'Hospitalization in adults'). While the most reliable method of gaining information on the emotional state of people seems to be to ask them, language plays a special role in the problem of identifying and measuring mood for aphasic individuals. The intersection of language is further problematic because mood manifests itself externally through facial expression, voice quality, rate and amount of speech, gesture and posture, as well as linguistic expression and comprehension, all of which can be affected in impaired mood and all of which can be affected by neurological damage.

Relatives and friends can assist to verify accuracy but determining mood in an individual with aphasia presents many problems. One approach to tapping inner feelings is to use the nonverbal *Visual Analogue Mood Scale* (VAMS). Despite its simplicity the VAMS has been shown to be reliable and valid (Folstein & Luria, 1973). The VAMS can be made more meaningful to severely aphasic speakers by substituting schematic faces for words (Stern & Bachman, 1991). Facial expression is the most direct method of communicating emotion and an ability that should be preserved in most aphasic individuals.

With an improved understanding of the social context of communication and its importance to the reintegration of an aphasic person to the community, approaches have developed that concentrate on the communication, rather than the aphasic impairments, and other speakers in the communicative exchange, like relatives, healthcare professionals, shop keepers, policemen and publicans. Research indicates that targeting these 'conversational partners' who have intact resources, rather than the aphasic person with reduced resources, can make a significant contribution to improved communication (Kagan *et al.*, 2001; Togher *et al.*, 2004).

Asthma

Ad A. Kaptein and Klaus F. Rabe

Leiden University Medical Centre

The English word ‘asthma’ comes from the Greek ‘*asthma*’, which means ‘panting with sound, wheezing’. Patients who suffer an asthmatic episode are short of breath, wheeze, cough and experience chest tightness. Given the still incomplete understanding of the mechanisms involved in asthma, ‘defining asthma is like defining love – we all know what it is, but who would trust anybody else’s definition?’ (Gross, 1980, p. 203). Recent guidelines

give the following definition of asthma: ‘... a chronic inflammatory disorder of the airways ... the chronic inflammation causes an associated increase in airway hyperresponsiveness that leads to recurrent episodes of wheezing, breathlessness, chest tightness and coughing. These episodes are usually associated with widespread but variable airflow obstruction that is often reversible either spontaneously or with treatment’ (GINA, 2001, p. 2;

www.ginasthma.com). The reversibility of the airflow obstruction, 'spontaneously or with treatment', is the hallmark of asthma, distinguishing it from the other two major chronic respiratory disorders, chronic bronchitis and emphysema (COPD – chronic obstructive pulmonary disease) which are largely irreversible (see 'Chronic obstructive pulmonary disease').

Asthma is a highly prevalent disorder. Estimates range between virtually 0% to some 60%, illustrating the wide variations in the genetic predisposition for developing asthma in different parts of the world population, and in the environmental factors eliciting asthmatic responses. In Inuit populations in North Canada the asthma prevalence is virtually zero; on the island of Tristan da Cunha it is about 57% (Zamel *et al.*, 1996). In industrialized countries, the asthma prevalence is on average 10% (Shafazand & Colice, 2004). In children, percentages of physician-diagnosed asthma range from 4% in Germany to 30% in Australia; in adults, these percentages range from 3% in Greece to 12% in the UK (GINA, 2001, p. 14, 16).

Asthma has become more prevalent worldwide over the past decades, although this increase may have come to a halt recently (Shafazand & Colice, 2004). There has also been an increased recognition of asthma by health professionals, and a greater willingness of asthma patients to acknowledge symptoms and seek medical care. These factors have contributed to a greater reporting and documenting of asthma cases. Recently, the so-called 'hygiene hypothesis' was put forward as another possible cause for the rise in asthma prevalence. This hypothesis posits that exposure to viruses and bacteria, in particular in the prenatal period or early childhood, protects against developing asthma. If true, this would imply that rather than aiming at a perfectly clean and allergen-free environment, living conditions that expose young children to infections and allergic stimuli would protect against developing asthma. The debate on this subject is still undecided (Strachan, 2000).

Contrary to popular belief, asthma can lead to death. Statistics indicate that in about 2 per 1 000 000 asthma patients, the respiratory disorder is the cause of death. In all likelihood, asthma medication is not a direct cause of mortality. Rather, inadequate management of asthma (by healthcare providers, patients and their social environment) is the most likely culprit. Black underprivileged women in the US, for example, constitute a high-risk group for death because of asthma, illustrating the importance of socioeconomic and psychosocial factors in asthma mortality (Beasley *et al.*, 1998) (see 'Socioeconomic status and health').

Psychology and asthma

The contribution of behavioural scientists to asthma research has clearly increased over the past decades, broadening the number and scope of asthma-related topics about which important empirical studies have been published (Kaptein, 2002).

Four theoretical and related empirical lines of work can be discerned:

- psychosomatic views
- learning theory techniques
- self-management approaches
- illness representation approaches

Psychosomatic views

Asthma was one of 'the holy seven', a set of disorders where psychological factors were supposed to play a major role in their causation. It was believed that a constitutional or acquired organ vulnerability; a characteristic emotional conflict pattern; and a precipitating life event that led to a breakdown of the patient's psychological defences, were the three conditions that had to be fulfilled in order for the organic disorder to come about. In asthma, these conflict patterns between the mother and her child were thought to be centred on autonomy vs. dependence. Empirical studies failed to find any support for psychosomatic views on asthma. However, traces to these outdated, unscientific and damaging views can still be found. In a recent study on the views of general practitioners on asthma, one practitioner is reported to have claimed '... the main reasons for asthma are psychological factors ... as children these people very often have overprotective mothers ... when they've become adults they often live in circumstances where they don't want to share the air with other people' (Wahlström *et al.*, 2001, p. 510). Explaining to mothers who hold such views that these views are unfounded and baseless is undoubtedly beneficial in helping them to aid their child to properly manage his or her asthma. Adults with asthma who harbour any worries about psychological factors being responsible for their asthma will also find benefit from clear and unequivocal statements from their doctor about these dubious views that go back to about half a century ago (Creer, 1979).

Learning theory techniques

In the nineteen sixties, the rapid and relatively successful involvement of (clinical) psychologists in the care for 'clients' or 'patients' with psychological problems encouraged them to extend their involvement to patients with somatic disorders (Kaptein, 2004). The 1970s and 1980s saw a series of empirical studies on learning theory applications to asthma (see 'Behaviour therapy'). Three major techniques, systematic desensitization, relaxation therapy, and biofeedback were examined closely.

In all three approaches, clinical wisdom from patients and health care providers formed the reason for examining the effects of various types of relaxation on pulmonary function and other outcome measures such as morbidity and quality of life. Patients report that they try to relax as much as possible during episodes of shortness of breath in order to control dyspnea. Healthcare providers reinforce these behaviours in patients who are short of breath. At the same time, the biological basis of breathing would dictate that relaxation would increase dyspnea rather than reduce it (Klennert, 2003; Wright *et al.*, 1998).

Systematic desensitization has lost its place altogether as a form of behavioural treatment of asthma. The most recent review on systematic desensitization dates back to 1986: neither pulmonary function nor behavioural outcomes were shown to be affected positively by this behavioural intervention (Cluss, 1986). Functional relaxation, progressive relaxation, yoga and autogenic training are the most frequently applied techniques in studies on relaxation in asthma. Symptoms, medication and healthcare use are the dependent variables studied most often. In a rigorous review on controlled studies on this subject, no significant positive effects

were observed on any of the outcome measures (Ritz, 2001). Similar conclusions were reached in another, unrelated review (Huntley *et al.*, 2002).

Biofeedback shares a similar fate (see 'Biofeedback'). In five studies, direct biofeedback was examined (i.e. feedback on pulmonary function); seven other studies examined indirect biofeedback (e.g. feedback on facial muscle electrocardiogram (EMG), heart rate). They all raised doubts about the positive effects of biofeedback on asthma patients. A recent systematic review found that important dependent variables such as healthcare use, pulmonary function and mood, were not affected by either type of biofeedback (Ritz *et al.*, 2004).

Physiotherapy (or chiropractic care) is usually highly appreciated by patients with asthma due to the perceived reductions in dyspnea it produces, and this therapeutic approach is sometimes part of the learning theory interventions discussed above. Systematic reviews on the effects of chiropractic care in asthma patients 'showed benefit in subjective measures; however, the differences were not statistically significant between controls and treated groups' (Balon & Mior, 2004, p. S55).

Self-management approaches

Descriptive studies on perceived symptoms of asthma have been instrumental in developing self-management programmes in asthma (see 'Self-management'). Patients were asked to describe in their own words what it felt like to be breathless (Skevington *et al.*, 1997). Their responses were categorized into four dimensions: physical; affective/evaluative; energy; and hyperventilation/speechlessness. In patients with acute severe asthma, it was observed that patients reported breathlessness, described by patients as 'work' and 'breathing effort', long after their pulmonary function returning to normal (Moy *et al.*, 1998). The authors point out that in addition to objective characteristics such as pulmonary function, the subjective description of dyspnea in asthma patients should also be taken into account. These views reflect the increased recognition of 'subjective' aspects of asthma in the clinical encounter between pulmonologists and patients with asthma.

Some twenty years earlier, psychologists of the Denver-group published an impressive series of papers on the subjective symptomatology of asthma, and its relationships with various aspects of medical outcome. Personality traits (anxiety), state characteristics (anxiety, panic) and attitudes (stigma, pessimism) were found to predict length of hospitalization, rates of re-hospitalization and severity of medication at discharge. Objective asthma characteristics played a minor role in these relationships. The concept of 'psychomaintenance' was coined to point at the clinical implications of the results of this research, emphasizing the role psychological factors play in maintaining asthma symptoms and its consequences (Kinsman *et al.*, 1982).

Other research groups took up this challenge, and developed self-management programmes for children and adults with asthma, incorporating elements from the studies described above. Components of self-management programmes are transformation of information, self-monitoring of pulmonary function, regular review of asthma status by a physician and a written action plan informing patients about how to act during exacerbations.

The effects of the programmes must be characterized as positive. In adults with asthma, hospitalizations, visits to accident and emergency departments (A&E) (emergency rooms) for acute severe asthma, unscheduled doctor visits, days lost from work and episodes of nocturnal asthma, are all significantly reduced (Gibson *et al.*, 2000). In children with asthma similar results are found: school absence; days of restricted activity; and number of A&E/emergency room visits were reduced; self-efficacy increased (Wolf *et al.*, 2003). Self-management research in asthma is at a quite developed stage nowadays, as is demonstrated in the two major Cochrane reviews in this area (Gibson *et al.*, 2000; Wolf *et al.*, 2003) Guidelines on the management of asthma explicitly state that self-management must be incorporated into regular medical management, and that physicians should adhere to stimulating patients to use self-management techniques (GINA, 2001). But not all is well. The goals set in international guidelines are not met, particularly with regard to patients accepting restrictions in their daily activities and in respect of healthcare professionals' usage of available knowledge on proper medication policy to control asthma symptoms (Rabe *et al.*, 2004). A recent *Lancet* editorial is critical of physicians for not adhering to these guidelines: 'many factors contribute to the marketing success of baseless treatments and cures for asthma and allergies, not just patients' naivety' (Schaub & von Mutius, 2004, p. 1390).

Illness representation approaches

The most recent addition to the area of behavioural research on asthma pertains to symptom perception, illness perceptions and emotional expression (see 'Symptom perception', 'Lay beliefs about health and illness' and 'Emotional expression and health').

Correctly perceiving symptoms of bronchoconstriction is a condition sine qua non for the performing of adequate self-management skills. Correlations between objective measures of airways obstruction and perception of breathlessness are far from perfect. Clinically this translates into patients seeking help (too) late, which increases the risk of morbidity and even mortality. Teaching patients to perceive asthma symptoms earlier and better seems beneficial (Rietveld, 1998). Interventions here often use the combination of having patients assess their pulmonary function together with observing their perceived breathlessness, which supposedly teaches them to refine their sensitivity to perceive the severity of bronchoconstriction more accurately (Klein *et al.*, 2004).

Research on illness perceptions in patients with asthma is a new area of psychological study (see Kaptein *et al.*, 2003, for a review on illness perceptions and asthma). In a recent study, the importance of illness representations and medication representations was illustrated: illness perceptions of adult asthma patients were found to be associated with use of healthcare services; medication representations predicted the use of preventer medication (Horne & Weinman, 2002). Intervention studies on the effects of intervening in illness representations and medication beliefs are underway (see Petrie *et al.*'s 2002 study on patients with cardiovascular disease).

A quite spectacular intervention study involved an emotional expression experiment in adult patients with asthma (Smyth *et al.*, 1999). In a randomized controlled design study adult asthma patients in the experimental condition were asked 'to write for 20 minutes on three consecutive days a week about the most stressful experience that they had ever undergone' (p. 1305). Patients in

the control condition were asked to describe their plans for the day. Statistically and clinically significant improvements in pulmonary function were observed in the patients in the experimental condition. Future research in this line of work should encompass behavioural outcomes as well.

Although somewhat speculative, a psychoneuroimmunological model in which emotions and cognitions about asthma are combined with self-management skills and with medical and behavioural outcomes might be useful in explaining the findings from the

emotional expression study by Smyth *et al.* Further research will be helpful in clarifying these issues.

Asthma is a disorder where a biopsychosocial approach appears to benefit the afflicted patients. Psychosomatic views have been followed by learning theory approaches and by self-management and illness perception models. Continued collaboration between medical and psychological researchers and clinicians, and with patients and their relatives, will be instrumental in improving the quality of life of patients with asthma.

Back pain

Amanda C. de C. Williams

University College London

Back pain is so common its impact is often under-estimated. Chronic back pain is a seriously disabling condition, which causes much distress (Smith *et al.*, 2001; Sprangers *et al.*, 2000). A survey of Scottish adults (Smith *et al.*, 2001) showed that 14% reported continuous or intermittent pain for at least 3 months, for which they had taken analgesics and sought treatment. Nearly half of these people reported severe functional limitations in direct proportion to the severity of their pain. Chronic pain, of which back pain usually constitutes the largest category, was also associated with poorer physical and mental health.

Much back pain is dealt with in the United Kingdom in primary care and often involves physiotherapeutic intervention. If the back pain does not resolve or the individual does not adapt, referrals are often made to orthopaedics, rheumatology, or in some cases to neurosurgery. Optimal treatment consists of explanation and reassurance, with minimal rest, and encouragement to return to activities despite continuing pain. This contrasts with traditional advice, which tends towards prolonged rest and a cautious approach to physical activity. Any delay in referral for investigation and expert diagnosis tends to leave the patient in limbo with neither reassurance nor advice, thereby contributing to disability.

There are many possible causes and mechanisms of low back pain (Waddell, 2004). Some symptoms or physical signs indicate urgent and often operable conditions, such as tumours. These symptoms and physical signs are labelled 'red flag' indicators and suggest referral onto specialist services is appropriate. However, the majority of cases of back pain present with few physical signs. In addition, the presence of physical signs is poorly related to the severity of pain or extent of disability. In fact, psychosocial factors are far stronger predictors of disability and the likelihood that back pain will become chronic than medical or physical variables (Pincus *et al.*, 2001; Linton, 1999). Psychosocial variables that have been shown to be important are depression, pain-related fear and associated behaviour (Vlaeyen & Linton, 2000), and catastrophizing (over-vigilance to symptoms, their negative interpretation and the lack of confidence in capacity to cope with them: Sullivan *et al.*, 2001). The presence of any of these factors constitute 'yellow flag' indicators which, taken in conjunction with the influence of the wider environment (workplace, home and healthcare and welfare systems), suggest psychological assessment is appropriate (see Pincus *et al.*, 2002).

Despite the importance of psychosocial factors in chronic pain and the recognition of 'yellow flag' indicators, the treatment of back pain typifies an area where there is continuing difficulty in embracing a genuinely biopsychosocial model of pain (see 'Pain').

Pain and pain responses

Pain is defined as 'an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage' (International Association for the Study of Pain, 1979). Chronic or persistent pain is defined variously as pain which has continued beyond six months, or beyond an expected time for healing. In practice, there may also be the implication that the pain is somehow 'excessive' in relation to the physical findings (most often healed damage or long term changes related to age and use) and the apparent gap is plugged using unsatisfactory psychosomatic explanations or assumptions of moral weakness or malingering. But there is no 'right' amount of pain for a particular lesion or pathology: the processes that result in the experience of pain are complex and inherently psychological as well as physical. Further, these explanations draw on moral and political values, rather than on psychological insights, and focus inappropriately on judging the authenticity of the patient's experience. It may be that this tendency is an example of social policing of anyone who complains of illness and claims the advantages due (Mechanic, 1978; Williams, 2002), since pain has no visible confirming signs.

Humans, like (arguably) all animals, are hard-wired so that pain will grab and dominate attention. This is associated with efforts to identify the threat, to escape and to attempt to mitigate the pain. This is accompanied by rapid learning of cues for future avoidance and conservation of resources during healing. However, some pains do not represent actual or threatened damage (e.g. muscle cramp, colic and almost all headache pains). In these instances the repeated interruption of ongoing mental and physical activity by pain leads, in the longer term, to counterproductive attempts to avoid all pain on movement or to recover through rest. The immediate meaning of the pain to the individual is crucial, making the difference between being able to dismiss a familiar pain and return to task, and becoming preoccupied by the pain, by its continuation and its possible short- and long-term implications (Eccleston & Crombez, 1999).

While the contribution of descending messages from the brain on pain transmission and processing was clearly stated in the gate control model (Melzack & Wall, 1965; Wall, 1999), it was not until the era of imaging brain activation that it became possible to start to describe it (Ren & Dubner, 2002; Petrovic & Ingvar, 2002). Acute pain, particularly if it is severe and prolonged, engenders changes in excitation and inhibition at a spinal level; descending influences representing the cortical and affective state of the organism interact at spinal synapses with afferent messages.

Serial and parallel processing of incoming pain information produces both immediate affective valence and response, and secondary affective and evaluative activity which further informs response priorities (Price, 2000). Early work with amputees, and subsequently on chronic back pain (Flor *et al.*, 1997), demonstrated extensive cortical reorganization in response to the pain experience and there is now a proliferation of imaging studies on such processes as catastrophizing (Gracely *et al.*, 2004; Petrovic & Ingvar, 2002) (see also 'Pain' and 'Pain assessment').

Treatment of back pain

Patients with back pain seek explanation and advice from their primary care physician rather than treatment and referral (Ring *et al.*, 2004; Salmon *et al.*, 2004; Saunders *et al.*, 1999). With good explanation and advice they are more likely to return to activity and avoid persistent pain (Burton *et al.*, 1999; Pincus *et al.*, 2001). However, it is more common for doctors to recommend or prescribe analgesics, to refer patients for physiotherapy or to other specialists in secondary care. At the same time, patients take action according to their own beliefs about what is wrong and the risks this implies, and may well be consulting alternative medical practitioners and receiving a variety of causal explanations and treatment (much of which is of unproven efficacy) (see 'Lay beliefs about health and illness' and 'Complementary medicine'). By the time it emerges that there is no remediable lesion or pathology and that the patient can 'safely' return to a normal life, s/he may have a bewildering set of pathological models of pain, entrenched habits of avoidance and secondary problems due to inactivity and attempts to minimize the pain, such as guarded movement. Over the longer term, losses of role and of valued activities can impact adversely on the person's personal identity, social and work life and contribute to depressed mood (Banks & Kerns, 1996; Pincus & Williams, 1999).

The few studies of the beliefs of healthcare professionals in relation to pain show a tendency to use an acute pain model long after resolution of any initial injury. This acute pain model includes a cautious approach to return to activity and a focus on abolition of pain as the only solution (Linton *et al.*, 2002). Patients themselves tend to hold damage-based models, which do not distinguish between acute and persistent pain (Rogers & Allison, 2004). Such confusions of models and disappointments in attempts to find treatment render many people with back pain sceptical and wary about further promises of treatment, and referral for rehabilitative treatment may be made with a sense of there being nothing

else to offer, rather than of being the appropriate treatment which could have been instituted earlier.

Various reviews and large trials have demonstrated the benefits of physical reactivation, most through physiotherapy exercise programmes or behaviourally-oriented training with education (Pincus *et al.*, 2002; Hayden *et al.*, 2005) (see 'Physical activity interventions' and 'Behaviour therapy'). Yet these studies should not be interpreted as demonstrating that physical exercise alone changes patients' behaviour. Many of these studies and reviews focus on clinical measures of outcome. More recent studies that look at multiple outcomes are still heavily dependent on self-rated disability as a measure of outcome, which is problematic (see 'Disability assessment'). If individuals with persistent pain remain fearful of most normal activity, exercises performed in a physiotherapy clinic are unlikely to challenge or resolve these fears, as elegantly demonstrated by Vlaeyen *et al.* (2001).

In reality, the treatment of back pain differs widely according to dominant models of treatment and availability. For example, in the USA stepped care is the dominant approach (Von Korff & Moore, 2001). In the UK, physicians are encouraged to match patients to provision, although neither evidence nor availability permits this. Provision varies from virtual placebo self-help groups to intensive multi-component programmes of behavioural and cognitive therapy delivered by a multidisciplinary team (see 'Cognitive behaviour therapy'). This kind of psychological rehabilitation is described in more detail in the chapter on 'Pain management'. These interventions are costly but effective and can lead to reductions in disability, a return to normal activities and to a better psychological state. However, trials of the addition of a psychological component largely use weak approximations and assume an additive model of psychological and physical treatment, which is not appropriate (Morley & Williams, 2002). More sophisticated models of multicomponent treatment are at an early stage of resolving questions about cause and effect (Burns *et al.*, 2003).

Conclusions

Psychologists have made a very significant contribution to the understanding of back pain and to its treatment. However, the over-used term of the 'biopsychosocial' model is not yet widely realized in the treatment of back pain. The psychological is mostly too abstract to be mapped on to the biological, and social aspects are largely neglected or formulated entirely in operant terms. Developing an integrated understanding is the task for the next decade.

Blindness and visual disability

Linda Pring

University of London

According to the Royal National Institute for the Blind (1991) there are about 20 000 children and about 1 million adults who are blind or partially sighted in the UK. Rahi *et al.* (2003) reported on the incidence and causes of severe visual impairment and blindness in children in the UK suggesting that 4 of every 10 000 children born in the UK will be diagnosed as severely visually impaired or blind by their first birthday increasing to nearly 6 per 10 000 by 16 years of age. The causes of blindness are varied and

complex but at least 75% of these children have disorders that are neither preventable nor treatable, in stark contrast to the situation found in underdeveloped countries. The age at which individuals with visual impairment experience sight loss, and the length of time over which their eyesight deteriorates, are both important factors in the ability to adjust. The over-75-year-old age-group make up 65% of the population who are blind. For adults, cataracts, glaucoma, general ill-health and diabetes can be singled out as

commonly reported causes of eye problems, for children born blind retinopathy of prematurity, coloboma and optic nerve hypoplasia are amongst the most common (see also 'Diabetes').

From a psychological perspective, the important questions have been related to the consequences of loss of vision for general development (Lewis, 2003); the role of vision in our understanding of space; and the related question of how far our senses provide independent, unitary or complementary information (Schiff & Foulke, 1982). These perspectives have meant that relatively little research has concentrated on the psychological correlates of visual impairment for those who go blind after childhood (see also 'Vision disorders').

In terms of early development, we find that total blindness from birth causes the greatest problems for the young infant; some of these can be significantly diminished if the total loss of sight is delayed even by just a few months. There is conflicting evidence concerning the repertoire of facial expressions in blind infants and possible reductions in expressiveness during early development connected to the failure of reinforcement (e.g. Galati *et al.*, 2001; Dyck *et al.*, 2004). Social smiling occurs at the same time as that expected for children who are sighted but the responses of caregivers to similar behaviours in infants who are blind and those who are sighted differ. This may be caused, in part, by the anomalous communication pattern seen in the mother/child interactions, where the infant may show less initiation of communication, fewer vocalizations and fewer positive responses to the mother. Infants who are blind may for example 'freeze' to listen more attentively to new experiences while the reverse, increased motor activity, occurs for infants without sight problems. Thus, the loss of sight in this regard has effects on the consistency and therefore predictability of pattern of non-verbal communication between the infant and mother.

Like children and young people with autism, children with severe or profound visual impairment seldom engage in symbolic play (such as pretending that a box is a bath for a doll, or a car capable of making loud engine sounds!). They may be socially withdrawn, self-absorbed and mute. Speech, if present, is often echolalic and repetitive. Infants may lack exploratory, functional or imaginative play and resort to repetitive behaviour stereotypes like rocking and eye-poking. There is increasing interest in the connections between autism and blindness (see Pring, 2004) because of the similarities between the behavioural and developmental picture observed. A substantial minority of infants with severe visual impairment are at risk of a developmental setback or regression occurring at about 18–24 months. This has long-term consequences but is not well understood.

In terms of motor development, there is likely to be a delay of most milestones but these appear to be affected both by a lack of experience with the world as well as by the failure to 'see' the world. It is interesting to note that, regardless of sighted status, infants will reach out, in the dark, towards a sound source at the same point in development, while for those who are blind reaching for an object, crawling and walking may be substantially delayed. 'Blindism' is a label for the movements displayed by children who are blind with no obvious communication role, e.g. arm flapping or pressing the eyes: these are suppressed in adults. Mobility and the use of navigational codes may be problematic for individuals with a visual impairment. The fact that vision is specialized for picking up information about the relation between external objects and planes means that forms of coding which depend on this information will

be more difficult to acquire by the visually impaired, but should not be impossible provided the information is communicated by some other means (Millar, 1990). People with visual impairment do use spatial imagery since vision is not the only sense that can supply spatial information. However, certainly those who are blind tend to use fewer external reference cues in some forms of spatial imagery than do the sighted, but the differences tend to reflect differences in strategy rather than imagery.

Some aspects of language may be delayed in those who are blind, but most are not. If the child can make up for experiences lost through impaired sight by the use of other channels then early delays in language and social communication may be alleviated through compensatory processes. This may explain why there are few accounts of genuinely deviant or divergent psychological processes or behaviours in adulthood among people with visually impairment. Nevertheless, the influence of an early impoverishment to the understanding of some concepts and word meanings may be difficult to completely correct. This can lead to flaws in communication and has, at times, been blamed for the failure of standardized tests to measure accurately, due to a misunderstanding of the instructions followed. Finally, a word needs to be said about 'verbalisms' a term used to describe a blind child's tendency to use words for which s/he does not have first-hand sensory experience, such as colour terms. This does not seem very unusual when considering how often everyone tries to use terms for which they have had little or no direct experience, but in addition, such terms can be used consistently and meaningfully. For example (Landau & Gleitman, 1985) a young blind child used the term 'see' to mean things with which she could feel with her hands.

Educational issues connected to visual impairment including a concern with reading, drawing and memory have been the focus of a great deal of research (Tobin, 1979; Millar, 1975; Pring, 1992; Kennedy, 1982). Certainly advantages in short- and long-term memory for certain kinds of materials, including verbal information and musical pitch, are commonly reported. Interestingly, children with little or no residual sight can draw human figures that can be said to be indistinguishable from the drawings of some sighted children. However, the figure a child who is blind draws is often lying down or at an angle to the vertical. This indicates that the vertical and horizontal anchors play a less natural role for them.

Psychological issues within the area of visual impairment have tended to look for cognitive inabilities caused by the loss of vision. As I have reported already, these do exist but have surprisingly little impact, especially where residual sight can provide a spatial framework in which to place touch/haptic experience. For O'Connor and Hermelin (1978), an important consequence of visual impairment was an emphasis on a cognitive style characterized as 'sequential' rather than 'parallel or gestalt-like' caused by the dominance of language and tactual perception. However, while the style of processing may explain some behaviours in children and adults who are blind, equally of interest are the brain mechanisms. The neural activations in the brain have recently come under increased scrutiny with technological innovations in this field of scientific enquiry. For those congenitally deprived of visual input there is evidence of adaptive compensatory cortical reorganization. Functional magnetic resonance imaging (fMRI) and electro-encephalography (EEG) are types of technique for determining which parts of the brain different types of physical sensation or activity, such as listening to

words or feeling tactile displays, activate. These brain imaging techniques have shown that for those with early blindness cross-modal sensory re-organization occurs such that tactual sensory input and also tactual imagery activate cortical areas traditionally associated with visual processing. Furthermore, studies have reported a higher activation level in the occipital brain areas of people who are blind with a variety of auditory tasks (e.g. Röder *et al.*, 2000). Their research shows that in some auditory tasks people who are blind outperform those who are sighted and this is linked with a neurological explanation. The pruning of over-produced neural connections as well as the process of myelination in the sensory cortical areas may be *incomplete* for the visually deprived and help explain the increased activations.

The consequences of blindness for adults are often social isolation and an increase in depression and anxiety, though the reports show higher levels of mental health problems in those with a hearing impairment than those with visual impairment. Some research sug-

gests that help with social cognition in young children may also have positive outcomes. Society has often failed to recognize the real needs of those adults and children with visual impairment. Rehabilitation, in terms of occupational and mobility training, plays a crucial role in the lives and psychological health of those who go blind after school age. Within the field of computing, the advent of the graphical user interface, for example Microsoft Windows, has meant that problems for the blind user were very significantly increased. However, technological solutions mean that the Internet can be available for the user whatever their sight status and has provided an up-to-date environment (including the imaginative use of blue tooth, wireless technology) to begin to meet the needs of people with visual problems. Additionally, the Disability Discrimination Act, 1995 has helped to make a positive contribution, but lack of sufficient resources have limited the environmental adaptations that could impact on the quality of life and occupational choices for those living in the UK.

Blood donation

Sarah A. Afuwape

Institute of Psychiatry

Blood donation – an overview

The donation of human blood, blood components and organs is an integral and indispensable part of modern medical care around the world with some countries having more success at

the recruitment of donors than others (Ferriman, 2005). Across all blood centres, the demand for blood and blood products is steadily increasing as the population ages and innovative medical and surgical techniques are introduced. The demands for blood have begun to exceed supply, and the increase in complexity

of donation has had a knock-on effect on recruitment of blood donors. Compared with two decades ago, the donation process has become increasingly regulated as attempts are made to acquire quality blood that is safe and free from disease and infection. The results of this increased regulation are increased donor loss through deferral, disqualification (Davey, 2004) and an apathy towards volunteering (Putnam, 2000). In the United States and the United Kingdom, blood stocks have been further impacted in recent years by the implementation of strict deferral guidelines for the prevention and transmission of variant Creutzfeldt-Jakob disease (vCJD) (US Department of Health and Human Services Food and Drug Administration & Centre for Biologics Evaluation and Research, 2003; United Kingdom Blood Transfusion Services, 2002; US Department of Health and Human Services & Food and Drug Administration Centre for Biologics Evaluation and Research, 2002). In the attempt to increase rates of new and returning donors, research has historically focused on investigating socio-demographic characteristics, and the attitudes and motivations of donors and non-donors (Oswalt, 1977; Piliavin, 1990).

Who are the blood donors?

Unlike in the United States, no attempt had been made in the UK prior to 1970 to fund systematic data collection of socio-demographic characteristics of blood donors. Still today, many blood centres around the world fail to routinely collect demographic data and rely upon anecdotal evidence (Wu *et al.*, 2001). However, results from one large-scale UK study into donor motivations and characteristics showed that of a sample of 3,813 donors, over half were men, 90% were aged 18–55, and most were from the higher social economic classes (Titmuss, 1970). Findings from the United States also identified the typical blood donor at the time to be male, White and better educated than the general population (Ownby *et al.*, 1999; Thomson *et al.*, 1998; Titmuss, 1970). Although this is still largely the case in many European countries (Mikkelsen, 2004), more recent findings from the USA show that the social demography of the blood donor is shifting, along with its changing population. There is now a slow, but steady, increase of first-time donors from minority ethnic groups, Hispanic groups in particular (Wu *et al.*, 2001). For other minority ethnic groups in the United States, such as those from Black and Southeast Asian groups, rates of single-time and repeat donation have increased at a much slower pace (Boulware *et al.*, 2002; Glynn *et al.*, 2002).

Why donate? Incentives and barriers to donation

A great deal of research has been conducted into the motivations underlying and predicting blood donation. Much of the literature has identified altruism as the primary reason for offering blood (Glynn *et al.*, 2002), with certain minority ethnic groups showing preference towards donating to members of their own ethnic/racial group if they were to have a choice about the recipient (Amponsah-Afuwape *et al.*, 2002). In first-time donors, other motivations have included awareness of the need for blood, a desire

to be tested for infection, feeling a sense of duty and social pressure from friends and family (Fernandez-Montoya *et al.*, 1998; Oswalt & Gordon, 1993; Piliavin & Callero, 1991). Although the desires for special recognition, or to receive an award have featured less often as reasons to donate, and have even been thought to negatively affect the intrinsic motivations of the blood donor (Glynn *et al.*, 2002), other non-tangible incentives such as the offer of medical testing, have been suggested to be possible methods of recruiting the first-time donor (Sanchez *et al.*, 2001). In contrast, reasons given for non-donation have included a lack of awareness of the need to donate blood, fear of contracting HIV or other diseases, fear of needles and pain, laziness and medical reasons (e.g. anaemia, being underweight) (Boulware *et al.*, 2002; Moore, 1991; Oswalt & Gordon, 1993; Thompson, 1993).

Increasing the donor pool

In 1995, approximately 70% of the US supply of blood was donated by established donors (Schreiber *et al.*, 2003). Whilst the potential donor pool is 60%, only 5% are blood donors and up to 50% of first-time donors often never return for subsequent donations. Although appeals for blood are still commonplace during shortages; with constant repetition, they become less effective in the recruitment of new donors and merely mobilize existing, regular donors (Davey, 2004). Others have highlighted the substantial increases in blood and blood product donation that often occur during national disasters, but have concluded that whilst increases are usually substantial during such crises (Glynn *et al.*, 2003a; Schmidt & Bayer, 1985), the effects are often short-lived and rates return to pre-crisis level fairly rapidly afterwards (Glynn *et al.*, 2003a). The decline in individuals' willingness to donate blood has been correlated with declining national levels of civic engagement. It has been proposed that membership of national associations and organizations, and an interest in politics and the environment brought with it a greater sense of belonging and a responsibility to respond to the civic duty to provide an adequate supply of blood to the community (Kolins & Herron, 2003). Putnam (2000) therefore calls for a greater understanding of the new values and interests of the younger generation in order to seek ways of making blood donation more convenient and meaningful. Others have suggested making a number of changes to the method by which donors are engaged, retained and qualified in an attempt to increase the donor pool and prevent 'burnout' of existing donors. Some of these include revising the donor history questionnaire and modifying the deferral criteria to exclude screening questions and tests of doubtful value; adjusting the haemoglobin cut-off levels according to age, sex and race to ensure haemoglobin levels are more physiologically sound and introducing iron supplements for women; lowering the minimum age of donation to age 16 and the use of non-monetary donor incentive (Newman, 2004). Work conducted by Glynn (2003b) and Piliavin (1990) suggest that prizes, raffles and other incentives do little to encourage donation, rather, the use of altruistic appeals with minimal social pressure as well as ensuring that first- and second-time donors are re-contacted promptly, are effective methods of recruitment and retention (Glynn *et al.*, 2003b). Research from Denmark has shown that absolute trust in the safety of

the products and the reputation of the centre, a belief in the sufficiency of the supply of blood, and a feeling that a valuable contribution is being made to the national blood supply, are all essential components (Mikkelsen, 2004). Finally, Simon (2003) questions past research which suggests that paid donors are a less safe source of blood for transfusion, and enquires whether the time has now arrived to begin investigating the effects of monetary incentives (Simon, 2003).

Breastfeeding

Antony S.R. Manstead

Cardiff University

Research on the psychological aspects of breastfeeding has tended to focus on one of two issues: (i) the factors that determine parental choice of infant feeding method, or (ii) the consequences of breastfeeding for the child's psychological development. This chapter will summarize the conclusions that can be drawn from research on these two issues.

Parental attitudes to and social and professional support for breastfeeding

Although the last two decades of the twentieth century witnessed an increase in the number of mothers who initiated breastfeeding, as compared with the steady decline seen during the earlier decades of the century, most mothers wean before the recommended age of six months postpartum because of perceived difficulties in breastfeeding (see Dennis, 2002). An illustrative example comes from research by Heath *et al.* (2002): although 88% of a self-selected sample of New Zealand mothers participating in this study initiated breastfeeding, only 42% were exclusively breastfeeding at three months.

In industrialized countries there are clear demographic differences between women who do and who do not breastfeed (see Dennis, 2002). Women least likely to breastfeed tend to be younger, to have lower incomes, to be from an ethnic minority, to receive less support for breastfeeding, to be employed full-time and to have more negative attitudes to breastfeeding and less confidence in their ability to breastfeed. Two sets of findings are especially noteworthy. First, there is an abundance of evidence that parental attitudes to and beliefs about breastfeeding are strongly associated with a woman's decision to breastfeed or with the duration of breastfeeding. Secondly, the degree of support a woman receives from professionals and laypersons has an impact on her breastfeeding decisions and behaviours.

With regard to the relation between attitudes and decision to breastfeed, Manstead *et al.* (1983) found that attitudes as measured in the last trimester of pregnancy were strongly predictive of whether mothers chose to feed by breast or by bottle during the first six weeks of the baby's life. Mothers who breastfed during these six weeks were significantly more likely than bottlefeeding mothers to believe that breastfeeding provides better nourishment for the baby, is good for the mother's figure, protects the baby against infection, and establishes a close bond between mother and baby. Mothers who bottlefed during the first six weeks were significantly more likely than breastfeeding mothers to believe that bottlefeeding is convenient, is trouble-free and makes it possible for the baby's father to be involved in feeding. Because these beliefs

and attitudes were assessed antenatally in a large sample of primiparous women, and were related to postnatal behaviours, it is reasonable to interpret the observed associations as reflecting the causal impact of beliefs on behaviours. Recent research by Shaker *et al.* (2004) confirmed the importance of maternal beliefs and attitudes but also showed that the father's attitudes and beliefs were associated with the decision to breastfeed or bottlefeed (for relevant theory on the role of attitudes in behaviour see 'Theory of planned behaviour').

With regard to the relation between attitudes and duration of breastfeeding, Jones (1986) interviewed 1525 mothers in hospital, shortly after delivery; those mothers who chose to breastfeed their babies ($n=649$) were interviewed again 12 months later. The majority of these mothers reported that they had received sufficient advice about breastfeeding, that they had found it enjoyable or satisfying, that they would breastfeed their next child, and that they would encourage their friends to breastfeed. Among those who did not find breastfeeding enjoyable or satisfying, the majority reported having experienced physical problems such as sore or cracked nipples, and there was a tendency for women having their first baby to report more of these problems. Unsurprisingly, the more of these problems a woman experienced, the less satisfied she was with breastfeeding; and the less satisfied she was, the shorter was the duration of breastfeeding, with 50% of those not finding it satisfying stopping within two weeks. There was also a consistently negative relation between enjoyment and satisfaction, on the one hand, and embarrassment experienced when breastfeeding in front of other persons, on the other, and how embarrassed a mother reported feeling was negatively associated with how long she continued to breastfeed. However, physical problems were cited more often than embarrassment as a reason for not wanting to breastfeed a next child.

There is an abundance of evidence that support for breastfeeding received from professionals and laypersons plays an important role. In a meta-analytic review of the literature on support for breastfeeding mothers, Sikorski *et al.* (2003) found that any support (professional or lay) increased the duration of breastfeeding once initiated. Dennis's (2002) review also points to the importance of support from the mother's partner or other non-professional, but adds that professionals can be a negative source of support if they give inaccurate or inconsistent advice. Finally, it is worth noting that in most non-Western societies a new mother is supported by a *doula* (often the mother's own mother) who provides emotional support and also practical advice and support (Hall, 1978). The decline of the extended family in industrialized societies means that partner support is likely to play a key role in such societies (see James *et al.*, 1994), making it all

the more important to take fathers' attitudes and beliefs into account.

Breastfeeding and child development

There is compelling evidence concerning the physical health benefits of breastfeeding. These benefits include reducing the incidence of infant deaths due to respiratory infection or to diarrhoea (see, for example, Arifeen *et al.*, 2001). There is also evidence that breastfeeding is associated with reduced risk of overweight among non-Hispanic white children (Grummer-Strawn & Mei, 2004). However, there is one health consequence of breastfeeding that is undoubtedly negative, for it is clear that breastfeeding is responsible for at least a proportion of the increasing prevalence of paediatric human immunodeficiency virus. In developing countries it is estimated that breastfeeding accounts for 12–14% increased risk of HIV infection, leading to the recommendation that in areas of the world where adequate sanitary replacement for breastfeeding is available, HIV-infected women should be advised not to breastfeed (Weinberg, 2000) (see also 'HIV and AIDS').

Turning now to psychological functioning, there is fairly good evidence of a relationship between breastfeeding and cognitive development. For example, Morrow-Tlucak *et al.* (1988) compared (a) children who had been bottlefed, (b) those who had been breastfed for four months or less, and (c) those who had been breastfed for longer than four months. A large number of potentially confounding variables were taken into consideration and, where appropriate, statistically controlled for in the main analyses. The primary measure was the Mental Development Index (MDI) of the Bayley scales. Children were assessed at 1, 12 and 24 months. At each age, the mean MDI scores of the three groups of children fell in the same order: breastfed for longer than four months, followed by breastfed for four months or less, followed by bottlefed.

Another study using different measures of cognitive development was conducted by Niemela and Jarvenpaa (1996). They compared

363 children who had been breastfed for less than five months with 363 children (matched pairwise for sex of child and maternal education) who had been breastfed for five months or more. The children were assessed when they were around five years old. Significant differences between the two groups of children were found on measures of general cognitive capacity and of visuomotor integration.

Horwood and Fergusson (1998) report the results of a study of the association between duration of breastfeeding and childhood cognitive ability and academic achievement over a period from 8 to 18 years. The research was conducted in the context of a longitudinal study of a birth cohort of 1265 children born in 1977 in Christchurch, New Zealand. Longer duration of breastfeeding was associated with IQ assessed at 8 and at 9 years, a variety of scholastic ability measures taken between 10 and 13 years, teacher ratings of reading and mathematics ability at 8 and 12 years; and level of attainment in school leaving examinations. After adjustment for possible confounding factors, children who were breastfed for 8 months or longer had mean test scores that were between 0.11 and 0.30 SD units higher than those who were not breastfed.

Such findings can be interpreted as evidence that breastfeeding has directly beneficial effects on cognitive development, although the causal mechanisms underpinning such effects remain unclear. It has been argued that known differences between formula and breast milk with respect to long chain polyunsaturated fatty acid levels and DHA (docosahexaenoic acid) levels could account for the observed associations (see Horwood & Fergusson, 1998). Another possibility is that breastfeeding has beneficial effects on psychological development by fostering a more intense relationship between mother and child. However, in the absence of hard evidence concerning the underlying mechanism, it remains possible that the observed psychological differences between breastfed and bottlefed children stem from genetic or environmental factors that are confounded with the decision to breastfeed or bottlefeed, rather than from the infant feeding method per se.

Burn injuries: psychological and social aspects

Claire Phillips

University of the West of England

Background

Approximately 175 000 people per year attend Accident and Emergency departments in the UK with burn injuries, 13 000 requiring admission to hospital (British Burn Association, 2001). Recent medical advances mean those with more extensive burn injuries now survive, but a larger burn injury potentially brings more visible and physical impairment. Relative to other forms of traumatic injury (e.g. fractures), burns have a greater propensity to cause widespread disfiguring injury and dysfunction. Furthermore, the time taken to recover and rehabilitate after burn injury is often much longer than the recipient anticipates.

Psychosocial sequelae of burn injury

Burns occur in a sudden event, giving no time for individuals to gather coping resources. The potential for psychosocial sequelae after burn injury comes from not only what was experienced or witnessed during the accident, but painful hospital treatment, resulting altered appearance, physical impairment and potential social anxiety. The experience of burn injury has been described not as a single event but as a 'continuous traumatic stress' (Gilboa *et al.*, 1994).

It has been observed for many years that burn injury brings with it the propensity for psychological disturbance (e.g. Woodward, 1959). Psychosocial sequelae researched includes depression and anxiety (e.g. Williams *et al.*, 1991), post traumatic stress disorder (PTSD) (e.g. Fauerbach *et al.*, 2000), body image disturbance and social anxiety (e.g. Lawrence *et al.*, 2004), and factors associated with these adjustment difficulties.

Depression and anxiety

The painful experience of hospital treatment and subsequent helplessness are widely thought to contribute to depressed mood. The experience of burn injury also often brings with it a sense of

loss and grief, not just for material items lost, but a loss of physical integrity. A sudden change in appearance, for example, is not in line with the gradual adaptation in body image that usually occurs across the lifespan. An adult with a disfiguring burn injury may mourn their lost looks (Partridge, 1990), experience depression or become anxious in social situations. For a parent whose child has been burned, a visible difference may represent the loss of their 'perfect child' or their loss of self image as a 'good' parent and may precipitate depression (Martin, 1970) and bring feelings of guilt.

Depression and anxiety are the most commonly reported psychosocial consequences of burn injury (Patterson *et al.*, 1993). Depression has been reported both within the hospital setting, 2–3 months after burn injury, and in the longer term. The prevalence of depression in burned adults has reportedly ranged from 13–23% post-burn with feelings of anxiety often co-existing (Van Loey *et al.*, 2003).

Post-traumatic stress disorder

More than 50% of burned adults experience some aspect of PTSD while in hospital (Ehde *et al.*, 2000). Prevalence of either full or partial PTSD is reportedly around 29% during hospitalization (Patterson *et al.*, 1990) and between 13–45% overall (Van Loey & Van Son, 2003). PTSD has also been identified in mothers of children with burn injuries (Fukunishi, 1998). To a certain extent, the post-traumatic stress response observed in burns is part of the normal adjustment process, perhaps part of survival – a reminder that what happened to threaten our survival must not be repeated. However, if symptoms persist and remain unchecked, there can be deleterious affects on rehabilitation both physically and mentally (see 'Post-traumatic stress disorder').

Body image dissatisfaction and social anxiety

An adult receiving an appearance-altering burn injury is also receiving a potential insult to their self-image. Adults are likely to have a mature sense of self and body image (their feelings or thoughts

about their physical appearance) and a sudden, rapid change in their physical appearance will require an adjustment. Likewise, in older children who are just developing a more stable sense of self, an altered appearance will potentially impact on their developing body image. Modern society places an incredible amount of importance on physical appearance. Subsequently, individuals with severe burn injury may tend to avoid public places, a kind of 'social disability' (MacGregor, 1979). Notably after burn injury, a person's scars will continue to change in appearance for 1–2 years after the injury as the healing process continues and the scar matures (Schwanholt *et al.*, 1994). Conceivably, body image (i.e. how we feel about our physical appearance) updating will be difficult within this period. It has been reported that up to 30% of people with burns report a life of social withdrawal and isolation 1–2 years after injury (Taal & Faber, 1998) as a consequence of their appearance.

However, not everybody with an altered appearance after burns develops a negative body image and associated social anxiety. This is where the personal and social meaning of scarring from burns becomes so important. It appears that perceived severity is important to post-burn adjustment (Kleve and Robinson, 1999).

Behavioural problems

With children, often it will be behaviour that acts as an indicator of psychological wellbeing after burn injury. Reported behavioural disturbances in children range from externalizing signs of aggression (Andersson *et al.*, 2003) to internalizing signs such as withdrawal, and sleep disturbances (Rose *et al.*, 2001). Blakeney *et al.* (1990, 1993) have demonstrated that even massive burn injuries in children need not necessarily cause psychosocial maladjustment. Several of this research group's studies highlight that most children are well adjusted and socially competent, even after severe burn injury. However, it should be borne in mind that in the USA, children with burn injuries receive more psychological input as part of their care than currently in the UK. Other researchers report more maladaptive behaviours in children with burns, compared with a normative sample (e.g. Meyer *et al.*, 1995). Sleep disturbances after burn injury have also been noted (Kravitz *et al.*, 1993).

Vulnerability factors, protective factors and psychosocial impact of burn injury

Having described the nature of psychological sequelae after burn injury, we have to consider why some people appear to be more vulnerable to negative outcomes. After all, not everybody who experiences burns is poorly adjusted, the majority of people appear to do quite well and many have a quality of life comparable to that of people without burns in the longer term (Altier *et al.*, 2002).

Individual differences

One might expect that previous vulnerability to psychological distress may play a part in post-burn adjustment. Indeed, possibly one of the most robust predictors of emotional distress or depression after burn injury is a history of mental health problems (e.g.

Patterson *et al.*, 2003; Van Loey & Van Son, 2003). Furthermore, it is also argued that the very existence of pre-burn mental health disorder predisposes an individual to burn injury. This appears to hold for both adults (Cobb *et al.*, 1991) and parents of children with burns (Kendall-Grove *et al.*, 1998).

Personality may also play a role in how a person adjusts after suffering a burn injury. Research has robustly demonstrated that the personality trait of neuroticism is associated with greater PTSD symptomology, whereas extraversion acts as a protective factor against PTSD (Fauerbach *et al.*, 2000). Kildal *et al.* (2004) related the trait of neuroticism to poorer psychosocial outcome, affect, interpersonal relationships, and physical outcomes after burn injury. However, one point to bear in mind when thinking about personality and outcome of burns is the point at which personality was assessed. Studies can only ever achieve retrospective assessments of personality and it is not clear how the experience of trauma and, in the longer term, the experience of an altered appearance and the public's reaction may affect someone's responses on a personality checklist.

An interesting piece of research recently examined the role of coping patterns in adjustment following burn injury. Previously, research examining successful coping had noted that avoidant coping (e.g. suppressing thoughts, distraction) was associated with poorer psychosocial outcome (e.g. Browne *et al.*, 1985) and was also linked to maladaptive personality traits such as neuroticism (Willebrand, *et al.*, 2002). Examining coping patterns after burn injury revealed that swinging between coping styles such as suppression (e.g. mental distancing) and extensive processing (e.g. venting) predicts depression and PTSD at 2 months post-burn (Fauerbach, Richter *et al.*, 2002). This is of interest because generally within the coping literature, having a range of coping strategies is seen as adaptive, whereas here, flitting between the two styles renders these processes useless in ameliorating the negative psychological effects of burn injury. The early use of disengagement as a coping strategy was also associated with a more negative social impact of disfigurement at 2 months (Fauerbach, Heinberg *et al.*, 2002), whereas the early use of acceptance and positive outlook as a coping strategy was protective against PTSD, anxiety and depression (Tedstone *et al.*, 1998).

Gender and age also appear to play a role in post-burn adjustment. It appears that females are more vulnerable to adverse psychosocial affects, being more likely to experience PTSD (e.g. Maes *et al.*, 2001) and more likely, for example, to experience depression after facial burn injury (Van Loey & Van Son, 2003). Younger age at injury appears to play a protective role in body image of children with burns (Jessee *et al.*, 1992). Receiving the burn before a stable body image is formed may allow an easier assimilation of the scar into the child's developing body image, whereas in adults receiving burns, relative youth was associated with more PTSD symptomology (El Hamaoui *et al.*, 2002).

One area of psychological import, regarding trauma, is the attribution of blame made by both adults and parents. In adults who have been burned, self-blame for the accident is a protective factor against PTSD symptomology (Lambert *et al.*, 2004), whereas in parents, self-blame is associated with poorer adaptation after their child has been burned (Ragiel, 1989). This can be understood in terms of blaming oneself as an adult means taking responsibility and gives a sense of control over the environment (Lambert *et al.*,

2004), whereas for parents blaming oneself adds to the sense of guilt, potentially perpetuating depression.

Social factors

In terms of social variables, it appears that socially disadvantaged families have a greater disposition to burn injury, a chaotic home life potentially creating vulnerability to injury (Kendall-Grove, 1998). This is often a cause for concern as one of the more stable protective factors for children after burns is the family environment. In particular, a cohesive, expressive family with good family relations fosters positive adjustment and body image (e.g. Blakeney *et al.*, 1990; Landolt *et al.*, 2002). Furthermore, a family that encourages autonomy and self-mastery over the environment seems to aid children in their post-burn adjustment (e.g. Blakeney *et al.*, 1990), and also adults (Gilboa, 2001).

The most robust social variable associated with post-burn adjustment for children and adults is that of perceived social support from family and friends (e.g. Davidson *et al.*, 1981). In adolescents, when peer acceptance becomes of central importance, it is the support of friends that buffers self esteem and body image, and ameliorates depression (Orr *et al.*, 1989). The majority of evidence in this area therefore endorses the buffering hypothesis of social support on life stress, postulated by Cobb (1976).

In younger children, the mother's adjustment and coping strategies may protect the child from negative psychosocial sequelae (Browne *et al.*, 1985), with maternal emotional distress linked to poorer adjustment in the child with burns (Sawyer *et al.*, 1982). Family variables also play a role in PTSD symptomology in adults with burns, with family instability noted as a vulnerability factor (Kulka *et al.*, 1990).

Positive self-regard has been suggested as a successful coping strategy for burned children. In a study by LeDoux *et al.* (1996), burned children actually had positive self-concepts on a standard measure. The children had re-evaluated their strengths and diminished the importance of athletic competence, physical appearance and social acceptance, compared with a non-burned group. Using a qualitative approach alongside the standard measure, such as an interview, would also have revealed how the children felt about this shift in their value system, giving a more in-depth understanding of how this re-evaluation had impacted on their daily life.

Physical factors

Research has highlighted the existence of certain factors that put an individual at more risk of experiencing negative psychosocial effects of burn injury. Contrary to lay belief, how big the burn is (i.e. total area of body surface burned), does not predict levels of psychosocial adjustment post-burn in adults (e.g. Tedstone *et al.*, 1998), children (e.g. Orr *et al.*, 1989), or in mothers of burned children (Kent *et al.*, 2000).

The level of physical impairment, however, seems to relate in part to levels of depression and social withdrawal in the longer term after burn injury (Pallua *et al.*, 2003).

Considering physical location, the literature is conflicting in terms of whether a visible burn has more negative psychosocial consequences than a hidden burn. Some report that hidden burns create more social anxiety due to concern about situations where

the scar might be revealed (e.g. Doctor, 1992) and that this may hinder involvement in social situations and delay body image updating (Pruzinsky & Doctor, 1994). Others suggest that people with visible burns have less interaction with people outside of the family and withdraw from activities that draw attention to appearance (e.g. Browne *et al.*, 1985). There are also reports that those with visible burns were no more adversely affected than those with non-visible burns, the explanation being that if a burn is visible you have no choice but to deal with the reactions of others (Landolt *et al.*, 2000). Visibility of the burn is also said to be related to PTSD symptomology (Van Loey & Van Son, 2003). Perhaps the more visible a burn scar, the more attention it will draw from the public and so reminders or intrusive thoughts about the accident and its consequences prevail. Furthermore, self-rated visibility of the burn associates with more perceived hostility from others, and more startled responses from others (Lawrence *et al.*, 2004).

This seems to highlight the need to understand the meaning and importance of the burn to the individual and what it will mean in their life. The physical location will have social consequences and perhaps alter the personal meaning of the burn in terms of importance to the individual, based on their everyday experiences. For a comprehensive discussion of issues and interventions with disfigurement, see Rumsey & Harcourt (2004).

Methodological issues

In the literature there is often conflicting evidence regarding the prevalence and occurrence of psychosocial maladjustment. There are several possible explanations for this. Methodological differences may play their part in that studies use a variety of methods to assess psychosocial maladjustment with measures that cannot be directly compared, samples used may be small or skewed, time of follow up may vary from months to years, and in some studies there has been a lack of comparison with a non-burned or control group (see Eyles *et al.*, 1984). Furthermore, many of the studies conducted in this area have mainly used standardized measures or checklists with the consequence that the knowledge gained is limited to the scope of the checklist. The use of mixed-methodologies incorporating both semi-structured interviews and checklists will provide a deeper understanding of the individual's perception of events by enabling their understanding and explanation of experiences to be more fully expressed. For example, Landolt *et al.* (2000) report that the children have no social impairment because of the burn injury, according to a child behaviour checklist completed by parents ('child' age range: 5–17 years). However, it would have been useful to ask those children themselves whether they had changed their social life, where they go, who they go with, when they go, and what they do when they are there. This level of understanding is not always possible using a fixed measure.

The future: positive psychology versus a 'pathologizing' culture

An interesting current debate regarding psychosocial outcome after burn injury concerns the 'pathologizing' approach to research in this field, as opposed to using a more positive psychology.

An old concept that is now being re-visited is that of resilience and the nature of resilience (Williams *et al.*, 2003). Is it a personality trait? Can it be fostered in individuals to increase hardiness towards the deleterious effects of burn injury? The term resilience has been around since the 1970s, following research where it became apparent that some children at high risk of developing psychopathology actually did well. These children were termed 'stress resistant' or 'resilient' (Caffo *et al.*, 2003). From recent debates, it seems that it would now be useful to further investigate 'resilience' as a psychological construct to assess its role within burns.

Camps for children with burns are now being established all over the UK, adopting an approach used in America with the notion that the chance to take part in confidence-building exercises in a place where they are perceived as and feel 'normal' will be a reparative step for self-esteem after burn injury (Williams *et al.*, 2004). Future researchers will hopefully work with these organizations to evaluate and identify aspects which are positive and foster these aspects in other areas of the children's lives.

Conclusion

There is considerable variability in psychosocial adjustment following burn injury. Difficulties reportedly lie in the areas of depression, PTSD, social anxiety and body image dissatisfaction. Regarding visible burns, attention must be paid to the personal and social meaning of the scar in order to understand why, for example, some people with visible scarring cope very well and others experience social withdrawal or social anxiety.

Individual and social factors seem to be more predictive than physical factors such as size of burn. Thus, a model incorporating physical (e.g. location, hand injury), social (e.g. perceived support) and psychological (e.g. personality, coping pattern) factors may best explain the variance observed in psychosocial adjustment after burn injury (Patterson *et al.*, 2000).

The future of research in this field appears to be in moving towards a more positive psychology, shedding light on how to foster protective factors in individuals with burn injuries.

Cancer: breast

Alice Simon and Kathryn Robb

University College London

Prevalence and risk factors

Breast cancer is the most commonly diagnosed cancer in women in both the UK and the US (Cancer Research UK, 2005; American Cancer Society, 2005). In the UK, around 41 000 women develop breast cancer and around 13 000 die from the illness each year. In the US, approximately 210 000 women are diagnosed and 40 000 die from breast cancer every year. It is possible for men to develop breast cancer but it is rare, with annually fewer than 300 cases in the UK and 1700 in the US.

International comparisons (Parkin & Muir, 1992) and studies of migrants (Kolonel, 1980) have provided evidence for the importance of environment in causing the disease. These observations are significant because they suggest that some breast cancers are caused by lifestyle and therefore could be prevented. The major risk factors for breast cancer include (see Colditz *et al.*, 2000): older age, being overweight after the menopause, having a family history of breast cancer, taking the oral contraceptive pill or hormone replacement therapy, starting menstruation early or having a late menopause, starting to have children at an older age, having fewer children, not breastfeeding and regularly drinking large amounts of alcohol. Fewer than 5% of breast cancers arise from inherited gene mutations such as BRCA1 and BRCA2 (Hodgson & Maher, 1999).

Early detection

Screening

Screening mammography has been found to reduce breast cancer mortality in women aged between 50–74 years (Kerlikowske *et al.*, 1995), while the benefits of screening women aged 40–49 years are not so clear (Moss, 2004). Participation in mammography screening does not appear to be associated with age, ethnicity, marital status, or level of education (Jepson *et al.*, 2000). However, having attended a previous mammogram, intending to participate and receiving a general practitioner's recommendation, have all been found to relate to increased attendance (Jepson *et al.*, 2000).

Any medical intervention aimed at a 'healthy' population needs to consider not only the benefits but also the potential harms. The psychological impact of screening is one such potential harm. A recent systematic review reported that mammography screening does not raise anxiety among women given the 'all-clear' (Brett *et al.*, 2005). Indeed, there is some evidence that levels of anxiety following an 'all-clear' mammogram were lower than in the population, suggesting that the procedure may be having a positive emotional impact (Scaf-Klomp *et al.*, 1997). Some population

sub-groups (younger age, lower education, living in an urban area, manual occupation, one or no children) are more likely to experience an adverse psychological impact of screening (Brett *et al.*, 2005).

A significant minority of women (5% in the UK) are recalled for further investigation (Smith-Bindman *et al.*, 2003), and among this group there is evidence of significant anxiety, at least in the short-term. Women who are required to have further investigations but are then given the 'all-clear' have been found to show a 'relief' effect, whereby they report lower levels of depression at 3 and 12 months relative to women initially given a clear result (Lampic *et al.*, 2001).

There is some concern that an 'all-clear' mammography result could cause complacency (Stewart-Brown & Farmer, 1997) and cause women to ignore future symptoms (Fowler & Austoker, 1996; Petticrew *et al.*, 2000). However, a review of the area found insufficient evidence for reassurance delaying subsequent symptom presentation (Ramirez *et al.*, 1999) (see also 'Screening: cancer' and 'Screening: general issues').

Symptoms and delay

Encouraging breast self-examination according to a regular schedule does not appear to reduce mortality from breast cancer (Thomas *et al.*, 2002); however women are encouraged to be 'breast aware' and to know what is normal for them. Symptoms of breast cancer include: a new lump or thickening in the breast or armpit; changes in the size, shape or feel; any puckering, dimpling or redness of the skin; changes in the position of the nipple, a rash or nipple discharge; and unusual pain or discomfort (see 'Self-examination').

Delay in the presentation of symptoms is associated with increased breast cancer mortality (Richards *et al.*, 1999). Older age has been identified as a strong predictor of patient delay, while fewer years of education, non-white ethnic origin, not disclosing breast symptoms to another and not attributing symptoms to breast cancer have been found to be moderate predictors of patient-related delay (Ramirez *et al.*, 1999). Younger age and the presentation of a symptom other than a breast lump have been associated with increased delay in diagnosis by health care providers (Ramirez *et al.*, 1999).

Impact of diagnosis

Treatments for breast cancer and their psychological consequences

For many women the primary treatment for breast cancer is surgery, often combined with radiotherapy. Early-stage, localized cancers

are frequently treated by the removal of the lump only rather than the entire breast. Breast-conserving therapy appears to have some advantages in terms of improved body image and sexual functioning and improving psychosocial outcomes over the longer term (Engel *et al.*, 2004). Radiation following surgery is used to eliminate any remaining cancer cells and is related to increased fatigue resulting in worse quality of life (Jereczek-Fossa *et al.*, 2002) (see 'Radiotherapy'). Chemotherapy and hormone therapy are also used as adjuvants in the treatment of localized disease as well as for the control of metastatic tumours. Apart from the obvious side effects, such as hair-loss and vomiting, chemotherapy is also associated with longer term cognitive dysfunction (Ahles & Saykin, 2002) (see 'Chemotherapy'). Up to 70% of all breast cancers are hormone-sensitive and there are a number of hormonal therapies for both pre- and post-menopausal women with early or advanced disease. Hormonal treatments can have adverse side effects such as vaginal dryness and hot flushes. But there is some evidence to suggest that patients prefer hormonal treatments over chemotherapy when there is a choice to be made (Fallowfield *et al.*, 2004). Women cite the avoidance of hair-loss, the convenience of the treatment (i.e. less disruption to everyday life) and an overall perception of fewer side effects as the reasons for preference of hormonal therapy (Fallowfield *et al.*, 2004). This illustrates the value placed on quality of life during treatment (see 'Quality of life').

Treatments commonly cause symptoms such as fatigue, pain and sickness. These symptoms are often debilitating and cause psychological distress (Bennett *et al.*, 2004). Some cancer treatments are also associated with increased levels of distress as a direct side effect of treatment, e.g. immunotherapeutic agents, such as interferon-alpha and interleukin induce depressed mood (Capuron *et al.*, 2001; Musselman *et al.*, 2001). Patients currently undergoing treatment tend to have increased distress compared with those who have completed treatment.

There are also other studies which conclude that type of treatment is not associated with distress. Younger age, past history of depression or anxiety and lack of social support, could be more important risk factors for depression and anxiety than cancer-related variables (Burgess *et al.*, 2005). These variables are risk factors for depression in general population samples.

Recovery

Survival, recurrence and long term psychological consequences

A number of issues continue to affect breast cancer 'survivors' despite their disease-free status. There are long-term side effects of treatments including, for example, restricted arm movement and early menopause (Hoda *et al.*, 2003; Ernst *et al.*, 2002) which can affect quality of life. Up to 70% of breast cancer patients express fears about recurrence (Mast, 1998). Some survivors attend outpatient clinics many years after the doctor recommends discharge in order to receive reassurance about their disease-free status (Thomas *et al.*, 1997). Women fear recurrence because of its association with advancing disease, initiating new treatments and possible association with death (Johnson Vickberg, 2001). Unsurprisingly, a

recurrence of breast cancer is associated with increased levels of anxiety and depression (Burgess *et al.*, 2005).

Having had a cancer diagnosis can also seriously affect a person's social identity and role through loss of employment or change in status within the family (Zebrack, 2000). This change in a person's expected life trajectory leads to a process of long-term reorganization and a search for meaning in the experience (Utley, 1999).

Recognizing and treating distress

Prevalence of distress in breast cancer patients

Newly diagnosed breast cancer patients face a number of psychological threats. Not only does the diagnosis often have a significant impact on life expectancy but women are also faced with challenges related to their sexuality, femininity and fertility. The illness can also have knock-on effects throughout women's social life in terms of employment or ability to work and social and family life (Kunkel & Chen, 2003).

Estimates of the prevalence of psychological distress in breast cancer patients vary greatly. At the lower end, one study of a breast cancer clinic waiting-room sample found approximately 9% had major depression, 7% had minor depression, and 6% had generalized anxiety disorder (Coyne *et al.*, 2004). At the higher end, Burgess *et al.* (2005) found 50% of a sample of breast cancer patients to have depression or anxiety in the first year after diagnosis. They also report that this level declines to 25% in the second year and 15% thereafter, showing that estimates of prevalence will vary according to the timing of the assessment. Other factors also contribute to this variation. Higher estimates may reflect use of symptom reporting recorded with self-report questionnaires rather than diagnostic interviews (Hotopf *et al.*, 2002). Higher frequencies may also be seen in inpatients who have more severe symptoms or advanced stages of disease (Lynch, 1995).

Assessing distress in breast cancer patients

Some of the challenges in recognizing clinical levels of distress in breast cancer patients stem from the overlap between symptoms of cancer and the side effects of its treatment, and the defining symptoms of psychiatric disorders such as depression (e.g. fatigue, loss of appetite, cognitive impairment). Symptoms that best distinguish between distressed and non-distressed persons in the general population may not provide the best discrimination among breast cancer patients (Trask, 2004). Attention must be paid to the effects of inclusive versus exclusive evaluations of energy loss, appetite and sleep disturbance, as well as the use of substituting cognitive symptoms for these physical symptoms in making diagnoses (Endicott, 1984; Uchitomi *et al.*, 2001).

The natural course of distress in breast cancer patients is also unclear. A proportion of depression cases in breast cancer patients will be recurrent or ongoing, rather than new, instances. A past history of depression or anxiety is important for predicting which cancer patients will become distressed (Maunsell *et al.*, 1992; Harrison & Maguire, 1994; McDaniel *et al.*, 1997). These patients may already have been prescribed anti-depressant medication or other psychological treatments currently or in the past.

Treatments for psychological distress in breast cancer patients

Psychological distress in breast cancer patients has been treated in similar ways to distress in other population groups i.e. by psychotropic drugs or psychosocial intervention or some combination of both.

Prescribing of antidepressants or anti-anxiolytics to breast cancer patients can be high and sometimes inappropriately so. Coyne *et al.* (2004) reported that 48% of breast cancer patients without a psychiatric disorder had been prescribed antidepressants inappropriately. There is also evidence that many people are not being prescribed an appropriate therapeutic dose (Sharpe *et al.*, 2004b). Effective use of psychotropic drugs in appropriately identified individuals is obviously key to the efficacy of these treatments.

Psychological interventions to treat depression and anxiety in cancer patients are moderately effective (Sheard & Maguire, 1999). Targeted interventions directed at those who are suffering psychological distress have stronger clinical effects than non-targeted interventions. Studies which target all cancer patients have weak results and probably lead to under-estimates of the potential effectiveness of psychological therapies. Group therapy seems to be as effective as individual therapy (Sheard & Maguire, 1999) (see 'Group therapy'). Similarly, telephone counselling can be as

effective as face-to-face therapy (Badger *et al.*, 2004, 2005). Recent studies looking at incorporating psychological therapies into the repertoire of oncology professionals, such as cancer nurses, can be effective (Greenberg, 2004; Strong *et al.*, 2004). Psychosocial interventions that reduce distress can save resources by reducing service use (e.g. number of visits to primary care physicians and specialists) (Carlson & Bultz, 2004). Unfortunately, a problem is that a high proportion of patients reject psychological intervention (Shimizu *et al.*, 2005; Sharpe *et al.*, 2004a). Referral for symptom management interventions could be a more acceptable format (McLachlan *et al.*, 2001) and could lead to a reduction in depression (Given *et al.*, 2004). Exercise interventions may also have the potential to improve psychological as well as physiological wellbeing (Oldervoll *et al.*, 2004) (see 'Physical activity interventions').

In sum, there are effective treatments for psychological distress in breast cancer patients. These include the use of antidepressants at effective doses and psychological interventions that focus on lifting depression or improving symptom management. Identifying the women who would benefit from these treatments is difficult, leading to problems estimating the need for clinical services.

Cancers of the digestive tract

Sharon Manne

Fox Chase Cancer Center

Cancers of the digestive tract, which include cancer of the colon, rectum, pancreas, stomach and esophagus, are among the most common and deadly types of cancer. Colorectal cancer (cancer of the colon or rectum) is the second leading cause of cancer-related deaths in the United States. The disease surpasses both breast and prostate cancer in mortality and is second only to lung cancer in numbers of cancer deaths. Approximately 146,940 new cases of colorectal cancer were diagnosed in the United States 2004 and 56,730 people died from the disease. Although relatively uncommon, oesophageal, stomach and pancreatic cancer are among the most deadly cancers, as they are typically diagnosed at more advanced stages. For example, cancer of the pancreas is the fourth leading cause of cancer death in the United States. The tendency of these cancers to be either asymptomatic at early stages or to present with vague symptoms at more advanced stages, as well as the lack of screening procedures for these cancers, contributes to diagnosis at a more advanced stage. This chapter will discuss the psychological impact of cancers of the digestive tract according to upper digestive tract (oesophagus and stomach) and lower digestive tract (colon, rectum, pancreas).

Cancer of the upper digestive tract

Many individuals diagnosed with cancers of the oesophagus or stomach have a poor prognosis because the cancer may have metastasized prior to diagnosis. For individuals diagnosed with gastric (stomach) cancer, studies have shown only a 2.5% (distant metastatic disease) to 23% (all stages) 5-year survival rate (American Cancer Society, 2004). For individuals diagnosed with stage I oesophageal cancer, the 5-year survival rate is 29% (American Cancer Society, 2004). Survival rate for later stages of oesophageal cancer is poor (2–13%). Treatment for oesophageal cancer usually involves partial removal of the oesophagus and often part of the upper stomach. This is a difficult surgery with a long period of recovery. Difficulty swallowing food and pain are common disease-related symptoms. Treatment for gastric cancer is usually total removal of the stomach. This surgery results in weight loss, malnourishment due to malabsorption, difficulty swallowing food, acid reflux. Post-prandial discomfort, such as bloating and urgent diarrhoea, are common symptoms (Vickery *et al.*, 2001). Unfortunately, curative surgery is not an option for many patients with gastric cancer. These patients are offered palliative care to manage pain and surgical intervention to manage perforation or obstruction.

Given the poor prognosis and many difficult disease-related symptoms, patients diagnosed with either gastric or oesophageal cancer may be understandably anxious and depressed at the time

of initial diagnosis and suffer from a greatly reduced quality of life. Indeed, the few studies of individuals with gastric cancer have suggested that this is the case. Svedlund and colleagues (1996) conducted a cross-sectional study evaluating quality of life among newly diagnosed, early stage gastric cancer patients one week prior to surgery. Compared with a healthy reference population, gastric cancer patients had lower health-related quality of life, with significant differences noted in eating, sleep/rest, work and home management. Psychological functioning was similar to the healthy reference population.

There have been two longitudinal studies of quality of life among gastric cancer patients. A prospective randomized clinical trial evaluating the impact of different types of gastrectomy on quality of life was conducted by Svedlund *et al.* (1997). The sample evidenced functional limitations, particularly with regard to digestive symptoms at the 3-month follow-up. Compared with the baseline assessment, patients who had total gastrectomy and those who had a total gastrectomy with a gastric substitute reported significantly lower quality of life compared with their pre-surgery functioning. Patients who had a subtotal gastrectomy did not report changes from their pre-surgery quality of life. One year after surgery, physical symptoms decreased more among patients who had a subtotal gastrectomy. These results suggest that there may be some health-related quality of life benefits of subtotal gastrectomy.

Relatively few studies have evaluated quality of life among patients with oesophageal cancer. Because swallowing food is a significant problem, alimentary comfort is generally considered the most prominent quality of life indicator (Sugimachi *et al.*, 1986). The majority of studies evaluating quality of life have investigated the effects of surgical/laser interventions to improve swallowing ability in both early stage patients whose surgery is curative, and among late stage patients, whose surgery is palliative. Sugimachi and colleagues (1986) evaluated the quality of life among early stage patients undergoing oesophageal replacement surgery one year after surgery. They reported better food tolerance, less dysphagia and less time needed to eat compared with pre-surgery functioning. Collard and colleagues (1992) evaluated quality of life among 17 patients who were disease free three years after oesophageal surgery. Patients reported that their comfort when eating was not as satisfactory as before the initial oesophageal symptoms began. However, body weight increased in three-quarters of the patients, and patients reported they were able to eat satisfactorily. The most common troubling symptoms were early fullness when eating, dysphagia and diarrhoea. Other aspects of quality of life, including mental health and social functioning, were not assessed.

van Knippenberg and colleagues (1992) assessed both physical and psychological aspects of quality of life three to four months after oesophageal surgery. In terms of physical symptoms, pain when swallowing, loss of appetite, tiredness, shortness of breath and diarrhoea all decreased significantly after surgery. However, 18% reported that swallowing problems worsened. Psychological symptoms, including degree of worry, desperation about the future and anxiety, declined significantly. About 48% of patients reported depressive symptoms at the post-surgical time point and about 37% reported anxiety. However, because a standardized scale was not used, exact distress levels were not reported, nor were comparisons with a normative sample. Modest associations were found between swallowing problems and quality of life ($r = 0.26$), suggesting that swallowing problems play a relatively small role in evaluations of quality of life. The authors suggest that patients may tolerate physical symptoms, such as difficulty swallowing, in exchange for a chance at a longer life. Two studies have evaluated the effect of two different endoscopic palliative treatments to control malignant dysphagia on quality of life of patients with advanced stages of cancer. Loizou and colleagues (1992) evaluated quality of life in a small sample of oesophageal cancer patients ($n = 43$). Results indicated that all patients followed until death reported improvements in ability to swallow with laser treatment and intubation. Treatment resulted in an initial improvement in quality of life, which was reduced over time with disease progression. The last post-treatment scores, which were taken within five weeks of death, were significantly lower than pre-treatment scores, despite continued successful palliation of dysphagia. The authors interpret these results as suggesting that dysphagia is a less important determinant of quality of life as disease progresses, because patients in terminal stages become anorexic and do not eat.

Cancer of the lower digestive tract

Only 4.4% of patients with pancreatic cancer survive beyond five years, and patients universally experience pain and associated suffering. Obviously, receiving a diagnosis of this disease can be catastrophic. An association between depression and pancreatic cancer was first reported in the 1930s when symptoms of anxiety and depression in patients diagnosed with pancreatic cancer were described (Yaskin, 1931). Indeed, a number of studies have suggested that depression is a presenting symptom at diagnosis (Joffe *et al.*, 1986), with studies suggesting that between 50% (Joffe *et al.*, 1986) and 76% (Fras *et al.*, 1967) of patients either meet criterion for depression or report depressive symptoms at diagnosis. In one study, patients with pancreatic tumours had psychological symptoms 43 months before physical symptoms (Fras *et al.*, 1967). Because depression is a presenting symptom at diagnosis, there has been more attention paid to assessing psychological distress in pancreatic cancer after diagnosis than other types of cancer. Holland and colleagues (1986) compared distress scores in patients with pancreatic cancer who were beginning chemotherapy with patients with gastric cancer. They found that distress scores were significantly higher among patients with pancreatic cancer. The prevalence of pain and depression in newly diagnosed patients with pancreatic cancer were evaluated in a cross-sectional study

by Kelsen *et al.* (1995). Approximately 38% of patients had depression scores in the moderate to severe range on a standardized inventory (Beck Depression Inventory). Patients beginning chemotherapy had significantly higher depression scores than patients about to undergo surgery. The anxiety inventory scores did not indicate high levels of anxiety. There was a significant correlation between pain intensity and depression and anxiety scores. Zabora and colleagues (2001) examined distress in nearly 5000 cancer patients of whom 112 had pancreatic cancer. Comparisons between tumour sites indicated that pancreatic cancer patients endorsed the highest mean scores for anxiety and depression. Whether an association between depression and pancreatic cancer is due to the cancer itself, or whether depression causes pancreatic cancer, is an issue that has been raised in the literature (Carney *et al.*, 2003).

For individuals with colorectal cancer, the only curative treatment is surgery. The type of surgery is dependent on the localization of the tumour relative to the anal verge. If the tumour is near the anal verge or if the patient presents with recurrent colorectal cancer, then the surgery performed includes the rectum and sphincter function is not preserved. With this procedure, patients must have a permanent ostomy. This is an intrusive surgery that can interfere with daily life. Patients must cope with an ostomy bag and its care along with frequent or irregular bowel movements.

Much of the literature on quality of life among individuals with colorectal cancer has focused on the impact of ostomy surgery, and the most common aspect of quality of life assessed has been depression. Several studies have reported that the prevalence of depression is higher among ostomates than non-ostomates (e.g. Wirtsching *et al.*, 1975; Williams & Johnston, 1983). Prevalence of depression has ranged from 7% to 50% (Fresco *et al.*, 1988). Approximately 25% of patients report anxiety (Cardoen *et al.*, 1982), but comparisons of patients who have an ostomy with patients who do not have an ostomy do not suggest a difference in rates of anxiety (MacDonald & Andersen, 1984). Twenty-three per cent of patients report a worsening of anxiety or depression compared with pre-surgery levels of functioning (Thomas *et al.*, 1984; White & Unwin, 1998). Risk factors for higher levels of distress include younger age, female gender, lower education level and lower levels of social support (Baider *et al.*, 1989; Vernon *et al.*, 1997). Among patients with ostomies, poorer adaptation has been associated with a higher level of ostomy self-care, less perceived support from family and friends and less psychosocial support to assist in accepting permanent changes in body image related to ostomy surgery (Piwonka & Merino, 1999).

In terms of social functioning, studies have indicated that patients report deterioration in the quality of their relationships with family and friends (Fresco *et al.*, 1988). Estimates of sexual problems have varied greatly across studies, but the sexual function of men with a colostomy is more impaired than among patients with intact sphincters.

Few studies have evaluated quality of life among long-term survivors. Ramsey and colleagues (2000) conducted one of the few evaluations of quality of life among survivors. They studied 227 patients surviving at least five years from diagnosis using standardized measures of health-related quality of life and depression. Fourteen per cent of patients scored at or above

the depression cutoff score. Depression was significantly more prevalent than among the general population. Depression was significantly higher among patients reporting comorbid health problems and low socioeconomic status. Mullens and colleagues (2004) evaluated risk perceptions and worry and anxiety in 81 survivors. They found that shorter-term survivors perceived the risk for recurrence to be higher and reported more intrusive worries about cancer. Overall levels of anxiety and worry about recurrence were low.

Issues

As described in the review above, the primary focus of research has been on physical symptoms and health-related quality of life. Much less attention has been paid to emotional distress and positive well-being, particularly among patients with gastric and oesophageal cancers. Because physical symptoms such as dysphagia and nausea are extremely troubling and likely to significantly interfere with quality of life, it is understandable why these aspects of quality of life are important targets for studies. However, greater attention should be paid to assessing emotional and social functioning.

The very small sample sizes of the majority of studies are noteworthy, particularly in evaluations of quality of life among patients

with oesophageal, gastric and pancreatic tumours. Most studies are not powered sufficiently to test differences between patients undergoing different treatments or surgeries. Data regarding refusal rates are rarely presented, and thus it is not clear whether the samples are biased. Because most studies are cross-sectional, we do not have information about the course of distress responses over the illness trajectory. Both issues are likely due to the fact that the majority of patients with these cancers do not live very long, and thus it is difficult to follow patients for a significant period of time. Patients may be too ill to complete study surveys over a lengthy period of time. Another issue is the lack of knowledge regarding attitudinal factors contributing to differences in quality of life and distress outcomes in patients with gastrointestinal cancers. The dearth of information on this topic is probably due to the fact that health-related challenges; particularly pain, nausea, problems with eating and difficulties after meals; are the main contributors to distress responses in this very sick group of patients. However, psychological interventions could be informed by more knowledge about psychological vulnerabilities and strengths that contribute to wellbeing in this population. Given the major challenges these patients face, it is surprising to see that so few psychological interventions have been tested.

Cancer: general

Barbara L. Andersen and Laura E. Simonelli

The Ohio State University

Introduction

The human cost of cancer is staggering. Worldwide there were 10.9 million new cases, 6.7 million deaths and 24.6 million persons alive with cancer (within three years of diagnosis; Parkin *et al.*, 2005). In many countries cancer is the second leading cause of death, only outnumbered by heart disease. In the United States, it has been the leading cause of death for persons younger than 85 since 1999, and over 1 million new cancer cases and almost 600 000 deaths are expected in 2005 (Jemal *et al.*, 2005). However, there is striking variation across geographic locations. Research on the psychological and behavioural aspects of oncology began in the early 1950s; however, significant expansion has occurred in the last 25 years. This research has clarified biobehavioural factors in illness (Andersen *et al.*, 1994), including relations between psychological responses and factors (e.g. personality, mood, coping style) and behavioural variables (e.g. compliance with treatment, diet, exercise), with more recent research incorporating biologic systems (e.g. immune and endocrine) and examining the interaction of these variables and their relationship to disease course (Andersen *et al.*, 2004).

This chapter provides a brief overview of the central findings which have emerged on the psychological and behavioural aspects of cancer. Other chapters in this volume can be consulted for site-specific findings. By way of introduction, we will begin with data on cancer incidence, death rates and gender differences. Where data from the US are used, we note that they represent the same general trends found in other industrialized, western countries. The remainder of the chapter organizes the findings by disease-relevant time points, from diagnosis to recovery and/or

death. We will conclude by highlighting psychological interventions which appear to be effective in aiding cancer patients.

Magnitude of the problem: incidence, death rates and gender differences

Cancers vary in their prevalence and mortality. Tables 1 and 2 display data from the USA on the incidence and death rates by specific sites and genders. Similarly, Tables 3 and 4 provide death rate data from other countries (Ferlay *et al.*, 2004).

Biobehavioural aspects

Diagnosis

An early clinical study suggested that the diagnosis of cancer produces an 'existential plight', meaning that the news brings shock, disbelief and emotional turmoil (Weisman & Worden, 1976). Today, we know that individuals even become anxious and alarmed at the time of medical screening. (French *et al.*, 2004; Wardle & Pope, 1992). When the diagnosis does come, the stress patients experience even relates to adverse biological consequences, such as a lowered immune response (Andersen *et al.*, 1998).

In the USA, as well as in most western countries, patients (including children) are told that their diagnosis is cancer (Krylov & Krylova, 2003). Cross-cultural research has indicated that the majority of patients want to be told their diagnosis

Table 1. Cancer incidence by site and gender in the United States (2005 estimates)

Cancer incidence					
Male (Total est. 710 040)			Female (Total est. 662 870)		
Site	Number	(%)	Site	Number	(%)
Prostate	232 090	(33%)	Breast	211 240	(32%)
Lung and bronchus	93 010	(13%)	Lung and bronchus	79 560	(12%)
Colon and rectum	71 820	(10%)	Colon and rectum	73 470	(11%)
Urinary bladder	47 010	(7%)	Uterine endometrial	40 880	(6%)
Melanoma of skin	33 580	(5%)	Lymphoma	27 320	(4%)
Lymphoma	29 070	(4%)	Melanoma of skin	26 000	(4%)
Kidney and pelvis	22 490	(3%)	Ovary	22 220	(3%)
Leukaemia	19 640	(3%)	Thyroid	19 190	(3%)
Oral cavity and pharynx	19 100	(3%)	Urinary bladder	16 200	(2%)
Pancreas	16 100	(2%)	Pancreas	16 080	(2%)

truthfully (e.g. Japan: Miyata *et al.*, 2004). However, in some countries, such as Turkey, cancer diagnoses are often viewed as death sentences leading to great distress, and poor physician-patient communication is considered one primary reason why many patients are not informed of their true diagnosis (Atseci *et al.*, 2004). These studies demonstrate the need for physicians and other health professionals to learn more effective means of communicating information (e.g. diagnosis, treatment, prognosis) to their patients (Atesci, 2004; Miyata *et al.*, 2004) (see 'Breaking bad news').

Patients experience a range of emotions, such as sadness, depression, hopelessness, fear, anxiety and anger, following their cancer diagnosis. It is not surprising that depression is the most common affective problem. Estimates of depressive symptoms vary from 5% to 50% in cancer patients, and it is thought that at least half of these patients would meet diagnostic criteria for clinical depression (Stommel *et al.*, 2004). There are several factors that affect the degree of emotional distress patients experience during this difficult time. Cancer site, stage, comorbidities, socio-demographic characteristics (i.e. age, education, gender), physical

functioning, symptom severity and treatment type have been identified as predictors of depressive symptoms in multiple cancer populations (Epping-Jordan *et al.*, 1999; Stommel *et al.*, 2004). For example, more advanced disease in cancer patients (e.g. breast) is related to poorer physical and mental health (Jacobsen *et al.*, 1998).

Psychosocial variables, such as coping (Epping-Jordan *et al.*, 1999), optimism (Andrykowski *et al.*, 2004), personality (Ranchor *et al.*, 2002) and social support (Varni & Katz, 1997) appear to be influential in psychological adjustment to cancer diagnosis and treatment. For example, low optimism moderated distress levels among women receiving abnormal transvaginal ultrasounds for ovarian cancer screening (Andrykowski *et al.*, 2004).

In addition to patient distress following diagnosis, several studies have addressed the emotional impact on patients' partners and families. Most studies have found that patients partners and offspring have comparable levels of anxiety and depressed mood throughout the various stages of cancer diagnosis and treatment (Edwards & Clarke, 2004). In addition, research suggests families that express feelings directly and solve problems effectively have lower levels of depression and anxiety (Edwards & Clarke, 2004).

Table 3. Age-adjusted death rates in adult males per 100 000 for disease sites and selected countries

Country	All sites	Colon/rectal	Lung	Prostate	Stomach
United States	152.6 (30)	5.2	48.7	15.8	4.0

Figures in parentheses are order of rank based on data from 50 countries in 2002. Adapted from J. Ferlay *et al.* (2004). GLOBOCAN 2002: Cancer Incidence, Mortality and Prevalence Worldwide IARC CancerBase No. 5. version 2.0, IARC Press, Lyon, 2004.

Nonetheless, it is clear that cancer diagnosis and its aftermath can be quite distressing for patients and their loved ones.

Treatment

A certain component of the emotional distress occurring at diagnosis is due to the anticipation of treatment. Current therapies include surgery, radiotherapy and radioactive substances, chemotherapy,

hormonal therapy, immunotherapy and combination regimens and procedures (e.g. bone marrow transplantation, intra-operative radiotherapy). Some patients also undergo difficult diagnostic or treatment monitoring procedures (e.g. bone marrow aspirations), as well as physical examinations, radiology studies and/or laboratory work. Thus, the diagnostic process of selecting the appropriate therapy and the subsequent treatment events bring multiple occasions of medical stressors. The data are consistent in their portrayal of more distress (particularly fear and anxiety), and slower rates of emotional recovery for cancer patients than are found with healthy individuals also undergoing medical treatment. As cancer treatments (e.g. surgery, radiation, etc.) vary considerably in their intent, morbidity and mortality, we will review each of the major modalities separately and also discuss three clinical problems that are common across therapies: compliance; appetite and weight loss; and fatigue.

Surgery

There have been few investigations of cancer surgery, but there are numerous descriptive and intervention studies of the reactions of healthy individuals undergoing surgery for benign conditions (see 'Surgery'). The latter studies are consistent in their portrayal of (a) high levels of self-reported preoperative anxiety predictive of lowered postoperative anxiety and (b) postoperative anxiety predictive of recovery (e.g. time out of bed, pain reports). What may distinguish cancer surgery patients are higher overall levels of distress and slower rates of emotional recovery. For example, Gottesman and Lewis (1982) found greater and more lasting feelings of crisis and helplessness among cancer patients in comparison with benign surgery patients for as long as two months following discharge.

Interventions to reduce stress have been tested. Components of these interventions include procedural information (e.g. how the surgery is to be performed, description of postoperative recovery from the perspective of the patient, Wyatt *et al.*, 2004), sensory information on the actual physical sensations of the surgery, behavioural coping instructions, cognitive coping interventions, relaxation and emotion-focused interventions. In a meta-analysis of this literature, Johnston and Vogeles (1993) reported that procedural information and behavioural instructions show consistent and strong positive effects on postoperative recovery. Effects are significant for a broad band of measures, including ratings of negative affect and pain, amount of pain medication, length of stay and indices of recovery (see also 'Coping with stressful medical procedures').

Radiotherapy

At least 350 000 individuals receive radiation therapy each year. Clinical descriptions have noted patients' fears (e.g. being burned, hair loss, sterility): while such outcomes do occur, they are site- and dosage-dependent. To understand radiation fears, the surgical anxiety studies described above have been a paradigm. Here again, anxiety can often cause more overall distress than physical symptoms (Stiegelis *et al.*, 2004). If interventions to reduce distress (especially anticipatory anxiety) are not conducted, heightened

post-treatment anxiety can be found (Larsson & Starrin, 1992) and maintained post-therapy, particularly when treatment symptoms linger (e.g. diarrhoea, fatigue; King *et al.*, 1985). In addition to radiation fears, radiation related morbidities can lead to increased symptoms, such as appetite loss, fatigue and pain, and subsequently, a decrease in quality of life (Bansal *et al.*, 2004) (see 'Radiotherapy').

Chemotherapy

It is estimated that approximately 30% of cancer patients will develop anticipatory nausea, 80% will experience post-treatment nausea, and 55% will develop vomiting in response to cytotoxic treatments (Morrow *et al.*, 2002). The routine use of anti-emetic drugs has resulted in an overall lower incidence and severity of nausea and vomiting as a clinical problem. However, this change in clinical practice may have been somewhat offset by the use of more toxic regimens and the adjuvant treatment for disease types or stages which were previously not treated with chemotherapy (Andrykowski, 1993). It is clear that, in general, anti-emetics need to be used from the beginning not only to control nausea and vomiting, but to reduce the likelihood of the development of anticipatory reactions. Once anticipatory nausea and vomiting develops, anti-emetics are less effective (Morrow & Hickok, 1993), and patients may need behavioural treatment.

Psychological interventions have included the use of hypnosis, progressive muscle relaxation with guided imagery, self-administered stress management, systematic desensitization, cognitive distraction, self-care education and biofeedback (see 'Chemotherapy'). Overall, behavioural interventions can effectively control anticipatory nausea and vomiting in adult and pediatric cancer patients undergoing chemotherapy, but the effects on post-treatment nausea and vomiting are less clear (Redd *et al.*, 2001).

Bone marrow transplantation (BMT)

Over the past few decades, BMT has evolved from an experimental procedure performed as a last resort into an effective treatment for a variety of cancers (e.g. leukaemia, Hodgkin's disease and non-Hodgkin's lymphoma, breast cancer). However, it can also be an aggressive last course of treatment used when standard treatments have failed or a relapse of cancer occurs (Trask *et al.*, 2002).

BMT is a complex, toxic, and potentially fatal, treatment. The target of the treatment, the bone marrow, is destroyed with high dose chemotherapy, with or without whole body radiation afterwards. The transplanted bone marrow then comes from a donor (allogenic BMT) or from the patient him/herself (autologous BMT) after the marrow is removed and treated. Although allogenic BMT has a role, its expansion is limited by the need for a suitable donor and the subsequent risk of graft vs. host disease for the patient. In the case of autologous BMT, a variety of ex vivo procedures are used to destroy the malignant cells in the patient's marrow prior to re-infusion, including treatment with cytotoxic drugs, exposure to monoclonal antibodies which will attach tumour-associated antigens, or harvesting and introducing stem cells from the patient's peripheral blood.

Patients (and their families) are faced with a number of stressors: a life-threatening illness; locating a suitable donor (for allogeneic transplants; Phipps, 2002); and potentially fatal side effects. There are many other side effects as well (e.g. hair loss, mouth and gastrointestinal mucositis and infertility), and, of course, the treatment can fail and the disease persist or rapidly recur (Winer & Sutton, 1994). Hospitalization is prolonged (often four weeks or longer) and it is generally spent in isolation (Trask *et al.*, 2002).

The many difficulties can contribute to patients feeling out-of-control (helplessness), alone, anxious and depressed (Beanlands *et al.*, 2003). Psychological efforts have focused on providing support to patients, their families and healthcare staff (Phipps, 2002), and maximizing control for patients, such as making choices about the hospital environment whenever possible (see also 'Hospitalization in adults').

Cross-modality problems and efforts to reduce treatment distress

Important steps have also been made towards understanding the aetiology and prevention of at least three common disease/treatment-related complications. First, appetite and weight loss are significant clinical problems for cancer patients susceptible to tumour-induced metabolism or taste changes, having tumour-related obstructions (often diagnosed as primary cachexia/anorexia), or receiving gastrointestinal toxic chemotherapy or abdominal radiotherapy (secondary cachexia/anorexia). Research in this area has pointed the way, for example, to interventions employing novel tastes or 'scapegoat' foods (e.g. lemon-lime Kool-Aid, unusually flavoured hard sweets such as coconut; Schwartz *et al.*, 1996) to 'block' conditioning to familiar diet items, reducing food and beverage intake prior to drug administration, and ingesting carbohydrate rather than protein source meals. While food aversions may not result in appetite or weight loss, patients may become averse to their favourite foods which can, in turn, affect their daily routine and perceived quality of life (Berteretche *et al.*, 2004; Schwartz *et al.*, 1996) (see 'Quality of life').

Fatigue is another common problem reported by patients receiving radio- or chemotherapy (Schwartz *et al.*, 2001). Fatigue is described by patients as tiredness, lack of energy, confusion and poor concentration. Although a common experience, little systematic research has been conducted on the correlates of fatigue. However, research has demonstrated that pain and depression are often predictive of fatigue (Hwang *et al.*, 2003). Fatigue appears to reduce overall functional ability, but there is some hope from intervention research (Given *et al.*, 2002).

The expectation and/or experience of unpleasant side effects can comprise a patient's quality of life to the point that the patient may miss treatment appointments and/or be unwilling/unable to continue treatment, regardless if the treatment is curative or palliative (Morrow *et al.*, 2002). With non-compliance with chemotherapy, dosage reductions can lower the cure rate or hasten recurrence or death (Budman *et al.*, 1998) (see also 'Adherence to treatment').

In addition to interventions targeting physical symptom side effects and treatment compliance, interventions have been offered for the mood and anxiety problems which cancer patient often experience. Such interventions use multiple approaches including

cognitive behaviour therapy, supportive counselling, education, relaxation procedures and supportive-expressive therapy, all of which are effective to some degree in reducing emotional distress (see 'Cognitive behaviour therapy', 'Relaxation training' and 'Counselling').

Choosing cancer treatments

Psychological and behaviour data have been important to patients and physicians alike for making choices among comparable treatments. Treatments that result in less quality-of-life disruption often become 'standard' treatment. The most obvious example of the importance of psychological data influencing cancer treatments was that documenting the more positive body image and sexuality outcomes for women treated with breast saving (lumpectomy plus adjuvant radiation and/or chemotherapy) procedures rather than modified radical mastectomy (Frierson & Andersen, 2006).

Recovery and long-term survival

The most important cancer endpoints have been treatment response rates, length of disease-free interval and survival. Yet, as the prognosis for some sites has improved, there has been increased attention to the quality of life, particularly for long-term survivors of cancer. The term 'survivor' typically refers to individuals surviving cancer at least five years, as the probability of late recurrence declines significantly after that time for most sites. As individuals recover and resume their life patterns, there may be residual emotional distress, other difficulties which require continued coping efforts, and even new problems (late sequelae) may occur.

An investigation by Helgeson, Snyder and Seltman (2004) sheds light on the various trajectories of adjustment to breast cancer over a period of four years. Helgeson *et al.* (2004) found that oldest patients had the lowest level of physical functioning and it deteriorated over time, while youngest patients had the highest physical functioning that substantially improved over time. In addition, personal resources, such as self-image and optimism, and social resources distinguished various courses of mental and physical functioning (see also 'Personality and health'). Lingering emotional distress from the trauma and consequences of diagnosis and treatment can occur for some cancer survivors (e.g. Gotay and Muraoka (1998)).

Sociodemographic variables may explain some differential outcomes in cancer survivors. For example, age at diagnosis has been found to be related to quality of life, with younger women experiencing more psychosocial difficulties and older women experiencing more physical difficulties (Bowman *et al.*, 2003). Furthermore, elderly cancer survivors with comorbidities (e.g. stroke, diabetes, hypertension and myocardial infarction) are at risk for impaired functional status (Garman *et al.*, 2003). Low socioeconomic status (SES) has been linked to higher rates of morbidity and mortality in cancer survivors (e.g. Zebrack *et al.*, 2002). Other SES markers such as years of education (Miller *et al.*, 2002) and employment status (Bloom *et al.*, 2004) have also been associated with poorer quality of life in gynaecologic and breast cancer survivors, respectively.

In addition to relevant sociodemographic variables; disease, treatment and psychosocial variables are also influential for outcomes in cancer survivors. For example, more advanced disease for breast cancer patients is related to poorer physical and mental health (Jacobsen *et al.*, 1998). Finally, several psychosocial factors appear to be relevant for adjustment in cancer survivors. First, regarding psychological variables, social support may influence physical symptoms and functioning, as well as distress in cancer survivors (Bloom *et al.*, 2004) (see also 'Social support and health'). Other psychosocial factors, such as coping, self-image, optimism and perceived control, have been identified as important influences on adjustment in longer-term survivors (Helgeson *et al.*, 2004).

Recurrence and death

Over 1.2 million individuals are diagnosed with cancer recurrence each year and over half will progress rapidly and die of their disease (Jemal *et al.*, 2005). Cancer recurrence and advanced cancer produce multiple psychological responses including depressive symptoms and difficulties with disability (Mahon & Casperson, 1997). At least at the time of recurrence diagnosis, stress is the predominant emotional response, and equivalent to that reported at the time of initial diagnosis (Andersen *et al.*, 2005). Later morbidities can include pain (Portenoy *et al.*, 1999), appetitive difficulties (e.g. anorexia, cachexia) and poor body image. It has been suggested that psychological factors, such as social support (Newsom *et al.*, 1996), emotional control (Classen *et al.*, 1996), or spirituality (Carr & Morris, 1996) may be moderators of patient distress.

At the time of cancer recurrence or advanced cancer, emotional turmoil and physical difficulty, psychological interventions appear to enhance the quality of life (e.g. Edelman *et al.*, 1999). Some interventions focus on management of pain, which is more common and less controllable for those with metastatic disease. The major cause of cancer pain in most cases is direct tumour involvement (i.e. metastatic bone disease, nerve compression), while other cases are due to medical therapy (e.g. postoperative, pain, radiation-induced pain). The remaining cases are individuals with pain problems unrelated to their cancer. The most difficult case is chronic pain associated with disease progression where combinations of anti-tumour therapy, anaesthetic blocks and behavioural approaches to pain control are considered. Behavioural research has focused on educational and assessment strategies and on pain reduction interventions, particularly hypnosis (for a review see Keefe *et al.*, 2005). When palliative therapy is of little use and/or brings further debilitation, psychological interventions may provide pain control and, secondarily, prevent or treat pain sequelae, such as sleep disturbances, reduced appetite, irritability and other behavioural difficulties.

Conclusion

Significant progress has been made in understanding the psychological and behavioural aspects of cancer. More is known about the psychological processes and reactions to the diagnosis and treatment of cancer than is known about any other chronic illness. Although most is known about the adjustment of breast cancer patients, other disease sites, men and children are becoming

more commonly studied, but need further attention. Future research is likely to test the generalizability of these descriptive data and formulate general principles of adjustment to illness. While providing estimates of the magnitude of quality of life problems, these data can be used for models which predict which patients might be at greatest risk for adjustment difficulties (see Andersen (1994, 2002) for discussions). The latter is an important step towards designing interventions tailored to the difficulties and circumstances of cancer patients.

Literature on the use of psychological interventions to improve cancer patient's quality of life is growing (Andersen, 2002). The effectiveness of these interventions is robust, as they have reduced distress and enhanced the quality of life of many cancer patients. Despite the challenges of studying these patients, well-controlled investigations have been conducted and improvements in emotional distress have been found. In addition, change in other areas (e.g. self-esteem) have been found. Important for quality of life, psychological interventions can also lower or stabilize pain reports, which is particularly important in terminal patients considering their worsening pain and/or increasing debilitation.

Intervention components may be unique for different phases in the disease, but there are some commonalities. Therapy components have included: an emotionally supportive context to address fears and anxieties about the disease; information about the disease and treatment; behavioural coping strategies; cognitive coping strategies; and relaxation training to lower 'arousal' and/or enhance one's sense of control. There also appears to be a need for focused interventions for sexual functioning, particularly those

treated for gynaecological, breast and prostate cancer, and previous intervention studies attest to the effectiveness of this specific component. It is important to understand how psychological interventions achieve these effects. In large measure, the psychological mechanisms may not be different from those operative from interventions designed for coping with other stressors. That is, confronting a traumatic stressor with positive cognitive states, active behavioural strategies and, eventually, lowered emotional distress may enhance one's sense of self-efficacy and one's feelings of control and provide realistic appraisals of stresses of the disease or treatment process. Similarly, for sexual interventions, information provides realistic expectations for sexuality and specific strategies to manage sexual activity when it is difficult or impossible.

Data suggests that the interventions produce more than situational improvement and may alter an individual's longer-term adjustment processes indicating that adjustment gains continue (and often increase) during the first post-treatment year. Immediate and longer-term psychological changes may, in turn, increase the likelihood of changes in behavioural mechanisms, such as increasing the likelihood of adaptive health behaviours (e.g. complying with medical therapy, improving diet exercise, etc.), to directly improve mental health, 'adjustment' and, possibly, medical outcomes. These data indicate that increasingly, issues of quality of life are being raised, and positive results have been achieved by behavioural sciences. However, as with most issues, further commitment and action is needed.

Cancer: gynaecologic

Kristen M. Carpenter and Barbara L. Andersen

The Ohio State University

Overview

Gynaecologic cancer cases account for approximately 12% of all new cancers in women; 49% of these involve the endometrium or uterus, 31% the ovary, 13% the cervix and 7% the vulva, vagina or other genital organs (Jemal *et al.*, 2004). Advances in screening techniques, (e.g. Pap smear for cervical cancer), and therapies have led to improved survival. Since the 1970s, death rates for gynaecologic cancers have significantly declined: currently a reduction of 49% for cervical cancer, 42% for endometrial, 27% for vaginal and vulvar and 11% for ovarian. See Table 1 for additional information by disease site. For the majority, gynaecologic cancer has become a survivable disease (Ries *et al.*, 2000). Thus, more women will survive and, necessarily, will be coping with the psychosocial morbidity associated with the disease and treatment.

Psychological reactions to diagnosis

The emotional reactions to gynaecologic cancer diagnosis are severe. In a review of studies using psychiatric (DSM-IV) criteria, Thompson and Shear (1998) reported that as many as 23% of patients might have major depressive disorder, an estimate four to five times higher than that for the general population (Spiegel, 1996). Anxiety symptoms are prevalent as well, particularly in women with poor physical functioning (Bodurka-Bevers *et al.*, 2000). In a sample of ovarian cancer patients ($n = 151$), a substantial portion of patients reported moderate to severe worry (55%), nervousness (40%) and irritability (34%) (Kornblith *et al.*, 1995). Psychological variables might also contribute; individuals who perceive their illness as severe tend to have greater mood disturbance (Marks *et al.*, 1986).

Physical & psychological sequelae of treatment

Gynaecologic cancer treatments have significant physiologic morbidities that affect both sexual and psychological adjustment.

Hysterectomies, which are common treatments, result in vaginal shortening and dyspareunia (see 'Hysterectomy'). Extensive surgery damages pelvic nerves, threatening genital sensitivity and bladder control (Wilmoth & Botchway, 1999). In women over 40 and women with ovarian cancer, oophorectomy (removal of the ovaries) is also indicated. The resulting decrease in circulating sex steroid hormones can reduce sexual desire, vaginal elasticity and lubrication. Other surgical procedures include vulvectomy for vulvar cancer and pelvic exenteration for extensive disease at diagnosis or recurrence in the pelvis. Significant changes result in pelvic anesthesia, chronic difficulty with excretory functions, and severe body image disruption (Andersen & Hacker, 1983).

Radiotherapy is commonly used in regional or advanced cases (see 'Radiotherapy'). Acute morbidities include fatigue, diarrhoea, pelvic cramping, bleeding and painful urination. Long-term sequelae include fibrosis of the blood vessels, limited vaginal lubrication and reductions in vaginal elasticity. Other long-term effects include persistent bowel and bladder dysfunction, vaginal stenosis and vaginal shortening (Wilmoth & Botchway, 1999). Chemotherapy is often used adjuvant to surgery and/or radiation and is commonly accompanied by nausea and vomiting, fatigue, pain, hair loss and cognitive deficits, all of which impact short-term quality of life (see 'Chemotherapy'). Because oestrogen is implicated in gynaecologic cancers, anti-oestrogen agents are often utilized. The ovarian failure that results from chemotherapy and/or radiation leads to infertility, decreased sexual desire and lubrication and vaginal pain (Wilmoth & Botchway, 1999). This loss of reproductive capacity poses a particular concern for younger women who have not yet begun or completed childbearing (see 'Infertility').

Survivorship

The adverse effects of disease and treatment constitute a significant physical and emotional adjustment. Women with advanced and persistent disease tend to have the poorest adjustment (Lutgendorf *et al.*, 2002), possibly due to compromised physical functioning and poor prognosis (Guidozzi, 1993). Site-based

Table 1. Sociodemographic, prognostic, disease and treatment information for gynaecologic cancer

Site	Estimated new cases (U.S., 2004) ^a	Median age at diagnosis (1996–2000) ^b	5-year survival rate (1996–2000) ^b	Risk factors ^c	Presenting symptoms by extent of disease ^d	Common treatments ^e
Cervix	10 520	47	71%	Low socioeconomic status; multiple sexual partners; intercourse before age 20; several pregnancies; HPV; smoking	Localized: vaginal bleeding; excessive or purulent vaginal discharge; bladder or rectal fistulae Advanced: pelvic pain; urinary frequency; hematuria	Stage IB-IIA: radical hysterectomy with lymph node dissection; adjuvant radiotherapy for parametrial invasion, large/grade 3 lesions, nodal metastases Stage IIB-IV: hysterectomy with adjuvant radiotherapy; chemotherapy for distant metastases Locally advanced or recurrent disease: neoadjuvant chemotherapy with radical hysterectomy or pelvic exenteration
Endometrium	40 320	65	85%	Postmenopausal status; obesity; diabetes; hypertension; nulliparity; chronic anovulation; irregular menses; exogenous oestrogen consumption; pelvic irradiation; unopposed ERT; late menopause	Localized: irregular vaginal bleeding; pelvic pain; purulent vaginal discharge Advanced: ascites; pelvic/abdominal mass; bowel symptoms	Standard treatment: total abdominal hysterectomy with bilateral salpingo-oophorectomy; adjuvant radiotherapy recommended for high-grade lesions, myometrial involvement, or limited nodal involvement; adjuvant chemotherapy recommended with lymphadenopathy Advanced disease managed with combination of surgery, radiotherapy, chemotherapy and hormonal therapy
Ovary	25 580	59	53%	Family history of ovarian, breast, endometrial, or colon cancer; nulliparity; older age at first marriage or childbirth	Localized: abdominal pain, bloating, or swelling; dyspepsia; pelvic pressure; ascites; pelvic mass Advanced: anorexia; weight loss; nausea; vomiting; severe pelvic pain	Standard treatment: total abdominal hysterectomy with bilateral salpingo-oophorectomy and omentectomy; cytoreductive surgery, colectomy and bowel resection as indicated; adjuvant therapy Stage I: adjuvant radiotherapy, but not chemotherapy Advanced or recurrent disease: combination adjuvant or neoadjuvant chemotherapy; hormonal therapy
Vulva	3970	68	76%	Low socioeconomic status; multiple sexual partners; regular coffee consumption; vaginal dystrophy; leukoplakia; vulvar or vaginal inflammatory disease; HPV; cervical cancer	Localized: vulvar lesion, nodules, or masses; chronic pruritis; vulvar pain, burning, bleeding, or discharge; dysuria Advanced: large masses on the labia, urethra, vagina and/or rectum	Standard treatment: radical vulvectomy, bilateral groin lymphadenectomy; preoperative radiotherapy to debulk tumor and conserve vulvar tissue; adjuvant radiotherapy recommended for local nodal involvement Distant metastases: combination chemotherapy Advanced disease: pelvic exenteration

Notes: ^aJemal *et al.*, 2004; ^bReis *et al.*, 2000; ^cGusberg & Runowicz, 1991; ^dAverette & Nguyen, 1995.

comparisons indicate that women with cervical cancer are at increased risk for maladjustment, particularly early in treatment, possibly because they are younger than other patients at diagnosis (Griemel *et al.*, 2002). While subjective distress diminishes in the months following diagnosis, overall quality of life might be compromised. Further, specific cognitive (e.g. ability to concentrate) and social support deficits may continue long after treatment has ended (Klee *et al.*, 2000).

Results from studies of sexual functioning, most of which sample cervical patients, reveal chronic difficulties for patients. Studies comparing treatments are equivocal. Results from the only randomized treatment study to be conducted in this population indicate that surgery and radiation result in comparable disruptions in sexual desire and frequency of intercourse (Vincent *et al.*, 1975), however a non-randomized comparison suggests that inhibited desire, post-coital pain and bleeding are more common among radiotherapy patients (Schover *et al.*, 1989). Studies comparing gynaecologic cancer patients to healthy controls/norms demonstrate that women with cancer resume intercourse, but are more likely to report diminished sexual responsiveness (Weijmar-Schultz *et al.*, 1991) or to be diagnosed with inhibited desire, dyspareunia or inhibited orgasm (Andersen *et al.*, 1989). Studies indicate that, despite the grim picture painted by descriptive studies, psychosocial interventions may have a positive impact (Robinson *et al.*, 1999).

There is little data on the aspects of physical health that might influence quality of life for gynaecologic cancer survivors, but the available data suggest three trends. Firstly, side effects of treatment are persistent (Carlsson *et al.*, 2000; Matthews *et al.*, 1999). In fact, some patients rate the physical sequelae of treatment as the most significant challenge of survivorship (Wenzel *et al.*, 2002). Secondly, comparisons between normative samples and gynaecologic cancer survivors indicate few group differences in mood and quality of life. Still, a portion of patients, ranging from 20% to 63% across studies, have poor quality of life and persistent psychological maladjustment (Matthews *et al.*, 1999). Thirdly, there appears to be a relationship between physical impairment and psychological maladjustment, particularly for adjuvant therapy patients (Carlsson *et al.*, 2000). Ovarian patients might be at greater risk for difficulty, due in part to aggressive treatment regimens (Miller *et al.*, 2002). Thus, the primary difficulties in gynaecologic cancer survivorship include physical impairments and psychological outcomes, however physical health might pose a greater challenge. In addition, other data suggest that gynaecologic cancer patients are at higher risk for psychological maladjustment than other cancer survivors. Parker *et al.* (2003) interviewed breast, gastrointestinal, gynaecologic and urologic cancer survivors ($n=351$) and assessed depressive symptoms, anxiety symptoms and psychological wellbeing. Depressive and anxiety symptoms were elevated for all survivors, but gynaecologic survivors reported significantly higher anxiety scores than all other patients, and higher depression scores and lower wellbeing scores than gastrointestinal and urologic survivors.

Psychosocial interventions

Psychosocial interventions can reduce distress, hasten resumption of routine activities and improve psychological and sexual outcomes. While a substantial literature examines the benefits of

interventions in breast and other cancer patients (see Andersen, 2002), to date only six studies have examined the potential of psychosocial interventions in gynaecologic cancer samples.

Houts and colleagues (1986) used a peer counselling intervention for newly diagnosed patients ($n=32$). Women were randomized to intervention ($n=14$) or information-only ($n=18$). All participants received a booklet containing information about effective coping strategies. Peer counselling was also delivered to intervention participants via telephone contacts with former cancer patients. Analyses indicated no between-group differences in emotional outcomes. Capone *et al.* (1980) provided brief, in-hospital counselling to newly diagnosed patients ($n=56$). A non-equivalent control group included previously treated women. Analyses indicated no between-group differences in emotional distress; however intervention participants reported less confusion and self-image disruption and returned to work sooner.

Therapist-led interventions appear to be more effective. For instance, McQuellon *et al.* (1998) developed a brief clinic orientation to reduce anxiety, distress and uncertainty in newly diagnosed patients ($n=150$). Participants were randomized into treatment and assessment-only groups. The programme lasted only 15–20 minutes and included a clinic tour, description of administrative procedures, provision of clinic information and a question-and-answer session. At follow-up, anxiety and mood disturbance decreased significantly for intervention subjects, whereas distress increased for assessment-only controls. Cain and colleagues (1986) compared individual and group intervention formats in a sample of 72 newly diagnosed patients ($n=21$ individual, $n=22$ group, $n=29$ no-treatment controls). Both eight-session interventions included discussion of cancer aetiology, cancer treatment, body image, sexuality, relaxation and coping. Both formats were superior to the control group in reducing depression and anxiety, improving psychosocial adjustment and enhancing sexual functioning.

Three additional studies have addressed sexual outcomes. Capone *et al.* (1980) included a sexual therapy component, in which information about coping with and reducing sexual anxiety was provided. Intervention participants were twice as likely as controls to resume sexual activity within one year (84% vs. 43%). Robinson *et al.* (1999) evaluated a psychoeducational group for early-stage cervical and endometrial patients receiving radiotherapy ($n=32$; $n=15$ intervention, $n=18$ controls). Use of vaginal dilators, which break fibrous adhesions as they develop, is recommended. The control condition included a brief counselling session in which subjects received a booklet on sexuality and cancer. The intervention comprised two 90-minute group sessions which included information about sexuality, discussion of sexual motivation and instruction on use of dilators, lubricants and Kegel exercises. Intervention participants had significantly less fear about sex after treatment and were significantly more likely to follow dilation recommendations. This was particularly true for younger women (<42 years), with intervention participants seven times more likely to comply with recommendations than controls. Caldwell *et al.* (2003) delivered a group intervention to 21 women (this study did not include a control group). Groups of three to five women attended weekly, 90-minute sessions for three months. Sessions focused on body image, sexuality, communication, infertility and other residual effects of adjuvant therapy. Results indicated improvement in sexual functioning following the intervention, with increased frequency of

intercourse and enhanced pleasure and arousal sustained for up to three months ($p < 0.10$).

Summary

Significant physical, psychological and sexual morbidity occurs immediately following diagnosis and treatment. Broad-based

psychosocial interventions appear to produce modest gains in psychological outcomes, and sexual functioning can be significantly enhanced with brief, cost-effective individual or group therapy. Additional research is needed to understand the experience of gynaecologic cancer patients and test quality of life enhancing interventions to help them recover and transition to survivorship.

Cancer: head and neck

Gerry M. Humphris

University of St Andrews

Head and neck cancer is the sixth most common cancer worldwide and is ranked third in the developed world (Parkin *et al.*, 1999). The large majority (90%) of these cancers are of a similar type known as squamous cell carcinomas. They comprise 4% of all cancers in the United States and 5% in the United Kingdom. Central and eastern Europe currently show greater than double the incidence rates of either the UK or USA. An incidence of 10.2 lip, mouth and pharyngeal cancers per 100 000 population in the UK in 1996 was reported (2940 new cases) (Quin, 2001). Men contract the disease more than women in the ratio of approximately 3 to 1. About 50% will die of the disease.

Prognosis of small oral cancer lesions is better than large lesions. For instance, the median survival time of a patient with a lesion greater than 4 cm in diameter is 4 years less than a patient with a smaller lesion after controlling for age (Platz *et al.*, 1986). The overall health of head and neck cancer patients tends to be worse than that of the general public (Funk *et al.*, 1997). Recurrence rates for head and neck cancer are comparatively high and result in death for about 20% of patients. Approximately 40% have a relapse with further malignancy following initial treatment. Survival rates for head and neck cancer have hardly improved over the past 30 years (La Vecchia *et al.*, 1997) although they are dependent on severity. Early diagnosis improves survival significantly.

Treatment consists of surgery, radiotherapy or chemotherapy, either singly or in combination. Many head and neck (H&N) cancer patients are treated with high-dose radiotherapy (see 'Radiotherapy'). Associated sensitive tissues such as mucous membranes, nerves and circulatory structures are also irradiated. The increase of treatment intensity has produced significant improvements to outcome but raises side effects. Delay (greater than 6 weeks) in starting radiotherapy following surgery has been shown to be detrimental to 5-year local recurrence rate in head and neck cancer patients (Huang *et al.*, 2003).

Public health issues

The public are poorly informed about oral cancer. Some attempts have been made recently to improve public awareness especially for signs and symptoms (Cruz *et al.*, 2002) and to encourage recognition of the disease, highlight risk factors and encourage earlier seeking for advice and assessment of suspicious lesions (Conway *et al.*, 2002). There is some evidence that these interventions have stronger effects with people at higher risk, for example smokers (Humphris & Field, 2004). The benefits of these preventive approaches are indicated as early identification improves survival markedly.

The major risk factors for head and neck cancer include tobacco and alcohol use (see 'Tobacco use' and 'Alcohol abuse'). These substances continue to harm patients following treatment of the disease. About 30–40% of treated head and neck cancer patients continue to smoke following initial treatment (Allison, 2001). Those who continue to smoke after diagnosis of head and neck cancer show four times the recurrence rate compared to a control group (Stevens *et al.*, 1983) and treatment is less successful (Browman *et al.*, 1993). Alcoholism prior to diagnosis of a first head and neck cancer is correlated to increased mortality five years post-diagnosis (Deleyiannis *et al.*, 1996). The patients who drink heavily and smoke suffer an increased risk as 'tobacco synergizes with alcohol' (Johnson, 2001). This risk is 'super-multiplicative' for the mouth. Other risk factors that have been implicated including diet, oral hygiene and the human papilloma virus.

Psychological morbidity

Psychological distress (30% 'cases') has been found in long-term survivors (>6 years) (Bjordal & Kaasa, 1995). The impact of diagnosis and treatment has been a focus for longitudinal study. A high

incidence of anxiety (35%) soon after diagnosis and peak levels of depression (30%) about 3 months following initial treatment have been reported in Scandinavia (Hammerlid *et al.*, 1999). One year following diagnosis both anxiety and depression returned to near pre-diagnosis levels. Comparable rates at 3 months following treatment adopting the same measures in the UK have been found (anxiety: 37%, depression: 28%) (Humphris, 2001).

Characteristics and course of treatment can have some influence on the patients' responses, however psychosocial variables have been clearly implicated in the development of anxiety and depression in this group.

Quality of life (QoL)

In the head and neck and oral cancer field there has been a rapid increase in the number of studies investigating patients' quality of life with eight specific measures developed (Ringash & Bezjak, 2001). For a recent description of the studies from 1980 up to 1998 see Rogers (Rogers *et al.*, 1999).

A 3-year longitudinal study in Sweden on the quality of life of 232 head and neck cancer patients from diagnosis used the EORTC QLQ-C30, which assesses core aspects and the EORTC QLQ H&N35 a specific module for head and neck cancer (Hammerlid *et al.*, 2001). After 3 years two-thirds (66%) of the patients were still alive. Their health-related quality of life was reduced to its lowest point immediately after treatment. However, virtually all of the sub-scales returned to pre-treatment levels after 12 months. Dry mouth, sexual responsiveness and dentition were significant problems that tended not to improve with time. There were very few changes occurring between the 1- and 3-year assessments. Mental distress made the strongest improvement after 3 years, whereas global quality of life increased as the next most significant change. Patients with advanced disease scored poorly on virtually all QoL measures. Other longitudinal studies assessing QoL, adopting standardized instruments, have reported a similar rise of QoL, on virtually all domains to pre-treatment levels after one year post-treatment (Rogers *et al.*, 1998).

The extensive work of de Graeff and de Leeuw with longitudinal assessment of quality of life and depression in head and neck cancer patients at the University Medical Centre of Utrecht, has shed light on the prediction of HRQoL. Raised depressive symptoms at pre-treatment predicted similar difficulties and difficulties in physical functioning at 6 and 12 months later (de Graeff *et al.*, 2000). The authors recommend the routine screening of psychosocial variables and physical symptoms before treatment may help to identify patients who may be susceptible to depression on recovery from surgery and/or radiotherapy for head and neck cancer (de Leeuw *et al.*, 2000a).

Recurrence fears

One study has reported the relationship of concerns with psychological disorder in 50 consecutive head and neck cancer patients in India (Chaturvedi *et al.*, 1996). These patients showed a significant relationship between the number of concerns and a screening measure for psychiatric 'caseness'. However, these investigators did not focus on recurrence fears specifically. One such study that has

concentrated on patient recurrence fears was a cross-sectional survey of 100 patients with orofacial cancer. It found a high incidence of recurrence fears which were unrelated to the extent of the disease or when the diagnosis was made (Humphris *et al.*, 2003). Fifty patients were revisited successfully 2 years later, and these fears were found to be relatively stable ($r_s=0.67$) (Lee-Jones, 1998). The point prevalence of concerns about the cancer returning was 65% in both the baseline and two-year follow-up samples. This is consistent with other reports of long-term survivors of head and neck cancer (Campbell *et al.*, 2000).

Patient reaction to recurrence

There are few research studies investigating the psychological reactions to recurrent cancer, and virtually none specific to head and neck cancer. An early report concludes that patients with a recurrence respond according to their reaction to their initial cancer diagnosis. (Schmale, 1976) For many patients their experience of a recurrence is a renewed sense of uncertainty for the future, grief and feelings of injustice (Chekryn, 1984).

Appearance

There is considerable variation in the concerns that patients express about appearance changes. An early study of 152 head and neck cancer patients showed that 82% had adapted to their disfigurement (West, 1977). Other investigators have alerted clinicians to unspoken distress at scarring and disfigurement resulting directly from surgery or radiotherapy. A Canadian study of 82 head and neck cancer patients showed a strong association between the level of disfigurement and depression (Katz *et al.*, 2003). Social support was shown to act as a buffer to women of their disfigurement (see 'Facial disfigurement and dysmorphology').

As previously mentioned, head and neck cancer patients express a variety of concerns which include recurrence fears and appearance. Many of these concerns are unresolved and coping strategies that tend to be employed include, avoidance, distraction and the use of alcohol (Chaturvedi *et al.*, 1996).

Social support

A statistically sophisticated study by the Utrecht group contributes some valuable findings in an under-researched area within the head and neck cancer specialty (de Leeuw *et al.*, 2000b). They studied 197 patients pre-treatment and followed them up 6 months later. Two competing models were tested, namely social support influenced depression or visa versa. Results were clear, as they showed that available support led to less depressive symptomology (see also 'Social support and health').

Psychological interventions

There have been a number of calls for introducing greater emotional support for head and neck cancer patients (Chaturvedi *et al.*, 1996). A psychosocial support programme was evaluated with head and neck cancer patients ($n=144$) using a longitudinal, prospective,

case-control study (Petrucci *et al.*, 2003). The support programme consisted of visits from the cancer team, including a weekly visit during treatment and then once a month for the first 6 months following treatment, and then again 1 and 3 years after diagnosis. Of the 81 patients offered the support, 15 did not want to participate, 11 did not attend the first visit and three died, leaving 52 patients in the study group. The control group consisted of 232 patients of whom 92 were matched to the study group on tumour location, stage, gender and age. The dependent variables were assessed by the EORTC QoL measures at diagnosis, and at 3, 12 and 36 months after the start of treatment. At one-year follow-up the control group had a clinically and statistically better global quality of life score but this difference was not sustained at 3 years. One possible explanation for the lack of improvement in QoL was explained by the authors as a design problem as randomization was not possible (see also 'Social support interventions'). The authors stressed the need for improved training for hospital personnel to recognize patients with affective disorders.

A psychological intervention designed specifically for head and neck cancer patients, to identify and reduce patients' fears of recurrence following primary treatment has been reported (Humphris, 2001). The intervention consisted of 6 structured sessions featuring the encouragement of the patient to express their concerns over future disease and what prompted them (e.g. symptoms) to seek reassurance from self-checking or professional review.

The intervention demonstrated a short-term effect that reduced worries about cancer, anxious preoccupation and increased global quality of life. Some patients who participated in the intervention stated that they would have preferred to have the intervention sooner following their initial treatment (surgery or surgery and radiotherapy).

A recent feasibility study conducted in Montreal using the NuCare coping strategies programme demonstrated that global QoL and social and physical functioning improved immediately following the intervention phase. Although not a randomized controlled study some promising results were reported (Allison *et al.*, 2004).

Conclusion

The psychological care of the patient with head and neck cancer is a neglected research area and moreover is traditionally a less developed service compared to more common cancers. However, clear features of the disease and its treatment indicate the need to study and intervene with this patient group. Due to the natural progression of the disease and the likelihood of recurrence, healthcare personnel are encouraged to identify the key concerns expressed by patients and their carers.

Cancer: Hodgkin's and non-Hodgkin's lymphoma

Jennifer Devlen

Dickinson College

The lymphomas are a heterogeneous group of neoplastic disorders of the lymphatic system of which there are two main types; Hodgkin's lymphoma (HL) and non-Hodgkin's lymphoma (NHL). Hodgkin's lymphoma was formerly called Hodgkin's disease after Thomas Hodgkin who first described it in 1832. It is rare, representing less than 1% of newly diagnosed cancers, with bimodal peaks in early adulthood and the elderly, and occurring slightly more frequently in males than females. The incidence of non-Hodgkin's lymphoma has been increasing steadily for the past 20 years for reasons that are as yet unclear (Evans & Hancock, 2003) and it currently accounts for approximately 4% of newly diagnosed cancers (Webster & Cella, 1998) in North America and western Europe where it is more common than in other regions of the world. Prevalence of NHL increases with age and there is a higher incidence in males (Evans & Hancock, 2003).

Treatment

Initial treatment of lymphoma generally involves chemotherapy often combined with involved-field radiotherapy. Courses of

chemotherapy are spread out over several months, while radiotherapy is usually given five days a week for several weeks (see 'Chemotherapy' and 'Radiotherapy'). Most HL patients can be cured (overall survival rate greater than 80% at 10 years, and better survival rates for early stage HL) (Yung & Linch, 2003). Cure rates for NHL vary from approximately 50% to 90% depending on type and stage (Sweetenham, 2003). Overall, the prognosis for the lymphomas has improved significantly over the past three decades so one might reasonably expect that psychosocial morbidity in this group might be less than that in other forms of cancer that have a poorer prognosis or whose treatment entails the loss of a body part or function.

Psychological morbidity

At some time during the discovery of their disease or its treatment as many as two-thirds of patients are likely to be anxious, depressed or both (Devlen *et al.*, 1987a; Nerenz *et al.*, 1982). The onset of disease and referral to a cancer specialist is the period associated with the

highest levels of emotional distress. Using standardized psychiatric interview schedules, Lloyd *et al.* (1984) identified 37.5% and Devlen *et al.* (1987a) found 36% of patients to be suffering clinically significant anxiety and/or depression during this time, rates consistent with cases of psychological distress obtained using the Brief Symptom Inventory (Zabora *et al.*, 2001), and similar to those found in patients with poorer prognosis diseases such as lung or pancreatic cancers (Zabora *et al.*, 2001). However, open and direct consultation with clinicians, a diagnosis and prognosis which may not be as terrible as they had feared, coupled with the commencement of treatment appears to resolve a great deal of the distress, and over one-third of those who were anxious or depressed during this time improved significantly once they started on chemotherapy or radiotherapy (Devlen *et al.*, 1987a).

At any point during treatment, the overall level of psychological morbidity is never as high as during the period surrounding diagnosis of the disease. However, morbidity persists in some patients, while others are at risk of developing a depressive disorder or anxiety state. A prospective study conducted by Devlen and colleagues (1987a) followed 120 newly diagnosed lymphoma patients over the first year, with in-depth interviews at diagnosis, then follow-up interviews at 2 months, 6 months and 12 months later. This allowed more detailed examination of the month-by-month prevalence, time of onset and duration of affective disorders. In total, 51% had clinical levels of psychiatric morbidity at some time during treatment with monthly levels of depression ranging from 8.3–15% for depression 5–12.5% for anxiety (Devlen, 1996). While the majority of this morbidity was found to occur in the first three months of treatment, new episodes, of depression especially, developed at any time up to one year after diagnosis.

Complications during treatment

Side effects of both chemotherapy and radiotherapy are very common in HL and NHL patients. Although the exact effects depend on the chemotherapeutic agents given, Devlen *et al.* (1987a) reported that 77.5% suffered nausea and 72% experienced vomiting, rates that are comparable to those recorded in other more recent samples of cancer patients receiving chemotherapy (Grunberg, 2004). In 27.5% of our sample, vomiting was severe, i.e. 6–10 episodes per day for 3 or more days post-treatment (Devlen *et al.*, 1987a). Nausea and vomiting are among the most troubling effects of treatment and can negatively impact patients' ability to function (Grunberg, 2004). There has been much speculation about the possibility of these effects prompting patients to withdraw from chemotherapy although there is little published data to indicate how much of a problem this really is. Up to 80% of patients may lose some or all of their hair (Devlen *et al.*, 1987a). Several patients who had wanted to keep their cancer private now had a publicly visible sign of their disease (Devlen, 1996). Less prevalent, but still significant complications of treatment include sore mouth, changes in perception of taste, sore skin, loss of or increase in appetite, constipation, diarrhoea, pain and peripheral neuropathy (Devlen *et al.*, 1987a; Nerenz *et al.*, 1982).

Conditioned nausea and vomiting

Like other cancer patients, those being treated for lymphoma experience pre-chemotherapy or anticipatory nausea (7–47%) and vomiting (20–28%) (Cameron *et al.*, 2001; Devlen *et al.*, 1987a). This phenomenon is commonly thought to result from classical conditioning (see 'Behaviour therapy'). Reminders of chemotherapy, such as the sight, smell or thought of the hospital, treatment or even the chemotherapy nurse can elicit nausea or vomiting. Although diminishing with time, these symptoms, nausea more so than vomiting, are not readily extinguished and have been reported to persist in a minority of patients (9–41%) many years post-treatment (Cameron *et al.*, 2001; Devlen *et al.*, 1987b). Decreased libido and sexual dysfunction whilst on treatment are common, and even after completion of treatment the prevalence of sexual dysfunction remains high (Devlen *et al.*, 1987b; Jonker-Pool *et al.*, 2004).

Cognitive impairments

Impairments in concentration (Cella & Tross, 1986) and memory have also been recorded. Although objective memory assessments indicate performance within normal ranges, Devlen *et al.* (1987a) and by Ahles *et al.* (2002) found significant differences in test scores for patients who reported such problems when compared with those who claimed no impairment. Mood disorders might account for some of these cognitive difficulties (Cull *et al.*, 1996) but not all (Brezden *et al.*, 2000; Devlen *et al.*, 1987a) and further investigation is warranted.

Predictors of morbidity

Psychological morbidity does not seem to be related to disease type (HL versus NHL) or stage (Devlen *et al.*, 1987a). There are no consistent gender differences in psychological morbidity in this group. Webster and Cella (1998) observed that older patients tend to report better emotional wellbeing than younger patients with equivalent objective health status. Greater distress was noted in HL patients who received combined-modality treatment when compared with those who were treated with only radiation (Ganz *et al.*, 2003). This may reflect the different levels of toxicity associated with these treatments, given that psychological morbidity has been related to treatment toxicity. Side effects involving the gastrointestinal tract: nausea, vomiting, diarrhoea, loss of appetite, sore mouth and taste changes were most likely to be correlated with both anxiety and depression (Devlen *et al.*, 1987a,b). Patients often stress the importance of eating well to maintain the strength necessary to endure treatment and combat the disease, and side effects that hinder this may explain some of this association. Patients may also misattribute treatment effects as being indicative of the recurrence of their disease, especially with vague effects such as tiredness and pain (Nerenz *et al.*, 1982) or when they occur some time after completion of treatment, as may be the case or post-radiation lethargy.

Long-term effects for survivors

As more lymphoma patients survive and residual problems become more apparent, attention has been directed toward investigating the long-term effects of these diseases and their treatments. Noted medical complications include second malignancies (the most common being lung cancer and breast cancer mainly attributable to radiotherapy that included those anatomical areas, and myeloid leukemia from chemotherapy agents), cardiac disease, endocrine disorders (particularly hypothyroidism after radiation) and dental caries and other oral diseases subsequent to neck irradiation (Parsa-Parsi *et al.*, 1998; Wiedenmann *et al.*, 2002; Yung & Linch, 2003). Furthermore, chemotherapeutic agents and gonadal radiation in the treatment can affect fertility: azoospermia in men and precocious menopause in women (Anselmo *et al.*, 2001).

Numerous studies have reported fatigue as a significant long-term problem in this group. (Ganz *et al.*, 2003; Loge *et al.*, 1999; Wettergren *et al.*, 2003), and there is some suggestion that it might be more prevalent in lymphoma patients than in other cancer survivors (Oldervoll *et al.*, 2003). When compared with samples from the general population, HL survivors have reduced health-related quality of life, including impairments in social and role functioning (Loge *et al.*, 1999). Problems with employment and difficulties with insurance and loan applications have also been recorded (Devlen *et al.*, 1987b; Fletchner *et al.*, 1998). The two prospective studies that followed samples of lymphoma patients over time (Devlen *et al.*, 1987a; Ganz *et al.*, 2003) suggest that many of the symptoms and impairments evident at the time of diagnosis or during chemo- or radiotherapy tend to diminish quite quickly after completion of treatment. However, any impairments still evident one or two years later are not likely to show any further improvement (Ganz *et al.*, 2003; Greil *et al.*, 1999).

Conclusions and clinical implications

Treatments continue to improve cure rates in these diseases, and the ongoing goal is to reduce short- and long-term effects without compromising efficacy. In spite of an increasing body of literature on this patient group, many problems may go unrecognized in clinical practice. One study reports that oncology physicians and nurses may underestimate the incidence and impact of chemotherapy-induced nausea and vomiting (Grunberg, 2004). Anti-emetic regimens available for controlling nausea and vomiting will also help prevent anticipatory nausea/vomiting and the associated distress this causes. The publication of guidelines

regarding anti-emetic prophylaxis has increased their use somewhat, but Grunberg claims there is still room for improvement.

Regular breast screening has recently been recommended for women who received radiotherapy that included the breast area and screening for other common malignancies in this group might also be advised.

Getting sufficient rest and limiting activity may be helpful whilst on active treatment, but Oldervoll and colleagues (2003) suggest this may be counterproductive for the chronic fatigue that persists after treatment has finished. They report significant benefits in HL survivors who participated in a 20-week home-based exercise programme. Future studies of interventions for fatigue might help to address this important problem.

Surveys of patients indicate significant levels of dissatisfaction with information and support concerning sexuality from the healthcare team, recommending that physicians initiate discussion of this topic at diagnosis and follow-up (Jonker-Pool *et al.*, 2004). Prior to starting chemotherapy banking sperm, eggs or fertilized embryos might be options for patients (Anselmo *et al.*, 2001). The post-menopausal uterus may still permit implantation and development of an embryo and Anselmo *et al.* (2001) report the use of egg donation in achieving successful full-term pregnancies in women previously treated for HL providing hope for this group that includes young adults who may want to start or complete a family.

A recent comprehensive review provides stronger evidence of cognitive changes related to chemotherapy in other cancers (Minisini *et al.*, 2004). Future clinical trials and routine monitoring of cognitive function are needed to describe this phenomenon and the underlying mechanisms more clearly (Ahles, 2004).

On a more positive note, two-thirds of HL survivors interviewed by Wettergren *et al.* (2003) reported positive changes such as having become more mature, grateful and tolerant. In summary, advances in the treatment for lymphomas have meant that many will now be cured. Yet, despite this favourable prognosis considerable research indicates substantial physical, psychological and social problems, at least in the short term. The diagnosis of cancer, even one with an outcome that might ultimately be good, is still a time of considerable psychological distress and the ensuing aggressive treatments have significant impact on patient's functioning and wellbeing. There are some persistent problems, notably fatigue, but there is also evidence that many survivors adapt well in the long-term.

Cancer: leukaemia

Janelle L. Wagner and Ronald T. Brown

Medical University of South Carolina

Overview

The leukaemias are a group of cancers of the blood forming tissues that are typically characterized by the type of white blood cells that is affected (lymphoid or myeloid) and the progressive nature of the abnormal cells (acute versus chronic). There are four common types of leukaemia: (i) acute lymphocytic leukaemia (ALL); (ii) chronic lymphocytic leukaemia (CLL); (iii) acute myeloid leukaemia (AML); and (iv) chronic myeloid leukaemia (CML). Specifically, ALL is defined as an abnormal white blood cell count and differential, abnormal haematocrit/haemoglobin and platelet counts, abnormal

bone marrow with more than 5% blasts (immature cells), and signs and symptoms of the disease (<http://cancer.gov>). ALL and AML occur in both children and adults, although the chronic leukaemias (CLL, CML) affect primarily adults. Approximately 89% of leukaemia cases occur in adults over the age of 60 years (Lesko, 1998). The incidence of leukaemia in the United States is 10.9 per 100 000 individuals compared to 8.5 per 100 000 individuals in the United Kingdom (Parkin *et al.*, 1997).

The specific aetiology of leukaemia is unknown, although risk factors may consist of prenatal exposure to radiation and post-natal exposure to various toxins (see 'Toxins: environmental').

Treatments typically used in the management of specific neoplasms often place individuals at secondary risk for other malignancies including leukaemia. Down's syndrome and other genetic disorders, such as neurofibromatosis also pose significant risk factors for the development of leukaemia (NIH Publication number 02-3775 retrieved from <http://cancer.gov>).

Common presenting symptoms of leukaemia include fevers, frequent infections, fatigue, headaches, bleeding and bruising easily, joint and bone pain, abdominal swelling, lymphadenopathy and weight loss. These symptoms often are evaluated employing a series of diagnostic tests (e.g. blood tests, bone marrow aspiration or biopsy, spinal tap and/or chest X-ray). Once a diagnosis of leukaemia has been made, the standard treatment options typically include chemotherapy or radiation therapy or both, and transplantation, including bone marrow transplantation, particularly if there is a relapse.

Treatment for ALL is divided into induction, consolidation or intensification and maintenance therapy, with central nervous system (CNS) therapy provided at each stage, particularly if the individual has CNS involvement. Approximately 50–70% of children develop CNS leukaemia. For children with ALL, intensive therapy results in a favourable prognosis, though older children and adolescents (over the age of 10 years) often have a less favourable outcome (Pui & Evans, 1998). Treatment outcome for adults diagnosed with ALL is less favourable than for paediatric populations (Hoelzer *et al.*, 2002). Typically, remission rates for adults are inversely associated with chronological age with older individuals having a more favourable prognosis than their younger counterparts (Keating *et al.*, 1982). For individuals with leukaemia, frequently the adverse side effects associated with treatment cause the individual greater difficulties than the symptoms of the disease itself. Such adverse effects of chemotherapy include fatigue, alopecia, gastrointestinal distress, infertility, impairments in cognition (e.g. memory) and complications associated with the endocrine system (Hoelzer *et al.*, 2002) (see 'Chemotherapy').

Psychosocial adjustment

Given the wide range of stressors (e.g. physical, social and financial) that individuals with leukaemia encounter, it is not surprising that studies have demonstrated significant adjustment difficulties in these individuals. For example, Montgomery and colleagues (2003) reported distress and mild to moderate depression in over half of their sample of adults with AML, and poor illness-specific adjustment in over 25% of the sample. Significant distress was predicted by two cognitive variables, namely helplessness/hopelessness and a 'fighting spirit'. In another study, 35% of patients undergoing induction and consolidation phases of treatment for leukaemia reported elevated levels of anxiety and depressive symptoms (Andrykowski *et al.*, 1999). Thus, there is evidence to suggest that individuals with leukaemia have difficulty adjusting to their disease, treatment and associated adverse side effects. Unfortunately, in a significant number of cases, these high levels of anxiety and depressive symptoms may go undetected (Zittoun *et al.*, 1999), despite evidence that depression is in fact associated with lower survival rates in individuals with cancer (Spiegel, 1996). Notably, cancer-related depression is not substantially different from depression in

other medical conditions, although psychological treatments should include components that directly address issues specific to cancer patients (Patrick *et al.*, 2003) (see 'Cancer: general').

The physical and psychological impact of having a life threatening disease such as leukaemia, undergoing invasive medical procedures, and experiencing associated side effects such as nausea, pain and vomiting are recognized traumatic events (Stuber *et al.*, 1994). Studies have demonstrated symptoms of post-traumatic stress disorder (PTSD) in survivors of leukaemia and their families (e.g. Best *et al.*, 2001; Lesko *et al.*, 1992). The severity of PTSD symptoms, such as levels of intrusive thoughts and imagery, are also associated with psychological distress (Lesko *et al.*, 1992) (see also 'Post-traumatic stress disorder').

Demographic variables, including gender, age and socioeconomic status play a significant role in the above mentioned psychological symptoms often seen in individuals with leukaemia (i.e. Stark *et al.*, 2002). To illustrate, men diagnosed with leukaemia reported increased general psychiatric distress while women reported poor social adjustment (Lesko *et al.*, 1992). In another study, Greenberg and colleagues (1997) found that younger AML patients with less education were more likely to report increased psychological distress following treatment. Thus, men and women evidence different patterns of adjustment to leukaemia and younger, less educated patients are at increased risk for greater distress than are their older more educated counterparts.

Factors associated with adjustment

The literature has repeatedly demonstrated that medical, individual differences and social factors contribute to psychosocial adjustment in individuals with leukaemia (Holland, 1998). We now address specific psychosocial issues that are central to psychosocial adjustment in individuals with cancer and include quality of life, social support and coping skills.

Quality of life

Not surprisingly, given their invasiveness and adverse side effects, treatments for leukaemia have consistently been shown to affect health related quality of life (HRQL). According to Aaronson (1989), HRQL is comprised of four core domains: (i) disease state and physical symptoms; (ii) functional status; (iii) psychological and emotional functioning; and (iv) social functioning (Aaronson, 1989) (see 'Quality of life').

In a review of 21 studies assessing HRQL in individuals with AML, Redaelli and colleagues (2004) note consistent associations between both medical (physical symptoms, irradiation, illness duration) and demographic variables (education and gender) and quality of life. Studies have demonstrated decreased HRQL immediately following a diagnosis of the leukaemia and during the course of active therapies. However, long-term survivors of leukaemia report no significant differences in HRQL compared with their healthy peers, with the exception of sexual impairments that may include infertility, impotence and pain during intercourse.

HRQL is not stable across treatment phases, but may vary depending on the potency of prescribed treatments. For example, Schumacher and colleagues (2002) demonstrated improvements in

quality of life over the course of inpatient chemotherapy treatment, and Stalfelt (1994) found differences in HRQL on a weekly basis that varied according to treatment regimen. Zittoun *et al.* (1997) also observed that individuals who experienced allogenic (allo) bone marrow transplants (BMT) reported more severe impairment in HRQL than those who underwent autologous (auto) BMT. In turn, individuals who received auto BMT reported worse HLRQ than their peers who were treated with chemotherapy only.

Social support

Social support has been demonstrated to be a resilience factor for both anxiety and depressive symptoms, and lack of social support may increase the risk for psychosocial difficulties (see 'Social support and health'). For example, poor social support during cancer treatment was associated with greater anxiety (Stark *et al.*, 2002). Alternatively, perceptions of the availability of social support in individuals with cancer also have been associated with fewer depressive symptoms (e.g. De Leeuw *et al.*, 2000) and better adjustment (for a review see Spiegel, 1997). Thus, it seems that an individual's perception of available social supports is critical to adjustment. Many individuals with leukaemia do report poor marital relations that in part may be due to several stressors, including financial strain and sexual impairments (Wellisch *et al.*, 1996).

Sources of social support typically derive from family or friendships; however, research suggests that communication and support from physicians also is associated with adjustment in individuals with leukaemia. For example, individuals who report distress are more likely to express dissatisfaction with information received by their healthcare provider and to indicate the need for additional time to discuss diagnostic and treatment issues (Montgomery *et al.*, 2003). Furthermore, over 90% of patients reported a preference for discussion of emotional issues with their physician, although over a quarter of the sample were of the notion that the physician should initiate the discussion (Detam *et al.*, 2000). Thus, unless physicians facilitate conversation of emotional adjustment, patients are unlikely to disclose such important information. When communication is open between patients and physicians, patients report greater use of adaptive coping styles and perceived autonomy in decision-making (Dermatis & Lesko, 1991) (see 'Healthcare professional-patient communication').

Coping skills

There are individual differences in the ways in which individuals with leukaemia cope with their illness. The use of adaptive coping strategies has been shown to be associated with decreased levels of distress in patients with leukaemia (Montgomery *et al.*, 2003). Various coping strategies may be modified over time and often correspond to the phases of cancer treatment (Caudell, 1996). Holland and Goen-Piels (2000) have outlined three phases of 'normal responses' to cancer. Phase I is the initial response that may include disbelief, denial and shock. Phase II involves dysphoria, characterized by slow acknowledgment of the diagnosis, and significant distress, which may manifest as insomnia, anxiety, depression and recurrent thoughts of illness and death. Finally, Phase III is characterized by longer-term adaptation. This is the period in which individuals employ available resources and various coping strategies

(Holland & Goen-Piels, 2000). Thus, depending on the stage of care, certain coping skills may be indicated and should be encouraged by health professionals. When faced with the stressors of a life-threatening disease such as leukaemia and its potential implications, including death, patients often explore the meaning of life and/or their beliefs of an afterlife. It is not uncommon for many individuals to consult religion or spirituality as a context for understanding their disease and promoting coping skills, such as prayer or meditation (Larson & Milano, 1995) (see also 'Coping with chronic illness' and 'Coping with death and dying').

Behavioural interventions

Intrusive and painful medical procedures associated with the experience of leukaemia, coupled with symptoms of anxiety and depression, as well as conditioned responses to treatment, create numerous stressors for an individual. Furthermore, individuals with leukaemia are often immunosuppressed, and for this reason, it is critical that they learn how to diminish arousal and enhance coping skills for the purpose of alleviating the effects of stress on their already compromised immune system (Caudell, 1996).

Behavioural interventions have long been employed to reduce pain in individuals with cancer as well as those with other chronic illnesses, and have repeatedly demonstrated beneficial effects on adjustment. For example, techniques such as relaxation, imagery and distraction have been shown to be effective in reducing pain, anxiety and nausea for individuals undergoing cancer treatment (for a review see Mundy *et al.*, 2003). When choosing a behavioural strategy, the clinician should attend to potential experiences of pain and fatigue and compromised functional status and to those techniques that are indicated for particular phases of care. Specifically, emotional support, stress management and cognitive restructuring are appropriate interventions for targeting fears and anxieties frequently common at diagnosis, while relaxation and imagery have been demonstrated to be effective in reducing pain, fear of procedures and nausea associated with the specific cancer treatments, including chemotherapy (for a review see Caudell, 1996) (see 'Behaviour therapy' and 'Relaxation training').

Burish and colleagues have conducted a series of randomized controlled studies to examine the effectiveness of relaxation and guided imagery techniques in reducing anxiety and nausea associated with chemotherapy. Specifically, Burish *et al.* (1987) found that progressive muscle relaxation and guided imagery were more effective than no behavioural treatment in either delaying or preventing nausea and vomiting. In another study, Carey and Burish (1987) demonstrated for individuals with leukaemia that relaxation training from a professional therapist was superior to no relaxation instruction or a relaxation audiotape at reducing anxiety associated with chemotherapy. Finally, Burish *et al.* (1991) provided data for a sample comprised in part of patients diagnosed with leukaemia to support the superiority of a coping preparation programme (e.g. information about procedure, tour of facility, etc.) compared with a relaxation training programme. Relaxation training alone was minimally effective in reducing anticipatory nausea associated with chemotherapy. Thus, these studies provide evidence supporting the efficacy of relaxation techniques and adaptive coping skills,

when delivered by a trained therapist, in reducing distress related to leukaemia treatments.

Conclusions

In conclusion, the leukaemias are a group of blood cancers for which various invasive medical treatments with adverse side effects are indicated. Not surprisingly, studies have demonstrated symptoms of anxiety and depression in individuals with leukaemia. Factors such as quality of life, social support and coping skills are associated with psychosocial adjustment, and are often the target of behavioural interventions that have demonstrated efficacy in the reduction of anxiety and pain and promotion of healthy coping strategies for individuals with leukaemia. However, research with

adults has largely neglected examining post-traumatic stress symptoms, despite a growing body of research on this topic in the pediatric literature (for a summary see Vannatta & Gerhardt, 2003). Indeed, many individuals with leukaemia may experience these invasive medical procedures as traumatic. Future research should focus on a more in depth examination of PTSD symptoms in adults with leukaemia and the development of specific psychosocial interventions to target these symptoms. Finally, researchers and clinicians should diligently work towards dissemination of cognitive-behavioural interventions so they can more readily be available to patients and healthcare providers (see 'Cognitive behaviour therapy').

Cancer: lung

Angela Liegey Dougall

University of Pittsburgh

Overview

Lung cancer is the most common cancer and the leading cause of cancer death worldwide, claiming more than one million lives annually (Stewart and Kleihues, 2003). Because patients with lung cancer usually do not experience symptoms until the disease has advanced, most patients are diagnosed in later stages of the disease with poor prognoses.

The leading cause of lung cancer is exposure to tobacco smoke. Smoking causes approximately 90% of lung cancer deaths in men and 80% in women (USDHHS, 2004). Non-smokers who are exposed to secondhand tobacco smoke at home, work, or in social settings are also at an increased risk.

Other risk factors for lung cancer have been identified, some of which are synergistic with smoking. Exposure to environmental carcinogens such as asbestos, radon, workplace chemicals and air pollution as well as diets low in fruits and vegetables increase risk (Boffetta, 2004; Miller *et al.*, 2004). A personal history of lung diseases such as chronic obstructive pulmonary disease and tuberculosis, a previous diagnosis of lung cancer, or a family history of lung cancer may also increase susceptibility (Ardies, 2003; Economou *et al.*, 1994).

Research evidence

The majority of patients are diagnosed with lung cancer after they start experiencing symptoms and have advanced disease.

Physical symptoms include fatigue, difficulty in breathing, cough, pain, spitting blood and loss of appetite (Hollen *et al.*, 1999). The discomfort and distress associated with these symptoms are often high and several studies have reported that patients with lung cancer report more symptom distress than do patients with other cancers (Degner & Sloan, 1995). High levels of symptom distress have been found to predict decreased psychosocial functioning and shorter survival times (Degner & Sloan, 1995; Okuyama *et al.*, 2001).

Many patients with lung cancer report depressive symptomatology. One study found symptoms of depression in more than a third of the patients (Kramer, 1999). Depressive symptoms have been associated with poorer physical status, especially with difficulty in breathing and fatigue, as well as declines in social functioning and treatment status (Kurtz *et al.*, 2002; Okuyama *et al.*, 2001). Furthermore, use of depressive coping strategies, such as brooding and withdrawing from other people, have been found to predict shorter survival times (Faller & Schmidt, 2004).

The physical and psychosocial symptoms of lung cancer can interfere with daily functioning and quality of life (see 'Quality of life'). Reductions in quality of life have been associated with shorter survival times and with tumours that are less likely to respond to treatment (Montazeri *et al.*, 1998). Medical treatments for advanced lung cancer focus on controlling symptoms so that patients can maintain quality of life (Simmonds, 1999).

Clinical implications

Psychosocial interventions can complement traditional treatment for lung cancer by helping patients cope with symptoms, decrease distress and depression, and improve quality of life (McCorkle *et al.*, 1989). Families of patients with lung cancer also experience considerable distress (Haley *et al.*, 2001) and may benefit from psychosocial interventions that help them to cope with their loved one's disease, treatment and possible death.

Psychosocial interventions can also be used in prevention because many of the risk factors for lung cancer are behaviours that can be modified. Prevention efforts primarily focus on encouraging people not to start smoking and on smoking cessation because of the high risk associated with smoking and the reduction in risk attributed to smoking cessation (Peto *et al.*, 2000). Many efficacious and cost-effective smoking cessation programmes have been developed, but advances need to be made in the dissemination of these programmes as well as the achievement of long-term maintenance (Niaura & Abrams, 2002; see 'Tobacco use'). Other behavioural risk factors that could be targets of psychosocial interventions are dietary changes to increase consumption of fruits and vegetables and avoidance of situations that involve exposure to tobacco smoke.

Risk factors for lung cancer may be used to identify people who are at high risk for the disease. Spiral computed tomography (CT) scanning is being used in several screening trials to examine the feasibility and effectiveness of detecting lung cancer at earlier stages (Gohagan *et al.*, 2004). Long-term outcomes from these trials will help determine screening recommendations for people who are at high risk. Psychosocial interventions may help lessen the anxiety associated with screening and improve adherence to recommendations (see 'Screening: cancer').

Conclusions

Patients with lung cancer could benefit from psychosocial interventions that focus on maintaining quality of life and reducing distress. Psychosocial interventions could also be used to help people decrease their risk for lung cancer by modifying behaviours that put them at high risk such as smoking and poor diet.

Cancer: prostate

Stephen J. Lepore¹ and Katherine J. Roberts²

¹Temple University

²Columbia University

Prostate cancer is one of the most common solid tumour malignancies in developed countries (Pisani *et al.*, 2002) and a leading cause of cancer death in American and European men (Bray *et al.*, 2002; American Cancer Society, 2005). This chapter highlights the effects of prostate cancer on quality of life and reviews the behavioural and psychosocial interventions designed to educate men about prostate cancer, enhance decision-making, or improve quality of life.

Quality of life

Prostate cancer and its treatments result in disease-specific and more general problems in quality of life (Eton & Lepore, 2002) (see 'Quality of Life'). The most common disease-specific problems are urinary and sexual dysfunction. Within a year after treatment, urinary problems often subside, but sexual problems tend to persist (e.g. Lubeck *et al.*, 1999). In men with localized disease, general problems, such as difficulties in social-, emotional- and physical-functioning are reported considerably less often than genito-urinary problems, and may not occur at all in some men (e.g. Lubeck *et al.*, 1999; Bisson *et al.*, 2002; Lepore *et al.*, 2003). Men with progressive disease are more likely to report social-emotional difficulties, as well as chronic pain and fatigue (e.g. Albertsen *et al.*, 1997). It is not yet clear how pharmacological and surgical control of progressive prostate cancer influences general quality of life outcomes.

Interventions

Informed decision-making about testing

Prostate cancer is often indolent and frequently affects men with other life-threatening illnesses, so it is difficult to evaluate the effects of screening and treatments on prostate cancer outcomes. This creates uncertainty over how best to detect and manage prostate cancer. Behavioural scientists have responded by creating decision support interventions that aim to increase men's knowledge about different screening and treatment options, assist them in clarifying their values for different outcomes related to screening and treatment, and improve decision quality.

Early prostate cancer is typically asymptomatic, so screening tests such as the digital rectal exam (DRE) and the prostate specific antigen (PSA) blood test provide the best methods of detection. Currently, screening populations for prostate cancer is not recommended by the US Preventive Services Task Force (US Preventive Services Task Force, 2002), mainly because there is no solid evidence that screening enhances survival odds. There is, however,

general agreement in the medical community about the need to educate patients to make individualized, informed choices about prostate cancer screening (e.g. Smith *et al.*, 2001).

In recent years, a spate of randomized controlled trials (RCTs) have evaluated the effects of decision-support interventions on screening decisions (for review, see Briss *et al.*, 2004). In one comprehensive trial (Davison *et al.*, 2002), men were randomly assigned to receive verbal and written information about the pros and cons of prostate cancer screening either prior to a periodic health exam (intervention group) or subsequent to the health exam and a follow-up interview (control group). Relative to controls, men in the intervention group took a more active role in the screening decision and had lower decisional conflict. The authors also found that the intervention did not create anxiety in men or alter their low rates of screening (see also 'Screening: cancer').

Research on decision-support interventions suggests that even minimal contact (e.g. an educational pamphlet) can increase knowledge (e.g. Volk *et al.*, 1999; Schapira & VanRuiswyk, 2000; e.g. Frosch *et al.*, 2001, 2003; Partin *et al.*, 2004). Intensive interventions may be warranted, however, because the knowledge gains tend to be modest, even though they are statistically significant in minimal interventions. One study showed that a decision support intervention led to more realistic beliefs about the benefits of prostate cancer screening (Schapira & VanRuiswyk, 2000). Several controlled trials (Volk *et al.*, 1999; Frosch *et al.*, 2001; Partin, Nelson *et al.*, 2004) showed lower screening interest among men who viewed a videotape, *PSA decision: what you should know*. The contrast between the results of these latter trials using the video and those of Davison *et al.*'s trial using verbal and written information raises questions about the specific factors that influence men's decisions in these studies. Given the controversial nature of prostate cancer screening, two important goals of these interventions should be to ensure that: (a) men's decisions are informed (i.e. they know their risk for prostate cancer, as well as potential benefits and limitations of testing), and (b) men's behaviours are congruent with their values or preferences (i.e. there are no barriers to testing if they want to test or undue pressure to test if they do not want to test). Further, there is a need to examine the effect of decision-support interventions on men at high-risk for prostate cancer, including first-degree relatives and men of African descent.

Informed decision-making about treatment

Medical uncertainties related to patient prognosis and responsiveness to different treatments makes treatment decisions

very complex. In addition, there are no data from randomized trials that directly compare different types of treatment in men with similar stages of disease. Thus, it has been recommended that physicians use independent medical judgement when formulating treatment decisions and tailor the treatment to patients' values and preferences (Scherr *et al.*, 2003). In practice, therapeutic recommendations vary with the type of specialist a patient consults. In a United States nationwide random sample of urologists and radiation oncologists, most radiation oncologists (72%) believed that their therapy was just as good as radical prostatectomy for men with localized prostate cancer, whereas most urologists (93%) believed that radical prostatectomy was the treatment of choice (Fowler *et al.*, 2000).

Most men with prostate cancer are expected to and prefer to be involved in treatment decisions (Davison *et al.*, 2002). Their decision is influenced by many sources, including medical professionals, family and friends, and the media. The quality of the input from these different sources is highly variable. For example, in a review of 546 publicly available education materials on prostate cancer treatment, 502 did not describe all standard treatments and the rest did not provide sufficient information about side effects or other factors relevant to decision making (Fagerlin *et al.*, 2004). Physician input possibly has the greatest effect on patients' decisions but, here too, the quality of the input is not always adequate. Crawford *et al.* (1997) interviewed 1000 men with prostate cancer and 200 urologists and found that almost 100% of the urologists stated that they always discussed important considerations such as options for no therapy, life expectancy with and without therapy, patient preferences, costs and changes in sexual function, yet only about 20% of patients recalled similar discussions.

Quality of life interventions

Most psychosocial interventions for men with prostate cancer aim to improve quality of life by reducing symptoms, increasing knowledge, improving coping skills and creating supportive social ties. By increasing knowledge about the disease, interventions can help patients set realistic expectations about recovery and the causes of symptoms, and, perhaps, gain a sense of control over their thoughts, feelings and behaviours. Patients also can learn specific behaviours and coping skills for improving general health and functioning or dealing with stress and symptoms. Interventions that bring patients together in dyads or groups can facilitate the exchange of support and provide models of adaptive behaviour (see 'Support interventions').

There have been relatively few controlled, psychosocial interventions in men with prostate cancer. In one RCT, Lepore *et al.* (2003) compared quality of life outcomes in men recently treated for localized prostate cancer after they received either standard medical care or one of two types of multi-week, group education interventions – education alone or education plus facilitated peer discussion. Both intervention groups resulted in improved knowledge, physical functioning and health behaviours, but only the education-plus-discussion group resulted in more stable employment and reduction of sexual dysfunction. Both interventions tended to be more beneficial to persons with less formal education. In another study, Mishel *et al.* (2002) found that a

nurse-delivered, multi-week telephone intervention, consisting of education and cognitive restructuring, improved problem-solving skills, enhanced appraisals of illness and improved urinary control among men treated for localized prostate cancer. Much work remains to be done in this area, including identifying the best type of intervention for men at different stages of disease.

Conclusions

Despite its prevalence, potential lethality and well-documented negative effects on men's genito-urinary functioning, there has been relatively little behavioural research aimed at reducing men's risk for prostate cancer, enhancing decision-making related to screening and treatment, or improving quality of life. Our review of the current literature suggests some promising directions for behavioural intervention, clinical care and future research.

In terms of quality of life, many side effects of treatments tend to subside within a year among men treated for localized disease, with the possible exception of sexual dysfunction. The impact on quality of life of men with metastatic disease may be greater, particularly with respect to symptom control and mental health. Descriptive research on quality of life outcomes will need to be updated continually, because medical treatment protocols evolve rapidly and may affect quality of life in ways that are as yet unknown. For example, hormonal therapy is increasingly being used in men with localized prostate cancer, but the literature provides scant information on how this therapy might affect quality of life.

Much of the current behavioural research is focused on decision-making related to screening or treatment. Interventions related to screening are effective at improving knowledge, yet the effects on screening behaviours and patient-physician communication are ambiguous. It also is not clear what effect decision-support interventions might have on men at high-risk for prostate cancer, including first-degree relatives and men of African descent. Interventions related to treatment also appear to be effective at increasing knowledge, but it is not entirely clear how they affect the decision-making process. It appears that most men rely on their physician's opinion, which may be biased toward his or her specialty (e.g. surgery, radiation), and does not necessarily take into account patients' values and preferences. It is critical for behavioural scientists to develop innovative, effective and economical ways to enhance informed and shared decision making related to treatment choices (see 'Medical decision-making'). There are new approaches on the horizon, such as a CD-ROM-based programme that uses a metaphor of rooms in a virtual health centre to organize information (Diefenbach & Butz 2004), but they have yet to be rigorously evaluated.

There are few high quality studies on the effectiveness of behavioural interventions aimed at quality of life. Early evidence suggests that these interventions can improve men's knowledge, coping skills and functional wellbeing. More work is needed to document the relative costs and benefits of different interventions, to respond to the needs of men with advanced disease and to address the potential needs of caregivers. Future research also should consider how to develop interventions that can be tailored to the unique needs of different individuals or groups. Intelligent computer-based systems may be a useful approach for men who will not attend groups or

who want more information than they can feasibly get from a health educator or nurse during a brief telephone contact.

Finally, it should be noted that morbidity, mortality and quality of life endpoints are not equally distributed across social groups (American Cancer Society, 2005). Men of African descent, in particular, have an excess burden of morbidity and mortality due to prostate cancer. Less educated, poorer and minority men also suffer greater declines in their quality of life and take longer to recover from treatments (Lepore *et al.*, 2003; Litwin *et al.*, 1999). Poverty,

lower educational achievement and minority status tend to be associated with less knowledge about prostate cancer (Smith *et al.*, 1997; Lepore *et al.*, 2003), suggesting that education interventions should be especially fruitful with this population. However, we do not know whether the currently available approaches to educating men about prostate cancer or facilitating decision-making will be effective with poorer and minority men.

Cancer: skin

Ron Borland and Suzanne Dobbison

Victoria Health Centre for Tobacco Control

Epidemiology of skin cancer

Skin cancers can be broadly classified into two types, melanomas and non-melanomas. Melanomas are cancer of the melanocytes, which lie in the basal layer of the epidermis. Melanomas, unless detected at an early stage have a high fatality rate. Non-melanocytic skin cancers include two major types, basal cell carcinomas and squamous cell carcinomas (SCCs). Both of these forms of skin cancer are relatively benign; however, if neglected they can result in significant morbidity and, in some cases, death (especially from SCC).

The incidence of skin cancer is rising among fair-skinned populations throughout the world with the highest rates in Australia. People whose skin burns easily are at the highest risk. The principle aetiological factor for skin cancer is ultraviolet (UV) radiation, mainly from the sun's rays (Marks & Hill, 1992; IARC, 1992). Around two-thirds of daily UV radiation is transmitted in the two hours each side of true midday. In tropical areas, UV levels are high all year round. In temperate zones, UV levels only reach high levels in the summer months, except at high altitudes, or in reflecting environments where the levels can be much higher than normal. Nonetheless, some sun exposure is important for production of Vitamin D and total sun avoidance is not recommended. Vitamin D deficiency causes various bone diseases and may increase risk of immune disorders and even cancer (Vanchieri, 2004; Luca & Ponsonby, 2002).

There is no clear consensus on the mechanisms by which UV radiation leads to skin cancers. One major problem is the difficulty of measuring UV exposure across the lifespan. There is some evidence that melanoma may be a result of both acute episodic over-exposure, best indexed by sunburn and very high levels of cumulative exposure (such as is achieved in tropical and subtropical climates). By contrast, non-melanoma skin cancers, especially SCC (English *et al.*, 1997), may be more closely linked to total UV exposure. Exposure in childhood and adolescence may be more important than adult exposure for later development of skin cancer. Regular use of sunscreen (which reduces UV exposure) can reduce squamous cell carcinoma (Green *et al.*, 1999). Reliance on sunscreen alone is not considered adequate protection and may lead to extended exposure especially during intentional tanning (Autier *et al.*, 1999).

Prevention

To reduce skin cancer risk involves reducing UV exposure, particularly acute over-exposure (or sunburn) and to focus these preventative activities on young people, while not neglecting the benefits that may come from appropriate exposure at all ages.

The most effective ways of reducing UV exposure are staying out of the sun when UV levels are high by staying indoors or seeking shade, covering up with clothing, wearing hats and using sunscreens. The sunscreens recommended vary from country to country, but generally a broad spectrum sun protection factor (SPF) 15 or greater is considered adequate, that is, sunscreens that block out around 94% of all UV radiation. In high UV exposure environments, SPF 30 sunscreen may be necessary.

The linchpin for the systematic scientific approach to melanoma control is good data: epidemiological data on the incidence and mortality from the disease, data on identified behavioural risk factors, data on the value of the risk behaviour to 'at risk' groups and data from the systematic evaluation of interventions.

Measuring sun protection

Strategies to measure sun protection fall into four broad categories: observation; diaries; recall of specific events; and reports of overall behaviour. Measuring sun protection behaviour is difficult because the need for it varies as a function of time of day, season of the year, time outside and prevailing weather conditions. Further, the extent to which extra protective action is required will vary as a function of the normal dress for the activities engaged in, e.g. swimmers need to rely more on sunscreen than golfers. This means that it is difficult for people to estimate what is usual across all kinds of activities and situations. Context-specific measures may be more valid. People tend to over-estimate the extent to which they take protective actions (at least in the context of a population who are well informed of the need to take such actions). This has been most clearly demonstrated in children. Estimates of sun protection based on overall reports should be treated with caution.

Direct observation, using observers or photographs can provide an accurate and potentially unbiased estimate of behaviour. However, it is restricted to visibly observable sun protection (thus excluding sunscreen use) and to public places (for practical and ethical reasons). It is also not practical to observe individuals over extensive periods, so data may not be representative of the people observed, though it can be of the situations observed.

Diaries of sun protective actions and outdoor experiences can be kept reliably (Girgis *et al.*, 1993) and thus they have the potential to accurately describe individual behaviour. However, there are limits on how long people will keep them for, and demand characteristics associated with keeping them may lead to changes in sun protection behaviour, either for social desirability reasons or to minimize the amount of recording necessary.

Recall of specific events can only reasonably be done for a relatively short period (days). Measurement cannot change the actual behaviour, but recall can be selectively influenced by demand characteristics and may also vary with the salience of the activities. Attempts to validate specific recall with observational strategies suggest they are reasonably accurate, at least for behaviours in public places. Specific recall is likely to be representative for situations, although it may not be for individuals. It is probably the best method for monitoring population-wide trends.

It is also important to assess exposure. Monitoring sunburn incidence is useful as a marker of over exposure and risk, some measurement issues are reviewed by Shoveller and Lovato (2001). Polysulphone badges can help to quantify potential exposures for different body sites, or help to validate other estimates (Gies *et al.*, 2004).

The challenge

Risk of UV exposure is related to lifestyle. Exposure can be incidental to outdoor activity or can be actively sought, as in sunbathing. There is limited capacity for getting people to spend less time outside, although it is possible to get people to schedule more of that time outside peak UV periods. The major focus needs to be on encouraging people to take suitable precautions when they are outside. Young people, especially males, spend more time out in the sun and expose more of their skin to the sun. Young people, especially women, are more likely to rely on sunscreens for sun protection. Men are more likely to wear sunhats than women, but women are more likely to avoid the sun or use sunscreens as protective measures. Both qualitative and quantitative research has identified a desire for a suntan as a major barrier to sun protection. Suntans are related to a self-image of being active, healthy and attractive, and others see suntanned individuals in a similar way (Arthey & Clarke, 1995). Other factors inhibiting sun protection include the perception that protective clothes and hats are unfashionable, particularly in the young; and, especially among men and older people, a reluctance to use sunscreen. Consistent with this, Hill *et al.* (1992) found that young people are more likely to get sunburnt than older people, and men are more likely to get burnt than women. men of African descent.

Behaviour change

The first stage of a prevention campaign involves informing the public about the risk; about strategies to reduce risk; and that risk reduction is worth considering (see 'Health promotion'). Health education programmes in schools and workplaces have been shown to produce improvements in sun protection, especially where they have used programmes that actively engaged participants. In many countries most, or all, of the population are at risk, so comprehensive mass-reach, population-based behaviour change strategies are required (Marks & Hill, 1992). These should include education and other activity directed at personal behaviour change, combined with activity directed at changing aspects of the physical or social context to make sun protection easier and/or more desirable.

One of the most extensive skin cancer prevention programmes has occurred in Victoria, Australia. In 1980, a small-scale campaign called 'Slip! Slop! Slap!' (Slip on a shirt!, Slop on sunscreen! And Slap on a hat!) was launched. By 1987 there was virtually total community awareness of the need for sun protection, but inadequate levels of behaviour change. In 1988, a more extensive campaign called 'SunSmart' was launched. At its peak it had a budget of about 30c US per person per year (for a population of around 4 million). The campaign aimed to change public perceptions of the acceptability of sun protection by linking it with fashionable images in TV and other advertising. The advertising also helped put skin cancer on the public agenda, which was important in encouraging community involvement both in education and in fostering appropriate structural change to support sun protection behaviour. For example, availability of fashionable sun protective hats and clothes, cheaper sunscreens, more appropriate outdoor policies in schools and workplaces, and increased provision of shade (Montague *et al.*, 2001).

The early years of this campaign were associated with a marked increase in sun protection behaviour: hat use and sunscreen use increased markedly, as did the proportion of the population avoiding at least part of the peak UV radiation period of 11am–3 pm (Hill *et al.*, 1993). Furthermore, reported desire for a suntan fell as did personal beliefs about the desirability of a tan and beliefs that others preferred tans. Continual monitoring of community reactions revealed threats to good practice. People said that often sun protection took effort, and they wanted more good reasons to act. They asked for graphic images of the consequences of inaction. This was done and the motivation to act increased. While the campaign was well resourced it was able to improve or sustain good practice, but when it reduced in magnitude, there was some evidence of a drift back to less 'sun-smart' practices (Dobbinson *et al.*, 2002; Dobbinson, 2004). This reversal provides extra evidence that the campaign had contributed to the community change. Keeping the public aware of the reasons why sun protection is important seems to be necessary for sustained attitudinal and behaviour change (for theories of health behaviour and behaviour change see 'Health belief model', 'Theory of planned behaviour' and 'Transtheoretical model of behaviour change').

Early detection

Because skin cancers grow in the skin, they are readily observable, particularly if they grow in easily visible areas. Thus it is potentially easy to detect them at an early stage of development when treatment is almost always successful. A variety of strategies have been used to encourage one-off self-screening. These can lead to an increase in melanoma detection through more people presenting to doctors with suspicious lesions (e.g. Doherty & MacKie, 1988) (see 'Screening: cancer'). Similar effects have occurred through increased community awareness of skin cancer. There is, however, still a need to improve people's understanding of what to look for. For example, most Australians believe melanomas are raised lesions even though virtually all early melanomas are flat (Borland *et al.*, 1992), the exception being nodular melanomas (Kelly *et al.*, 2003). Educational resources are needed that enable people to accurately distinguish potentially dangerous spots from those that are clearly benign.

There is increasing medical interest in instituting systematic programmes of self-screening or screening by professionals where all or most of the body could be checked on a regular basis. As yet there is no evidence about whether this would increase detection sufficiently to justify its adoption, even for high-risk groups. Behavioural research is needed to determine levels and frequencies of self-screening people will persist with. Efforts to maximize screening will involve developing strategies to minimize embarrassment, provide the skills to do the self-examination properly, ensure appropriate confidence in decisions to engender appropriate action, and ensure that people perform self-examinations regularly. A balance will need to be found between the potential benefits to health and what people are willing or able to do.

When people have identified spots which are of concern, it is crucial that they seek medical advice as quickly as possible. There is no good data available on the extent of delay in presenting, but some people do delay enough to affect their prognosis. Research is needed to identify modifiable determinants of delay (see 'Delay in seeking help').

A self-detection programme depends on more than an educated and willing public. It also requires doctors and other health practitioners who have the necessary knowledge and skills in accurate diagnosis and management, and who encourage the public to engage in appropriate self-screening.

Carotid artery disease and treatment

Jan Stygall and Stanton Newman

University College London

Thrombo-embolism and haemodynamic ischaemia secondary to atheromatous stenotic disease of the carotid and vertebral arteries are important causes of ischaemic stroke. In those patients with carotid stenosis the risk of stroke has been directly related to the severity of stenosis and the presence of symptoms (Inzitari *et al.*, 2000). The average risk of stroke following a transient ischaemic attack (TIA) is about 8% in the first year and then 5% per annum, but, in patients with severe carotid stenosis, the risk even with medical treatment increases up to 28% over 2 years (NASCETC, 1991). Detection of significant carotid or vertebral artery stenosis after a TIA or stroke provides the opportunity for secondary preventive treatment of the stenosis to prevent a further stroke (see also 'Stroke').

Carotid endarterectomy (CEA), the surgical removal of the atheromatous plaque, was first performed fifty years ago and is, at present, still considered the gold standard in the treatment of severe symptomatic disease (Grace, 2004). The procedure usually involves the insertion of a silicon tube (shunt) directly into the opened internal and common carotid arteries. Blood then flows through the shunt from the carotid artery to the brain allowing the removal of the atherosclerotic plaque from the artery wall. A number of randomized clinical trials on selected groups of symptomatic and asymptomatic patients have indicated the benefits of CEA (NASCET, 1991; ACAS, 1995; ECST, 1998). However, it has been suggested by some investigators that there is insufficient evidence to recommend CEA in asymptomatic patients (Rabe & Sievert, 2004). Recently, the MRC Asymptomatic Carotid Surgery Trial (ASCT) Collaborative Group published a study indicating a positive effect of CEA in reducing stroke and death in asymptomatic patients over a 5-year period (MRC ASCT, 2004). However, in certain high risk patients (2–7%) CEA can in fact cause a stroke (NASCET, 1991; ECST, 1991). It has been suggested that perioperative risk of endarterectomy is higher in centres with surgeons of less experience (Alhaddad, 2004; Rabe & Sievert, 2004).

Factors which can lead to complications following CEA, include older age, female sex and the presence of co-morbidities such as obstructive pulmonary disease, advanced coronary artery disease and congestive heart failure (see 'Chronic obstructive pulmonary disease' and 'coronary heart disease: heart failure'). The majority of patients with carotid stenosis are older and have other co-morbidities. Various anatomical problems may also restrict the number of patients eligible for CEA. Due to these issues less invasive and potentially safer procedures have been explored.

Carotid artery balloon dilatation (angioplasty), and more recently carotid artery stenting (CAS) have become an alternative to CEA, especially for high risk sub-groups of patients. This technique

involves the advancing of a balloon-tipped catheter into the carotid artery, the balloon is then inflated dilating the artery at which point a mesh tube (stent) which supports the artery is then opened to fill the artery and left in place. Five hundred and four patients with carotid artery stenosis were randomized to either CEA or angioplasty (26% with stents) in the Carotid and Vertebral Artery Transluminal Angioplasty Study (CAVATAS) similar major risks and efficacy of prevention of stroke were reported for both procedures, however CEA was associated with more minor complications such as cranial nerve injuries and haematomas (CAVATAS, 2001). The main complication of CAS is related to plaque fracture occurring in the carotid artery during balloon inflation. Some of this atherosclerotic material may become dislodged into the cerebral circulation potentially leading to a stroke. Several emboli protection devices (EPDs) have been developed to reduce the risk of embolization of atherosclerotic debris into the cerebral circulation during CAS to decrease the risk of stroke. Ongoing prospective randomized studies of lower-risk patients comparing the two procedures and the use of emboli protection devices are currently being performed.

Whilst frank stroke is an important cause of disability various studies have provided evidence that suggests that carotid stenosis is also associated with more subtle neuropsychological problems in both those with symptomatic and asymptomatic disease (e.g. Auperin *et al.*, 1996; Kaplan *et al.*, 1996; Rao, 2002). However, the majority of studies have been cross-sectional in design. Interestingly, Lloyd *et al.* (2004) found evidence of pre-existing cognitive deficits in patients who showed the generation of spontaneous microembolism prior to their CEA. A longitudinal study by Bakker *et al.* (2004) assessed 73 patients who had TIAs or moderately disabling cerebral ischaemic strokes that were proven by angiography to be attributable to carotid stenosis. Seventy per cent of these patients with a stroke and 39% of patients with a TIA were rated as being cognitively impaired at baseline. At one year, patients who had recurrent TIAs remained impaired whereas those with no recurrence of symptoms improved.

Researchers have also examined neuropsychological function pre- and post-CEA, with inconsistent findings being highlighted by two systematic reviews (Irvine *et al.*, 1998). Improvement in performance following surgery was reported in over 50% of studies, no change in 43% with one study showing deterioration (Lunn *et al.*, 1999). Methodological factors have often been cited as the cause of these discrepancies. There have also been suggestions that cognitive domains are differentially affected by the procedure. For example, Heyer *et al.* (1998) conducted a study of 112 patients undergoing CEA for symptomatic and asymptomatic carotid artery disease. They found that while 60% of patients showed an improvement in one or

more test scores, 80% showed a decline in at least one test. Decline was detected most frequently in verbal memory tests whereas improvement was seen most commonly in psychomotor and executive function tests. However, more recently, Lloyd *et al.* (2004), defining cognitive deficit as a decline of one standard deviation or more on at least 2 tests, found that 45% of patients have cognitive deficits at 6 months post-procedure. In their study, patients were often poorer on tests of attention and word recognition and improvement was regularly seen in tests of delayed prose recall and non-verbal intelligence. Heyer *et al.* (1998) suggested that improvement in performance may be attributed to an increase in cerebral blood flow following surgery while decreased performance related to ischaemia from global hypoperfusion or microemboli. Unfortunately, unlike Lloyd *et al.* (2004), the occurrence of microemboli was not measured in the Heyer *et al.* study.

Transcranial Doppler (TCD) ultrasonography is the most commonly used technique to detect and monitor the occurrence of microemboli during various invasive procedures including CEA. Smith *et al.* (1998) have suggested that monitoring of the carotid artery during CEA is important in quality control and training. Studies have demonstrated that the number of emboli produced in the dissection stage of a CEA is related to the likelihood of infarcts as detected by MRI (Jansen *et al.*, 1994; Aackerstaff *et al.*, 1996). In a study by Gaunt *et al.* (1994) the incidence of microemboli was found to be related to changes in cognition: they also established that the detection of more than ten microemboli during the initial carotid dissection was associated with an increased likelihood of post-operative cognitive deterioration. Lloyd *et al.* (2004) also demonstrated intra-operative microemboli to be a significant predictor of cognitive decline.

A one centre study of a sub-group of patients in the CAVATAS trial showed substantially more microemboli detected during carotid angioplasty compared to CEA (Crawley *et al.*, 1997). However, two centres in the CAVATAS trial examined neuropsychological outcome following CEA compared to angioplasty and found no significant differences between the groups 6 months after treatment (Sivaguru *et al.*, 1999; Crawley *et al.*, 2000).

Quality of life (QoL) in patients with carotid artery occlusion has received relatively little attention. In a recent study by Bakker *et al.* (2004) self-perceived QoL remained affected 12 months after initial symptoms of a TIA or moderate stroke due to carotid occlusion even in the absence of further symptoms. Trudel *et al.* (1984) found that activities of daily living were not particularly affected following CEA. In contrast, there were marked restrictions in social and leisure activities. Salenius *et al.* (1990) examined the results of 44 surgically and 40 non-surgically treated patients with carotid stenosis documented by angiography in 1974–1976. During the follow-up period, the occurrence of cerebrovascular complications (death, stroke and/or TIA) was more frequent in the non-operated than in the operated group. No differences were found in the quality of life between the two groups, but the operated group expressed higher levels of satisfaction than the non-operated group. Sirkka *et al.* (1992) assessed patients 8–11 years after surgery and compared them with two control groups, one consisting of healthy individuals, the other group of patients having been considered for CEA approximately 11 years earlier, but not operated upon. The groups were matched on age, education, gender and, if applicable, duration of illness and lateralization of stenosis. They found that only those patients who had undergone two operations had a poorer quality of life than either of the control groups. Vriens *et al.* (1998) using the Sickness Impact profile to measure quality of life found no disruption 3 months after CEA. Lloyd *et al.* (2004) using the Short Form 36 (SF-36) also found that patients' self-reported health quality of life had not deteriorated at 6 months post-procedure. However, Dardik *et al.* (2001) also using the SF-36 found that patients with symptomatic carotid artery disease undergoing uncomplicated CEA reported an improved quality of life and overall health 3 months after the procedure. Conversely, those patients with postoperative complications reported a decline in both 'emotional health' and 'change in health' sub-scores. However, it has been suggested that generic quality of life measures do not tap all the factors which concern patients with carotid artery disease and that these measures should be supported by disease specific questionnaires (Hallin *et al.*, 2002) (see 'Quality of life' and 'Quality of life assessment').

Chemotherapy

Ingela Thuné-Boyle

University College London

'Chemotherapy' refers to treatment with drugs and can describe the treatment with drugs in any illness. It is however, mainly associated with the treatment of cancer where chemotherapy is short for 'cytotoxic chemotherapy'. Cytotoxic (cell poison) chemotherapy constitutes a group of drugs used to treat cancer by interfering with the process of cell reproduction.

Chemotherapy is a systemic therapy affecting the entire body. It is particularly toxic to rapidly dividing cells, a primary feature of tumour development, and it works by disrupting cellular function. Unlike radiotherapy, which is mainly used to treat local disease (see 'Radiotherapy'), the purpose of chemotherapy is to destroy cancer cells that may have spread from the primary site. It is therefore typically given to patients where there is evidence or suspicion of a regional disease spread (i.e. nodal involvement).

The goal of chemotherapy treatment may be (i) as a primary therapy with curative intent; (ii) as adjuvant therapy with curative or long term survival intent, i.e. by controlling the cancer, keeping it from spreading or by slowing its growth; (iii) as a neoadjuvant therapy with the aim of reducing tumour burden or to spare an organ; and (iv) as palliative therapy to relieve symptoms such as pain caused by advanced cancer, to help patients live more comfortably (Knobf *et al.*, 1998).

Side effects and the role of psychological factors

Although chemotherapy works best on rapidly dividing tumour cells, it may also damage healthy cells, especially those that also have a tendency to divide quickly such as cells in the blood, mouth, intestinal tract, nose, nails, vagina and hair. This can cause patients to experience a range of side effects such as nausea, vomiting, diarrhoea, hair loss, skin rash, sore mouth, loss of appetite, immunosuppression, weight gain, tingling and numbness, cessation of menstruation, neuropsychiatric effects and negative affects such as anxiety and depression (e.g. Holland and Lesko, 1990). In addition, 20% to 65% of patients may develop anticipatory nausea and vomiting (ANV) (Burish & Carey, 1984), (for more information on ANV, see 'Vomiting and nausea').

The number and severity of side effects vary widely depending on the drug combination, dosage, number of cycles and whether or not these drugs are given in combination with radiotherapy. However, there are also large variations in levels of side effects occurring in patients' receiving the same cytotoxic agents (e.g. Gralla *et al.*, 1981), suggesting that non-pharmacological factors may play a role (Haut *et al.*, 1991). It also suggests that toxicity ratings of chemotherapy do not reveal information about the actual experience of symptoms during treatment, or their influence on psychological wellbeing. Rather, they suggest an important role of psychological

factors in response to chemotherapy treatment. For example, patient's pre-infusion expectations have been found to predict post-treatment nausea independent of pharmacological effects (e.g. Montgomery & Bovbjerg, 2000) and patient's expectations may also play an important role in the development of ANV separate to that of conditioning (Hickok *et al.*, 2001) (see 'Expectations and health'). Further, coping style such as the monitoring/blunting concept (Miller, 1995) and repressive coping (Byrne, 1961) may play a role in the number and severity of side effects experienced and/or reported by patients during and after treatment (e.g. Lehman *et al.*, 1990). Levels of anxiety have also been found to be associated with higher levels of symptom reporting during chemotherapy (e.g. Watson *et al.*, 1998) (see 'Symptom perception').

Cognitive functioning

Patients on chemotherapy often report difficulties with their abilities to remember, think and concentrate (e.g. Minisini *et al.*, 2004). There is evidence that chemotherapy can have an indirect effect on cognitive function caused by anaemia and through a reduction in hormone levels associated with chemotherapy induced menopause (e.g. Jacobsen *et al.*, 2004). It may also have a direct effect on the central nervous system. Problems with language, the visual-motor domains, memory, attention and concentration have been noted (e.g. Ahles *et al.*, 2002). However, a review by Minisini *et al.* (2004) found that most studies to date have suffered from methodological problems such as a small sample size, a lack of baseline measurement and many have also failed to control for other possible influential variables such as educational status and IQ. Further, factors such as age, ability to cope, anxiety, depression and fatigue can also influence cognitive ability and were often not controlled for in studies. Despite methodological limitations, current evidence to date nevertheless suggests that chemotherapy does cause cognitive dysfunction in a significant number of patients with cancer. Treatment-induced cognitive dysfunction may, in turn, affect the patient's ability to return to work, resume their previous activities and can therefore be detrimental on their quality of life.

Psychological impact

Chemotherapy engenders fear and uncertainty for many patients, as it is generally associated with upsetting side effects and distress. However, the prevalence of distress during chemotherapy varies across studies. Some have found clinical levels of distress in around a quarter of patients (e.g. Mooray *et al.*, 1991) while others

have found as many as three quarters report moderate to severe levels of distress (Meyerowitz *et al.*, 1979). Distress has also been shown to increase during and up to a month following chemotherapy among patients with breast cancer and lymphoma (e.g. Buick *et al.*, 2000). End of treatment distress may occur as a result of patient's feelings of vulnerability to tumour recurrence as they are no longer monitored closely by hospital staff (Sinsheimer & Holland, 1987). However, a recent pilot study examining distress among males with testicular cancer before, during and after chemotherapy, found that initial anxiety before the start of treatment was highest and primarily anticipatory, but decreased over the course of chemotherapy (Trask *et al.*, 2003). This suggests that the course of distress during chemotherapy may be different in different cancers groups and that generalizations from one cancer group to another should be made with caution (see 'Cancer: general').

Some studies have also examined factors associated with psychological distress during chemotherapy treatment and have produced a range of different findings, even in the same cancer group. In breast cancer, Sinsheimer and Holland (1987) found that psychological distress was largely associated with hair loss, weight gain and fatigue. Knobf (1986) found fatigue to be the most distressing symptom in this cancer group, and Nerenz *et al.* (1984) found nausea and vomiting, fatigue, weakness and pain to have the strongest associations with distress in a sample of patients with breast cancer and lymphoma. What is common in these studies is the association of distress with fatigue, which is an increasingly recognized important symptom in many chronic conditions and treatments.

Some studies have also found that the number of side effects experienced by patients during chemotherapy to be associated with distress (e.g. Nerenz *et al.*, 1984). However, Thuné-Boyle *et al.* (2006) in a multivariate analysis, found that the number of symptoms was associated with patient's beliefs about the consequences of their illness and treatment and that these beliefs served as a mediator between symptoms and anxiety, and, to a lesser extent, depression. The aetiology of distress during chemotherapy is often complex and may also be influenced by other factors such as personality, coping style, age, type of cancer and prognosis (Knobf *et al.*, 1998).

Interventions

Physical symptoms during chemotherapy can be perceived as being so severe and so distressing that patients may delay or even stop treatment altogether (Carey & Burish, 1988). It is therefore important to find ways of reducing treatment-related distress, as poor adherence is likely to influence survival.

There are various medical interventions that are successful in reducing some of the unpleasant side effects during chemotherapy. For example, there has been a significant improvement in reducing nausea and vomiting with the development of new and more

effective anti-emetic drugs during the last decade (Morganstern & Hesketh, 1999), and better ways of classifying emetogenic risk are now available (Hesketh *et al.*, 1997). Further, many cancer centres now administer erythropoietic agents to patients during chemotherapy to reduce anaemia and its associated fatigue. This, in turn, has been shown to improve quality of life during the treatment period (e.g. Iconomou *et al.*, 2003).

There are also scalp cooling methods that can be effective in preventing or reducing hair loss and its accompanying distress (e.g. Macduff *et al.*, 2003). They work by reducing the blood supply to the hair follicles and thereby decreasing the likelihood of the drugs reaching the area. They are however, not suitable when chemotherapy must be circulated through the body for longer periods of time or when very high doses are needed, and they vary in efficacy according to the chemotherapy drug used.

Many studies have examined the effectiveness of psychological interventions in reducing unpleasant side effects and the accompanying distress associated with these. A review by Carey and Burish (1988) investigating the usefulness of five such interventions: hypnosis, systematic desensitization; biofeedback; distraction; and relaxation and guided imagery, found that hypnosis was effective in reducing side effects associated with both pre- and post-chemotherapy and in reducing negative affects associated with cancer treatment (see 'Hypnosis'). The efficacy of systematic desensitization procedures appeared to be useful in reducing (ANV), while biofeedback, in combination with progressive muscle relaxation and guided imagery, showed promising results overall (see 'Biofeedback', 'Behaviour therapy' and 'Relaxation training'). Progressive muscle relaxation with guided imagery reduced physiological arousal and nausea as well as anxiety, and proved especially effective in reducing vomiting. Distraction techniques were found to be especially useful in children although it was not clear how long-lasting their effect was or whether the novelty of the distraction wore off over time. More recent reviews have found relaxation training alone or with guided imagery given during chemotherapy generally reduced treatment-related symptoms and improved emotional adjustment and quality of life (Luebbert *et al.*, 2001; Walker *et al.*, 1999).

A meta-analysis by Meyer and Mark (1995) investigated the effects of behavioural, educational, social support, counselling and therapy interventions found clear evidence that all of these had an effect on emotional and functional adjustment, and on treatment and disease-related symptoms, although the effect size was found to be relatively small. In fact, Dreher (1997) has argued for a need to develop and evaluate better interventions in order to minimize the psychological impact of cancer treatment. It is therefore important to identify other factors that may influence distress and how patients' experience and interpret their symptoms and their illness during the treatment phase (List & Butler, 1999). Examining the role of patient's beliefs about illness and treatment for example, may provide useful information in the design of interventions and may provide a focus for the content of interventions (see 'Lay beliefs about health and illness').

Child abuse and neglect

Kevin D. Browne and Catherine Hamilton-Giachritsis

University of Birmingham

Introduction

Prevention of child maltreatment is traditionally classified into three levels: primary prevention (universal services aimed at the whole population); secondary prevention (targeted services for families identified as in need of further support); and tertiary prevention (services offered once difficulties have occurred). However, increasingly it has been argued that child maltreatment should be considered within the broader context of child welfare, families and communities (World Health Organization, 1998*a,b*). This approach assists in moving the focus away from child protection professionals to highlighting the role of the Health and Social Services in general. This has been termed the public health approach which promotes child care and protection within the broader context of child welfare, families and communities.

For example, the Health Service can look at areas of service provision for families and children, where good practice can impact on child welfare; specifically, pregnancy and childbirth-related services (primary prevention), targeting resources to families at risk of child maltreatment (secondary prevention) and the management of childhood health and illness (secondary and tertiary prevention). Families who come into contact with health and social services can be assessed in terms of need by considering the following three factors (Department of Health, 2000):

- Assessment of children's development needs in general
- Assessment of the parent(s) capacity to respond appropriately to their child's needs
- Assessment of the wider social and environmental factors that impact on the capacity to parent.

Most authors conclude that a multi-sector, inter-disciplinary approach is the most effective way of working together to promote children's rights to grow and develop in a safe family environment and provide care and protection to children (e.g. United Nations Convention on the Rights of the Child, 1989; Hallett & Birchell, 1992). In the UK, guidelines have been published by the Department of Health (1999; 2000) on how a range of professionals can work together to safeguard children. These guidelines have since been adopted by some other countries (e.g. Hungary, Romania) as they clearly define what is meant by child abuse and neglect.

Definitions

Child maltreatment is typically broken down into four different types. However, many children suffer more than one type of maltreatment at the same time and there are a minority of cases where the child is victimized in a ritualistic and terrorizing way.

Physical abuse

The child is physically hurt, injured, maimed or killed by a parent or caretaker, or the risk of such injury. This may include, but is not limited to, punching, beating, kicking, shaking, biting, strangulation, burning, or immersion in scalding water, with resulting bruises, welts, broken bones, burns, internal injuries or scars. Physical harm may also be caused when a parent or carer feigns the symptoms of, or deliberately causes ill health to a child whom they are looking after. This situation is commonly described using terms such as factitious illness by proxy or Munchausen syndrome by proxy.

Sexual abuse

Children are used to gratify adult sexual needs and fantasies by carers in position of responsibility, trust or power who force or coerce a child into sexual and/or pornographic (contact and/or non-contact) activities. These include: sexual penetration (rape, buggery, oral sex), sexual touching, fondling, voyeurism, exposure, frottage (rubbing against a person), child prostitution, production of pornographic materials. Children are incapable of providing informed consent to sexual interactions with adults.

Psychological/emotional abuse

The child is subject to threats, verbal attacks (belittling, humiliating, ridiculing, shouting), violent outbursts directed at others (e.g. spouse, sibling or elder abuse). S/he is threatened, frightened or placed in dangerous situations. Some level of emotional abuse is involved in all types of ill-treatment of a child, though it may occur alone.

Neglect

This is the failure of a parent or caretaker to provide their child with basic needs (such as food, clothes, shelter, warmth, education and healthcare), protection and supervision which may result in harm to health and development of the child. This also includes *Psychological neglect* – the consistent failure of a parent or caretaker to provide a child with appropriate support, attention, love and affection.

Incidence

The incidence of child abuse and neglect varies widely across different countries. This may be related to different reporting

definitions and procedures. For example, reporting rates range from 43 per 1000 children in the USA to 3 per 1000 children in Belgium (Gilbert, 1997).

A survey of 50 States in the USA carried out by the National Center on Child Abuse Prevention Research (Wang, 1999) identified approximately three million cases (45 per 1000 children) of reported child abuse but only one third (15 per 1000) were later substantiated by a case worker, 54% of these were neglect cases, 20% were physical abuse, 10% sexual abuse and 3% emotional abuse. The remaining 14% were mixed and not easily categorized (Wang & Harding, 1999).

In England for the year ending 31 March 2004 (Department of Education and Skills, 2005) 72 100 children (6.5 per 1000) were subject to a child protection enquiry. Over half of these (38 500; 3.5 per 1000) were subject to a case conference and 80% of these resulted in the child being placed on a child protection register.

Therefore, 2.4 in 1000 children under 18 years were on child protection registers for actual or likely abuse and/or neglect. Of these, 41% were registered for neglect, 19% for physical abuse, 9% for sexual abuse, 18% for emotional abuse and 14% for cases of mixed abuse and/or neglect. The highest rates were found in very young children less than one year old (51 per 10 000, 11% of the total), with the likelihood of being on the register decreasing with age. Therefore, 68% of children on registers are aged less than 10 years. There were slightly more boys (2.4 per 1000) than girls registered overall (2.3 per 1000). However, 11% of girls were registered for 'sexual abuse' compared with 8% of boys, while more boys than girls were registered for 'physical abuse' (16% and 15% respectively). One in eight children registered in 2004 had previously been on the child protection register. In terms of placements, approximately 13% of those on the register (26 300) on 31 March 2004, were 'looked after' by local authorities (this figure represents 6% of all children in public care); of these, 79% were placed with foster parents, 5% were living in children's home or secure unit, 13% were placed with parents and 3% are placed for adoption or living independently.

Nevertheless it is claimed that the incidence figures for child abuse and neglect represent only a small proportion of those children who are victimized in childhood. Victim surveys and prevalence studies indicate that the number of people reporting that they have been abused in childhood is approximately ten times the incidence rate (Browne *et al.*, 2002). Given the fact that infants are more at risk of maltreatment than any other age group, it is essential to intervene early with health and social services in order to prevent child abuse and neglect (Browne & Herbert, 1997).

Advantages of early intervention

The most important indicator that there is a need for early intervention is the level of fatal abuse and serious injury to children (Reder & Duncan, 2002). Child abuse and neglect is one of the most common causes of death and disability to children under five years, although children under one year are at greatest risk (Browne & Lynch, 1995). Parents are the most common offenders. It is estimated that in the United Kingdom that at least two children per week die from maltreatment (NSPCC, 2001), compared with 23 children per week in the USA (Wang & Harding, 1999). Therefore, these figures emphasize the need for timely interventions to reduce the number of children who continue to die or who are disabled for life because

interventions are either too late or the preventative services are inadequate. Although child protection systems have changed in the last 30 years, there has been little decline in the rate of child death (Creighton, 1995) which remains unacceptably high (NSPCC, 2001).

Early intervention is important from the perspective of the victim and the family, but also may significantly reduce the large financial cost of child abuse and neglect to society. These costs are both overt (e.g. medical care for victims, treatment of offenders, legal costs for public childcare) and less obvious (e.g. criminal justice and prosecution costs, specialist education). Over a decade ago, it was estimated that the total economic cost in the United Kingdom is £735 million per annum (National Commission for the Prevention of Child Abuse, 1996). Estimates at the same time in the USA claimed \$12 410 million dollars per annum (WHO, 1998b).

Alongside the impact on children, families and society, the cost of child protection once child abuse and neglect has occurred provides sufficient economic justification for more expenditure on preventative measures and services to support children and their families.

Primary prevention

Primary prevention techniques are aimed at the whole population and attempt to create a fundamental change across society. For example, public awareness campaigns that challenge misconceptions and aim to increase the public's understanding of the extent and nature of child maltreatment. Primary prevention services could include:

- maternity services (promoting safe pregnancy and childbirth)
- home visits by health workers
- school programmes on parenting and child development
- education of parents and caregivers
- community support
 - day nursery places
 - telephone helplines
 - drop-in community centres

Safe pregnancy and childbirth (maternity services)

Recommendations for pre-, peri- and antenatal care focus on providing safe pregnancy and childbirth (WHO, 1998b), which in turn impacts on the development of parental bonding and attachment formation (see also 'Pregnancy and childbirth').

During pregnancy, emphasis is placed on prenatal screening to identify potential disabilities, which (aside from the obvious implications for child and family) is also a known risk factor for child maltreatment (see 'Screening: antenatal'). Furthermore, maternal healthy lifestyle is vital for foetal development. Traditionally, this has focused on avoidance of alcohol, drug and cigarette use, as well as physical and mental wellbeing. However, a recent development is concern regarding mothers who are under-eating due to fears of weight gain.

During birth, the promotion of natural delivery and use of appropriate technology should be encouraged. Like other economically developed countries, in the UK the rate of Caesarean births has

risen significantly in recent years and is an issue for discussion. Furthermore, significant evidence demonstrates the role of midwives in promoting a positive birth experience for mothers. Most importantly, perhaps, the presence of significant others (usually the father) during the birth and skin contact between mother and baby immediately following birth can impact on bonding between parent and child (Sluckin *et al.*, 1983).

Following birth, 24-hour access of significant others to the mother and child in the maternity unit reduces feelings of social isolation and promotes support and paternal involvement. Advice on appropriate neonatal care and practical parenting skills is essential (e.g. breast feeding, bathing, etc), assisting the parents to adjust to their new role (New & David, 1987) (see also 'Breastfeeding'). Overall, the aim is the promotion of sensitive parenting through positive post-birth experiences.

From first involvement with professionals due to pregnancy, midwives are best placed to provide continuity of care to expectant parents. A 'good practice' model is seen as the same midwife offering individualized support with pre-birth home visits, assistance in childbirth and infant care. In terms of child protection, positive birth experiences and bonding promote positive parenting and thereby limit the possibility of infant abandonment, poor parenting, insecure attachment and maltreatment (Browne & Saqi, 1988a; Roberts, 1988).

Home visits by health workers

Family doctors and community nurses (health visitors) in a number of countries (e.g. UK, France, New Zealand) make home visits and have ongoing contact with all children under five years. They are in a unique position to provide advice on practical parenting skills, health and wellbeing of the child and their parents and counsel parents to reinforce positive parenting and sensitive interactions with the child.

School programmes on parenting and child development

Professionals from health and education (e.g. nursery workers, teachers, school nurses and psychologists) are important in providing appropriate advice and education to parents as well as informing children about their rights and what it is like to be a parent. In addition they are well placed to monitor child development and family influences.

Education of parents and caregivers

Many initiatives aimed at promoting positive parenting now exist (Sure Start in England; Triple P in eight countries across the world). The advantage of Triple P (Positive Parenting Programme; Sanders & Cann, 2002) is the long-term evaluation that has taken place and its application in a variety of countries across the world (see Saunders, 1999). It is a multi-system approach, available for use by different professionals to promote positive parenting skills and sensitivity, e.g. raising awareness of verbal abuse and the implications of this on the development of a positive self-image in the child. Outcomes of such programmes implemented through home visits have shown improvements in parenting skills and the quality of the home

environment, a reduction in child behavioural problems and accidents, better management of postnatal depression and social support for mothers and improved rates of breastfeeding (Elkan *et al.*, 2000).

The overall purpose of any support is to assist positive parenting skills and to encourage the development of a secure attachment between child and parent (Bowlby, 1969; Cassidy & Shaver, 1999). Secure attachment is repeatedly referred to as the main aim of interventions, because of the significance of attachment formation both for long-term wellbeing (e.g. positive self-image) and in the early prevention of child maltreatment. In situations where a high number of risk factors for child maltreatment are present, child abuse and neglect are more likely to occur in the absence of positive interactions and secure attachments (Browne & Saqi, 1988b; Morton & Browne, 1998).

It is important, however, for professionals to remain aware that, whilst providing simple explanations to parents may assist in development of parental sensitivity to the child and infant attachment, the assessment of parenting and attachment is not simplistic and requires appropriate training. A common misperception is to refer to a child as 'attached'. Nearly all children are attached in some way; it is the quality of infant attachment which is of importance. This is dependent on the levels of acceptance, accessibility, consistency, sensitivity and co-operation of the primary caregiver (usually the natural mother; Maccoby, 1980). However, whilst maltreated children are more likely to show patterns of insecurity, it does not always follow that a maltreated child is insecurely attached or that a child who clings to their mother is securely attached. A meta-analysis of 13 studies showed three-quarters (76%) of maltreated samples were classified as having an insecure attachment to the mother compared to just one-third (34%) of non-maltreated samples (Morton & Browne, 1998).

Community support

When considering parenting, it is also very important to recognize that the transition to parenthood is a critical period in adult psychological development. Support should be provided to parents who are unable to cope. Again, these can be offered at a population level, such as via telephone helplines, drop-in centres, community support groups and voluntary groups, as well as at a secondary level where parents in difficulties are referred to specialist health and social services. Hence, multi-disciplinary training is required to enable primary care professionals to recognize and intervene with spouse abuse parental low self-esteem, anxiety, depression and alcohol/drug misuse. For example, a parent who has depression will struggle to respond to the child's needs on a consistent basis whilst dealing with his/her own difficulties (Roberts, 1988). All these factors strongly influence the quality of parental care and infant attachment which may have long-term effects on child development (Goldberg, 2000; Simpson & Rholes, 1998; Solomon & George, 1999) (see 'Postnatal depression').

Secondary prevention

Secondary prevention involves targeting resources to families identified as being 'high priority' for additional services. This can be

achieved by identifying known 'risk' factors for child maltreatment in a family and offering additional services before maltreatment occurs. However, it is important to note that not all families who have the presence of these 'risk factors' will go on to maltreat their child. This screening is merely a means of ensuring that families who have additional needs are provided with support. Thus, whilst this approach can be seen as controversial, if the intervention following screening is positive and empowering, the effects of incorrectly identifying a family as 'high priority' or 'in need' of further services should be minimal. Furthermore, it has the potential to prevent victimization from ever beginning.

Numerous 'risk' factors have been identified through research. For example, Browne and Saqi (1988a) undertook a 5 year follow-up of 14 252 newborns in Surrey, England. A comparison of 106 abusing families with 14 146 non-abusing families identified from this population established 12 factors that distinguished between the two groups. These included:

- Child characteristics (i.e. infant premature and/or low birth weight; infant separate from mother at birth; infant mentally or physically disabled; twins or less than 18 months since last birth).
- Parental characteristics (i.e. step-parent or co-habitee; parent with history of childhood abuse; history of mental illness or substance misuse; parent less than 21 years of age at time of birth; parent indifferent, intolerant or over-anxious towards child)
- social and environmental characteristics (i.e. single or separated parent; history of family violence; socioeconomic difficulties).

However, using a one-off screening instrument based on a checklist of risk factors around the time of birth can create high numbers

of false positives (i.e. identified high risk, but non-maltreating; Browne, 1995a). Therefore, it has been argued (Browne & Herbert, 1997; Hamilton & Browne, 2002) that additional assessment of the parent-child relationship should be undertaken. In England, this led to the development of the Child Assessment and Rating Evaluation (CARE) programme that is carried out over four home visits during the first year of the infant's life (Browne *et al.*, 2000; Dixon *et al.*, 2005a). Following the use of an initial screening checklist completed in association with parents (see Table 1), community nurses rate:

- parental perceptions
- parental attitudes
- indicators of attachment formation
- quality of parenting.

Initial evaluation on 1508 families in Essex showed that using Index of Need score (see Table 1) 4% of families were identified as a 'high priority' (with a score of 6 or more), 30% as low priority (with a score of 1-5) and 66% as having no risk factors at all. On follow-up it was found that 97% of all parents showed positive parenting skills and only 3% demonstrated insensitive, unrealistic and negative parenting. Those parents with poor skills were significantly more likely to have come from the high priority group. Where both a high number of risk factors and negative parenting existed, these families were regarded as requiring immediate interventions.

In the USA, the value of home visitation to families with newborns has been highlighted through the work of David Olds (Olds *et al.*, 1993, 1997, 2002). The research was conducted over a 15-year period and on follow-up a number of significant differences were found between those families visited and those families with new-borns

Table 1. The prevalence of risk factors displayed by Abused Parent families (AP) and Non-abused Parent families (NAP) with a child 4 to 6 weeks of age (N = 4351)

Risk factors	Weighting ⁺	AP (n = 135) n%	NAP (n = 4216) n%	Test statistic
Complications during birth/separated from baby at birth	1	23 (17%)	462 (11%)	$\chi^2_{1=4.875}$, p < 0.05*
Mother or partner under 21 years of age	1	23 (17%)	257 (6%)	$\chi^2_{1=25.995}$, p < 0.0001**
Mother or partner not biologically related to the child	1	1 (0.7%)	12 (0.3%)	Fishers Exact > 0.05
Twins, or less than 18 months between births	1	19 (14%)	299 (7%)	$\chi^2_{1=9.413}$, p < 0.001**
Child with physical or mental disabilities	1	4 (3%)	59 (1%)	Fishers Exact > 0.05
Feelings of isolation	1	17 (13%)	105 (3%)	Fishers Exact < 0.0001**
Serious financial difficulties	2	20 (15%)	143 (3%)	$\chi^2_{1=47.336}$, p < 0.0001**
Mother or partner treated for mental illness or depression	2	64 (47%)	303 (7%)	$\chi^2_{1=273.989}$, p < 0.0001**
Dependency for drugs and/or alcohol	2	7 (5%)	18 (0.4%)	Fishers Exact < 0.0001**
Infant seriously ill, premature or weighed under 2.5 kg at birth	2	17 (13%)	226 (5%)	$\chi^2_{1=12.975}$, p < 0.0001**
Single parent	3	13 (10%)	268 (6%)	$\chi^2_{1=2.319}$, p = 0.128
Adult in the household with violent tendencies	3	16 (12%)	33 (0.8%)	Fishers Exact < 0.0001**
Mother or partner feeling indifferent about their baby	3	64	441	Fishers Exact < 0.01**

*p < 0.05; **p < 0.01.

⁺Weighted Score summed to produce an Index of Need score for each family (Taken from Dixon *et al.*, 2005a).

who were not. In summary, the visited families showed the following differences:

- Mothers
 - Less family aid received
 - 79% reduction in child abuse and neglect
 - 44% reduction in maternal alcohol/drug difficulties
 - 69% fewer arrests of mothers
- Teenagers
 - 54% fewer arrests of 15 year olds
 - 58% fewer sexual partners
 - 51% fewer days consuming alcohol
 - 28% fewer cigarettes smoked

Intervention with families that have been identified as maltreating children could be reduced if good primary and secondary prevention were available following the principles of a public health approach. This requires a shift in focus from child protection (usually seen as the responsibility of social services and law enforcement agencies) to safeguarding children through promoting child welfare and development. Therefore, health professionals need to focus on the psychological as well as the physical needs of children and their families with appropriate networks for referral and support. The health sector is the most appropriate agency for early prediction and prevention of child maltreatment (Browne, 1995*b*) but also has a significant role to play in identification and detection of child abuse and neglect in partnership with social services.

Tertiary prevention

Even in the presence of proactive primary and secondary prevention, the health professional's role in services that detect and identify child maltreatment is essential. The primary focus of healthcare professionals is the prevention of child disability, morbidity and mortality. However, children coming to the attention of health services through home or clinic visits also offer the potential to screen for the possibility of maltreatment alongside standard procedures for dealing with physical injuries and illnesses. To consider child maltreatment, history-taking by doctors and nurses should include components to promote identification of and protection from child abuse and neglect:

- History of family circumstances (e.g. presence of isolation, violence, addiction or mental illness)
- History of child's condition (e.g. story doesn't explain injury, delay in seeking help)
- Child's physical condition when undressed (e.g. presence of disability, lesions or genital discharge)
- Child's physical care (e.g. cleanliness, teeth, hair, nails, hygiene)
- Child's behaviour (e.g. frozen hyper-vigilance or aggressive hyperactivity)
- Parents/caretaker's behaviour and demeanour (e.g. low self-esteem, depressed, over-anxious, insensitive, careless, punishing, defensive).

Although abuse and/or neglect may already have occurred, an opportunity is available for healthcare professionals to recognize

and respond to the situation. In the long-term this can prevent the child and sometimes the mother from experiencing further incidences of abuse and/or neglect which increase in severity with time (Browne & Hamilton, 1999; Hamilton & Browne, 1999).

Therefore, tertiary prevention offers services to children and families where abuse and/or neglect have already occurred. Reactive surveillance and identification of abused and/or neglected children leads to intervention both to stop the current maltreatment and to prevent recurrent victimization. The poor cost-effectiveness of tertiary prevention is highlighted by a study of police child protection units in England which showed that one in four children identified as victims of child maltreatment were referred again within a 27-month follow-up period, despite social service interventions following the initial referral (Hamilton & Browne, 1999).

Conclusion

Any involvement of health professionals in child protection must be seen in the broader context of multi-disciplinary networking and referral processes, preferably organized through a local child protection coordinating committee. The prevention of child abuse and neglect needs to take into account the United Nations Convention on the Rights of the Child (UNCRC, 1989). This requires all member states to offer effective child protection services placing the rights of the child and their best interests above those of adults, including the child's own parents. This notion is reflected in the UK Children Act (1989, 2004), which considers the child's welfare as paramount.

It is the child's right under international legislation to grow and develop in a family environment, preferably raised by their biological parents. Therefore, health and social services should be available to all parents in order to support those who are failing to cope with the demands of parenting. Where the child is in danger or their social, emotional and developmental needs are not being met, intervention is required. Family rehabilitation can be achieved often by working with the family in their home but sometimes short-term foster care is necessary where the foster carer acts as a role model to the parents. Only when the parent is assessed as not responding to intervention, or is unable to change within the developmental time frame of the child, should long-term alternatives (i.e. long-term fostering or adoption) be considered. Under no circumstances should young children (either with a disability or not) be placed in residential care institutions (including the use of maternity/paediatric units as a social care facility) without a primary caregiver as this has been shown, as with neglect situations, to have significantly detrimental effects on brain development (Glaser, 2000). Consequently, problems in the development of self and social relationships with others persist in those children who have grown up in institutional care (Browne *et al.*, 2005). Ministries of Health are predominantly responsible for residential care of children less than three years old and currently there are 23 000 young children living in institutions within the European Union (including accession countries) for more than three months without their parents (Browne *et al.*, 2005). Hence, the health sector has a large role to play in the prevention of child maltreatment both within families and within institutions.

Chromosomal abnormalities

Jeremy Turk

St. George's, University of London

Introduction

Genetic influences on psychological functioning are well established (McGuffin *et al.*, 2004). A multifactorial interactional model between polygenic inheritance and environmental experience is most commonly proposed. However, many single gene anomalies have characteristic psychological profiles.

The term 'behavioural phenotype' (O'Brien, 2002) describes aspects of psychological functioning attributable to a discrete underlying genetic anomaly, even when other contributors such as age, gender and social background are accounted for. The first published use of the term was by Nyhan in his proposal of an association between the inborn error of metabolism and severe self-mutilation in Lesch–Nyhan syndrome (Nyhan, 1972). Nyhan also reported behaviours characteristic of Cornelia de Lange syndrome including self-injury, hyperactivity and autistic features (Berney *et al.*, 1999).

Somewhat earlier, Langdon Down described characteristic personality traits in individuals with Down syndrome including strong powers of imitation, a lively sense of humour, obstinacy and amiability. Research confirms greater similarity of personality and temperament between people with Down syndrome than expected by chance (Nygaard *et al.*, 2002). It also confirms increased risks of Alzheimer's dementia (Holland *et al.*, 2000) and depression (Collacott *et al.*, 1998).

Clinical considerations

Information on psychiatric, psychological and behavioural functioning can be categorized into:

- intellectual functioning
- speech and language
- attentional deficits and impulse control

- social functioning and understanding
- other behavioural disturbances

Intellectual functioning

Intellectual abilities in those with a particular condition can vary widely. People with Down syndrome usually have moderate-to-severe intellectual disability, while those with fragile X syndrome usually have mild-to-moderate intellectual disability (Cornish *et al.*, 2004b). Profile of intellectual functioning varies too. Individuals with fragile X syndrome and Turner's syndrome commonly experience numeracy and visuospatial difficulties. Children with velocardiofacial (VCF) syndrome, caused by a chromosome 22 microdeletion (Murphy, 2004), also typically attain higher verbal than performance IQ scores. Individuals with Klinefelter's syndrome, who have one Y and two X sex chromosomes, usually have language problems.

Speech and language

Speech may be entirely absent as in Angelman syndrome (Clayton-Smith & Laan, 2003), of particular quality as in fragile X syndrome (jocular, litanic, perseverative, cluttered) (Cornish *et al.*, 2004a) or characterized by particular deficits such as the expressive language impairments in Klinefelter's syndrome (Mandoki *et al.*, 1991). Individuals with Williams syndrome are characteristically superficially grammatically correct with complex and fluent expressive language which may lead to over-estimation of general intellectual ability (Metcalfe, 1999).

Attentional deficits

Attentional deficits range from mild inattentiveness and distractibility through to severe hyperkinesis. Some conditions show specific associations, for example fragile X syndrome (Turk, 1998), Turner's

syndrome (Rovet & Ireland, 1994) and Sanfilippo syndrome (Bax & Colville, 1995).

Social impairments

Social difficulties are common in people with intellectual disability. They may present as shyness and social anxiety as in fragile X syndrome. Their significance is magnified when associated with language disorders and ritualistic/obsessional tendencies indicative of an autistic spectrum disorder. Autistic features are pronounced in many individuals with fragile X syndrome (Turk & Graham, 1997) and tuberous sclerosis (Baker *et al.*, 1998).

Other behavioural disturbances

Self-injury is common and troublesome for many people with severe intellectual disability. Its nature ('topography') is surprisingly syndrome-specific. People with Lesch-Nyhan syndrome display skin scratching, lip biting and knuckle gnawing (Robey *et al.*, 2003). Those with fragile X syndrome usually bite at the base of their thumb in response to anxiety or excitement (Symons *et al.*, 2003). Smith-Magenis syndrome (17p11.2 deletion) is associated with usually mild-to-moderate intellectual disability, but particularly extreme self-mutilation including pulling out finger nails (onychotillomania) and inserting objects in to bodily orifices (polyemolokoilomania) (Sarimski, 2004). It is also associated with extreme sleep disturbance and hyperactivity (see 'Hyperactivity').

A general review of behavioural phenotypes

Behavioural phenotype syndromes can relate to anomalies throughout the human genome.

Sex chromosome anomalies

Turner's syndrome (45X)

Short stature and infertility are usually associated with average intellectual functioning, although IQ mean and distribution are shifted downwards slightly. There is a verbal/performance discrepancy with relative language strengths but special needs in numeracy and visuospatial abilities as well as social relationship and social competency problems and attentional deficits (McCauley *et al.*, 2001).

Klinefelter's syndrome (47XXY)

Speech and language impairments belie relatively intact non-verbal skills. Characteristically speech and language development is delayed with visual-motor and sensory integration problems (Mandoki *et al.*, 1991). Mean full scale IQ is in the low 90s (Bender *et al.*, 1999).

XXY syndrome

Up to half of people with XYY syndrome have language and reading difficulties, delayed motor development and psychosocial problems (Geerts *et al.*, 2003). Antisocial behaviour is rare though temper tantrums, impaired social relationships and oppositional or conduct disorders are common. Intelligence is usually average.

Fragile X syndrome

Fragile X syndrome is the most common identifiable inherited cause of intellectual disability (Hagerman & Hagerman, 2002). Abnormal DNA enlargement on the X chromosome expands transgenerationally, interfering with production of a protein critical for normal neurodevelopment. Mild to moderate intellectual disability (IQ 35–70) is usually associated with numeracy and visuospatial deficits. Rates of intellectual development parallel those of non-disabled peers until puberty when discrepancies widen, due to sequential information processing problems. Female 'carriers' may have a full mutation (greater than 200 DNA repeats) or a pre-mutation where repeat length is approximately 50–200. Intellectual anomalies occur in female carriers, being more severe with full mutations (Franke *et al.*, 1996). Social, language and attentional deficits arise. Female carriers experience early menopause with premature ovarian failure and may also develop an adult tremor-ataxia syndrome (Hagerman & Hagerman, 2004). This also occurs in adult pre-mutation males.

Speech and language are usually delayed and distorted with echolalia, repetitive and perseverative utterances and cluttering; a combination of rapid and disrhythmic language. Talking often sounds humorous with up-and-down pitch swings.

Attentional deficits and overactivity are common and challenging. Comparison with non-fragile X intellectually disabled peers confirms higher levels of inattentiveness, restlessness and fidgetiness in boys with fragile X, even if gross motor activity levels are less remarkable (Turk, 1998). Unlike non-fragile X peers, those with fragile X do not tend to improve spontaneously with age, emphasizing the need for early identification and treatment.

Up to 30% of males have autism. Many more show communicatory and ritualistic impairments with a friendly and sociable, albeit shy and socially anxious, personality (Turk & Graham, 1997). Common features include delayed echolalia, repetitive speech, hand flapping, hand biting in response to anxiety or excitement, gaze aversion, preference for routine and sameness, sensory defensiveness and delayed development of symbolic and imaginative play.

Autosomal chromosome disorders

Down syndrome

Down syndrome is the most common cause of intellectual disability. Apart from the rare translocation variety it always occurs as new mutations producing trisomy 21, the major risk factor being increasing maternal age. Given the mean level of intellectual functioning, in the moderate-severe intellectual disability range, rates of autistic spectrum disorder and attention deficit-hyperactivity disorder are surprisingly low. However autistic spectrum disorder does occur in as many as 10% of people with Down syndrome and diagnosis is often considerably delayed (Rasmussen *et al.*, 2001). Hyperactive behaviours occur in up to 50%. Alzheimer's dementia has a markedly raised incidence and must be distinguished from depression (Collacott *et al.*, 1998), 'challenging behaviour', and psychological reactions to life events.

Tuberous sclerosis

Tuberous sclerosis is a common and incapacitating cause of intellectual disability associated with three different genetic anomalies.

75–80% experience infantile spasms with a chaotic disorganized EEG ('hypsarrhythmia'). Number and size of pathological brain tubers are associated with degree of intellectual disability (O'Callaghan *et al.*, 2004). Their presence in temporal lobes is associated with autistic spectrum disorders (Baker *et al.*, 1998). Hyperactivity is common and relates to degree of cerebral damage and intellectual impairment.

Williams syndrome

Idiopathic hypercalcaemia is caused by a chromosome 7 microdeletion. Speech and language anomalies are universal, yet many show superior verbal skills compared to visuospatial and motor abilities (Atkinson *et al.*, 2001). Hyperacusis (dislike of loud or intense sounds) is common. Full scale IQ is usually in the 50s or 60s. Rates of behavioural disturbance are high, particularly hyperactivity, anxiety and eating and sleeping difficulties (Metcalf, 1999).

Angelman and Prader–Willi syndromes

Angelman and Prader–Willi syndrome demonstrate the significance of chromosomal imprinting, whereby parental inheritance of the affected chromosome is all important. Both are caused by anomalies on the long arm of chromosome 15. Prader–Willi syndrome results from inheritance of a paternal chromosome 15 microdeletion, or from inheritance of two maternal chromosome 15s. The consequence is infantile floppiness, poor feeding, weak or absent cry and failure to thrive, with expressive language and articulation problems. Compulsive over-eating and gross obesity develop unless strict behavioural eating programmes and severe restrictions of food availability are maintained. There is absence of satiety and lack of the usual need to vary nature of food consumed in order to maintain interest in eating. Challenging behaviours include skin picking, stubbornness and temper outbursts in response to frustration combined with decreased pain sensitivity. Visuospatial skills are good, yet numeracy and short-term memory are areas of special need (Donaldson *et al.*, 1994). Intellectual functioning varies widely and there is liability to cyclical mood disorders (Descheemaeker *et al.*, 2002). Common sleep problems include sleep apnoea, snoring, early waking and excessive daytime sleepiness (see 'Sleep apnoea').

Angelman syndrome problems arise from inheritance of maternal chromosome 15 microdeletions, or inheritance of two paternal chromosome 15s. Individuals usually have severe intellectual disability with a happy disposition, paroxysmal laughter, jerky ataxic gait, sleep problems and tendency towards an open mouth (Clayton-Smith & Laan, 2003). Epilepsy occurs in over 80% and can take any form although atypical absences and myoclonic seizures are most common in adulthood (Laan *et al.*, 1997). Autistic features

with marked aloofness and passivity are common with substantially delayed social and communication skills (Peters *et al.*, 2004).

Disorders ascertained initially on basis of behavioural and developmental profiles

Many conditions have been described with developmental and behavioural profiles sufficiently characteristic to convince one of a behavioural phenotype's presence. Increasingly these are found to have underlying genetic anomalies. An example is Rett's syndrome where manifestation in females only was explained by X-linked inheritance with lethality for males who lack a healthy X chromosome (Colvin *et al.*, 2003). Following relatively unremarkable early development, intellectual and social decline commences at 6–12 months with subsequent levelling off of abilities. Autistic, social and communicatory impairments are common (Mount *et al.*, 2003). There is loss of purposeful hand movements, midline hand-wringing, hyperventilation, breath-holding, bruxism and tremulousness. The gene responsible (MECP2) is located on the X chromosome's long arm. Over 90% have epilepsy with frequent seizures (Steffenburg *et al.*, 2001).

Sotos syndrome (chromosome 5 long arm microdeletion) has behavioural associations with classic physical features of excessively rapid growth, and intellectual disability. Hyperactivity, clumsiness and poorly articulated speech occur (Rutter & Cole, 1991). There may also be social difficulties and emotional and behavioural disturbance including tantrums, sexual precocity, sleep problems, anxious behaviour, object phobias and attention deficits (Sarimski, 2003).

The importance of diagnosis (Turk, 2004)

Individuals and families have a right to know the exact natures and causes of their disabilities. Outdated notions that diagnosis produces negativism, inertia and suspension of efforts to overcome disadvantage have been superseded by awareness of how important such labels are in facilitating grief reactions, dissipating inappropriate guilt and anger, orientating families towards helpful and appropriate supports and interventions, and allowing them to relate to appropriate support groups (Carmichael *et al.*, 1999). Successful grief resolution enables focussing on the future, adjusting individual and family life accordingly, and planning ahead. Crucial genetic counselling can often be offered to extended families following successful diagnosis. Diagnostic awareness also allows for more rational interventions relevant to individuals' particular profiles of strengths and needs.

Chronic fatigue syndrome

Ruth Cairns and Trudie Chalder

King's College London

Introduction and definitions

Fatigue is a very common complaint but is typically transient, self-limiting or explained by other circumstances. Chronic fatigue syndrome (CFS) is characterized by persistent or relapsing unexplained fatigue of new or definite onset lasting for at least six months. It is not a new condition and corresponds very clearly to an illness called neurasthenia, commonly seen in Europe around the turn of the twentieth century (Wessely *et al.*, 1998). The terms 'myalgic encephalomyelitis' (ME) and 'post-viral fatigue syndrome' have also been used to describe CFS but are misleading and unsatisfactory: ME implies the occurrence of a distinct pathological process whereas post-viral fatigue syndrome wrongly suggests that all cases are preceded by a viral illness.

Operational criteria developed for research purposes by the US Centres for Disease Control and Prevention (CDC) (Fukuda *et al.*, 1994) and from Oxford (Sharpe *et al.*, 1991) are now widely used to define CFS. The American criteria require at least six months of persistent fatigue causing substantial functional impairment and at least four somatic symptoms (from a list of eight) occurring with the fatigue in a 6-month period. The presence of a medical disorder that explains the prolonged fatigue excludes a patient from a diagnosis of CFS, as do a number of psychiatric diagnoses. Although the British definition is similar it differs by requiring both physical and mental fatigue but no physical symptoms. By including a requirement for several physical symptoms, the American definition reflects the belief that an infective or immune process underlies the syndrome.

Aetiology

The prevalence of CFS has been reported as 0.1–2.6% in community and primary care-based studies, depending on the criteria used (Wessely *et al.*, 1997). Women are at higher risk than men (Relative risk 1.3–1.7) (Wessely, 1995). In relation to aetiology, physiological and psychological factors are thought to work together to predispose an individual to CFS and to precipitate and perpetuate the illness (Afari & Buchwald, 2003). For example, many patients link the onset of their symptoms to infection and while it is unlikely that serious viral illness acts as a continuing focus of infection in CFS, it is known to trigger its onset in some individuals (Cleare & Wessely, 1996). Other risk factors for developing CFS include previous psychological illness (Wessely *et al.*, 1998), and severe life events or difficulties in the months before onset (Hatcher & House, 2003; see 'Life events and health').

A wide range of factors may act to perpetuate chronic fatigue. Coping responses to acute fatigue are important determinants of

prolonged fatigue: extreme physical activity after an acute illness may allow insufficient time for recovery whereas prolonged bed rest may cause physical deconditioning and further exacerbate symptoms. Illness beliefs and the attribution of symptoms to a physical cause, with minimization of psychological or personal contributions, are also important and have been related to increased symptoms and worse outcomes in CFS (Wilson *et al.*, 1994; see 'Illness perceptions'). Similarly, catastrophic beliefs that exercise will be damaging or will worsen symptoms lead to the avoidance of physical and mental activities and greater disability (Petrie *et al.*, 1995). Disrupted sleep patterns resulting from excessive daytime rest may contribute to fatigue, muscle pain and poor concentration.

The response and attitudes of others are also important in determining the course of fatigue. Overly concerned carers may reinforce patients' maladaptive beliefs and coping strategies by inadvertently encouraging disability. Sceptical or stigmatizing reactions from relatives, health professionals or work colleagues can cause frustration and leave the patient feeling isolated and unsupported (Deale & Wessely, 2001; Van Houdenhove *et al.*, 2002; see 'Stigma').

Diagnosis

There are no diagnostic signs or symptoms of CFS. The clinical evaluation of chronically fatigued patients is aimed at excluding underlying medical or psychiatric causes of fatigue. In individuals with fatigue of more than six months duration a thorough history, physical examination, routine laboratory tests (full blood count, ESR, renal, liver and thyroid function and urinary protein and glucose) and mental state examination are sufficient to reach a diagnosis of CFS in most cases. Where abnormalities are revealed on physical or laboratory investigation, further investigations can be helpful to help establish alternative diagnosis but should otherwise be limited to avoid the risk of iatrogenic harm. Specialist referral should be limited to situations where there is an increased probability of an alternative diagnosis.

The relationship between CFS and psychiatric illness is more complex. Fatigue is a common symptom in mental illness and where an individual's fatigue is fully explained by a specific psychiatric disorder, a diagnosis of CFS should not be made. However, psychiatric co-morbidity (particularly with depressive, somatoform and anxiety disorders) is also common and when present should be diagnosed and treated in addition to the symptoms of CFS. This does not mean that psychiatric disorders are the cause of CFS and indeed a substantial minority of patients do not fulfil criteria for any psychiatric diagnosis (Wessely *et al.*, 1998).

Treatment

The evidence suggests that the most effective treatments for CFS are cognitive behavioural therapy (CBT) and graded exercise therapy (see chapters on 'Cognitive behavioural therapy' and 'Exercise interventions'). The CBT model attempts to incorporate the heterogeneous nature of the condition and stresses the role of perpetuating factors (Wessely *et al.*, 1991). The treatment for CFS therefore involves planned activity and rest, graded increases in activity, a sleep routine and cognitive restructuring of unhelpful beliefs and assumptions. One systematic review showed that CBT administered in specialist centres by skilled therapists led to improved physical functioning and quality of life compared with relaxation therapy or standard medical care (Price & Couper, 2002). In addition, a multi-centre randomized controlled trial (RCT) involving less experienced CBT therapists has reported improvements in fatigue severity and self-reported fatigue compared with guided support and no treatment (Prins *et al.*, 2001).

Graded aerobic exercise involves a structured exercise programme that is individually tailored to the patient's current level of activity and aims to gradually increase his or her aerobic activity. The exercise is usually walking and patients are advised not to exceed the prescribed exercise duration or intensity. RCTs evaluating graded exercise therapy have found that it improves measures of fatigue and physical functioning compared with flexibility training and relaxation training or general advice (Reid *et al.*, 2004).

There is insufficient evidence to suggest that antidepressants, corticosteroids or other pharmacological agents are beneficial in the treatment of CFS and no reliable evidence that dietary supplements, evening primrose oil or intra-muscular magnesium are

helpful (Reid *et al.*, 2004). Prolonged rest cannot be recommended as a treatment for CFS and may actually perpetuate or increase fatigue in people recovering from a viral illness. A review of treatments for CFS reported both limited benefits and substantial adverse effects with immunoglobulin therapy (Rimes & Chalder, 2005). There is insufficient evidence for the use of interferon as an effective treatment for CFS.

Prognosis

CFS is not associated with an increased mortality rate and rarely constitutes a missed medical diagnosis when an attempt has been made to exclude organic illness prior to making the diagnosis. A recent systematic review of studies describing the prognosis of CFS identified 14 studies that used operational criteria to define cohorts of patients with CFS (Cairns & Hotopf, 2005). Full recovery from untreated CFS is rare and an improvement in symptoms is a more commonly reported outcome than full recovery. The median full recovery rate was 5% (range 0–31%) and the median proportion of patients who improved during follow-up was 39.5% (range 38–64%). Less fatigue severity at baseline, a sense of control over symptoms and not attributing illness to a physical cause were all associated with a good outcome. Psychiatric disorder was associated with poorer outcomes. The review looked at the course of CFS without systematic intervention but as reported above there is now increasing evidence for the effectiveness of cognitive behavioural and graded exercise therapies. Further research is necessary to explore the prognosis of CFS after such treatment has been given.

Chronic obstructive pulmonary disease (COPD): chronic bronchitis and emphysema

Ad A. Kaptein and Klaus F. Rabe

Leiden University Medical Centre

Chronic bronchitis and (pulmonary) emphysema are two respiratory disorders with similar patterns of symptoms: shortness of breath (dyspnea), sputum production, coughing and chest tightness. The two disorders also share important aetiological and pathophysiological characteristics (smoking tobacco, inflammation and destruction of lung tissue). For these reasons, chronic bronchitis and emphysema increasingly are combined into the concept of chronic obstructive pulmonary disease: COPD.

Chronic bronchitis is defined in behavioural terms: 'the presence of cough and sputum production for at least three months in each of two consecutive years' (GOLD, 2001, p. 7). Emphysema is defined in pathological terms: 'destruction of the gas-exchanging surfaces of the lung (alveoli)' (GOLD, 2001, p. 7). Chronic obstructive pulmonary disease is defined as 'a disease state characterized by airflow limitation that is not fully reversible. The airflow limitation is usually both progressive and associated with an abnormal inflammatory response of the lungs to noxious particles or gases' (GOLD, 2001, p. 6; www.goldcopd.com).

The prevalence of physician-diagnosed COPD is about 2% for men and 1.5% for women. Differences in prevalence per country or region are attributable to a large extent to differences in the prevalence of cigarette smoking (see 'Tobacco use'). Morbidity in terms of hospitalization, physician visits, emergency department visits, is substantial. Socio-economic costs in terms of absenteeism from work, early retirement and medical care are impressive. The quality of life of COPD patients is severely impaired (Maillé *et al.*, 1996). The Global Burden of Disease Study predicts that in 2020 COPD will reach fifth rank in terms of disability-adjusted life-years and third in leading causes of death (Murray & Lopez, 1997). Given its prevalence and impact, research on COPD is relatively underfunded, compared with such conditions as AIDS and breast cancer (Gross *et al.*, 1999; Pauwels & Rabe, 2004).

Psychology and COPD

In contrast to patients with asthma (see 'Asthma'), patients with COPD have only recently become an object of study and care by psychologists. The first study by psychologists on COPD patients examined 'basic personality traits characteristic of patients with primary obstructive pulmonary emphysema' (Webb & Lawton, 1961). The issue of personality characteristics and trait-like phenomena continued to be the focus of early psychological and psychiatric research about patients with COPD. Agle & Baum (1977) used a psychiatric interview for that purpose within male patients enrolled in a pulmonary rehabilitation programme, and found relatively high

levels of anxiety ('respiratory panic'), depression, body preoccupation, alcohol problems and sexual dysfunctions. Some thirty years later, similar results were reported: hospitalized COPD patients and a community-based COPD sample reported 58% and 43% prevalence of psychological distress, respectively, compared with 4% for a healthy control group and 14% for a sample with various chronic illnesses (Andenæs & Kalfoss, 2004).

A second line of research pertained to examining the neuropsychological consequences of COPD. Compared with age- and education-matched healthy controls, hypoxemia in COPD patients was found to be associated with neuropsychological deficits (e.g. complex perceptual motor performance, simple motor tasks and abstracting ability; Grant *et al.*, 1982).

A third research line was developed on illness behaviour in COPD patients. Kinsman and his colleagues were the first to assess the emotional and cognitive responses in patients with chronic bronchitis and emphysema towards their disorder (Kinsman *et al.*, 1983). They employed a symptom checklist, based on patient interviews. In descending order of frequency, the patients reported dyspnea, fatigue, sleep difficulties, congestion, irritability, anxiety, eating difficulties, helplessness/hopelessness, poor memory and alienation as consequences of their respiratory problems. These findings helped in extending earlier work (e.g. Agle & Baum, 1977) and refining psychological assessment in patients with COPD. They were also instrumental in informing the fourth line of psychological research in patients with COPD; i.e. quality of life.

Empirical and theoretical work about quality of life in patients with COPD became of age in the 1980s (see 'Quality of life'). In Canada, Guyatt and colleagues developed the Chronic Respiratory Disease Questionnaire (CRDQ; Guyatt *et al.*, 1987), and, in the UK, Jones and colleagues developed the St. George's Hospital Respiratory Questionnaire (SGRQ; Jones *et al.*, 1992). The CRDQ assesses dyspnea, fatigue, emotional function and mastery. The SGRQ has three component scores: symptoms; activity; and impacts on daily life; and a total score. The dimensions in both questionnaires reflect the dimensions identified by Kinsman and colleagues, and the functional effect of COPD and its consequent therapy upon a patient, as perceived by the patient. It is striking to observe the high number of biomedical publications on the topic of COPD that now include quality of life measures. 'Quality of life resources' is one of the components of the website of the American Thoracic Society (www.thoracic.org), and quality of life has become a secondary outcome measure in many studies, and a primary outcome measure in a few (Bateman *et al.*, 2004). This would have been unheard of even ten years ago

(Kaptein *et al.*, 1993). Quality of life and patient reported outcomes are two concepts that have built bridges between biomedical respiratory scientists, respiratory clinicians and behavioural scientists (Curtis *et al.*, 1997).

Pharmacological treatment is in itself not always effective in controlling COPD. Pulmonary rehabilitation – the fifth topic of psychological research in the COPD field – is intended to supplement medical interventions. ‘Pulmonary rehabilitation is a multidisciplinary programme of care for patients with chronic respiratory impairment that is individually tailored and designed to optimize physical and social performance and autonomy’ (ATS, 1999, p. 1666). It combines pharmacological treatment with a set of other components, such as physical therapy that encourages exercise training and more effective breathing and coughing techniques, education (for patients, partners, family), together with psychosocial and behavioural interventions. It is only recently that psychologists have become involved with pulmonary rehabilitation. This coincides with psychology’s emerging role in COPD research in general. Initially, physical rehabilitation was the focus in such programmes: exercise training; physical therapy; breathing exercises; pursed lip breathing; and smoking cessation. Patient education consisted of patients passively listening to classes about anatomy and physiology of lungs and breathing. Increasingly, components such as discussing the emotional impact of COPD, consequences for the partner, sexuality and coping skills training were added to pulmonary rehabilitation programmes. Meta-analyses indicate positive effects of pulmonary rehabilitation on exercise capacity, breathlessness, quality of life, number of hospitalizations, length of hospitalization and reductions in anxiety and depression (GOLD, 2001; Lacasse *et al.*, 2003).

A number of medical interventions in COPD patients have not yet been evaluated extensively. The effects of improving nutritional status in patients with more severe stages of COPD are currently being studied (Wouters, 2004). Psychological research on this topic is virtually lacking. Oxygen therapy is given to patients with severe COPD. A systematic review indicated that oxygen therapy can influence mortality positively in selected categories of patients (Crockett *et al.*, 2001). Lung volume reduction surgery (LVRS) intends to reduce the volume of lung tissue that is not involved with gas exchange, thereby improving oxygenation and exercise capacity. Its effects are still uncertain, although there is some evidence that LVRS positively affects exercise capacity and quality of life (GOLD, 2001). Large randomized controlled trials are in progress, with quality of life as a major outcome measure (Kaplan *et al.*, 2004). Increasingly, lung transplantation is perceived by patients with end-stage COPD as a form of miracle surgery. These perceptions, however, are not borne out yet; the number of donor organs is one major limiting factor. Moreover, long-term effects on survival, exercise capacity and quality of life are uncertain, and the costs are substantial (Studer *et al.*, 2004).

A sixth major area of psychological research in COPD pertains to smoking cessation. Although patients with COPD may prefer a technological and medical approach to their breathing problems, evidence points out that ‘cigarette smoking is the major cause of COPD in the world, and smoking cessation is the only therapeutic intervention so far shown to reduce disease progression’ (Barnes & Hansel, 2004, p. 985). Smoking cessation is the area where psychology’s contribution to care for COPD patients

is clearly evident: the Transtheoretical Model of Behaviour Change and evidence-based smoking cessation intervention programmes are included in international guidelines on the management of COPD (see ‘Transtheoretical model of behaviour change’). Intensive behavioural programmes (relapse prevention) combined with various types of pharmacotherapy (including antidepressants) and nicotine replacement products are usually part of stop smoking interventions (Wagena *et al.*, 2004) (see ‘Tobacco use’). Relatively short-term (6–12 months) abstinence rates are around 10% (Wagena *et al.*, 2004). COPD patients tend to be very resistant when it comes to giving up smoking. A COPD patient’s plea is a strong reminder of this: ‘I’ll do whatever you say, take my medications every day, I’ll exercise three times a week, practice my belly breathing technique – just don’t take my cigarettes away’ (Berry, 2001).

Therapeutic pessimism among physicians, psychologists and patients, about therapeutic gains from any intervention (except giving up tobacco use) has recently and gradually moved towards a cautiously more optimistic outlook. Psychological interventions in COPD patients contributed to this change (Kaptein, 2002). Self-management interventions for COPD patients represent the seventh major field of study, and it seems a promising line of research and intervention (Kaptein, 1997) (see ‘Self-management’). The study by Atkins *et al.* (1984) was one of the very first studies in this area. Its theoretical and methodological standards are very high, and its results are encouraging. In the study, a cognitive-behavioural intervention was applied to outpatients with COPD. In a randomized controlled design, the intervention’s effects were assessed on quality of life and exercise capacity, with various control conditions. The cognitive-behavioural intervention consisted of challenging pessimistic and passive cognitions, and replacing them by more positive and constructive self-statements, a physical exercise programme and home visits by trained psychology students. Results indicate the superiority of the cognitive-behavioural intervention condition over the other conditions on the major outcome variables (see ‘Cognitive behaviour therapy’). Cochrane reviews of this area, however, indicate that more research is needed before generalizations about positive effects of self-management techniques can be made (Monninkhof *et al.*, 2003).

Closing remarks

In line with the groundbreaking work by Atkins *et al.* (1984) in COPD, further research is required on behavioural-cognitive interventions in COPD. Theoretical models such as the Self Regulation Model seem helpful in guiding empirical work on the identification of maladaptive illness perceptions and examining the effects of changing them (Scharloo *et al.*, 2000) (see ‘Lay beliefs about health and illness’). Other areas of psychological research which need further exploration are smoking cessation programmes, refinements in assessment of psychological issues in COPD patients, for example, disease specific feelings of depression, sexuality and refinement of psychological assessment and interventions in the context of pulmonary rehabilitation.

A virtually neglected area is the image of COPD in the society at large (Viney, 1989). Work on illness cognitions seems to indicate a quite strong sense of self-blame among COPD patients

about their own behaviour in relation to respiratory problems (Kaptein *et al.*, 2003). Not every smoker of cigarettes develops COPD, however, and not every COPD patient is, or was, a smoker. A better image of COPD may help boost feelings of self-esteem in

afflicted patients and thereby improve their quality of life. The COPD initiative and the COPD alliance of the American Thoracic Society are excellent steps in this direction (www.goldcopd.com; www.thoracic.org).

Cleft lip and palate

Brent Collett and Matthew Speltz

University of Washington School of Medicine

Orofacial clefts are openings in the lip or roof of the mouth that result from arrested embryonic development in the first trimester. They are among the most common congenital malformations, with an incidence of 1 to 2 per 1000 live births (Derijcke *et al.*, 1996). Presentations include cleft lip only (CLO), cleft palate only (CPO) and cleft lip and palate (CLP). Clefts can also be categorized as 'unilateral' or 'bilateral' (involving one or both sides of the lip and/or palate), and 'incomplete' or 'complete' (involving only the soft palate versus both the soft and hard palates, and/or involving only the lip versus the lip and gumline). Most clefts are 'nonsyndromic', meaning that they are not associated with other malformations. Although aetiology remains unclear, most cases are believed to result from a combination of genetic vulnerability and prenatal exposures (e.g. tobacco, anticonvulsant medications), possibly interacting with maternal nutritional status (Prescott & Malcolm, 2002).

Clefts of the lip and palate can be detected by ultrasound in utero. Though this technology is developing rapidly, many cases are missed and often the diagnosis is not made until birth (see 'Screening: antenatal' and 'Foetal wellbeing'). During the neonatal period, most families are referred to a specialty hospital-based clinic for management of their child's care. Surgical repair of the cleft lip is typically undertaken by age 5 months, followed by cleft palate repair when children are 12–18 months old. Subsequent procedures and surgical revisions are scheduled according to patients' needs (see 'Reconstructive and cosmetic surgery'). Frequently encountered medical complications include difficulty in feedings, poor physical growth, velopharyngeal insufficiency (i.e. incomplete closure of the velopharyngeal sphincter, resulting in 'nasal' speech and/or regurgitation during feeding), chronic otitis media, orthodontic concerns and airway obstruction.

Psychological research with cleft populations dates back to the 1950s, with primary interest in social-emotional outcomes. The highly visible and stigmatizing nature of these conditions, in addition to the stress associated with multiple medical procedures during the early years, have prompted researchers to hypothesize that children with clefts have elevated risk for poor psychological and social adjustment. Research has focused on parents' emotional responses to having a child with a deformity; the quality of parent-child relationships; and children's social, emotional and behavioural functioning (see also 'Facial disfigurement'). Investigators have also studied the cognitive, language and academic development of youngsters with orofacial clefts and the related factors that contribute to these areas of functioning. The interdependent development of the face and central nervous system has generated interest in abnormal brain structures and/or functions that may predispose children with clefts to neuropsychological problems.

In this chapter, the research on parents' adjustment to their child's cleft diagnosis and the psychological and neurodevelopmental functioning of children with clefts will be reviewed. Implications of this research for clinical care and directions for future studies are also discussed.

Psychological and neurodevelopmental functioning

Parental adjustment

Qualitative studies have shown that many parents experience a period of bereavement after their child's birth, accompanied by a search for information about the cause and broader implications of their infant's cleft condition. Parents may develop idiosyncratic beliefs regarding the aetiology of the disorder including pseudo-medical explanations (e.g. pre-natal stress, medications used) and spiritual attributions (e.g. punishment for parental transgressions; Tisza & Gumpertz, 1962) (see also 'Attributions and health'). In survey studies, parents have expressed dissatisfaction with the manner in which their child's cleft diagnosis was provided and the information they received from medical providers in response to questions about the developmental and medical consequences of their child's condition (Strauss *et al.*, 1995).

In one study, the mothers of children with various craniofacial disorders (including orofacial clefts) reported higher levels of parenting stress, lower evaluations of self-competence, and higher levels of marital conflict than did the mothers of typical children (e.g. Speltz *et al.*, 1993). However, other studies have not supported the hypothesis that parents of children with clefts have more difficulties than do parents of non-cleft infants.

Parent-child relationships

Researchers have examined parents' and children's mutual responsiveness and social engagement during interaction, as well as the quality of the relationship as indexed by observations of attachment behaviours (e.g. using the Ainsworth 'Strange Situation'; see Speltz *et al.*, 1997). Some studies suggest that infants with clefts and their parents are less active, playful and responsive during parent-child interactions than are controls (Barden *et al.*, 1989). However, few differences in attachment behaviours between infants with clefts and control infants have been found.

Studies of toddler/preschooler-parent dyads have also produced variable findings, with some investigators reporting that the mothers of children with clefts show elevated levels of engagement and direction during interaction (e.g. Allen *et al.*, 1990). Although studies of parent-adolescent relationships in the cleft population are

lacking, this is a promising area of investigation, given the increasing involvement in medical decision-making of youth at this age (e.g. whether or not to pursue further cosmetic surgery) and its potential stress on the relationship.

Children's psychosocial functioning

Orofacial clefts have a stigmatizing social effect on children with this condition, as indicated by numerous studies of peer and adult perceptions. Children with clefts are consistently rated as less attractive and are described in less desirable terms than non-affected peers; findings that parallel those obtained in studies of typical children's physical attractiveness and observers' social perceptions. Even in the absence of a cleft lip, raters are able to detect the subtle craniofacial anomalies associated with 'invisible' clefts of the palate (e.g. mid-facial retrusion, orbital hypertelorism; Speltz *et al.*, 1997). Studies have also investigated social attributions based on speech samples of children with clefts. Data on this issue are mixed, with early studies showing that children with clefts were rated as less preferred by peers based on their speech and more recent studies failing to show such an effect (Berry *et al.*, 1997).

Research on the emotional and behavioural adjustment of children with clefts has produced conflicting results. The most commonly reported finding, based primarily on work by Richman *et al.* (e.g. Millard & Richman, 2001), is that children with clefts are more socially inhibited than controls, particularly in the classroom. Consistent with this description, findings from an observational study showed that preschoolers with clefts showed greater emotional restraint than non-cleft peers (Endriga *et al.*, 2003). Adults with clefts have been found to report lower quality of life in multiple domains than comparison groups (e.g. Marcusson *et al.*, 2001), an outcome often associated with a socially reclusive lifestyle.

It has been hypothesized that children with clefts are more likely than typical children to form negative self-perceptions, as they 'internalize' the presumably negative social responses of others (e.g. in relation to their anomalous physical appearance or speech). Commonly assessed domains of self-perception include appearance, friendships, problem-solving ability and intellectual competence. Children with 'visible' clefts (i.e. those with CLO and CLP) have reported poorer self-concept with regard to physical appearance than those with 'invisible' clefts of the palate only (Broder *et al.*, 1994). However, few differences are found in other dimensions of self-perception. Indeed, in some studies children and adolescents with clefts have reported higher levels of self-concept in some domains (e.g. satisfaction with friendships, problem-solving and intellectual competence; Broder *et al.*, 1994), a finding that may reflect a defensive response set.

Neuropsychological and academic outcomes

Research on early motor and mental development suggests that infants and toddlers with clefts lag slightly behind their peers on standardized measures, and have a higher than expected percentage score in the 'developmentally delayed' range (Kapp-Simon & Kruckeberg, 2000; Speltz *et al.*, 2000). Comparisons among cleft groups suggest that those with CPO receive the lowest scores, followed by children with CLP and CLO, who tend to score roughly

within the average range (Kapp-Simon & Kruckeberg, 2000). Children with associated malformations in addition to a cleft lip or palate appear to be at particular risk of developmental delay (Swanenburg De Veye *et al.*, 2003).

Deficits in expressive and receptive language among children with orofacial clefts have been reported on the basis of standardized and observational measures (Morris & Ozane, 2003). Researchers have also shown that children with clefts score in the low average range on standardized measures of intelligence, with particular weakness in the verbal domain (Richman, 1980). However, differences are not consistently observed, and others have found that children with clefts score well within normal limits. An elevated rate of reading disabilities has been reported, with an estimated 30–40% of youth with clefts struggling in this area (Broder *et al.*, 1998). When diagnostic sub-groups are compared, males with CPO tend to evidence the most notable cognitive, language and learning deficits in comparison with all other diagnosis-gender combinations (Broder *et al.*, 1998). There is a paucity of neuropsychological and academic investigations of adolescents and adults, though it appears that deficits continue to be observed (Nopolous *et al.*, 2002). Recent studies using neuroimaging suggest underlying differences in brain structure among individuals with clefts that may account for functional differences observed (Nopolous *et al.*, 2002).

Clinical implications

The inconsistency and small magnitude of group differences in the preceding studies suggest that the majority of children with clefts show normal development. However, these studies also point to a significant minority of children with significant problems who need psychological assessment and treatment. Standards set forth by the American Cleft Palate-Craniofacial Association identify the need for childhood screening and assessment of developmental status, neuropsychological testing in older children, and various psychological interventions including pre-surgery anxiety reduction and social skills training. The elevated rates of reading disability among children with clefts indicate a particular need for routine screening and remediation of deficits in verbally mediated functions, including phonemic awareness and verbal fluency.

Research suggests that parents would benefit from psychological and educational interventions as well. During the first year of life, these services might target stress reduction; maternal feeding and teaching skills; and education regarding diagnosis and anticipated outcomes. A group format may be the most appropriate, and would promote social support among parents with similar experiences, in addition to providing education and training (see 'Social support interventions'). The anticipated effects of such interventions not only include better parental functioning, but also enhancement of the parent-child relationship. There is little doubt that the quality of parent-child interaction affects infant development. For example, in a cleft population, Speltz and colleagues (2000) found that quality of maternal teaching interactions in the first year predicted later cognitive functioning. Similarly, the quality of maternal feeding interactions was concurrently related to infants' physical growth (Coy *et al.*, 2000) and their subsequent security of attachment (Speltz *et al.*, 1997). In other high-risk infant groups, there is evidence

that parent ‘interaction coaching’ can enhance infant development and preliminary evidence suggests that this approach is useful for cleft populations (Pelchat *et al.*, 1999).

Early childhood interventions in the cleft population should target parents and infants showing particularly high social and demographic risk. For example, in one study of infants with clefts, male infants of young, primiparous mothers reporting high depression (on a screening instrument) were at the highest risk of parent–child relationship difficulties (Speltz *et al.*, 1997), suggesting that this sub-group might especially be in need of assistance.

Conclusions and research recommendations

Research on the psychological aspects of clefts has yielded quite variable results. In part, this may reflect methodological limitations

(e.g. use of small and diagnostically heterogeneous samples) and procedural differences across studies (e.g. lack of agreement on the most appropriate outcome measures). However, it is also likely that outcomes are diverse, depending on a host of medical and psychosocial factors. There is continuing need for well designed studies that examine the multifactorial context in which clefts are associated with better and worse outcomes. Cross-sectional, ‘between-group’ comparisons of cleft and non-cleft samples are numerous, but longitudinal, predictive analyses of developmental processes within cleft groups are rare and sorely needed. There is also need for randomized trials of the types of interventions already described (e.g. early reading interventions), which would advance theoretical understanding of developmental processes and provide clinically useful information that could improve the lives of individuals with orofacial clefts.

³Mills College

Upper respiratory infections (URI) as a group are responsible for 50% of all acute illnesses, with the common cold syndrome being most familiar. Colds are caused by over 200 viruses and are characterized by sore throat, congestion and mucus secretion. When exposed to viruses or other infectious agents, only a proportion of people develop clinical illness. Reasons for variability in response are not well understood and the possibility that psychological factors play some role in the aetiology and progression of infectious disease has received increased attention.

It is commonly believed that stressful life events influence the onset of URI by causing negative affective states (e.g. anxiety and depression) which, in turn, exert direct effects on biological processes or behavioural patterns that increase disease risk. The influence of stress on the immune system is considered the primary biological pathway through which stress can influence infectious disease susceptibility. While there is substantial evidence that stress is associated with changes in immune function (Herbert & Cohen, 1993; Segerstrom & Miller, 2004) (see 'Psychoneuroimmunology'), the implications of stress-induced immune changes for susceptibility to disease have not been established. To date, studies of stress and URI susceptibility have focused on establishing a link between stress and disease with little attention to pathways through which such an association might occur. The major findings of these studies are examined below.

There is consistent evidence that persons under stress report greater levels of URI symptoms and that stress results in greater health care utilization for URI (Cohen & Williamson, 1991). For example, Glaser *et al.* (1987) demonstrated that medical students report more infectious (mostly URI) illness during examination periods than at other times. Similarly, Stone *et al.* (1987) found that, for 79 married couples followed over three months, daily life events rated as undesirable increased three to four days prior to onset of self-reported symptoms of URI, close in time to the incubation period of many common cold viruses. The self-reported symptoms of URI measured in these studies may tap underlying pathology; however, it is also possible that they reflect a stress-induced misinterpretation of physical sensations without underlying illness. The latter interpretation is supported by studies in which effects of stress on symptoms, but not verified disease, are observed, and by evidence that stress is associated with increased symptom reporting in general, not only with symptoms directly associated with infectious pathology (Cohen & Williamson, 1991) (see 'Symptom perception').

Other investigators have verified the presence of pathology by physician diagnosis or biological methods. Several of these studies

provide evidence that life stressors increase risk for verified upper respiratory disease. For example, Meyer and Haggerty (1962) followed 100 members of 16 families for a 12-month period. Daily life events that disrupted family and personal life were 4 times more likely to precede than to follow new streptococcal and non-streptococcal infections (as diagnosed by throat cultures and blood antibody levels) and associated symptomatology. Similar results were reported in a study of viral URIs in 235 members of 94 families (Graham *et al.*, 1986). Here, high stress, as defined by scores on reported major stressful life events, daily events and psychological stress, was associated with more verified episodes and more symptom days of respiratory illness. Turner Cobb and Steptoe (1996) also found that higher levels of life event stress were associated with increased clinically-verified URI among 107 adults followed for 15 weeks. In sum, studies verifying infectious episodes suggest that stress increases risk for upper respiratory disease. However, community studies, like these, do not control for the possible effects of stressful events on exposure to infectious agents. Moreover, the literature on this topic is not entirely consistent; indeed, several studies have failed to find a relation between stress and upper respiratory disease (for review see Cohen & Williamson, 1991) (see also 'Life events and health').

Several prospective studies have eliminated the possible role of psychological effects on exposure by experimentally inoculating healthy individuals with common cold viruses (viral challenge studies). Here, volunteers are assessed for degree of stress and then experimentally exposed to a cold virus or placebo. They are then kept in quarantine and monitored for the development of infection and illness. Early viral challenge studies were limited by a range of methodological weaknesses (Cohen & Williamson, 1991), including insufficient sample sizes and lack of control for factors known to influence susceptibility to viral infection (including pre-existing antibodies to the infectious agent and age). Furthermore, the possible role of stress-elicited changes in health practices such as smoking and alcohol consumption was not considered. These limitations may account for initial failures to find consistent relations between stress and susceptibility to URI.

In contrast, recent viral challenge studies have included multiple controls for factors known to be independently associated with susceptibility to viral infection (e.g. Cohen *et al.*, 1991, 1993, 1998; Stone *et al.*, 1992). These studies consistently find a positive association between stress and susceptibility to URI. For example, among 394 healthy adults, stressful life events, perceptions of current stress and negative affect were all associated with an increased risk of developing biologically verified URI, with greater stress related linearly to

susceptibility (Cohen *et al.*, 1991, 1993, 1998). Further examination of findings revealed that perceptions of stress and negative affect increased risk for illness through a different pathway than stressful life events. The former measures increased the probability of becoming infected (replicating virus), while the latter increased the probability of infected people developing clinical symptoms (Cohen *et al.*, 1995). More recent research from this group suggests that the longer the duration of stressful life events, the greater risk of becoming infected (Cohen *et al.*, 1998). A large group of control factors including age, sex, allergic status, body weight, season and virus-specific antibody status before challenge, could not explain the increased risk of colds for persons reporting greater stress. Smoking, alcohol consumption, diet, exercise and sleep quality also failed to explain the association between stress and illness.

In a similar study, Stone *et al.* (1992) examined development of symptoms among persons infected with rhinovirus. They found that those with more life events were more likely to develop clinical colds, although perceptions of current stress and negative affect were unrelated to symptom development. In contrast to studies described earlier, this investigation included only infected persons and hence could not assess susceptibility to infection where Cohen and colleagues found perceptions of stress and negative affect were related to susceptibility.

Recent attention has turned to an examination of psychosocial factors that may decrease susceptibility to URI by regulating emotion-sensitive biological systems and/or encouraging

health-enhancing behaviours. These factors include dispositional positive affect and social engagement. Initial findings from viral challenge studies suggest that susceptibility to URI decreases in a dose-response manner with increased diversity of the social network and with trait sociability (Cohen *et al.*, 1997; Cohen *et al.*, 2003a) (see Social Support and Health). Furthermore, higher positive affect has been associated with decreased incidence of objective symptoms of upper respiratory illness among infected people (Cohen *et al.*, 2003b). These relationships appear to be independent of negative emotional styles, baseline immunity, demographics and health practices. Thus, there is some initial evidence that certain psychosocial factors are protective, being related to greater resistance to infection and the expression of fewer objective clinical symptoms.

In sum, well controlled studies support prospective studies of community samples in indicating that psychological stress is associated with increased susceptibility to the common cold. In addition, there is consistent evidence for increased symptom-reporting under stress. Recent studies also suggest that positive emotional styles, sociability and more diverse social networks are associated with greater resistance to developing colds. A number of potential pathways exist through which an association between psychosocial factors and infectious pathology might occur, including behavioral, hormonal and immune mechanisms. Future work is needed to explore these alternatives.

Complementary medicine

Felicity L. Bishop¹ and George T. Lewith²

¹Aldemoor Health Centre

²University of Southampton

Introduction

Complementary and alternative medicine (CAM) includes a wide range of practices which do not fit in with the dominant biomedical model of health care and are not commonly provided within conventional medicine settings. In the 1960s CAM was on the fringe of the mainstream, in the 1970s it was positioned as alternative and in the 1990s it became complementary. In the new millennium, the position of CAM has changed again and is moving towards integration with conventional medicine, for example CAM therapies are commonly offered in palliative care and pain clinic contexts. Currently substantial numbers of people are turning to CAM. The prevalence of CAM use increased from 34% to 39% during the 1990s in the general population in the USA (Eisenberg *et al.*, 1998). In the UK 46% of the population can be expected to use one or more CAM therapies in their lifetime and 10% visited a practitioner of an established CAM therapy in 1998 (Thomas *et al.*, 2001). This chapter addresses the nature of these therapies which are proving so popular with patients, how are they regulated, whether they are seen as complementary or an alternative to conventional medicine and how conventional medicine is reacting to the rising popularity of other approaches to health care.

Popular CAM therapies

The most popular CAM therapies in the UK include acupuncture, osteopathy, chiropractic, herbal medicine and homeopathy. Descriptions of these therapies are provided in Table 1.

Patients perceive that CAM is effective, but within the context of evidence-based medicine there is substantial difference between efficacy and effectiveness. Patients perceive antidepressants to be effective, but the true efficacy of the chemical remedy versus placebo may confer only 15–20% of the overall effect of prescribing an antidepressant (see 'Placebos'). A similar situation may exist in acupuncture. It is known, for instance, that a single acupuncture point is effective for nausea. This may include post-anaesthetic nausea, chemotherapy-induced nausea and early morning sickness (Vickers, 1996) (see 'Nausea and vomiting'). However, the situation for the relative efficacy of acupuncture for pain is less clear (White *et al.*, 2002). There is evidence that herbs may be effective in certain specific conditions, for instance the use of St John's Wort in depression (Linde *et al.*, 1996), but while it is possible to accept that herbal extracts have real chemical efficacy, it is difficult to accept that homeopathy may work with no explicable mechanism, in spite of the available evidence which suggests that homeopathy is not simply a placebo (Linde *et al.*, 1997). CAM is a vast field that offers many

challenges to researchers within both qualitative and quantitative research. Clearly there are some areas where it has proven efficacy, but these are relatively few and far more investigation is required before CAM can be fully integrated into an evidence-based framework.

The recent UK House of Lords' report (2000) highlighted the fact that much CAM practice was occurring without appropriate regulation. While the efficacy of each individual CAM treatment may be far from proven, it is a matter of public safety that CAM practitioners should be properly regulated, practising in an ethical and professional manner and providing treatments which are fundamentally safe. Osteopaths and chiropractors took the lead in the matter of statutory regulation and both are now regulated and have appropriate and elected general councils governing the profession, its processes and ethics. Acupuncture and herbal medicine are in the process of being regulated in the UK with discussions at an advanced stage, but no final decision on the exact form that this

Table 1. Popular forms of CAM

CAM Form	Description
Acupuncture	<ul style="list-style-type: none">• Based on an energetic view of the body.• Stimulation of acupuncture points used to restore energy balance, promote healing and alleviate illness.
Osteopathy	<ul style="list-style-type: none">• Holistic system of diagnosis and manual treatment for mechanical problems of the body.• Employs manipulation and massage of the soft tissue and joints to promote self-healing and treat musculoskeletal problems.
Chiropractic	<ul style="list-style-type: none">• Manipulative technique founded on the idea that musculoskeletal problems are caused by the misalignment of vertebrae.• Spinal manipulations and adjustments are employed to improve alignment and alleviate musculoskeletal problems.
Herbal medicine	<ul style="list-style-type: none">• Holistic model of health and illness, separate traditions include European, Chinese and Indian herbal medicines.• Plant-based herbal remedies are used to treat the cause of health problems and offer a cure beyond symptomatic relief.
Homeopathy	<ul style="list-style-type: none">• Based on the Law of Similars (a substance that causes symptoms in a healthy person will alleviate those symptoms in a patient).• Treatment focuses on the whole person and tailors treatments to individuals, aiming to facilitate natural healing abilities through the prescription of remedies.

regulation may take. Furthermore, the manufacture, prescription and claims that can be made on various herbal products are in the process of review with the intention of harmonizing procedures on a European-wide basis.

Who uses CAM and why?

People who use CAM are more likely to be female, middle-aged, highly educated and have higher incomes. This picture is relatively consistent across population-based surveys (Astin, 1998), comparisons between users of CAM and conventional medicine (Furnham & Beard, 1995), and surveys of specific illness populations (Moore *et al.*, 2000). CAM is used in the maintenance of current health, prevention of future problems and in relation to current illnesses. There is a tendency for CAM to be used by people with chronic, long-standing illnesses. For example Murray and Shepherd (1993) found that a higher proportion of CAM users (69%) than non-users (49%) had conditions such as anxiety, depression, asthma, eczema, hayfever, or musculoskeletal problems.

CAM use is associated with beliefs about medicine. People who use CAM are more likely than those who use conventional medicine to believe that:

1. They are able to have some control over the course of their health and that they should have a participatory role in treatments (Balneaves *et al.*, 1999) (see 'Self-efficacy and health').
2. Health and illness are holistic in nature, for example psychological factors are important in the development of illness, and that treatments should involve the mind, body and soul (Astin, 1998).
3. Treatments should be natural and that natural treatments are more effective and less toxic than prescription medications (O'Callaghan & Jordan, 2003).

Thus people who use CAM hold beliefs which are broadly consistent with the philosophical ideas underlying certain forms of CAM. There is evidence that in addition to being attracted to CAM, people hold negative beliefs about conventional medicine. People who use CAM tend to be dissatisfied with a number of aspects of conventional medicine, including:

1. Failure of conventional medicine to offer cure or control over long-standing illness (McGregor & Peay, 1996).
2. Lack of time available and general communication and interpersonal skills of practitioners (Moore *et al.*, 2000).
3. Side-effects and invasiveness of conventional medical treatments (Paterson & Britten, 1999).

Thus CAM use is related to dissatisfaction with conventional medicine. However, dissatisfaction is not equivalent to rejection. The majority of people who use CAM do so alongside conventional medicine, and CAM use has been associated with increased use of conventional medicine (Astin *et al.*, 2000). People are attracted to certain features of CAM and are dissatisfied with, but have not rejected, conventional medicine. Future research needs to consider other possible reasons for CAM use and needs to investigate what happens once people have started to use CAM. There has been relatively little research so far on issues such as why people use specific CAM therapies and not others, and the factors that influence adherence to and ongoing use of CAM (see also 'Lay beliefs about health and illness').

CAM and conventional medicine

The recent increase in CAM popularity can be seen as a patient-initiated movement which is linked to a general increase in consumerism in western societies. Patients are taking their healthcare into their own hands, seeking out CAM therapies which are mostly still accessed through the private sector. At the same time as this increase in CAM use, paternalistic healthcare has fallen out of favour and is being replaced by a patient-centred model of care, which emphasizes patient autonomy and empowerment as ideals (see 'Patient-centred healthcare'). Furthermore, it is not only the general public who are turning to CAM: conventional healthcare professionals are now using CAM to a similar extent (Burg *et al.*, 1998) and many refer patients to CAM practitioners or practice CAM themselves. This shift away from paternalism in conventional medicine combined with the increasing popularity of CAM has raised the profile of CAM therapies within the conventional medical community and so there are moves towards integration. For example, the teaching of CAM in medical schools is now commonplace (e.g. Owen & Lewith, 2001).

Despite this generally positive attitude of conventional practitioners towards CAM, the relationship between complementary and conventional medicine is far from unproblematic. Patients do not always disclose information to their doctors about their CAM use (Astin *et al.*, 2000), and attempts to discuss CAM with medical doctors are not always successful. At a broader level, debates continue concerning appropriate methodological approaches to furthering the evidence base for CAM (Richardson, 2000). Recent moves towards integrated medicine have problematic issues for both conventional and complementary providers surrounding issues such as the evidence base, professional identity and conflicting ideologies. So, while there are movements towards integration there remain tensions between the dominant and complementary health care systems.

Looking to the future

There are no signs of the general interest in, and popularity of, complementary medicine decreasing. Research in CAM is still in its infancy and is a growing multidisciplinary area. The key issues now in CAM research are related to:

1. Understanding what the benefits and outcomes of CAM use are from the patient's perspective, in particular through the use of qualitative approaches and consulting expert patients.
2. Increasing research capacity through schemes such as those provided by the Department of Health (in the UK) and the NCCAM (in the USA). Such schemes will encourage and facilitate much needed quality research into many areas of CAM, including efficacy research and social science approaches to CAM.
3. Developing safe clinical approaches to the integration of CAM in appropriate clinical contexts. The position of CAM within a clinical framework needs to be formalized, and issues such as clinical governance, practitioner quality and regulation need to be negotiated within this context.

Contraception

Beth Alder

Napier University

Introduction

Birth rates vary worldwide and are related to economic and social factors as well as contraceptive choice. In parts of Africa the birth rate is high (e.g. in Niger, 48.9 births per 1000 women and a fertility rate of 6.83 children born per woman). In Europe it is dramatically lower (in Germany 8.04 births per 1000 women and a fertility rate of 1.38 children born per woman) (CIA World Factbook, 2004). Although there is such global variation there is little cross-cultural evidence about psychological aspect of contraceptive choice and so this chapter will refer to evidence from western societies. In England

and Wales, conceptions fell from over 850 000 in 1991 to 190 000 in 2002. In spite of the development of safe and effective contraceptive methods unintended pregnancies are common. In England and Wales, the percentage of conceptions terminated by abortion rose from 19.4% in 1991 to nearly 23% in 2002 with the highest percentages in those aged under 20 or over 40. The Total Fertility Rate (TFR) is the sum of age and specific fertility rates expressed per woman and controls for the changing age distribution over time. In 2002, the TFR in England and Wales was 1.65 per woman, which is similar to the rates between 1920 and 1940, before the widespread use and acceptability of contraception.

These observations mean that a simple relationship between knowledge and availability of contraception and its use is unlikely (Office of National Statistics, 2004*b,c*; <http://www.statistics.gov.uk/>).

The evidence for a contraceptive career suggests that young people use either condoms or no contraceptive method at all in their first sexual encounters. With increasing sexual and contraceptive experience they move to oral contraceptives. Once their family is considered to be complete they choose either male or female sterilization. Oddens (1996), in a population survey of contraceptive use in the UK and Germany, found that patterns of contraceptive use were closely related to variables such as age, parity, marital status and intention to have children. Age and the desire to have children are the major factors associated with contraceptive choice. The decline in the use of oral contraceptives with age has been related to perceptions of health risk.

The *UK General Household Survey* in 2002 included questions on the use of contraception for the first time since 1998. Since then, the most common methods for avoiding pregnancy used by women aged 16 to 49 have been the contraceptive pill, surgical sterilization (both male and female) and the male condom. In 2002, 72% of women aged 16 to 49 used at least one form of contraception, a figure that has remained relatively constant since it was first measured (Office of National Statistics, 2004*a*). In 2002/03 the contraceptive pill was used by 26% of women aged 16 to 49 in the UK. Sterilization, of either the woman or her partner was used by 21%, and the male condom by 19% (Office of National Statistics, 2004*a*).

After termination of pregnancy it might be expected that women would be highly motivated to use effective contraception. In a study of 100 women in Switzerland, 69% of women attending for termination of pregnancy claimed that they had used contraception in the cycle that had resulted in the pregnancy (Bianchi-Demicheli *et al.*, 2001). Most (83%) intended to use contraception to prevent another pregnancy. Most (60%) were using the pill 6 months later and fewer used condoms. After their termination most changed their method of contraception from their previous method, even though that method would have been recommended (Bianchi-Demicheli *et al.*, 2003) (see 'Abortion').

Oral contraception

Most pill users use the combined pill, which contains both oestrogen and progesterone. Oral contraceptives are easy to use, very effective, safe, inexpensive and readily available. They work by inhibiting ovulation with the progesterone component causing changes to the endometrium, which inhibits implantation, and to the cervical mucosa, which decreases sperm penetration. They do not interfere with the act of sexual intercourse and give women control over their fertility. There is evidence which shows that the more detached contraception is from sexual activity the more acceptable it is (Cramer, 1996). They also have the advantage that they reduce menstrual and premenstrual problems and give women the ability to time their menstruation (withdrawal bleeding). A recent study of Canadian university students found that only half had taken the pill, with an average length of use of 33.5 months (Fletcher *et al.*, 2001). Healthy, educated women showed a

surprising lack of knowledge of the medication taken: 39% were unaware of the type of pill prescribed and 8% had not reviewed the risks and benefits with a health professional.

However, oral contraception is not without some disadvantages. Side effects reported with the early high oestrogen-dose oral contraceptive pills included reduced sexual interest and depression, but these are minimal in current low dose preparations (Oddens, 1999). Condon *et al.* (1995) carried out a retrospective study of 145 women and found that nearly half reported side-effects and most changes in wellbeing were perceived as negative. Fletcher *et al.* (2001) found that 43% attributed the following side-effects to the pill: weight gain (23%); nausea (16%); spotting (15%); depression (9%); headaches (7%); increased blood pressure (0.8%); and blood clots (0.8%). Few of these effects have been demonstrated in clinical trials. A survey of over 100 nursing students found that fear of side-effects or health risks were the most frequently cited reasons for stopping pill use, and the views of healthcare providers were influential (Gardner, 2001). It is difficult to carry out good prospective studies of pill users because of ethical difficulties and high attrition rates. Women who experience side-effects may stop using the pill, and those who continue are less likely to report side-effects. Women who take the pill probably do so because it is very important to them to have a very safe form of contraception and they may be more likely to tolerate side-effects.

Sterilization

Vasectomies in men and laparoscopic sterilizations in women are safe and effective. In the UK, the use of female sterilization has increased significantly from 35% in 1986 to 44% in 2002 (Office of National Statistics, 2004*a*). However, sterilization operations are effectively irreversible and so the decision to be sterilized means the couple need to be very sure that they will not want more children. Studies on long-term effect of vasectomy have found no evidence of adverse psychological effects. A study of 115 Chinese women who had been sterilized and were followed up over a year found that there was no adverse effect on sexual adjustment and that their mental health measured by the GHQ (Goldberg, 1972) significantly improved. The regret rate after one year was 3.4% (Tang and Chung, 1997). Women requesting sterilization appear to have no higher rates of psychiatric disorder than the general population.

Male condom use

There has been a steady rise in the proportion of women whose partners use condoms, from 13% in 1986 to 19% in 2002. Again, this trend was not observed across all age groups. Among women aged 45 to 49, condom use has declined since 1986. It has remained fairly constant among women aged 35 to 44 and increased among women under the age of 35.

Most recent research into psychological aspects of condom use has considered them as protecting against disease rather than pregnancy. Grimely *et al.* (1995) tested the Transtheoretical Model of Behaviour Change (Prochaska and DiClemente, 1984) on

248 American college students and found that it could predict patterns of condom use (see 'Transtheoretical model of behaviour change'). Mahoney *et al.* (1995) tested the Health Belief Model in college students in relation to condom use and HIV infection. Sporadic users differed from both consistent and non-users in the actual number of sex partners in the previous year and actual frequency of drunkenness during sexual intercourse; but only perceived susceptibility to infection and self-efficacy differed between the groups (see 'Health belief model' and 'Self-efficacy and health').

Other methods

The intrauterine device (IUD) is mainly used by parous women and confers good protection. Like the pill, it does not interfere with sexual activity. IUDs have been associated with heavier, prolonged and more painful menstruation but a positive impact on sex life (Oddens, 1999).

Emergency contraception is available on prescription in the USA and over the counter in over 30 countries. After unprotected intercourse it reduces the risk of pregnancy by 85%. Smith *et al.* (1996) carried out a population based survey of 1214 women in Grampian, Scotland (65% response rate). They found that although most women (94%) were aware of emergency contraception, only 39% knew the correct timing for its use. In a survey of attitudes in Scotland, Romania and Slovenia it was found that 72%, 81% and 94% of women respectively felt positive to the idea of a pill which inhibited ovulation. Over 50% thought that a pill which inhibited or interfered with implantation was an acceptable idea. Attitudes to abortion, availability of contraception and religious beliefs are likely to be important (Rimmer *et al.*, 1992).

In the USA, a study of 371 low-income English- or Spanish-speaking women found that only 3% had used emergency contraception, 36% had heard of it and only 7% knew the correct timing for its use (Jackson *et al.*, 2000). The lack of knowledge was associated with being older, multiparae and monolingual Spanish-speaking. One approach to increase its use is to provide supplies of emergency contraception to women in advance of need. It has been shown that this does not reduce the abortion rate (Fairhurst *et al.*, 2004). Women were reluctant to ask for supplies and health professionals feared that women would overuse, abandon more reliable methods or might see this as sanctioning promiscuous behaviour. In the USA, the Food and Drug Administration (FDA) approved oral contraceptive pills as emergency contraceptives in 1997, but in 2004 the FDA rejected calls for over-the-counter status for emergency contraception and claimed that adolescent women had not been shown to understand the instructions (Tanne, 2004).

To try and understand women's use of emergency contraception Free *et al.* (2002) carried out an in-depth interview study of 30 sexually active women. Their attitudes and concerns included perceptions of low vulnerability to pregnancy, negative self-evaluation, knowledge and service barriers and concerns about what others think. These correspond well to variables identified in social cognition models such as the Health Belief Model and Theory of Planned Behaviour.

There is undoubtedly a demand for safe, effective and acceptable contraception and while there are new developments based on increased understanding of reproductive physiology (Baird and Glasier, 1999), the psychological aspects of acceptability and effective use remain important. The male pill is another possible development, but there is some doubt about whether women would trust men to take it regularly (Guillebaud, 1991). Large doses of testosterone can induce azoospermia but the side effects are intolerable and progress towards safe doses of androgens is slow. Sjogren and Gottlieb (2001) followed up 25 men during a year's use of testosterone contraception. Most rated the method as expected or better and the frequency of sexual intercourse and quality of sex life in general increased significantly. There was some evidence of increased aggression. The men were not blind to the therapy and their reports may have been influenced by their expectations, which might also have been a reason for accepting the therapy.

If, in spite of safe and effective methods, there are still unplanned pregnancies, then it is arguable that current methods of contraception are unacceptable. This has led to the search for new methods. Hormonal contraception was originally given orally but there are now contraceptive vaginal rings, transdermal patches and gels. It remains to be seen whether these are more acceptable.

Contraceptive choice

In a report based on surveys in 1992, Oddens (1996) suggests that attitudes towards the perceived medical nature of some contraceptive methods (oral contraceptives, sterilization and IUDs) influence contraceptive choice. Miller and Pasta (1996) carried out a study on 40 couples' contraceptive choice over a four-year period. They distinguished between method-choice and method-use in decision-making. Method-choice is about continuing with the present method or changing to a new one. Method-use is the actual use of the selected method, e.g. taking the oral contraceptive pill daily or inserting a diaphragm. They found that husbands and wives appeared to have equal influence on method-choice but intentions depended on their own preference.

Coronary heart disease: impact

Paul Bennett

University of Cardiff

A myocardial infarction (MI) – potentially the most acute manifestation of coronary heart disease (CHD) – may be a devastating event. Its onset can be sudden, distressing and potentially life-threatening. Even if this is not the case, knowledge of disease status can trigger strong and frequently long-term emotional reactions as well as acting as a catalyst for risk behaviour change. As a consequence, it has been the focus of much of the psychological research in CHD.

Behavioural change

An infarction does seem to trigger appropriate behaviour change, although some changes may be relatively short-term. Hajek *et al.* (2002), for example, found that 6 weeks following MI, 60% of former smokers who did not intervene were reported to be not smoking. One year after MI, the figure had dropped to 37%.

Similarly, Dornelas *et al.* (2000) found 43% and 34% of patients not receiving any form of intervention were abstinent at 6 and 12 months respectively. Of note, here, was the finding by Scott and Lamparski (1985) that only patients who believed that smoking contributed to their cardiac problems were likely to maintain abstinence. Diet may also change in the short-term (Bennett *et al.*, 1999), although old habits may creep back over time. Leslie *et al.* (2004), for example, found the target of their nutritional programme of 5 portions of fruit and vegetables per day was achieved by 65% of participants involved. Thirty-one percent of their control group achieved this goal. The percentage of those eating healthily in the intervention group fell over a one-year follow-up period and did not differ from the control group by this time (see also 'Diet and health' and 'Tobacco use').

As with other risk behaviours, changes in exercise may be modest and fall over time. Bennett *et al.* (1999), for example, found significant spontaneous changes in mild to moderate exercise levels in the three months following MI. Levels in fitness may change markedly following participation in specific exercise programmes (e.g. Hevey *et al.*, 2003). However, how long such changes are maintained in the absence of continued follow-up is not clear. Lear *et al.* (2003) reported minimal changes from baseline on measures of leisure time exercise and treadmill performance one year following MI, despite participants taking part in a general rehabilitation programme (see 'Physical activity and health', 'Physical activity interventions' and 'Coronary heart disease: rehabilitation'). One final outcome is that of sexual activity. Wiklund *et al.* (1984) reported that compared with two months prior to MI, at one-year follow-up only 35% of the participants in their study claimed they had experienced no change in their sexual activity, while 60% 'had noted a decline'. Five percent reported that they had ceased sexual activity altogether. While fear was the predominant reason for reduced sexual activity at two-month follow-up, impotency and loss of interest were the most frequent explanations one year after MI. The use of beta-blockers, frequently used to stabilize and strengthen the cardiac function following MI (Ko *et al.*, 2002) would have contributed to these data. The incidence of erectile disorder after myocardial infarction ranges from 38–78% (Sainz *et al.*, 2004) (see also 'Sexual dysfunction').

Emotional distress

The psychological consequences of an MI may be profound and persistent. Wiklund *et al.* (1984), for example, interviewed a number of patients who had experienced an MI one year previously. Over a third of them thought about their heart disease frequently and 74% worried about their cardiac state. Fifty-eight percent reported that they were protected from physical exertion by friends and family, frequently as a consequence of anxiety rather than symptom severity. Psychometric measures or clinical interviews confirm these high levels of distress. Dickens *et al.* (2004), for example, reported the incidence of depression found by clinical interview as 20% in the period immediately following the infarction. Twenty-one percent of those not depressed at this time subsequently became depressed over the following year. Again using clinical interviews, Strik *et al.* (2004) found that 31% of a cohort of MI patients developed major or minor depression in the year following first MI.

The highest incidence rate was in the first month following their MI. Lane *et al.* (2002) found a 31% prevalence rate of elevated depression scores during hospitalization. The 4- and 12-month prevalence rates were 38% and 37%. The same group reported the prevalence of elevated state anxiety to be 26% in hospital, 42% at 4-month follow-up and 40% at the end of one year. They also reported high levels of co-morbidity between anxiety and depression. Grace *et al.* (2004) reported that one-third of patients experienced elevated anxiety at the time of their MI: 50% of their cohort remained anxious one year later. Interest in the rates of post-traumatic stress disorder as a consequence of MI has recently increased, with prevalence rates typically being around 8–10% up to one year following infarction (e.g. Bennett *et al.*, 2002).

Emotional benefits

Despite the consistent data suggesting the potential for negative emotional reactions to MI, the obverse may also be found. Petrie *et al.* (1999) reported that nearly two-thirds of people who had survived an MI reported some personal gains as a result of their illness some three months after its onset. The most highly endorsed positive outcome (endorsed by over 60% of respondents) was a change to a healthier lifestyle, although improvements in relationships, an appreciation of health and life, a change in life priorities and gains in empathy were also reported.

Predictors of emotional distress

Factors associated with distress may change over time. Dickens *et al.* (2004), for example, found that predictors of depression at the time of the MI were being a younger age, female, having a past psychiatric history, being socially isolated, experiencing other life problems and lacking a close confidant. Onset of depression over the year following the infarction was associated with having frequent angina. Strik *et al.* (2004) found similar associations between previous psychiatric history, depression, gender and age. Women and young men were most likely to be depressed. Post-traumatic stress disorder (PTSD) may be predicted by a number of factors, including neuroticism, the level of intrusive thoughts about the event while in hospital and lack of social support (Bennett *et al.*, 2002) (see 'Post-traumatic stress disorder').

Consequences of emotional distress

There is little doubt that the emotional reactions can influence important outcomes following MI. Depressed and anxious individuals are less likely to attend cardiac rehabilitation classes than those with less distress (Lane *et al.*, 2001). Paradoxically, they are more likely to contact doctors and to make and attend outpatient appointments, as well as have more re-admissions (Strik *et al.*, 2004) in the year following infarction. Many of these will be due to worry and health concerns rather than further validated cardiac problems. The impact of mood on health behaviour change is modest – although good quality longitudinal data addressing this issue are surprisingly lacking. Huijbrechts *et al.* (1996) reported that depressed and anxious patients were less likely to have stopped

smoking five months after their MI than their less distressed counterparts. Similarly, Havik & Maeland (1988) reported that the MI patients who were least likely to quit smoking were those who had become increasingly depressed in the months immediately following their MI. Bennett *et al.* (1999) reported a modest association between low levels of exercise and depression, but no differences between depressed and non-depressed individuals on levels of smoking, alcohol consumption or diet. Finally, Shemesh *et al.* (2004) found that high levels of PTSD symptoms, but not depression or global distress scores, were significant predictors of non-adherence to aspirin.

Depression may also impact on important economic factors. Occupational factors mean that white-collar, male, and young workers are most likely to retain their jobs. However, mood and expectations about work will also significantly influence return to work. Depression has consistently been associated with delayed or failure to return to previous work after rehabilitation and low ratings of work or social satisfaction. Soderman *et al.* (2003), for example, found depression to predict low levels of resumption of full-time work and reduced working hours. Delay in returning to work was predicted by greater concerns about health and low social support. Resuming work at a lower activity level than before infarction was associated with older age, higher health concerns and patients' expectations of lower working capacity (independently of actual capacity).

Cognitive responses

The mechanisms through which depression and other negative emotions influence behaviour has not been fully investigated in cardiac patients. However, the likelihood is that any impact on behaviour is mediated by cognitive processes. One framework through which these have been investigated involves the Illness Perceptions Questionnaire (see 'Illness cognition assessment'). Using this, Petrie *et al.* (1996) found that attendance at cardiac rehabilitation was significantly related to a stronger belief during admission that the illness could be cured or controlled. Return to work within six weeks was significantly predicted by the perception that the illness would last a short time and have less grave consequences for the patient. Patients' belief that their heart disease would have serious consequences was significantly related to later disability in work around the house, recreational activities and social interaction. A strong illness identity was significantly related to greater sexual dysfunction at both three and six months. Although they did not

investigate it, these negative attributions and expectations are likely to be associated with depression and/or anxiety.

Impact and interaction with partners

The partners of patients also experience high levels of distress, often greater than that reported by the patient. Moser and Dracup (2004) also found that patients' adjustment to illness was worse when their partners were more anxious or depressed than themselves and was best when patients were more anxious or depressed than their partners. Stern and Pascale (1979) found that the women at greatest risk of depression or anxiety were those married to men who denied their infarction. In this situation, partners experienced high levels of anxiety when their partner engaged in what they may considered to be unsafe behaviours, such as high levels of physical exertion or continued smoking, which they are unable to control. In addition, many wives appear to inhibit angry or sexual feelings and become overprotective of their husbands (Stewart *et al.*, 2000). Bennett and Connell (1999) found two contrasting processes to influence anxiety and depression in patients' partners. The primary causes of partner anxiety was the physical health consequences of the MI, and in particular the perceived physical limitations imposed on their spouse by their MI. In contrast, the strongest predictors of partner depression were the emotional state of their spouse, the quality of the marital relationship and the wider social support available to them. Three disease factors were particularly associated with anxiety: the severity of the MI; the patients' perceptions of their health and physical limitations as a consequence of disease (see also 'Lay beliefs of health and illness'). Two patient coping responses to the MI, i.e. mental withdrawal and seeking instrumental social support, were also associated with partner anxiety.

Summary

While many people recover well from a myocardial infarction and make appropriate behavioural changes, many do not. In addition, a significant minority of individuals experience significant negative emotional effects. These may impact on all areas of life, from the social and sexual to the economic. Any of these changes may be mediated by cognitive processes, which may be responsive to relatively brief interventions at an early stage in the rehabilitation process (Petrie *et al.*, 2002).

Coronary heart disease: cardiac psychology

Robert Allan¹, Stephen Scheidt¹ and Christopher Smith²

¹Weill Medical College, Cornell University

²Yeshiva University

'Cardiac psychology' and 'behavioural cardiology' are two new closely related sub-specialties in mental health and cardiology, respectively, informed by many hundreds of empirical studies conducted over nearly half a century. The fields have evolved with a unifying hypothesis that psychological and social variables, termed 'psychosocial factors', can affect the development and outcome from coronary heart disease (CHD), the leading cause of death and disability in the western world. Indeed, the recent case-control INTERHEART study of more than 15 152 cases and 14 820 controls in 52 countries reported that most risk factors for myocardial infarction (MI) have behavioural components that are modifiable, including cigarette smoking, regular physical activity, dietary lipids, abdominal obesity, daily consumption of fruits and vegetables and hypertension (Yusuf *et al.*, 2004) (see also 'Diet and health', 'Physical activity and health', 'Tobacco use' and 'Hypertension'). A second INTERHEART study of psychosocial factors with 11 119 patients and 13 648 controls from 262 centres around the world determined that stress at work, at home and with finances, as well as major adverse life events, also increased the risk of acute MI (Rosengren *et al.*, 2004).

In the late 1950s, some of the earliest research linked the Type A behaviour pattern with increased risk of MI. Since then, depression, social isolation, anger, anxiety and job strain, among others, have attained some degree of empirical validity as CHD risk factors. The as-yet unrealized 'holy grail' of cardiac psychology/behavioural cardiology is a reduction in cardiac morbidity and mortality with intervention to ameliorate negative behavioural or psychosocial characteristics. At this point in time, research linking some psychosocial factors with CHD onset and outcome is quite convincing. The intervention literature, however, is less consistent.

Psychosocial risk factors

Over the past few years, behavioural cardiology has attained substantial credibility in medicine. In 1999, Rozanski *et al.* (Rozanski *et al.*, 1999) published a 'new frontiers' article in *Circulation*, the premier journal in cardiology, providing an exhaustive review of the literature. Since then, other comprehensive reviews have appeared (Allan & Scheidt, 2004); (Smith & Ruiz, 2002) as well as numerous reviews focused on specific psychosocial factors, including: depression (Smith & Ruiz, 2002); (Lett *et al.*, 2004); (Barth *et al.*, 2004); (van Melle *et al.*, 2004) anxiety and depression; (Januzzi *et al.*, 2000) psychosocial factors for sudden cardiac death; (Hemingway *et al.*, 2001) for heart failure; (MacMahon & Lipp, 2002) and in women. (Bankier & Littman, 2002) See Eng *et al.* (Eng *et al.*, 2002)

for the most recent database on social isolation in the introduction to their large-scale study of social ties and CHD.

Depression and social isolation are consistent and powerful risk factors, particularly for outcome after the diagnosis of CHD. A constellation of negative emotions (depression and anger) and one consequence of such negativity (social isolation) has emerged with striking predictive power from a number of studies. A recent, provocative twin study reported a possible genetic basis for the relationship between depression, anger and social isolation (Raynor *et al.*, 2002).

An area of emerging importance is psychosocial adjustment in implantable cardioverter defibrillator patients. Many ICD patients are sudden death survivors and a significant percentage suffer from anxiety, depression and post-traumatic stress disorder (see 'Post-traumatic stress disorder') (Sears *et al.*, 1999).

Autonomic imbalance is likely to be a major physiologic mechanism responsible for the harmful effects from psychosocial factors. Among many others, Curtis and O'Keefe (Curtis & O'Keefe, 2002) have discussed the hypothesis that heightened sympathetic and reduced parasympathetic nervous system activity are the major underlying links between mind, behaviour and CHD. In addition to direct effects of heightened sympathetic, or decreased parasympathetic activity, which include increased blood pressure, heart rate and myocardial contractility, there are indirect effects of autonomic imbalance, including increased platelet and clotting system reactivity, predisposition to thrombosis and atherosclerotic plaque rupture, as well as increased propensity to arrhythmia (see also 'Stress and health' and 'Psychoneuroimmunology').

Depression

A number of prospective studies have noted an increased relative risk (~1.5 to 2.0) of acute MI and cardiovascular mortality in depressed, but otherwise healthy individuals (Ferketich *et al.*, 2000). The data linking depression with adverse events among patients with established cardiac disease are particularly striking, with a 1998 review noting that 11 of 11 studies reported worsened outcome (Glassman & Shapiro, 1998). The relative risk of future adverse cardiac events and cardiovascular mortality in depressed patients with established cardiac (usually coronary artery) disease is increased approximately three- to four-fold (Lett *et al.*, 2004); (Barth *et al.*, 2004); (van Melle *et al.*, 2004). Between 35–45% of post-MI and post-coronary artery bypass graft surgery (CABG) patients suffer from some level of depression, ranging from a few symptoms to major depressive disorder. Results from two recent

intervention trials suggest that much cardiac depression may remit spontaneously within a few months of the cardiac event (Glassman *et al.*, 2002); (Writing Committee for the ENRICH investigators, 2003). Autonomic dysfunction is the physiologic mechanism most often cited as linking depression to increased cardiac mortality (Carney *et al.*, 2001).

Social isolation

In 1984, Ruberman *et al.* (Ruberman *et al.*, 1984) were among the first to provide evidence of increased mortality in socially isolated cardiac patients among 2320 male survivors of acute MI. In 1992, Case *et al.* (Case *et al.*, 1992) reported on 1234 patients six months after MI; the recurrent event rate for nonfatal MI or cardiac death was nearly double for those living alone compared with those living with a companion. Similarly, Williams *et al.* (Williams *et al.*, 1992) followed a consecutive sample of 1368 patients undergoing cardiac catheterization over 5 years. Unmarried individuals without a confidant had $>3\times$ increased risk of death compared with those who were married or had a close friend.

In a recent study of 430 CHD patients, Brummett *et al.* (Brummett *et al.*, 2001) reported that the most isolated individuals, those with 3 or fewer people in their social support network, had the worst outcome, with a relative risk of 2.43 for cardiac and 2.11 for all cause mortality. Once past a threshold of minimal support, additional social ties did not appear to provide extra benefit (see also 'Social support and health').

Hostility and anger

Free-floating or easily aroused anger, is one of the two major symptoms of the Type A behaviour pattern, one of the first psychosocial conditions suggested as a risk factor for CHD. A 1996 meta-analysis of 45 studies by Miller *et al.* (Miller *et al.*, 1996) suggested that chronic hostility is an independent risk factor for CHD as well as all-cause mortality, with the relationship strongest among younger patients.

More recently, J.E. Williams *et al.* (Williams *et al.*, 2000) studied 12986 Americans without known CHD at baseline and reported a strong graded relationship between increasing 'trait anger' and subsequent MI and CHD mortality. Results were significant for only normotensive individuals, approximately two-thirds of the population under investigation. A similar relationship between scores on the Spielberger Trait Anger Scale and increased risk of haemorrhagic and ischaemic stroke was found in a sample of 13851 men and women (Williams *et al.*, 2002). Eng *et al.* (Eng *et al.*, 2003) administered a slightly different measure of anger, the Spielberger Anger-Out Expression Scale, to 23552 health professionals. Moderate, compared to low, expressed anger conferred a protective effect. It is remarkable that these three large studies have come to inconsistent conclusions about the expression of anger using similar anger measurement instruments (see 'Hostility, Type A behaviour and coronary heart disease').

In addition to depression, social isolation and hostility, there is limited evidence that several other psychosocial factors may increase risk of CHD, including job strain (Kivimaki *et al.*, 2002), 'phobic' anxiety (Kawachi *et al.*, 1994), Type D (distressed) personality (Denollet & Van Heck, 2001), and 'vital exhaustion' (Kop *et al.*, 1994).

Triggering of acute cardiac events

Within the past several decades, observational studies after both natural (Leor *et al.*, 1996) and man-made disasters (Meisel *et al.*, 1991) have reported higher rates of both MI and sudden cardiac death (SCD) than in normal times. We have also learned a great deal about 'triggering' from the recently completed Determinants of Time of Myocardial Infarction Onset Study. In the 'MI Onset study', most MIs could not be attributed to a specific cause. It is important to note that the absolute risk of MI in any given hour is quite low, only 1 in a million for a healthy 50-year-old male (Muller *et al.*, 1997). However, a number of behavioural 'triggers', some potentially avoidable, have been identified, including strenuous exertion (Mittleman *et al.*, 1993), intense anger (Mittleman *et al.*, 1995), sexual activity (Muller *et al.*, 1996), assuming the upright posture upon awakening (Muller *et al.*, 1997), use of marijuana (Mittleman *et al.*, 2001) and cocaine (Mittleman *et al.*, 1999). A small, but statistically significant Monday morning peak in MI, presumably related to beginning the work week, has also been noted (Willich *et al.*, 1992).

Triggers are suggested in approximately 17% of cases of MI (Muller *et al.*, 1997), with strenuous exertion the most potent. In the MI Onset Study, 4.4% of patients engaged in strenuous activity in the hour prior to their infarction (Mittleman *et al.*, 1993). However, the increased risk during and immediately following exercise is more than offset by a reduction in cardiac events during the rest of the week in active vs. sedentary people. In the MI Onset Study, 8% of patients reported an episode in which they were at least 'very angry' in the 24 hours prior to MI and 2.4% reported such anger in the 2 hours preceding their infarction (Mittleman *et al.*, 1995). Each time an individual becomes angry there is a $2.3\times$ increased risk of triggering an MI during the angry episode and for a 2-hour hazard period afterwards.

Sexual activity is a modest trigger, accounting for fewer cases of MI than assuming the upright posture on awakening, reassuring information for cardiac patients with an active love life (Muller *et al.*, 1996).

A 1-hour hazard period has been identified after marijuana use with a 4.8 fold increased relative risk (Mittleman *et al.*, 2001). Similarly, cocaine elevated risk of MI 23.7 times over baseline for 1 hour after use (Mittleman *et al.*, 1999).

Two studies reported that physical and psychological stress, as well as anger, can serve as 'triggers' for ICD discharge (Fries *et al.*, 2002); (Lampert *et al.*, 2002). Intriguingly, 2 studies recently reported increased ICD discharge after the September 11, 2001 attack on the World Trade Center, both in the New York Metropolitan area (Steinberg *et al.*, 2004) and as far away from the disaster as Florida (Shedd *et al.*, 2004). Whether ICD discharge might be reduced with psychosocial intervention has not, to our knowledge, been reported.

Psychosocial interventions

A 1999 meta-analysis of 37 studies by Dusseldorp *et al.* (Dusseldorp *et al.*, 1999), concluded that psychosocial interventions provide a significant positive effect on cardiac risk factors, a 29% reduction in recurrent MI and a 34% reduction in cardiac mortality.

However, since then, clinical trials have produced mixed results. Following is a brief description of the trials that we consider most noteworthy (see also 'Coronary heart disease: rehabilitation').

The Recurrent Coronary Prevention Project (RCPP)

The Friedman and associates' Recurrent Coronary Prevention Project (RCPP) (Friedman *et al.*, 1986) was the first large-scale post-MI Type A behaviour modification programme, completed in 1987. After 4.5 years of group counseling, there was a 44% reduction in second MI, which was associated with reductions in Type A behaviour. The control group was subsequently offered Type A counselling and showed a similar reduction in MI recurrence rates over an additional year (Friedman *et al.*, 1987). The RCPP also determined that Type A counselling was most protective against cardiac death for patients with less severe MI (Powell & Thoresen, 1998), suggesting that psychosocial intervention is most effective when individuals are still relatively healthy. Further, there was a significant reduction in sudden, but not non-sudden, cardiac death (Brackett & Powell, 1988), providing support for the hypothesis that behavioural factors may precipitate lethal arrhythmias.

Enhancing Recovery In Coronary Heart Disease patients – 'ENRICHD'

The largest psychosocial intervention to date, ENRICHD was a randomized clinical trial of individual and group cognitive-behavioural psychotherapy vs. usual care for 2481 post-MI patients who met modified DSM-IV criteria for major or minor depression and/or low perceived social support (Writing Committee for the ENRICHD investigators, 2003). Cognitive-behavioural therapy is widely regarded as a well-researched and effective psychological treatment for depression (see 'Cognitive behaviour therapy') (Deckersbach *et al.*, 2000). Sertraline (Zoloft®) was provided for patients with high scores on the Hamilton Rating Scale for Depression or having less than a 50% reduction in Beck Depression Inventory scores after 5 weeks.

At 6 months, the cognitive-behavioural intervention reduced depression and social isolation in the treated groups compared with usual care controls. However, group differences diminished over time and became non-significant for depression at 30 months and for low perceived social support by 42 months. There were no reductions in recurrent MI or cardiac death rates with the intervention compared with usual care. Depression spontaneously improved to an unexpected degree in the usual care group, reducing the statistical power of the study design. A post hoc analysis of ENRICHD reported that white males, but not other sub-groups, had reduced recurrent nonfatal MI and cardiac mortality with the intervention compared to controls (Schneiderman *et al.*, 2004).

The Sertraline Antidepressant Heart Attack Randomized Trial – 'SADHART'

'SADHART' (Glassman *et al.*, 2002) was a drug trial, with no psychotherapy, for depression in post-MI and unstable angina

patients, conducted to establish the safety and efficacy of sertraline in the cardiac population. Sertraline was found to be safe, with no reductions in ejection fraction. The incidence of major cardiovascular events was 14.5% in the sertraline treated group compared with 22.4% in the placebo group, a non-significant difference.

As with ENRICHD, SADHART found an unexpectedly high rate of improvement in depression in the control group. Nonetheless, sertraline-treated patients showed significantly greater improvement than controls on the Clinical Global Impression Improvement Scale, supporting a potential benefit of psychotropic intervention for depressed post-MI patients.

Intensive lifestyle change

The Lifestyle Heart Trial (Ornish *et al.*, 1990) achieved great national attention by demonstrating angiographic evidence for reversing coronary atherosclerosis with intensive lifestyle modification. Additionally, positron emission tomography (PET) scans have shown improved myocardial perfusion with such lifestyle changes (Ornish *et al.*, 1998).

In the Lifestyle Heart Trial, 48 CHD patients were randomized to intensive intervention or routine medical care. The intervention required a very low fat vegetarian diet, daily yoga and meditation, twice weekly support groups and regular exercise: approximately 14 hours per week of active participation (see also 'Physical activity interventions', 'Relaxation training' and 'Social support interventions'). After one year, 82% of experimental subjects showed regression of atherosclerotic lesions compared to 42% of controls (Ornish *et al.*, 1990). After four years, average stenosis diameter decreased in experimental patients but progressed in the control group (Ornish *et al.*, 1993).

Ornish's most recent work, the Multicenter Lifestyle Demonstration Project (Ornish, 1998), was a non-randomized study at 8 sites across the USA, designed to assess whether patients could avoid revascularization by making similar lifestyle changes. After 3 years, there were no significant differences in MI, stroke or deaths for treated vs. control subjects. The major finding of this demonstration project was an average cost savings of \$29 529 per patient.

A most important unanswered question about Ornish's intensive lifestyle programme is whether a significant percentage of the population can be persuaded to live in ways so far from cultural norms. In addition, the number of patients studied in the Ornish programme is small and falls far short of the standards that warrant recommendations from respected authorities such as the Centers for Disease Control (CDC), National Cholesterol Education Program, American Heart Association or American College of Cardiology.

Psychological interventions

Jones and West (Jones & West, 1996) randomized 2328 post-MI patients to either routine medical care or 7 two-hour psychological interventions. Although there were encouraging reductions in angina and cardiac mortality at 6 months among

intervention patients, after 1 year there were no significant differences in psychological factors, such as depression and anxiety or cardiac endpoints. One question posed by these results is that since the intervention was not successful at reducing psychosocial factors, why would it be expected to improve cardiac outcome? In our clinical experience, 14 hours of patient contact over a year would not be expected to have much of an impact. Additionally, patients were not pre-selected for any psychological condition, such as depression or distress: all patients, including those who did not need 'stress reduction' were included in the study.

In contrast, Blumenthal *et al.* (Blumenthal *et al.*, 2002) randomly assigned 107 CHD patients with evidence of ambulatory or mental-stress-induced myocardial ischaemia to a 4-month programme of exercise or 'stress management'. The study was, in part, modelled after the RCPP. Psychosocial intervention consisted of 16 one-and-a-half-hour group sessions based a 'cognitive-social' model. After an average of 38 months, stress management was associated with a 0.26 relative risk ($p=0.04$) of an adverse cardiac event compared with usual care control subjects who did not live near the medical centre. Follow-up after 5 years showed a similar reduction in adverse cardiac events as well as considerably reduced medical costs.

A number of clinical trials have been undertaken in Europe. In the Netherlands, Denollet and Brutsaert (Denollet & Brutsaert, 2001) studied 150 men with CHD who received either usual care or special intervention that added weekly two-hour group therapy sessions with a significant other to standard exercise cardiac rehabilitation for 3 months. In addition, 49% (38 of 78) of patients received weekly individual psychotherapy. At the end of 3 months, 43% of patients reported improvement and 15% worsening of distress. At 9 year follow-up, rate of death was 17% for control patients compared with 4% for intervention patients ($p=0.009$).

Hamalainen and associates (Hamalainen *et al.*, 1995) studied a group of 375 (74 women) acute MI patients in Finland who were provided with a comprehensive rehabilitation programme that included psychological discussion groups. Patients were followed for 15 years, after which there was a significantly lower incidence of sudden cardiac death (16.5% vs. 28.9%; $p=0.006$) and cardiac mortality (47.9% vs. 58.5%; $p=0.04$) in the intervention compared with the control group. The protective effects of the comprehensive cardiac rehabilitation programme were significant twelve years after all intervention had ceased.

In Sweden, Burell (Burell, 1996) randomized 268 non-smoking post-coronary artery bypass graft (CABG) patients to a group programme for modification of the TABP and cardiac risk factor education or a control group that received routine care. During the first year, intervention patients met for 17 three-hour sessions with 5-6 'booster sessions' in years two and three. At follow-up 4.5 years after surgery, there was a significant difference in total [7 vs. 16 ($p=0.02$)] and cardiovascular [5 vs. 8 NS] deaths between treatment and control patients respectively. There were 14 fatal and non-fatal cardiovascular events in the intervention group compared with 19 in the control group ($p=0.04$).

The current state of behavioural cardiology/cardiac psychology

Over the past several decades, the database linking psychosocial factors with the onset and outcome from CHD has been greatly expanded, with depression and social isolation strongly linked with worsened outcome. The intervention literature, however, has produced mixed results. Interventions to modify the TABP, the RCPP, Project New Life and Blumenthal's trial, have all reported improved outcome. Ironically, several large studies have reported that TABP is not a risk factor for CHD (Case *et al.*, 1985); (Barefoot *et al.*, 1989); (Ragland & Brand, 1988) and recent research on the global TABP has been largely abandoned in favour of a more specific focus on hostility, one of its core components (see 'Hostility, Type A behaviour and coronary heart disease'). The ENRICHED study, designed to treat depression and social isolation, essentially failed to improve both psychological and cardiac outcome over the long term. Results strongly suggest that much post-MI depression remits spontaneously; important information for the design of future clinical trials.

Measurement of psychosocial variables is still a major issue. Most recent studies have relied on self-report questionnaires, which bias responses by limitations in subjects' self-awareness, as well as their willingness to acknowledge socially undesirable personality characteristics. At present, there are no agreed standards for assessment of any of the psychosocial risk factors, although some questionnaires, such as the Beck Depression Inventory, the Cook-Medley Hostility Scale and the Spielberger anger scales, have been used extensively.

A critical issue for intervention is its frequency and intensity. Ornish's programme requires great effort (14 hours a week), while Jones and West provided treatment of 14 hours over a year. We find that it is difficult for most cardiac patients to maintain heart healthy habits and after a 'honeymoon' of several months, most revert back to of their former unhealthy lifestyles. A 'healthy dose' of psychosocial intervention is likely needed for improved outcome.

Although the 'holy grail' of cardiac psychology/behavioural cardiology is the reduction of morbidity and mortality, this has not yet been achieved. It should be noted, however, that most psychosocial interventions have reported improvements in quality of life, a worthy goal in its own right: it is not just how long one lives, but also how well (see 'Quality of life'). Many of the interventions in clinical cardiology, such as CABG (other than for 'left main coronary artery' and 'triple vessel' (disease) and percutaneous transluminal coronary angioplasty (PTCA), do not necessarily lead to reductions in morbidity and mortality either. Modern trials of new medical therapies increasingly include assessments of quality of life and cost-effectiveness, often measured as Quality Adjusted Years of Life (QAYL) [gained]. Although psychological or behavioural interventions have yet to definitely increase survival or decrease future cardiac events, it seems likely that the recent attention given to psychological issues in cardiac patients yields improved quality of life, and it is probably cost-effective.

Coronary heart disease: heart failure

Kathleen Mulligan and Stanton Newman

University College London

Heart failure

Heart failure is a complex syndrome that can result from any structural or functional cardiac disorder which impairs the ability of the heart to pump (Cowie & Zaphiriou, 2002). Impairment in the pumping action of the heart can lead to a build-up of fluid in the lungs and extremities, causing symptoms of breathlessness and fatigue and signs of fluid retention in pulmonary congestion and peripheral oedema. It is primarily a disease of the elderly with an average age at diagnosis of 76 years and is more common in men than women. Heart failure is a major public health problem having an estimated prevalence of 0.4–2% in the general European population (Cowie *et al.*, 1997). Recurrent prolonged hospital admissions are common and mortality is high. In the Framingham Heart Study, among a cohort with onset of heart failure between 1990–1999, one-year mortality was 28% in men and 24% in women; five-year mortality was 59% and 45% respectively (Levy *et al.*, 2002).

Quality of life and mood

People with heart failure have reported poorer quality of life than that of the general population and those with a range of other chronic illnesses (Hobbs *et al.*, 2002) (see 'Quality of life'). The extent to which their quality of life is impaired appears to be related to the extent of functional impairment as measured by the New York Heart Association classification (NYHA). Impairment in quality of life has been found to be related to both morbidity and mortality. In the Studies of Left Ventricular Dysfunction (SOLVD) trial, the quality of life dimensions of heart failure symptoms, impairment in activities of daily living and patients' assessment of their general health were found to be independent predictors of heart failure related hospitalizations and mortality (Konstam *et al.*, 1996).

Depression is common in heart failure although reported prevalence varies, probably due to differences in the assessment and criteria for classification of depression and in the study populations. Most studies use questionnaire assessments which identify 'possible' or 'probable' depression but a diagnostic interview is required to confirm the presence of clinical depression (see 'Diagnostic interviews'). The percentage identified as depressed using clinical interview is therefore likely to be smaller than when using questionnaire assessment. Reported prevalence of depression in outpatient populations of heart failure has ranged from 11% who met the criteria for syndromal depression by diagnostic interview schedule (Turvey *et al.*, 2002), to 48% who scored in the depressed range on the Beck Depression Inventory (Gottlieb *et al.*, 2004). Prevalence of depression tends to be higher among inpatient populations. In one study, 13.9% of patients were diagnosed with major depressive

disorder by clinical interview (Jiang *et al.*, 2001). Using a questionnaire assessment Vaccarino *et al.* (2001) found that 77.5% scored within the depressed range. Depression appears in some studies to be more common in younger people and in women with heart failure (e.g. Freedland *et al.*, 2003), although this finding is not consistent.

While it may be reasonable to hypothesize that higher rates of depression among inpatients result from greater illness severity this is generally not found. The absence of a correlation between depression and measures of severity of heart failure, such as left ventricular ejection fraction, indicates that in those with similarly severe disease, patients who are depressed report more severe symptoms than those who are not depressed (Freedland *et al.*, 2003). There is evidence for a relationship between depression and the New York Heart Association (NYHA) classification of functional limitation, with higher rates of depression among those with greater functional limitation (Gottlieb *et al.*, 2004). The direction of this relationship merits further examination; while the symptoms and functional limitations of heart failure may lead to depression, the presence of depression could also exacerbate symptoms and functional limitations (see 'Symptom perception').

Depression also appears to be associated with a poorer prognosis, although there are some conflicting findings. Hospital readmission has been found to be more frequent in depressed patients and depression has also been found to predict mortality (Faris *et al.*, 2002). Vaccarino *et al.* (2001) found that after adjustment for demographic factors, medical history, baseline functional status and clinical severity, an increasing number of depressive symptoms was associated with a significantly higher risk of the combined endpoint of functional decline or death.
