The important role of depression in heart failure extends to research which suggests that depression may increase the risk of developing heart failure. In a study of 4538 people aged 60 and over who were followed for an average of 4.5 years, people with depression were at more than twice the risk of developing heart failure as those without depression (Abramson *et al.*, 2001). It has been suggested that the relationship between depression and heart failure may be due to a common pathophysiology. The neurohormonal activation, rhythm disturbances, inflammation and hypercoagulability that have been postulated to play a role in development and prognosis of heart failure are also seen in depressed patients (Joynt *et al.*, 2004). Another study however, did not find that depression was an independent risk factor for subsequent development of heart failure (Chen *et al.*, 1999), so further investigation is necessary in order to clarify the nature of the relationship.

The link between depression and heart failure raises the question of the extent to which heart failure patients receive treatment for

depression. The evidence suggests that only a small proportion of those heart failure patients with depression receive treatment (Jacob *et al.*, 2003). A screening assessment for depression should be considered in all patients with heart failure.

In contrast to depression, there is little research on anxiety in heart failure. In a study of male inpatients, anxiety was not higher than in a group of healthy subjects but in the heart failure patients, those in NYHA class III reported higher anxiety than those in classes I and II (Majani *et al.*, 1999). No association between anxiety and mortality or hospitalization was found in the SOLVD trial (Konstam *et al.*, 1996). A link between anxiety and depression in heart failure was reported by Freedland and Carney (2000) who found anxious reactions to dyspnoea to be more common in depressed than non-depressed patients.

Self-management

Heart failure can worsen quickly so detection of early indicators of deterioration is important. One way to achieve this is for patients to self-monitor for signs of fluid retention such as shortness of breath, weight gain and oedema. In addition, self-management of the medication regimen and care over salt and fluid intake are important. Other lifestyle factors can have a significant impact and patients are encouraged to take regular exercise, give up smoking and abstain from alcohol if it was the cause of their heart failure (see 'Coronary heart disease: rehabilitation'). Many people with heart failure do not incorporate or maintain these self-management activities (Carlson *et al.*, 2001) and this can lead to rapid deterioration in their condition, often requiring hospital care. To date, most approaches to reduce the risk of hospital admission have involved more intensive follow-up at home or in clinic by multidisciplinary teams, or telephone follow-up; most programmes also include education. Many of these interventions have shown reductions in hospitalizations for heart failure and, in the case of multidisciplinary follow-up, all-cause hospitalization and mortality (McAlister *et al.*, 2004).

An interesting issue is the proportion of patients who, after these interventions, adopt the self-management behaviours that they have been taught. Uptake of self-management behaviours was examined in a study by Wright *et al.* (2003). Patients were randomized to either usual care or to a programme that included specialist and primary care follow-up, education, a diary and instructions for daily weighing. Of 100 patients in the intervention group, 76 used the diary, 51 of whom weighed themselves regularly (\geq once a week). Importantly those patients who weighed regularly were less likely to have a hospital admission and there was a trend for them to have

a longer time to first readmission and more days alive and out of hospital over the course of the study. Given the apparent benefits, studies need to examine ways of increasing the numbers of patients who adopt self-management behaviours (see 'Self-management').

In other illnesses, such as arthritis, asthma and diabetes, provision of information alone has been found to be insufficient to bring about behaviour change, leading to the incorporation into self-management interventions of psychological strategies such as motivational interviewing, problem-solving and cognitive-behavioural techniques (Newman *et al.*, 2004) (see 'Cognitive behaviour therapy' and 'Motivational interviewing'). In heart failure, few studies to date have gone beyond the provision of advice and instruction. Some do refer to the use of 'counselling' but the meaning of what is meant by counselling in this context and the theoretical approach used, if any, are unclear.

Interventions to improve people's self-management of their heart failure need to take account of cognitive, emotional and social factors which could act as barriers to behaviour change. The link between depression and outcomes in heart failure highlighted above may also involve behaviour in that depressed patients may be less likely to take their medication (Carney *et al.*, 1995) (see 'Adherence to treatment'). Other factors such as patients' beliefs about their illness and recommended treatment, as well as their cognitive capacity to follow advice, are also relevant. For example, one issue concerns the interpretation of symptoms and how they influence the taking of action. A qualitative study found that most patients did not accurately interpret worsening symptoms and act upon them promptly. Patients perceived heart failure as an acute, episodic condition and treated it as such, rather than as a chronic condition requiring ongoing monitoring and self-management (Horowitz *et al.*, 2004) (see 'Lay beliefs about health and illness' and 'Symptom perception').

Clinical implications of cognitive dysfunction were reported in a study by Ekman *et al.* which found that a low score on the Mini Mental State Exam was associated with non-participation in a nurse-directed outpatient programme (Ekman *et al.*, 2001). Research in this area is not well developed but studies to date suggest that cognitive impairment, particularly in memory and attention, is fairly widespread (Almeida & Flicker, 2001) and may be an influence on adherence to medication.

Coronary heart disease: rehabilitation

Robert J. Lewin

University of York

History and ethos

Cardiac rehabilitation (CR) began in the 1960s. The rationale was that part of the heart muscle was no longer pumping but that a programme of exercise would strengthen the remaining muscle thereby restoring the patient's ability to lead a normal life. By the 1990s it was established that middle-aged, white males who had sustained a mild myocardial infarct (MI) could significantly increase their physical fitness, but that this had little impact on the poor psychosocial outcomes exhibited by approximately a third of patients. The term 'comprehensive cardiac rehabilitation' was introduced to redefine CR as an activity that also attended to the psychosocial needs of patients (World Health Organization, 1993) and this is now widely accepted.

Content

The main tool for behaviour change is usually education in the form of group talks. It is unusual for psychosocial needs to be formally assessed and the only 'psychological' treatment provided in most centres is group relaxation classes. There is some evidence suggesting benefit from adding breathing retraining, (van Dixhoorn & Duivenvoorden, 1999) and stress management (Trzcieniecka-Green & Steptoe, 1996) (see 'Relaxation training' and 'Stress management').

Most national clinical guidelines have called for CR to move away from group programmes to an individualized programme based on assessment of need (including medical, psychological and social) and offering a 'menu' of treatment choices (Department of Health, 2002).

Delivery of cardiac rehabilitation

Social class, gender, area of domicile, ethnicity and age are all associated with low levels of uptake. Poor compliance is common, as many as 50% of patients will drop out of treatment (see 'Adherence to treatment'). A recent research monograph reviews these problems and the few published attempts to remedy them (Beswick *et al.*, 2004). Services are mainly delivered by nurses and/or physiotherapists.

A large number of patients remain untreated, for example, in the UK each year only 60 000 of the 350 000 potential patients receive CR. The numbers involved suggest that delivering psychological interventions would in most cases have to be done by non-psychologists. An interesting possibility is to train laypeople or CHD patients to deliver the treatment. Using information technology (IT) may also reduce the demand on personnel: several research projects are underway assessing Internet- or computer-delivered CR programmes and at least one has reported results similar to traditional methods (Gordon *et al.*, 2001).

Alternative methods

Two methods that use 'psychological' techniques and offer an alternative delivery method are in routine use. One used in the United States of America, is the MULTIFIT programme (Taylor *et al.*, 1997). It is based on Banduras' theories of self-efficacy and involves self-recording and brief phone contacts with a facilitator for goal setting (see 'Self-efficacy and health'). The second, widely used in the UK, is the Heart Manual (HM) (Lewin *et al.*, 1992). It is a six week, home-based, cognitive-behavioural (CB) intervention based around a patient-held workbook and audiotapes. Methods include reframing 'cardiac misconceptions', enhancing perceived global health and perceived control over the illness, self-recording, stress management, relaxation, breathing retraining and self-management advice for anxiety and depression (see 'Cognitive behaviour therapy'). It is administered by a 'facilitator' who has undertaken a 2-day training in the CB methods. Home-based programmes may improve uptake and compliance. In a choice trial offering the Heart Manual or hospital-based rehabilitation 44% of MI patients chose the HM and 87% completed it whereas 33% chose a hospital programme and 49% completed it (Dalal & Evans, 2003). Other studies have shown similar results (e.g. Smith *et al.*, 2004).

Psychologically orientated individual counselling delivered by a nurse (Johnston *et al.*, 1999) has also produced improvements in psychosocial outcomes and Petrie *et al.* have evaluated a pre-discharge, psychologist-led, 3-session (30–40 minutes each time) intervention designed to change illness beliefs and develop with the patient a post-discharge action plan. Scores on the Illness Perception Questionnaire changed inline with predictions and participants were more likely to have returned to work at 12 weeks post-discharge (Petrie *et al.*, 2002) (see 'Lay beliefs about health and illness' and 'Illness cognition assessment').

Effect of cardiac rehabilitation on mortality and morbidity

A recent meta-analysis included 48 randomized trials (8940 patients) and showed a 20% reduction in all cause mortality at 2–5

years (odds ratio = 0.80; 95% CI: 0.68 to 0.93) (Taylor *et al.*, 2004). It also showed an improvement in smoking but none in reinfarction rates, cholesterol (total and fractional), blood pressure or quality of life. A few trials have shown very significant benefits in all of these areas. A recent example is a study in Hong Kong that: improved anxiety and depression; improved scores on 6 of the 8 SF-36 quality of life dimensions and saved 640 US\$ per patient through reducing the need for angioplasty (Yu *et al.*, 2004). It was a long-term programme beginning in hospital and sustained over 2 years. It is probably fair to conclude that, when the standard UK 6–12 week outpatient model of CR is tested, there is improved exercise capacity but that quality of life and psychological factors are not improved (e.g. Bertie *et al.*, 1992).

Taylor (2004) divided the studies in the meta-analysis into those regarded as being 'comprehensive' or exercise-based and found no advantage in survival for 'comprehensive' rehabilitation programmes. Three trials of psychosocial interventions have been powered to show a reduction in mortality. In the first, 2328 patients were randomized to usual care or to attend seven, 2-hour sessions with a clinical psychologist (Jones & West, 1996). The M-HART trial, randomized 1376 post-MI patients to monthly screening using the General Health Questionnaire or to routine care: patients scoring greater than 5, received one or more nurse visits aimed at 'reducing stress' (Frasure-Smith *et al.*, 1997). Neither intervention had any effect on psychological outcomes or mortality. Both have been criticized for being atheoretical, having no detailed account of the therapeutic protocol or specific training for the 'therapist'. The third study, the ENRICHD trial, recruited and randomized 2481 patients to cognitive-behaviour therapy for depression. Depression improved but there was no reduction in mortality (Blumenthal *et al.*, 2004).

The evidence reviewed above provides support to those who believe that psychology has little to contribute to CR. This, however, ignores the key tasks faced by most patients in returning to a normal or near normal life which are: changing an unhealthy lifestyle; adjusting to a frightening diagnosis; coping with anxiety and depression; relationship and sexual difficulties and the problems of managing a long-term chronic disease (see 'Coping with chronic illness').

Adjunctive psychological treatments

A recent systematic review of whether psychological interventions benefit CHD patients included 36 trials (12 841 patients). It concluded that any kind of psychological or stress management intervention caused small reductions in anxiety and depression and that there was a reduction of non-fatal reinfarctions (OR 0.78, 95% CI = 0.67, 0.90) but that publication bias made these conclusions 'insecure' (Rees *et al.*, 2004). By way of contrast a review by Dusseldop *et al.* (1999) examined the effect of educational and psychological interventions on behavioural risk factors and showed that when interventions were successful there was an effect on mortality. Altogether there have been six systematic reviews of the same question and most were positive. However, despite the fact that each asked the same question, there is almost no agreement in the papers selected.

Cognitive-behavioural cardiac rehabilitation

The same lack of relationship between impairment and disability exists in CHD as in other chronic disease states. There is no significant relationship between ejection fraction (the efficiency of the pumping action of the heart) and functional ability, or between the extent of atheroma and angina. Or between impairment and psychological distress (except in end-stage disease when the symptom burden becomes overwhelming). There are moderate correlations between psychological predictors and functional performance, readmission to hospital, symptom report, quality of life, anxiety, depression, treatment costs and adherence to treatment.

The ways in which these factors interact in the case of angina suggested that CB chronic pain management techniques might be appropriate (Lewin, 1997) (see 'Pain management'). A hospital-based (Lewin *et al.*, 1995) and a home-based (Lewin *et al.*, 2002) Angina Management Programme has been developed and evaluated. Both forms had significant benefits showing a 70% and 40% reduction in angina respectively as well as improving aspects of disability. In addition to employing the common aspects of CB programmes this targets a set of symptom-specific and CHD-generic beliefs about heart disease which have been called 'cardiac misconceptions' (Maeland & Havik, 1989; Furze *et al.*, 2003). It is hypothesized that these lead to 'fear avoidance' of activity, leading to physical deconditioning and greater symptom load and further

avoidance. There is evidence that a change in these beliefs predicts greater activity (Furze & Lewin, 2004).

Conclusions

Cardiac rehabilitation has a powerful effect in deferring death but little effect on reducing disability or improving a poor quality of life. Despite an obvious role, few psychologists are directly involved in delivery. There is evidence from systematic reviews that psychosocial interventions for CHD patients can have an effect on anxiety, depression and risk factors for CHD. Evidence of an effect on mortality is missing.

No conclusions can be drawn about the relative value of different treatments due to a lack of common outcome measures and failure to attempt independent replication. The psychologically malleable factors that predict disability in patients with CHD are the same as those in other chronic diseases. They include anxiety, depression, health beliefs and poor self-management strategies. A promising direction for research is to use CB chronic disease management methodology whilst paying attention to disease-specific beliefs. Psychological interventions in CR are most likely to be adopted if they can be delivered by other health professionals and in the future they may also be delivered by trained laypeople and the Internet.

Coronary heart disease: surgery

Jan Stygall and Stanton Newman

University College London

Psychological responses to cardiac surgery

It has been suggested that a relatively high level of psychological morbidity follows cardiac surgery in contrast to other forms of surgery. However this view has not been borne out in formal research. Studies of general psychiatric morbidity, using standardized instruments, have shown a general reduction following cardiac surgery. Studies have also demonstrated that patterns of anxiety are similar to those found in other forms of surgery with a significant increase in anxiety in the days immediately before and after surgery followed by a significant drop in the weeks and months following surgery (Rymaszewska *et al.*, 2003). The prevalence of depression has been found to be the same before and after cardiac surgery, in the range of approximately 20–25% (Connerney *et al.*, 2001). Furthermore, studies have shown no differences in the emotional effects of either coronary bypass graft (CABG) surgery or valve replacement/repair (see also 'Stressful medical procedures' and 'Surgery').

Both anxiety and depression have been shown to predict adverse outcomes post-cardiac surgery (e.g. Connerney *et al.*, 2001; Rymaszewska *et al.*, 2003). Whereas early small studies (e.g. Connerney *et al.*, 2001) failed to find a relationship between depression and mortality after cardiac surgery, a large 12-year follow-up

study by Blumenthal *et al.* (2003) found depression to be an important independent predictor of mortality.

It is not surprising that the most potent predictor of mood state after cardiac surgery is mood prior to surgery. For example, Timberlake *et al.* (1997) found that 37% of patients were depressed pre-operatively, 50% at 8 days, 24% at 8 weeks and 23% 1 year after surgery. The pre-operative depression score was the best predictor of post-operative depression at all times of assessment.

Studies have demonstrated that depressed mood following surgery is influenced by a range of factors. For example, Coombs *et al.* (1989) found emotional social support to be highest in the days after surgery with higher social support at 5 days and 3 months being significantly associated with lower levels of depressed mood. This relationship, however, was not apparent at assessments conducted at 6 and 12 months post-surgery suggesting that perceived social support has an effect on mood only in the early period following CABG.

Patients' perceptions of their health have also been shown to be important in relation to mood state following cardiac surgery. Coombs *et al.* (1989) found that recurrence of chest pain and patient's perception of their overall health both contributed significantly to depressed mood when assessed 3 and 6 months after

surgery. They attribute the importance of these findings to patients' increasing concerns regarding the success of the procedure (see also 'Lay Beliefs about health and illness' and 'Symptom perception').

The effect of pre-operative education programmes on outcome have been evaluated. In one of these, Shuldham *et al.* (2002) compared patients receiving a 1-day pre-operative education programme with patients undergoing normal care and found no differences in the groups on outcome measures of pain, anxiety, depression and wellbeing but, surprisingly, found that the programme was associated with increased hospital stay. In contrast, Arthur *et al.* (2000) found that patients who received exercise training, education and reinforcement were discharged from hospital earlier and had an improved quality of life 6 months post-surgery. It is as yet unclear what the key components should be for a pre-operative programme in cardiac surgery, but it is important to note that the latter study had a very intensive programme spread over a number of weeks.

Changes in cognitive function

Neuropsychological (NP) complications affecting memory, concentration, attention and speed of motor and mental response have been shown to occur in patients following cardiac surgery. However, the reported frequency of these changes varies widely between studies. Studies assessing participants 5–10 days post-operatively have reported the incidence of neuropsychological morbidity to range from 12.5% to 79%. Whereas, later assessments, conducted between 6 weeks and 6 months have detected neuropsychological dysfunction in 12–37% of participants (S. Newman & Stygall, 2000). Longer term consequences have shown a significant deterioration in a small number of patients up to five years post-surgery (e.g. M.F. Newman *et al.*, 2001; Selnes *et al.*, 2001; Stygall *et al.*, 2003).

This variation has been attributed in part to methodological factors which include differences in the number, type and sensitivity of neuropsychological tests used, the definition of dysfunction and the method of statistical analysis employed. These methodological issues have been addressed at international consensus conferences (Murkin *et al.*, 1995, 1997). Arguably, the most important factor is the timing of the assessment. Assessments conducted later in the recovery period (over 6 weeks) are considered to be more stable and to reflect a more persistent neuropsychological problem. However, although it has often been argued that pre-discharge assessments are likely to be contaminated by general surgical recovery (see, for example, 'Anaesthesia'), there is an indication that these assessments may predict longer-term decline (e.g. Stygall *et al.*, 2003; van Dijk *et al.*, 2004).

Studies examining NP decline and cardiac surgery have been conducted since the early 1980s. During this time major advances have been made in surgical and anaesthetic techniques, as well as the type of equipment used. Patients operated upon now tend to be older and have more co-morbid illness than those in the early studies and, as patient variables such as age and disease severity have been associated with post-operative cognitive decline, these issues further contribute to the variations seen.

Type of surgery

Some authors have suggested that valve replacement surgery, which is an open heart procedure, should show a higher incidence of neuropsychological problems than that observed in CABG. Although most studies comparing these two forms of surgery have found a higher risk of stroke in valve replacement patients (e.g. Burcerius *et al.*, 2003), very little research has been conducted comparing the more subtle NP changes. Those few studies that have been carried out have produced contradictory results, some reporting poorer NP outcome in valve patients (e.g. Andrew *et al.*, 2001) and others suggesting no difference (e.g. Browndyke *et al.*, 2002).

Factors associated with neuropsychological dysfunction

Studies have suggested a relationship between patient characteristics and NP decline following cardiac surgery. These include older age, diabetes, aortic atherosclerosis, cerebrovascular and peripheral vascular disease. Higher levels of education have been found to be protective (Ho *et al.*, 2004). In line with their higher morbidity and mortality (Edwards *et al.*, 1998) and increased risk of neurological events (Hogue *et al.*, 2001), it has been suggested that females may be more susceptible than males to NP decline following cardiac surgery. However, Bute *et al.* (2003) found that although women were more likely to report cognitive difficulties, objective NP assessments found no difference between men and women one year post-surgery.

Other studies have examined the effect of different surgical and anaesthetic techniques on NP outcomes. These include cardiopulmonary bypass (CPB), hypothermia and acid-base management. A number of studies have found a relationship between the duration of CPB and NP decline. Equipment used for CPB is constantly changing. A number of studies have examined whether newer forms of equipment lead to lower levels of neuropsychological problems. One example is the method of oxygenating the blood, where membrane oxygenators have been found to produce less decline than bubble oxygenators. A second has been the use of arterial line filters in the CPB circuit to filter out microscopic particles of debris and air where the use of a 40 micron filter was found to reduce the frequency of NP decline (see Newman & Stygall, 2000 review).

It is common for cardiac surgery using CPB to involve hypothermia. Hypothermia has been considered to be protective against ischaemic damage. However, studies using stroke or NP decline as an outcome measure have shown mixed results (Newman & Harrison, 2002). One possible explanation given is that any neuroprotection produced by hypothermia may be offset by damage that occurs during the rewarming process. A feasibility study by Bar-Yosef *et al.* (2004) has shown that limiting the maximum temperature during the rewarming phase of the operation can prevent cerebral hyperthermia and randomized controlled trials are currently being conducted to evaluate this approach.

Two techniques have been used to manage the effects of hypothermia on pH levels. In one, the fall in pH is corrected by adding CO₂ (pH stat); in the other, the CO₂ is kept constant (alpha stat). It has been demonstrated that alpha stat management leads to fewer individuals with cognitive deficits (e.g. Patel *et al.*, 1996).

Relationship between neuropsychological deficit and putative mechanism of damage

The mechanisms contributing to post cardiac surgery neuropsychological deficits are uncertain. However, two inter-related factors, microemboli and altered cerebral perfusion, have often been suggested. Although profound hypotension during surgery may cause severe cerebral consequences, there appears to be little relationship between less severe differences in blood pressure and NP dysfunction.

In recent years transcranial Doppler detection has been applied to detect high frequency signals that appear to reflect either air or particulate matter going into the brain (microemboli) during cardiac surgery. The candidates for particulate matter include artheromatous matter, fat and platelet aggregates. These microemboli are thought to originate from the CPB equipment and artheromatous plaque in the heart vessels. Some studies have reported an association between number of microemboli detected and NP decline, others have found no such relationship. The association between microemboli and NP dysfunction is problematical as, at present, the size, composition and ultimate location in the brain of the microemboli cannot be reliably determined.

The emergence of beating-heart (off-pump) surgery as a common technique for multi-vessel revascularization has opened up an avenue of research to isolate the role CPB plays in cognitive decline post cardiac surgery. Many of the early studies were biased as they were retrospective and used patients that were specially selected for off-pump surgery. Although these studies provided some evidence that off-pump surgery may lead to a reduction in the occurrence of microemboli and strokes, a more recent randomized controlled trial (Van-Dijk *et al.*, 2002) found no difference in mortality, cardiac outcome or quality of life between patients receiving on or off-pump surgery at 1 month follow-up. At 3 months post surgery off-pump patients were found to have a better cognitive outcome compared to on-pump patients but these differences were not detected at 12 months. Further trials of this type are required to examine neurological and neuropsychological outcome following cardiac surgery.

Quality of life (QoL) following cardiac surgery

It would be expected that, without the constraints of chest pain and breathlessness associated with cardiac disease, increased levels of physical and social activity would occur after surgery. The advice given to the patient frequently includes a recommendation for increased physical activity. Consequently, it is not surprising that studies on both valve replacement and CABG surgery have found the majority of patients report increased levels of physical and social activity and improved QoL following cardiac surgery (e.g. Bute *et al.*, 2003). However, these improvements are not experienced by all patients. Approximately, 25–49% of patients report decreased activity levels (Rymaszewska *et al.*, 2003). Age, education, decline in NP functioning, pre-operative health status, co-morbid conditions and social isolation have all been shown to be important predictors of QoL outcome.

The research is less clear however with respect to gender differences. Various studies have suggested that women fare less well post-operatively, whilst others have found similar long-term outcomes for men and women. Women presenting for CABG tend to be older, less well educated, more likely to be single, living alone and unemployed. They are also more likely to have hypertension, diabetes and be overweight (see 'Diabetes mellitus' and 'Obesity'). It has therefore been argued that women do less well post-operatively due to pre-operative health status. A recent study by Bute *et al.* (2003) found that even when adjusting for pre-existing risk factors, women were more anxious, had a diminished ability to perform daily and work-related activities and lower exercise capacity in comparison to men. However, in another study looking at the impact of pre-operative health on QoL, Rumsfeld *et al.* (2001) found that whilst pre-operative health status was the major predictor of QoL following surgery it was those patients with poor pre-operative health that derived most QoL benefit from surgery. Various studies have found similar cardiac outcome and quality of life following off-pump compared to on-pump CABG (e.g. Ascione *et al.*, 2004).

Cystic fibrosis

Claire A. Glasscoe

Royal Liverpool Children's Hospital

The disease

Cystic fibrosis (CF) is the most common fatal hereditary disease in the Western world; although not confined to those of European ancestry, CF is rare in oriental and native African people (Tsui, 1990). The recessive gene is carried by 4% of the populations in the UK and US affecting 1:2000–3000 live births (Bobadilla *et al.*, 2002). The disease is characterized by generalized dysfunction of the exocrine glands. These produce excessively viscous mucus secretions that block ducts and are prone to infection. Lung

infections are the most serious complication with 90% of those affected with CF eventually succumbing to pulmonary disease. Pancreatic insufficiency is present in 85–90% of patients with malabsorption of fat and protein. Sterility occurs in 98% of males whereas female fertility is near normal. Puberty is generally delayed by two years in both sexes reflecting the reduced height and weight potential.

During 1969–90 the median age of survival doubled in the US from 14 to 28 years (FitzSimmons, 1993) and was reported to be 30 years in the UK in 1994 (Dodge *et al.*, 1997). This improved

prognosis is attributable to specialist multidisciplinary CF centres, early diagnosis and breakthroughs in management. Neonatal screening for CF has been piloted and implemented in some parts of Europe and in the US and Canada and scheduled to start nationally in the UK in 2006 (see 'Screening: antenatal').

Although discovery of the CF gene defect on the seventh chromosome (Kerem *et al.*, 1989), and its malfunction, brought real hope for an eventual cure, gene therapy has proved difficult to accomplish. Treatment is mainly palliative and aimed at slowing or preventing some of the secondary effects of the disease (Hodson & Geddes, 2000). The daily regimen typically includes:

- replacement of pancreatic enzymes and nutritional supplementation
- antibiotics administered orally and/or intravenously
- chest physiotherapy and postural drainage
- nebulization of bronchodilators and mucus thinning agents.

Psychosocial impact

Patients

Findings relating to psychological effect of CF for patients are inconsistent. Some researchers find no evidence of abnormality while others report symptoms of anxiety, depression and eating disorder. Thompson *et al.* (1990) compared children aged 7–14 years, with psychiatrically referred and non-referred children. Those with CF showed no more psychological disturbance than non-referred children, although they reported equivalent levels of worry, anxiety and poor self-image to children referred to child psychiatry.

Pearson *et al.* (1991) examined differences in two age groups, 8–15 years and 16–40 years and found elevated levels of disturbance. This was manifested by anorexic type eating disorder in younger patients (16.4%) and symptoms of anxiety (22.2%) and depression (42.4%) in the older age group. The developmental trend that emerged suggests that younger children may have expressed distress through oppositional behaviour with food consumption as a control issue. Adolescents and young adults showed more preoccupation with self-image perceptions and apprehension about the future (see 'Children's perceptions of illness and death').

Parents

Parenting a child with a chronic life-shortening condition poses unique challenges at every stage. Quittner *et al.* (1992) focused on the diagnosis phase and demonstrated that when stressors were linked to CF a strong association was found between role strain and depression for mothers. The same was not the case for fathers despite both parents reporting elevated levels of depression (64% of mothers, and 43% of fathers). Fathers were less involved in childcare and acknowledged more difficulty in carrying out treatment routines; their worries revolved around the financial burden associated with the disease. In this same study partners tended to rate their relationship between the norms for married and divorced couples, suggesting some degree of marital difficulty. A subsequent study at a later disease-stage with children aged 2–6 years by the same authors showed no significant differences in psychological distress or partner satisfaction from control parents (Quittner *et al.*, 1998).

Nevertheless, role strain represented by role frustration and conflict over child rearing continued to predict partnership dissatisfaction in mothers.

Families

Interplay between family lifecycle events, developmental processes in patients and siblings, and the course of the disease can be problematic. Families endeavour to contain the intrusion that CF makes into their lives by establishing routines for tasks, compartmentalizing information, redefining normality, reassessing priorities and the future and avoiding reminders of the disease (Bluebond-Langner, 1991). In a 2-year ethnographic study Bluebond-Langner observed these strategies being employed adaptively at salient points in the overall disease process allowing families to live as normal a life as possible. Wilson *et al.* (1996) found some support for the notion that family functioning operates in a compensatory way to avert the effects of physical decline. In this study increased symptoms mobilized a coping response and factors that undermined this homeostatic mechanism were extraneous life events such as loss of friends, change of school and house moves.

Psychological functioning and health status

Although earlier studies into the psychological aspects of families with a child with CF tended to emphasize dysfunction, recent research has focused more on resilience, coping strategies and adaptation. The work of Simmons and Goldberg (2001) suggests that the physical benefits of an early diagnosis may be tempered by potential disruption of the parent–child relationship, which may occasionally undermine the infant's physical growth. Patterson *et al.* (1990) used the Family Adjustment and Adaptation Response (FAAR) model to examine the effects of family functioning on health changes. The variables of family stress, family resources and parental coping combined explained 22% of the variance in height and weight changes over a 15-month period. Although the association is undoubtedly reciprocal this finding lends credence to the view that the whole family system needs to be considered with respect to children's health.

Treatment burden and adherence

As biomedical treatments become more complicated, physicians have expressed concern about the heavy burden of treatment families affected with CF are asked to carry. The involvement of both parents and the healthcare team in achieving a reasonable balance while ensuring adherence to core treatments is critical. Chest physiotherapy is crucial in preventing the onset of pulmonary disease, which is responsible for 90–95% of CF deaths, and yet it is the least adhered to aspect of treatment; only 40% completely adhering (Stark *et al.*, 1987) (see 'Adherence to treatment'). Dietary management is also necessary to prevent physical decline. The energy requirement needed to maintain optimum height and weight is 120–200% of the recommended dietary allowance (RDA) for healthy children, yet the average reported intake for children with CF is only 80% RDA (Stark *et al.*, 1990).

Koocher *et al.* (1990) argue that patients with CF do not all fail to follow medical advice for the same reasons. Three categories are outlined: those who for a variety of reasons are misinformed about treatment requirements; those who for emotional or psychological reasons are resistant to treatment and those who have arrived at a rational decision to refuse treatment. In the first instance a psychoeducational approach might be indicated, while in the second individual, group or family therapy may be more appropriate. In the final case the patient's wishes should be respected and accommodated as far as possible.

Psychological interventions

A systematic review (Glascoe & Quittner, 2002) revealed genetic counselling, promotion of airway clearance, dietary management and moving towards independence as main targets for intervention trials. Interventions with specific relevance for CF include:

Biofeedback

In association with physiotherapy biofeedback may assist airway clearance and improve lung function (Delk *et al.*, 1994) (see 'Biofeedback').

Behavioural and cognitive therapy

Individual behavioural contracting and a group behavioural approach with parents and children can help promote adherence to chest physiotherapy and dietary requirements (Stark *et al.*, 1987; Stark *et al.*, 1990) (see 'Behaviour therapy' and 'Cognitive behaviour therapy').

Psychoeducation

Parents of children with CF are expected to perform complex medical tasks at home and monitor changes in their child's health. Such responsibility requires sound judgement and swift decision-making. A health education programme for the self-management of CF developed by Bartholomew *et al.* (1997) addresses these issues. The StarBright CD-ROM has a similar aim to promote knowledge and coping skills in children and adolescents (Davis *et al.*, 2004).

Family therapy

A CF diagnosis reverberates throughout the family, touching each individual and their relationships. Transitions during adolescence take on additional meaning in the context of CF and can be particularly difficult for families to negotiate (DeLambo *et al.*, 2004). A biopsychosocial systems perspective facilitating communication between family members can assist in these negotiations.

Conclusions

Cystic fibrosis is a chronic life-shortening disease with wide-reaching implications for patients and families. Although characterized more by resilience and coping than dysfunction this is a vulnerable group with sub-clinical levels of psychological distress. Most studies conclude that adequate family functioning is more important for psychological adjustment than illness severity. A fully integrated response considers the relationships between physical and psychological factors and views the disease and its management within a family context.

Acquired hearing loss

Laurence McKenna and David Scott

Royal National Throat, Nose and Ear Hospital

Hearing loss that is acquired after the development of language is distinct from pre-lingual hearing loss in its psychological and social manifestations. This chapter is concerned with hearing loss that occurs after the development of language.

Audiological background

Hearing loss is categorized by the site of the lesion causing the loss. A lesion of the outer ear, ear drum or middle ear causes a conductive hearing loss, due to a reduction in hearing sensitivity. A cochlear hearing loss may lead to reduced auditory discrimination as well as reduced hearing sensitivity. A lesion affecting the auditory nerve may also cause reduced sensitivity and discrimination. Finally, a category of Central Auditory Processing Disorder (CAPD) has been identified in which cochlear function may be normal, but the person has auditory perceptual problems particularly in the presence of background noise. The categories of cochlear, retro-cochlear and central auditory dysfunction are referred to as sensori-neural hearing loss (SNHL). Most adults with an acquired hearing loss have cochlear dysfunction, with the most common aetiology being age-related hearing loss. Davis (1997) reported that 13.9% of the adult population (aged 18–80) have a SNHL equal to, or worse than, 25 dB (the level of a whisper) in the better ear. This prevalence rises with age such that 42% of elderly people have such a loss. This criterion of SNHL represents the point at which an individual might benefit from a hearing aid. Unfortunately, the shortfall in provision is such that millions of people in England and Wales who would benefit from a hearing aid do not have one (Davis, 1997).

Even in the presence of one normally hearing ear, a hearing impairment in the other may cause considerable hearing handicap. Acquired profound deafness is rare, but the consequences may be devastating. Conductive hearing loss is often amenable to surgical or medical treatment. In SNHL, surgical intervention is usually not possible, and those affected can only be offered hearing aids that

will not result in normal hearing abilities. In some cases of profound hearing loss, cochlear implantation is possible. Modern digital hearing aids and cochlear implants now help some people who previously could not benefit from older hearing aid equipment devices. Patients often fail to comply, however, with a technological approach to the management of hearing impairment and there is a risk of such advances producing technology-centred rather than patient-centred therapy.

Psychological profile of people with acquired hearing loss

A popular image of people with hearing impairment is that they suffer from psychological disturbances such as depression or paranoia; however, this idea is only partly supported by the literature (Andersson, 1995). The link between hearing loss and psychological status has been investigated in a number of ways. One approach has been to examine the prevalence of psychological problems among a population of hearing impaired people. For example, McKenna *et al.* (1991) reported that 27% of people attending a neuro-otology clinic with a main complaint of hearing loss were suffering from significant psychological disturbance. This is considerably higher than the prevalence of psychological disturbance among the general population but is lower than the prevalence rates associated with other audiological symptoms such as tinnitus or vertigo (McKenna *et al.*, 1991; Asmundson *et al.*, 1998). An alternative approach has been to examine the extent of hearing loss among populations of known psychiatric patients, but it has proved difficult to draw conclusions from this research as hearing loss can lead to misclassification of psychiatric morbidity (Kreeger *et al.*, 1995). When other health problems are taken into consideration, the correlations between hearing loss and anxiety and depression are weaker. The presence of multiple audiological symptoms increases the likelihood of significant psychological distress. The high co-morbidity between

hearing loss and tinnitus is particularly relevant in this respect (see 'Tinnitus').

A different approach to the study of hearing loss was taken by Kerr and Cowie (1997). They described the subjective experiences of people with acquired hearing loss in terms of six factors derived from a factor analysis of questionnaire responses. Only one of the factors obtained referred to the communication problems that one might expect to be associated with hearing loss. The others were concerned with psychological and social issues including a factor that referred to positive consequences such as increased social support and inner philosophical resources. The finding that hearing loss might be associated with positive consequences may seem surprising but there are other sources of evidence that the effects of hearing loss are not always those that one might suppose, e.g. not all cochlear implant users report a positive psychological outcome, even when the implant provides obvious acoustic benefit.

It is clear that the relationship between hearing loss and psychological wellbeing is a complex one. Many people do not complain about their hearing loss and some people deny that they have a hearing problem even when confronted by the audiometric evidence (Gilhorne Herbst & Humphrey, 1980). Audiological measures do not, however, predict the extent of psychological disturbance (Gilhorne Herbst & Humphrey, 1980; Thomas & Gilhorne Herbst, 1980; Kerr & Cowie, 1997). One study (Thomas & Gilhorne Herbst, 1980), however, found that there was a higher degree of psychological disturbance among those with particularly severe hearing loss and poor speech discrimination who received little benefit from hearing aids. The ambiguous findings concerning the relationship between hearing loss and psychological wellbeing may be in part due to an overly simplistic assessment of psychological status. Many studies (e.g. Thomas & Gilhorne Herbst, 1980; Singerman *et al.*, 1980) have classified people as either psychiatrically disturbed or not. Such a basic dichotomy excludes many distressed people who may fall short of the dysfunctional classification. Stephens and Kerr (2000) have suggested that the World Health Organization (WHO, 2000) classification of losses or abnormalities, limitations of activities, restrictions in participation and contextual factors may be useful in understanding the relationship between hearing loss and psychological disturbance. The WHO classification is set within the context of the social model of disability and suggests that disablement occurs within and by means of social and personal contextual factors (see 'Disability').

While the notion that social factors affect levels of hearing disability is now considered self-evident (e.g. a hearing impaired person is disabled by background noise), from a clinical point of view, it is also apparent that deafened people encounter psychological obstacles through factors such as anxiety and reduced motivation. Research from the field of cochlear implants adds to this picture. McKenna and Denman (1993) assessed a group of cochlear implant users' retrospective perceptions of changes in their psychological status and found that almost all believed that their lives were close to ideal prior to the onset of hearing loss, and that their lives were radically changed by deafness. It seems implausible that so many in any group would have had near perfect lives before losing their hearing. It is likely that this idealized view of their life as a hearing person represented a cognitive shift that increased the perception of loss and this reappraisal was, in turn, a determinant of the subsequent disability behaviour. To date, little work has been

done to delineate the psychological processes that might be involved in this context, although the Theory of Planned Behaviour (Ajzen, 1988) may have some resonance with the clinical observations made within audiology (see 'Theory of planned behaviour'). Skinner and Vaughan (1983) viewed hearing in behavioural terms. They suggested that hearing can be viewed as an operant, i.e. it is influenced by contingencies of reinforcement (see 'Behaviour therapy'). Skinner advocated that individuals should adopt an assertive approach to hearing difficulties while acknowledging that when it is impossible to hear: 'You do best to stop trying to hear things when you are having trouble. You are probably not enjoying what is said in a television programme if you are straining to hear it' (Skinner & Vaughan, 1983, p. 44).

It has also been suggested that auditory processing problems can affect cognitive functioning which itself may be compromised by stress (Pichora-Fuller, 2003; McKenna, 1997). The identification of this type of difficulty highlights the importance of including psychological factors in any model of hearing disability and rehabilitation.

Psychological treatment approaches

Although most people with a hearing loss will receive practical support and counselling from an audiologist, few will have their psychological needs identified or met via this route. For those who do receive psychological counselling, the emphasis is likely to be on working through a grief process, which is most relevant where the onset of hearing loss was sudden. Usually, it is only when a patient exhibits enduring distress that a referral to a psychologist is made. In such cases, difficulties adjusting to hearing loss are often associated with negative beliefs about the implications of the loss. In common with patients with other physical symptoms, patients with hearing loss may attach too much weight to beliefs concerning the adverse consequences of having a hearing impairment. Cognitive-behavioural therapy is often employed to address this source of distress (see 'Cognitive behaviour therapy').

A cognitive-behavioural approach to the management of hearing loss in elderly people has been described in a series of studies by Andersson and colleagues (Andersson *et al.*, 1995, 1997). This work focused on setting individualized treatment goals, behavioural tasks and communication strategies to assist the patient to employ hearing tactics, i.e. the methods used by hearing impaired people to solve everyday hearing problems such as facing the speaker, having the light shining on the speaker's face and asking the speaker to talk slowly and clearly. They found that patients treated in this way were better able to cope with their hearing loss and concluded that disability resulting from hearing impairment could be regarded as a behavioural problem which can form the focus of rehabilitation. They suggested that cognitive, and especially motivational, factors are of central importance in understanding hearing disability.

The work on hearing tactics has been reconsidered in the light of coping research. In a review, Andersson and Willebrand (2003) suggested that some of the benefits of hearing tactics may be a product of changes in appraisal rather than the application of the tactics themselves. They concluded that although coping research has much to add to our understanding of hearing loss, the concept of

coping has usually been regarded as being simply equivalent to communication strategies or distress in relation to communication failure. This is in contrast with the more complex concept of coping endorsed by health psychologists (Lazarus, 1993). In a recent study (Andersson & Hägnebo, 2003), coping strategies were assessed using

more standard coping measures (i.e. the Ways of Coping Questionnaire). The results showed that the participants with hearing loss ($N=94$) used planned problem-solving and self-controlling coping strategies, whereas escape/avoidance responses were less frequently used than the other coping strategies.

Dementias

Jenny Rusted

University of Sussex

Worldwide, we are currently witnessing an unprecedented demographic transformation, as life expectancy increases from the present 66 years of age to 77 years of age by 2050, and the proportion of the population over 60 doubles from 10 to 21%. A result of this increase in life expectancy is that the number of persons over the age of 60 years will rise from the current 600 million to around 1.5 billion by 2050. Britain will have over 6 million people over

75 years – double the 1985 figure, but significantly the great majority of older adults will reside in the less developed regions of the world (see also 'Ageing and health behaviour'). Currently around 60% of the world's older population live in less developed countries, i.e. an estimated 279 million: by 2050 this proportion is projected to increased to 88%. This explosion in numbers of the over-70s will

bring higher incidences of age-related illness and infirmity. Longevity is one of humanity's major achievements, but it brings with it the challenge to adjust our societies to this new reality by changing attitudes, introducing new political, social, health and economic measures that shift us from the current youthful pyramidal structures that are becoming obsolete in most world regions, though at a significantly faster rate in the more industrialized countries. Many less developed countries are currently experiencing a significant downturn in natural population increase (births minus deaths), similar to the decline that occurred in industrialized nations a few decades earlier. Italy is currently the world's 'oldest' major country (around 20% of its population being over 65), and indeed, except for Japan (19% of population over 65), the 20 'oldest' countries are all in Europe, ensuring that it will remain the 'oldest' world region well into the twenty-first century. While the older share of the population is expected to more than double between 2000 and 2030 in Asia, Latin America and the Caribbean (from around 5% to around 12%), ageing is occurring more slowly in sub-Saharan Africa, where relatively high birth rates, and the devastating power of the HIV/AIDs pandemic are keeping the population 'young' (current estimates of around 3% projected to increase by only 1% by 2030).

While an increasing body of evidence shows that ageing is not synonymous with gross deterioration in skills and abilities, there are, however, diseases for which incidence is age-related. Arguably the most devastating of these are the dementias. From the onset of the dementia, an individual is living with constant and growing sense of confusion. Idiosyncratic patterns of emergence of symptoms, and the essentially unpredictable slope of decline associated with the disease create an immensely difficult environment for both the patient and the carer. Because of the worldwide ageing phenomenon, existing in both developed and developing countries, dementia has a growing public health relevance. Indeed, international incidence and prevalence data for the dementias indicate little geographical variation across different countries.

Defining and characterizing the dementias

Dementia (of all types) affects 10% of the over-65s and some 20% of the over-85s. Worldwide, forecasts indicate a considerable increase in the number of demented elderly from 25 million in the year 2000 to 114 million in 2050 (84 million in less developed regions).

Technically speaking, dementia is a syndrome, a group of symptoms, that may vary significantly across sufferers. A number of disorders can produce the syndrome of dementia, and it is often hard to tell them apart. Of the dementias of organic origin, the three main types of dementia are vascular or multi-infarct dementia (VD, MID), dementia of the Alzheimer's type (DAT, SDAT, AD) and mixed MI/DAT. Vascular dementias result from multiple small strokes that ultimately produce sufficient tissue loss to produce cognitive and behavioural effects, often presenting as an uneven distribution of cognitive deficits, reflecting focal brain damage, and a stepwise deterioration of function, reflecting the temporal sequence of the brain infarcts. Less common dementias include Lewy body dementia (characterized by fluctuating and confused intellect; animated behaviour and intense visual hallucinations); Picks disease/fronto-temporal dementias (characterized by early emergence of behavioural symptoms, slow loss of language/vocabulary and preserved

spatial orientation; disinhibition). Chronic conditions such as CJD and variant CJD, Parkinson's disease, HIV, Huntington's Chorea and Korsakoff's disease may induce a dementia in the later stages.

Over half of all dementias are of the Alzheimer type (DAT), characterized by insidious progressive and irreversible decline in cognitive function. Clinical diagnosis depends on a history of progressive cognitive impairments and personality change (once all other potential causes of problems are excluded), with memory impairment a central feature, and aphasia, apraxia, agnosia and disturbance of executive function all possible (see also 'Aphasia'). The patient is also likely to demonstrate significant decline in social and occupational functioning (Diagnostic and Statistical Manual of Mental Disorders, version IV, (2000)). A progression through five phases can be expected:

- Phase I (incipient dementia) is associated with repeated objective evidence of memory failures; decreased performance in demanding work or social settings; and moderate anxiety.
- Phase II (mild dementia) is associated primarily with memory deficits and mood disturbances; an inability to perform complex tasks previously achieved, a conscious withdrawal from challenging situations, and denial.
- Phase III (moderate dementia) brings a marked increase in language aphasias; difficulties recalling major events and memories; poor short-term recall, and repeated 'checking' behaviours; and the need for some assistance with what had previously been 'routine' tasks.
- Phase III (severe) involves pronounced language and motor disturbances, hallucinations and disturbed sleep patterns; a patient will have little memory for events/activities completed thirty minutes previous, will have gross failures of long established memories, and will require assistance with toileting, dressing and other routine activities of daily living.
- Phase IV (final stage) is associated with loss of all verbal abilities and memory for life events, though some recognition of key people can still be evidenced. Physically, the patient requires 24-hour care, exhibits uncontrollable behavioural disturbances, decreased arousal and loss of control of bodily functions.

Alzheimer-type dementia is familial in around 25–40% of cases, but is most likely to reflect complex interactive effects of genetic risk and environmental factors that increase diagnostic and prognostic heterogeneity. Indeed, only around 45% of MZ twins are concordant for DAT, and those that are show different patterns of expression, age of onset, severity and rate of decline (e.g. Welsh, 1993). The two biggest risk factors for DAT, in order, are age and a family history of Downs' syndrome or DAT. Identified genetic links include chromosome abnormalities at chr21, an ApoE connection via chr19, and a presenilin link via chr14 and chr1 (see Hardy, 2003).

Discriminating dementia from geriatric depression

An additional difficulty in the diagnosis of dementias is that of distinguishing early stages of dementia from geriatric depression. In the UK, for example, around 8% of patients admitted for dementia are in fact suffering from depression; geriatric depression is often referred to, indeed, as pseudodementia (see also 'Psychological care

of the elderly'). Depressed individuals often complain of poor memory, poor concentration and poor short term memory, although there is usually little correlation between complaint and objective measures of memory performance. A more clinical assessment will in fact differentiate dementia from pseudodementia on an array of measures, including the more rapid onset of cognitive deficits in depressed elderly, the type and time course of mood disturbances, sleep/appetite disturbance, the specific pattern of short-term memory deficits and motivational indices on memory tasks (depressed elderly present with motivational deficits rather than actual decline in competence, but perception of difficulties results in frequent complaints of memory problems from depressed elderly).

There is some evidence for the co-existence of the two syndromes, but co-occurrence is neither necessary nor inevitable. Certainly it is unsurprising that early signs of dementia may lead an individual to feel depressed, but it remains unclear whether this response is a primary effect of the disease (associated with the fronto-temporal pathology, the brain structures responsible for mood), or a secondary reaction to awareness of an emerging condition. It is possible that a substantial number of individuals presenting with depression are in early stages of dementia, but there remains little consensus on the prognostic indicators that might distinguish between the progressors and the non-progressors (see Lee & Lyketsos, 2003).

Diagnosing a dementia

The presence of cognitive dysfunction reflecting a dementia can be assessed by administration of any of a number of very basic cognitive tests designed to provide a measure of current cognitive status. One of the most widely used cognitive assessment is the Mini Mental State Examination (Folstein *et al.*, 1975). This is a 30-item brief assessment of the client's orientation in time, place, short term memory registration, attention, working memory, language and hand dexterity. Despite its brevity, it is a robust and well established tool, picking up early stages of cognitive impairment quite accurately. The test does not claim to differentiate different forms of dementia, however, nor to discriminate between dementia and geriatric depression.

Improved accuracy of clinical diagnosis is most easily achieved by looking at the progressive nature of the impairment. Test-retest changes differentiate DAT from normal ageing, with a steeper slope of decline reflecting pathological over normal ageing. Longitudinal evaluation, however, presents no prospect for early intervention. Moreover, the dementias are characterized by large and idiosyncratic differences in rates of decline. With early diagnosis important both for treatment and resource management, factors that might predict rate of decline have generated particular interest, although again with very little consensus. Baseline cognitive status (educational level, opportunity for intellectual stimulation), gender, previous depression and lifestyle factors (associated with elevated blood pressure and high cholesterol, for example) have all been mooted as significant factors in prevalence and progression of dementia.

Difficulties associated with validation of clinical assessments of memory dysfunction lend further impetus to development of

neurobiological measures for validating clinical results. In vivo CT scans and PET scans have established that the dementias are associated with reduced brain weight, cortical atrophy and ventricular enlargement. Measurement of cerebral blood flow and metabolism also indicate significant deficits in individuals with dementia. Other neuropathological markers such as CSF levels of amyloid or tau proteins are possible, but for all of these measures, the absence of clear boundaries between 'normal' and 'abnormal' brain measures remains a significant problem in dementia diagnosis (e.g. Blennow & Vanmechelen, 2003).

Clinical diagnosis alone is correct in about 75% of cases; if supplemented with neuroimaging of the medial temporal lobe or hippocampal regions, premorbid accuracy increases to around 90% of cases. The costs and limited availability of imaging facilities, however, have mitigated against their routine use in dementia diagnosis, at least in the over 65s, though newer 'reporter' molecules and development of technologies (e.g. SPECT) that provide 3D images of cerebral blood flow will reduce costs and increase availability to psychogeriatricians (see 'Brain imaging and function').

Definitive diagnosis of a dementia depends upon examination of the brain pathology (neuropathological markers) and can only be confirmed at autopsy. Markers include significant atrophy of the brain, most importantly in the regions of the temporal lobe and frontal cortex, and specific neuropathological changes (for DAT, neurofibrillary tangles and senile plaques) (detailed in a seminal paper by Braak & Braak, 1995). In addition to neuropathological changes, there is a reduction in function in most brain neurotransmitters, and most significantly in the cholinergic system. Although neurotransmitter changes are probably secondary to the neuropathological changes in the cortex, reduced cortical choline acetyltransferase activity (the enzymatic marker for cholinergic system activity) provides a reliable correlate of clinical severity of the dementia (consistent with its vital role in memory encoding and retrieval).

Treatment

Recognising the documented role of the cholinergic system in learning and memory, therapeutic research in the past two decades has been aimed at treatments to correct the chronic deficiency in cholinergic activity, and thus to ameliorate the primary symptom, namely memory failure. All currently licensed cholinomimetics are cholinesterase inhibitors (ChEIs). Numerous studies document maintenance of baseline performance by ChEI treatment, particularly if the treatment programme is established early in the course of the dementia. This improvement may be maintained over a number of years (e.g. Rogers *et al.*, 2000). Vitamin E and the anti-oxidant drugs may also be of use for people who cannot tolerate cholinesterase inhibitors. Additional families of drugs that are currently under research include anti-inflammatory drugs, oestrogens, NMDA antagonists and anti-amyloid vaccines.

Supplementing the drug treatment, recent years have seen an increase in the development of cognitive rehabilitation programmes for people with dementia. These have focused on the value of memory training, cognitive orientation and on multimodal supplementation of verbal memory skills (see reviews by Rusted & Clare, 2004; Clare & Woods, 2004; Grandmaison & Simard, 2003).

In general, the evidence suggests that cognitive rehabilitation techniques produce short-term benefits for mildly impaired volunteers, over and above those that might be seen from general programmes of mental stimulation, but that they are time-consuming in their implementation, and may not generalize beyond those situations explicitly trained (see 'Neuropsychological rehabilitation').

Recognizing dementia

Dementia often only becomes apparent to the primary care physician when revealed in crisis situations such as the absence of the usual carer, or the onset of another medical problem (infection, or a household accident resulting in a hospital admission). Although symptoms may have been present for some time, loss of daily

skills, forgetfulness or even confusion, are expected as part of normal ageing, and do not in the majority of elderly, constitute reasons for visiting their primary care physician. The lateness of identification, and therefore intervention, of an emerging dementia exacerbates problems of care management and treatment.

Iliffe (1997) suggested guidelines for good practice in dementia diagnosis that include provision of earlier diagnosis of dementia and anticipation of crises, improved diagnostic skills among primary workers, networks of responsive social, voluntary and medical agencies providing continuing care, improved symptomatic treatment and better family support. Unfortunately for the majority of families currently looking after a relative with dementia, the availability of such a well-rounded management programme is a long way off.

Diabetes mellitus

Alison Woodcock and Clare Bradley

Royal Holloway, University of London

Introduction

Diabetes mellitus is a chronic disorder, characterized by raised glucose levels in blood (hyperglycaemia) and urine (glycosuria). The cause may be inherited and/or acquired deficiency of insulin production by the pancreas, or insulin resistance, where the insulin produced is ineffective. Increased blood glucose concentrations can cause structural damage, particularly to blood vessels and nerves. Microvascular complications of diabetes (diabetic retinopathy, nephropathy and neuropathy) bring problems of blindness, kidney failure, foot ulcers, gangrene and erectile impotence. However, heart

disease accounts for around 50% of deaths of people with diabetes. Management involves striving to maintain blood glucose at near-normal levels through behaviour change and medication, prevention or early detection and treatment of microvascular complications and reduction of cardiovascular risk, including hypertension, lipids and weight.

There are three main forms of diabetes. Type 1 diabetes usually develops in childhood or early adulthood. The pancreas stops producing insulin, so insulin by injection or infusion pump is essential for survival. Inhaled insulin is under evaluation. Type 2 diabetes

typically begins in late adulthood, though maturity onset diabetes of the young (MODY) is increasing in children. Often, though not always, associated with high body mass index, insulin production and/or the body's response to insulin declines. Management initially involves diet and exercise, perhaps with tablets to increase insulin production or uptake. In time, insulin may be required. The third form, gestational diabetes, is not considered in detail here. Diabetes prevalence is increasing rapidly worldwide, with notable ethnic differences. For example, South Asians are particularly prone to Type 2 diabetes.

The landmark Diabetes Control and Complications Trial (DCCT) (1993) compared usual care of Type 1 diabetes with intensified management to tighten control. It provided clear evidence that chronic hyperglycaemia increases risk of microvascular complications. However, tight control increased episodes of severe hypoglycaemia (very low blood glucose levels). The influential United Kingdom Prospective Diabetes Study (UKPDS) (1998) demonstrated similar relationships between hyperglycaemia and microvascular complications in Type 2 diabetes. Additionally, intensified blood pressure management reduced macrovascular complications.

Because stabilizing blood glucose is a primary clinical goal of diabetes management, accurate measures are needed. At home, finger-prick samples and reagent strips can be used, with or without metres. The most commonly-used laboratory measure, haemoglobin A1c (HbA1c), measures average blood glucose over the previous 2–3 months. The normal range for HbA1c varies between assays but increasingly, laboratories provide 'DCCT-aligned' results. In the DCCT, normal HbA1c was below 6.05%, but in diabetes, HbA1c should probably not fall below 6; UK clinical guidelines for diabetes recommend keeping HbA1c between 6.5 and 7.5%, depending on cardiovascular risk (NICE, 2003). Although HbA1c is useful when making treatment decisions, the average may conceal episodes of hypoglycaemia. Hypoglycaemic symptoms are idiosyncratic and may include hunger, sweating, irritability, disorientation, concentration lapses or hallucinations. Mild symptoms can be resolved with quickly-absorbed carbohydrate (e.g. fruit juice or glucose tablet). More severe but conscious cases need help to administer oral carbohydrate. Hypoglycaemic coma may require a glucagon injection, to release glucose from the liver. At the other extreme, hyperglycaemia associated with lack of insulin in Type 1 diabetes can cause diabetic ketoacidosis and, if untreated, life-threatening coma.

The role of psychology

Diabetes management mostly occurs outside the medical setting and the daily life of someone with diabetes can involve many restrictions, as well as recommended activities including medication-taking and blood glucose monitoring. The knowledge, beliefs and behaviour of people with diabetes and their healthcare professionals may all affect diabetes control (see, for example, 'Lay beliefs about health and illness'). Psychological perspectives can therefore be valuable in enhancing self-care. Several important interventions have been devised and evaluated by multi-disciplinary teams that include psychologists (Norris *et al.*, 2001; Ismail *et al.*, 2004). Moreover, measurement of patient-reported psychological outcomes is becoming the norm in clinical trials of pharmacological interventions, including new insulin analogues. We will outline a few of the many ways in

which psychologists familiar with diabetes and its management have already made valuable contributions towards enhancing care of people with diabetes (for more, see Anderson & Rubin, 2002; Anderson & Wolpert, 2004; Bradley *et al.*, 1998; Glasgow *et al.*, 1999; Riazi & Bradley, 2000). Our brief overview of the role of psychology begins with measurement.

Measurement of psychological outcomes and processes

When only metabolic outcomes are measured, clinicians and pharmaceutical developers may value new treatments only if metabolic control improves. They may underestimate treatment benefits. This happened when an innovative diabetes education and training programme developed by Muhlhauser, Berger and colleagues in Germany was shown to improve glycaemic control. Psychological outcomes were not measured initially, but were later shown to improve markedly alongside glycaemic control when the programme was evaluated in the UK (DAFNE Study Group, 2002). It is important to aim for the best achievable profile of biomedical and psychological outcomes.

Questionnaires measuring psychological outcomes, developed with and for people with diabetes (e.g. Bradley, 1994; Bradley & Speight, 2002; Polonsky, 2000; Pouwer *et al.*, 2000) consider issues important and relevant to people with diabetes. In contrast, commonly used generic measures typically focus on health and illness, rather than the impact of diabetes, with the demands and restrictions of long-term self-care (Bradley, 2001). Measures of perceived health cannot be expected to detect diabetes-related quality of life impairments in someone without symptoms, who feels well (see also 'Quality of life assessment').

Where problems are identified in one or more biomedical or psychological outcome, measures of psychological processes such as diabetes-related knowledge, self-care skills and behaviour, locus of control and coping strategies can indicate what action might be appropriate. Thus, someone with poor glycaemic control, despite good diabetes-related knowledge, is unlikely to benefit from further information-giving. Patient-completed questionnaires can illuminate reasons for glycaemic control problems, preferences for different treatment regimens and for therapies such as relaxation training (Bradley, 1994).

Facilitating diabetes consultations

Psychologists can be most effective when sharing with healthcare professionals consultation skills such as negotiated target-setting, open questioning and listening to patients' perspectives and priorities. Although some cultures may still believe 'doctor knows best', the prevailing twenty-first century Western philosophy involves 'empowering' patients to manage their own diabetes (Glasgow & Anderson, 1999; Department of Health, 2003). Training health professionals in 'empowerment' and 'patient-centred consulting' can have significant patient benefits. In Sweden, Rosenqvist's team has developed patient-centred methods of working with patients and training interventions that encourage professionals to change how they work. For example, Holmström *et al.* (2004) have demonstrated that professionals can shift from a prescriptive,

information-giving model to a reflective, supportive model or combined model of consulting (see also 'Patient-centred healthcare').

There has been limited success with brief interventions promoting patient participation in diabetes consultations. Kidd and colleagues (2004), aimed to encourage patient question-asking through brief interventions such as written encouragement to ask questions. Although intervention-group patients reported greater self-efficacy in asking questions, they asked no more questions than did controls. Although more satisfied, their glycaemic control was no different. It seems that some brief interventions may change beliefs without improving clinical outcomes, so there is still potential to develop feasible yet effective interventions. Unfortunately, wellbeing and quality of life have not always been included as outcomes in such studies.

By combining a short training intervention for primary care doctors and nurses with a booklet encouraging patients newly-diagnosed with Type 2 diabetes to prepare questions, Kinmonth and colleagues (1998) significantly improved wellbeing, treatment satisfaction and satisfaction with the doctor's consulting a year later, compared with controls. Although HbA1c did not differ, body mass index was higher in intervention patients. This illustrates the need to attend to the patient's concerns without losing sight of the medical agenda. Partnerships between psychologists and clinicians will be important in further developing feasible programmes to improve both psychological and biomedical outcomes.

Optimizing blood glucose monitoring

Most insulin-treated and some tablet-treated patients monitor their own blood glucose. If glycaemic control improves, and microvascular complications and hospital treatments are reduced, these benefits may far outweigh the costs of metres and reagent strips and the pain and inconvenience of self-testing. However, self-monitoring is not always performed optimally (see also 'Self-management'). Amongst children and adolescents, parental involvement predicts adherence to home monitoring and diabetes-related family conflict is related to poorer glycaemic control. Good practice needs to be established soon after diagnosis, through building positive family interaction and involvement in diabetes management (Anderson *et al.*, 2002).

Glucose monitoring is cost-effective only when patients understand their readings and respond appropriately at the time, rather than seeking the doctor's verdict on a book of results, months later. Many patients with Type 2 diabetes who self-monitor do not even know their blood glucose targets. Problems may be overlooked when patients monitor at set times of day. If they learn to recognize how they feel when their blood glucose levels are outside the normal range and how their own body responds to medication, exercise, food, illness and stress, they can then test their blood at times likely to detect problems. Cox and colleagues developed a blood glucose awareness training (BGAT) programme and manual, subsequently refined as BGAT-2. Blood glucose monitoring is used, alongside symptom ratings, mood and environmental cues, to identify each patient's predictors of high and low blood glucose. An 'error grid' highlights error judgments that matter clinically, such as failure to detect extreme blood glucose levels. Efforts are then concentrated on reducing clinically important errors and learning when to take appropriate action, such as deciding not to drive. Impressive results have been demonstrated in several studies of people with Type 1 diabetes. The training

improved not only estimation accuracy but also glycaemic control and occurrence of car accidents. BGAT-2 has been found to have multiple long-term benefits, over and above detection of hypoglycaemia and hyperglycaemia, including reduced fear of hypoglycaemia and improved diabetes knowledge a year later (Cox *et al.*, 2001).

Psychological treatments of sexual dysfunction

Nowadays, erectile dysfunction (ED) is often treated as an organic, vasculogenic disease, with increasing focus on pharmacological treatments. Opinions vary on the importance of psychogenic causes (e.g. relationship issues, inadequate stimulation and performance anxiety) and the need to consider psychological as well as biomedical issues in treatment. Despite the 'blockbuster' status of sildenafil citrate oral medication for men with ED (Salonia *et al.*, 2003), men with diabetes appear to respond less well long-term to a range of ED treatments than do those without (Penson *et al.*, 2003). Diabetes is associated with sexual dysfunction for women too. Amongst men, ED is related to demographic and clinical factors (age, body mass index, diabetes duration and complications), but for women, psychological and social factors (depression and poor partner relationships) predict sexual dysfunction (Enzlin *et al.*, 2003). To achieve more enduring treatment benefits, Heiman (2002) recommended combining pharmacological and psychological therapies for both men and women. Psychologists thus have an essential role in redressing the current imbalance in treatment perspectives (see also 'Sexual dysfunction').

Weight management programmes

In the 1980s and 90s, Wing and colleagues conducted studies evaluating various weight management programmes for people with Type 2 diabetes, where excess weight can obstruct diabetes control (see Wing's chapter in Anderson & Rubin, 2002). Programmes included combinations of nutrition education, behaviour modification, very low calorie diets and exercise, and resulted in some dramatic weight losses, with results improving as the programmes were developed and refined. The main problem is weight loss maintenance, suggesting a need for continuing support and encouragement. Clark (2004) reviewed obesity management in diabetes, highlighting the failure of any behavioural, dietetic or pharmacological treatment to achieve long-term weight loss. She questions the wisdom of encouraging eating restraint, with its many negative consequences, including self-blame, and suggests that encouraging weight *maintenance* rather than weight loss may be better for some individuals. A Cochrane review (Moore *et al.*, 2004) considered 18 trials in which the main intervention was dietary advice and concluded that it was the adoption of regular exercise that appeared to improve glycaemic control.

Conclusion

Psychological perspectives are already evident in many innovative approaches to diabetes care in hospital and community settings, in policy documents such as the UK National Service Framework for Diabetes (Department of Health, 2003) and in clinical trial reports, demonstrating how psychologists can work with healthcare professionals to improve the lives of people with diabetes.

Domestic violence, intimate partner violence and wife battering

Irene H. Frieze¹ and Maureen C. McHugh²

¹University of Pittsburgh

²Indiana University of Pennsylvania

Partner violence occurs in all types of intimate relationships including marriages, cohabitating and dating. Estimates are that one-quarter to one-third of US marriages involve at least one incident of physical assault. Annually domestic violence will result in serious injury to more than 3.4 million US women. Dating violence is as extensive as marital violence, and violence is at similar levels in gay and lesbian relationships (McHugh *et al.*, 1993).

Until recently, it was generally assumed that women were the only victims of battering, and many people referred to marital or domestic violence as 'wife battering'. Research has shown that, although women are more often injured by their partners, men can also be victims of violence from male partners and from their wives (Archer, 2000; Frieze, 2000). Because of this, researchers are beginning to use the term 'intimate partner violence' as a more neutral description (see Frieze, 2005). In the majority of cases of intimate partner violence, both partners use some level of violent behaviour toward the other. There are, however, different types of violent relationships, with some involving severe violence that is one-sided or mutual, and others involving only minor violence, either one-sided or mutual (Frieze, 2005; Williams & Frieze, 2005; McHugh & Bartoszek, 2000).

Intimate partner violence ranges from quite mild, involving actions such as slapping or shoving, with no resulting injury, to battering that can result in serious injury. Injuries typically involve bruises, lacerations and/or broken bones to the head, chest, abdomen and/or extremities and in some cases may extend to stab and/or bullet wounds. Certain types of partner violence can escalate in frequency and severity over time. In some cases a spouse/partner may be murdered. In other cases, partners may engage in low levels of violence over long periods of time and this does not become serious or create many injuries, except unintentionally. The timing of violence is not random, with more incidences at weekends, in the evenings and in the warm summer months. Over 60% of battered women report beatings during pregnancy.

Intimate partner violence is believed to be an under-reported crime, although women report the incidents to friends, family, police, lawyers, physicians, ministers, counsellors and social service agencies, such as shelters. In particular low-level violence is rarely reported to any authorities. Even when it is reported to formal authorities, there may be no effective way of reducing partner violence (Gondolf & Fisher, 1988). This is especially true for battered men and lesbians, who have few sources they can turn to for help, and whose concerns are rarely addressed.

Physicians are instructed to ask the woman about the origin of her injuries, document the injuries on her chart; determine the woman's

safety; alert her to the danger of returning to the abuser; and make referrals to shelters or other agencies and programmes (Kurtz, 1987). Despite having such instructions, healthcare personnel do not identify a large proportion of battered women (Kurtz, 1987). There are many potential clues to the occurrence of battering. These include evidence of old injuries and injuries inconsistent with the 'story' given are clues to identification of battering. The battered woman may be depressed and/or suicidal, abuse alcohol and/or drugs and report psychosomatic complaints. Although less understood, it is now believed that battered men are even less likely to be identified than female victims of partner violence.

Although 65% of battered women have received psychiatric care, most of their therapists failed to inquire about violence. Advocates have called for a proactive approach by therapists to assess for violence, even when it is not the presenting complaint. Battered women frequently present with problems of anxiety, depression and somatic complaints. Intake interviews and schedules should include questions about interpersonal violence. Corroborating evidence, when available, suggests that battered women tend to under-report both the frequency and the severity of the violence they experience. Forgetting and minimizing are two coping strategies used by battered women (McHugh *et al.*, 1993).

Research (Hansen & Harway, 1993) indicates that therapists often fail to identify the importance of reported physical violence and fail to generate appropriate interventions. Cessation of the violence should be the treatment goal. To date, most intervention strategies have focused on the victim. However, this perspective is increasingly seen as both victim-blaming and counter-productive (McHugh, 1993; Yllo & Bograd, 1988). Previously, much of the literature and treatment was based on the model proposed by Walker (1984) that battered women suffer from learned helplessness, a series of behavioural, cognitive and motivational deficits resulting from the randomness and aversiveness of the beatings. Newer approaches emphasize the help-seeking and coping mechanisms of battered women, viewing them as survivors rather than victims (e.g. Frieze, 2005; Gondolf & Fisher, 1988).

Psychotherapy for battered women typically addresses the following themes: isolation; self-esteem; expression of anger; life choices and decision-making; grief and loss; and termination issues. Alternatively, Hansen and Harway (1993) recommend that appropriate treatment for the battered woman include the following: an assessment including questions regarding the lethality of the situation and the client's safety; crisis intervention and provision of immediate protection to the victim; education including

information about battering; and referrals (e.g. to shelters and to legal resources).

Research indicates that women remain at risk for violence and homicide even after terminating the abusive relationships and physically relocating. Also, men who batter in one relationship are likely to batter in subsequent relationships. There is also some evidence that some women are also violent toward more than one partner. Thus, it is imperative to intervene legally or therapeutically with the batterer.

Treatments for male batterers have been developed. These stress the need to challenge the abuser's rationalizations and excuses. Interventions with batterers frequently take the form of batterers' groups. Typically, batterer groups offer a combination of skills training and resocialization: group sessions address definitions of abuse;

anger management; assertiveness training; challenging negative sex role stereotypes; communication skills and conflict resolution strategies. Research indicates that from one-half to three-quarters of men who complete such treatments are labelled non-violent at follow-up (McHugh & Bartoszek, 2000). When batterers are in treatment, their partners may be imperilled while falsely believing that the abuser is cured. It should be made clear to batterers and their partners that the risk of violence still exists. Therapists need to provide resources for safety and support of the partner, and monitor the situation for re-occurrence of violence. Indications of potentially lethal violence include serious depression, drug and alcohol use, threats and available firearms: these indications warrant warnings (to the spouse) and intervention (Hansen & Harway, 1993).

Drug dependency: benzodiazepines

Heather Ashton

University of Newcastle-upon-Tyne

Benzodiazepine tranquillisers were the most commonly prescribed drugs in the world in the 1970s and many patients took them regularly for years. Benzodiazepines include anxiolytics, such as diazepam, chlordiazepoxide, lorazepam, oxazepam and clonazepam; hypnotics, such as nitrazepam, temazepam, lormetazepam and loprazolam; and anticonvulsants such as clobazam. However, in the early 1980s long-term prescribed benzodiazepine users themselves realized that the drugs were associated with adverse effects. In particular, patients found it difficult to stop taking benzodiazepines because of withdrawal effects. Controlled trials of such patients (Petursson & Lader, 1981; Tyrer *et al.*, 1981) demonstrated beyond

doubt that withdrawal symptoms in chronic users of 'therapeutic' doses of benzodiazepines were real and that such reactions indicated dependence on the drugs.

However, definitions of drug dependence have shifted in the last decade. A withdrawal syndrome is no longer considered sufficient evidence of dependence. The present criteria for a diagnosis of substance dependence include tolerance, escalation of dosage, continued use despite efforts to stop and knowledge of adverse effects and a withdrawal reaction (Table 1). Benzodiazepine dependence meets all these criteria and many long-term users develop a classic drug-dependence syndrome.

Table 1. Criteria for substance dependence^a

A maladaptive pattern of substance use leading to significant impairment or distress, manifested by three or more of the following in the same 12-month period:
Tolerance
Withdrawal syndrome
Substance taken in larger amounts or for longer than intended
Persistent desire or unsuccessful attempts to decrease or control use
Excessive time spent obtaining, using or recovering from effects of substance
Important activities given up or reduced because of substance
Substance use continued despite knowledge of problem.

^aAbridged from DSM-IV American Psychiatric Association (1994).

Tolerance and dosage escalation

Benzodiazepines exert five therapeutic actions: hypnotic, anxiolytic, anticonvulsant, muscle relaxant and amnesic effects (Table 2). Tolerance develops at different rates and to different degrees for these various actions.

Tolerance to the hypnotic effects develops rapidly, within days or weeks of regular use, during which sleep profiles tend to return to pre-treatment levels. Recent evidence indicates that long-term benzodiazepine use no longer aids sleep (Curran *et al.*, 2003). Although many poor sleepers report continued efficacy of benzodiazepine hypnotics, this is probably because they prevent withdrawal symptoms such as rebound insomnia. A considerable proportion of hypnotic users increase their dosage, sometimes to above recommended levels.

Tolerance to the anxiolytic effects of benzodiazepines develops more slowly. There is little evidence that benzodiazepines retain their anxiolytic efficacy after four months of regular treatment and clinical observations show that long-term benzodiazepine use does little to control, and may even aggravate anxiety. There is also evidence of dosage escalation in anxiolytic benzodiazepine users. In one clinical study over 25% of 50 patients were taking two prescribed benzodiazepines, the second having been added when the first ceased to be effective (Ashton, 1987). Tolerance to the anticonvulsant and muscle relaxant effects of benzodiazepines occurs within a few weeks of regular use in a high proportion of patients.

However, complete tolerance to the amnesic effects and other cognitive impairments does not appear to develop even after years of chronic use. Many studies of long-term benzodiazepine users have shown deficits in learning, memory, attention and visuospatial ability. These effects are most marked in the elderly in whom they may suggest dementia (see 'Dementias'). Improvement occurs when benzodiazepines are stopped (Curran *et al.*, 2003), although it may be slow and perhaps incomplete.

Withdrawal effects and continued usage

Benzodiazepine withdrawal reactions include many symptoms common to anxiety states in general and some more characteristic of benzodiazepine withdrawal (Table 3). The syndrome, which includes both psychological and physical symptoms, can be mild and short-lived or severe and sometimes protracted. The incidence

Table 2. Therapeutic actions of benzodiazepines

Actions	Clinical uses
Hypnotic	Short-term treatment of insomnia
Anxiolytic	Short-term treatment of anxiety Aid to alcohol withdrawal Acute treatment of agitated psychoses
Anticonvulsant	Epileptic and drug-induced convulsions
Amnesic	Premedication before surgery
Muscle relaxant	Muscle spasms, dystonias

of acute withdrawal symptoms varies between 30–100% in different reports but many long-term users decline to participate in, or drop out from, studies because of withdrawal effects. Withdrawal symptoms prolong benzodiazepine use which often continues for years after the initial indication for taking the drugs has passed. Many long-term users, aware that the drugs are no longer effective and are causing adverse effects, have tried to stop or reduce dosage but have been unsuccessful because of the emergence of withdrawal symptoms.

Benzodiazepine-dependent populations

Therapeutic dose dependence

This population is large and consists of patients who have inadvertently become dependent on benzodiazepines prescribed by their doctors over months or years: estimates suggest that there are about one million long-term users in the UK, four million in the USA and several million worldwide. At least 50% of these are likely to be benzodiazepine dependent. A considerable proportion of such patients are elderly females taking benzodiazepine hypnotics, while other long-term users include patients with physical and psychiatric problems.

Prescribed high-dose dependence

A minority of patients who start on prescribed benzodiazepines may unintentionally begin to require higher and higher doses. Personality factors may contribute to this perceived need. At first their doctors may be compliant and some patients today are prescribed excessive doses, but on reaching the prescribed limit some may contact several doctors or hospital departments to obtain further supplies and may resort to 'street' benzodiazepines if other sources fail.

Recreational benzodiazepine abuse

Recreational abuse of benzodiazepines is a growing problem involving at least 140 000 individuals in the UK today. Illicit benzodiazepine abuse is common in polydrug users and alcoholics (Strang *et al.*, 1993). Some people use them as their primary recreational drug, bingeing intermittently on high doses or injecting recreationally. Reasons given for taking benzodiazepines intravenously are that they enhance the 'high' obtained from illicit drugs (opiates,

Table 3. Some common benzodiazepine withdrawal symptoms

Symptoms common to anxiety states	Symptoms relatively specific to benzodiazepine withdrawal
Anxiety, panics	Perceptual disturbances, sense of movement
Agoraphobia	Depersonalization, derealization
Insomnia, nightmares	Hallucinations
Depression	Distortion of body image
Excitability	Tingling, numbness, altered sensation
Poor memory and concentration	Skin prickling
Dizziness	Sensory hypersensitivity
Weakness	Muscle twitches, jerks
Tremor	Tinnitus
Muscle pain, stiffness	Psychosis ^a
Night sweats	Confusion, delirium ^a
Palpitations	Convulsions ^a
Blurred or double vision	

^aUsually only on rapid or abrupt withdrawal from high doses.

amphetamines, cocaine) and alcohol and also alleviate withdrawal effects from these drugs. Benzodiazepines can themselves produce a 'kick' when taken in high doses. Many illicit users of benzodiazepines become dependent and show typical withdrawal symptoms which can be severe (Seivewright & Dougal, 1993).

Pharmacological basis of benzodiazepine dependence

Positive and negative reinforcement

The reinforcement potential of a drug is judged by its ability to maintain or increase drug-taking or drug-seeking behaviour. Positive reinforcement is associated with rewarding effects directly exerted by the drug, while negative reinforcement is associated with the drug's ability to alleviate aversive states such as anxiety or withdrawal symptoms. Griffiths and Weerts (1997) argue that reinforcement is the major mechanism underlying both chronic long-term use and recreational use of benzodiazepines. These authors reviewed 26 studies showing reinforcing effects of benzodiazepines in man. Reinforcing effects, both positive and negative, of a number of benzodiazepines were clearly apparent in subjects with histories of drug or alcohol abuse, social alcohol drinkers, anxious subjects, insomniac subjects and patients undergoing abrupt benzodiazepine withdrawal.

Nearly all drugs that produce positive reinforcement (cocaine, amphetamine, nicotine, alcohol, opioids, cannabis and others) induce dopamine release in the limbic system (nucleus accumbens and/or prefrontal cortex) and it has been argued that dopamine activation in these rewarding areas is the final common pathway for all addictive drugs. High doses of benzodiazepines may have a similar effect and it is noteworthy that recreational benzodiazepine abusers take doses many times greater than therapeutic dose users. By contrast, low doses of benzodiazepines do not release dopamine but act essentially as 'depunishing' drugs, providing negative reinforcement, possibly by decreasing activity in brain 'punishment systems'.

Mechanisms of tolerance and withdrawal

The basic mode of action of benzodiazepines is to enhance central gaba-aminobutyric acid (GABA) activity by interaction with specific sites on postsynaptic GABA_A receptors. These contain multiple (at least 18) subunits and at present it seems that mainly α_1 , and α_2 subtypes mediate benzodiazepine actions. It is proposed (Bateson, 2002) that chronic benzodiazepine use induces a chain of events in which uncoupling of the linkage between GABA_A and benzodiazepine receptor sites leads to preferential degradation of these subunits which become internalized within the neurones. This provides a signal for changes in gene transcription, resulting in benzodiazepine tolerance. This pathway could operate on different time scales depending on the receptor subtypes and/or brain region involved, giving rise to differing rates of development of tolerance to various benzodiazepine actions.

Withdrawal of benzodiazepines once tolerance has developed would expose the recipient to all the drug-induced changes in GABA receptors. The result would be underactivity in the many central functions normally modulated by GABA-ergic mechanisms. Since GABA is a universal inhibitor of neural activity and decreases the release of many excitatory neurotransmitters, there would be a surge of excitatory nervous activity. Such activity, coupled perhaps with adaptive increases in sensitivity of excitatory receptors, may account for benzodiazepine withdrawal symptoms (Table 2). These changes may be slow to reverse and may do so at different rates, accounting for the variable duration and sometimes protracted nature of the benzodiazepine withdrawal syndrome (Ashton, 1995a).

Clinical implications

Adverse effects of long-term use

Apart from dependence, long-term benzodiazepine use is associated with many other adverse effects (Ashton, 1995b). These include psychomotor and cognitive impairment, interactions with other sedative drugs including alcohol, emotional clouding, depression, paradoxical excitement, aggressiveness and the insidious development of psychological and physical symptoms. Sociological costs include increased risk of traffic and other accidents, falls and fractures in the elderly, shoplifting (due to amnesia) and violent behaviour.

Prevention of dependence

These effects could largely be prevented by limiting prescriptions to short-term use (2–4 weeks only) in minimal dosage (Committee on Safety of Medicines, 1988). When used short-term, benzodiazepines can have great therapeutic value (Table 2) and dependence is not a problem, though care is needed in prescribing them to patients with a history of alcohol or drug abuse or dependent personality types. Although benzodiazepines are still the leading treatments for anxiety and are often initially helpful, long-term treatment is more appropriate with antidepressants and/or psychological intervention.

Management of dependence: benzodiazepine withdrawal

Unfortunately benzodiazepines are still prescribed long-term and there is a large population of long-term users who are already

dependent. Withdrawal of benzodiazepines is a desirable option for many of these patients. The management of withdrawal consists essentially of gradual dosage reduction (usually over a period of several months) combined with psychological support (Ashton, 1994). The degree of support required varies from minimal intervention to formal psychological techniques. No adjuvant drugs have been found to be generally helpful, but antidepressants may be indicated if depression is severe. The success rate for withdrawal in motivated therapeutic dose users is good, up to 80–90% or more in some studies; physical and mental health improves after withdrawal or dosage reduction (Heather *et al.*, 2004; Curran *et al.*, 2003) and the relapse rate is low. Withdrawal failure and relapse rates may be higher in high-dose abusers.

The future

With rational prescribing, benzodiazepines are likely to remain useful drugs for short-term use. Prevalence of use should continue to decline as the number of chronic users decreases and fewer new patients become dependent. Caution is needed in prescribing non-benzodiazepine anxiolytics and hypnotics such as zopiclone (Zimovane, Imovane), zolpidem (Ambien) and zaleplon (Sonata), which have already been shown to have a dependence and abuse potential similar to that of benzodiazepines.

Drug dependence: opiates and stimulants

Michael Gossop

Institute of Psychiatry

The nature of the disorder

Drug misuse is a complex and multifaceted phenomenon which can be understood in terms of three dimensions: consumption behaviours, problems; and dependence. Although conceptually distinct, in reality these dimensions tend to be related (sometimes closely) in a number of ways.

Opiates and stimulants (predominantly heroin and crack cocaine) are among the drugs most commonly used by people presenting for treatment, and dependence upon these drugs is the most common reason for treatment. However, the classification of drug problems by specific substance can be misleading. Most drug misusers who require treatment are heavy and problematic users of more than one drug (Gossop, 2001).

Multiple drug use may involve the concurrent or sequential use of different substances. Among the reasons for multiple drug use are:

- *drug enhancement* (several drugs may be used at the same time to increase the desired effects)
- *modification of effect* (e.g. to counteract the adverse or unwanted effects of one or more drugs as with cocaine and heroin used together so that either the heroin takes away some of the unpleasant overstimulation of the cocaine, or the stimulant offsets the sedation of the heroin)
- *substitution* (taking a different drug as a substitute where the preferred drug is not available).

Assessment and setting treatment goals

Assessment is not an impersonal procedure to be completed prior to treatment. It is an important first stage of treatment. The therapist should use assessment as an opportunity to encourage the involvement of the drug user in their own recovery. It is more appropriate to regard this first stage of treatment as reaching mutual agreement about goals rather than simply setting goals.

For all types of drug misuse treatment, the intervention should be tailored to the needs and circumstances of the individual. This apparently simple and uncontentious statement turns out to have complex and far-reaching implications for policy and services if it is seriously applied in clinical practice. There is not, nor can there be expected to be, any single best treatment for these problems (Gossop, 2003). Both aetiology and outcome are influenced by a broad range of different factors. A thorough assessment should identify, for each individual case, the nature of the problem and appropriate and achievable goals for treatment. Also, the treatment process should identify as early as possible those particular factors

(often outside the treatment setting) that will assist or hamper the achievement of the treatment goal(s).

It is important that both the therapist and the drug user should agree upon the goal(s) of treatment. This does not mean that the therapist cannot aspire to goals more ambitious than those set by the patient. However, it does imply that where the therapist seeks to attain some goal beyond that which is immediately acceptable to the patient, this may create certain tensions and require careful management.

Psychological treatments

There is a wide range of psychological treatment interventions. These differ in many respects, not least in the degree of emphasis given to cognitive, behavioural and social factors. In general, psychological treatments assume that addictive behaviours are substantially influenced by normal learning processes; that addictive behaviour is functional for the drug users; and that, as a learned behaviour, addictive behaviour can be modified or 'unlearned'.

Motivational Interviewing (MI) (see 'Motivational interviewing') has been popular and clinically influential in recent years (Miller, 1983; Miller & Rollnick, 1991). Its aim is to increase levels of cognitive dissonance until sufficient motivation is generated for consideration of the options and interventions for change. MI is primarily a counselling style concerned with the patient-therapist interaction, rather than an intervention procedure. The therapist initially adopts an empathic stance using techniques similar to those operationalized by Carl Rogers. This process is, however, modified to selectively reinforce statements of concern and elicit self-motivational statements.

One limitation of some addiction treatments is that they presume a prior commitment to change. MI has been found to be useful in many phases of treatment but it has been particularly useful in helping people who are still at an early stage of committing themselves to treatment or to changing their behaviour. However, motives do not translate directly into outcomes. Motivation alone is unlikely to be sufficient for change or the maintenance of change among many of the long-term, severely dependent drug users who seek treatment in addiction services.

An important distinction should be made between initial change and the maintenance of change. The factors and procedures which are most effective in inducing behaviour change may not be the most effective for producing generalization and maintenance of treatment effects. The problem of relapse is an important characteristic of all of the addictive disorders. A large proportion of people who have been treated for such problems tend to return to those behaviours within a short time of leaving treatment.

Marlatt and Gordon's (1985) Relapse Prevention (RP) model was the first major cognitive behavioural approach (see 'Cognitive behaviour therapy') to be used in the treatment of substance use disorders, and provides a straightforward conceptual model for understanding drug misuse problems. The primary goal of RP is to teach drug users who are trying to change their drug-taking behaviour how to identify, anticipate and cope with the pressures and problems that may lead towards a relapse. Two essential features are the identification of high-risk situations which increase the risk of relapse, and the development and strengthening of effective coping responses. High-risk situations may be events, objects, cognitions or mood states which have become associated with drug use and/or relapse. Many lapses are related to negative emotional states, social pressure and interpersonal conflicts, but antecedents to lapse may also include subjective experiences of 'urge' (sudden impulse to engage in an act) and 'craving' (Heather & Stallard, 1989). Risk factors often occur together, either in clusters or in sequence (Bradley *et al.*, 1989) and they may operate in an additive or interactive manner (Shiffman, 1989).

Relapse Prevention requires an individualized assessment of high-risk situations for relapse involving a microanalysis of drug-related factors for each patient in terms of their social and environmental circumstances, and their cognitive appraisal of those situations. The effective delivery of RP requires a close inter-relationship between assessment and treatment planning.

Contingency management provides a system of incentives and disincentives according to which treatment delivery is organized by setting specific objective behavioural goals, and structuring the environment in a manner that is conducive to change (Stitzer *et al.*, 1989) (see 'Behaviour therapy'). Contingency management has been found to be useful for extinguishing negative or undesirable behaviours, such as continued drug use or failure to comply with treatment requirements, and as a means of encouraging positive behaviours, such as engagement with treatment services. A persistent problem for addiction treatment services involves those patients who do not comply with the requirements of treatment programmes or who do not get better as a result of their contact with treatment. Contingency management has been found to be particularly useful as a treatment intervention for 'non-responsive' patients.

Twelve-step programmes and therapeutic communities

For more than six decades Alcoholics Anonymous (AA) has influenced the treatment of addiction problems. Together with its offshoot, Narcotics Anonymous (NA), this organization has been seen as the paradigm of the self-help movement for recovery from addiction, though many members tend to dislike the *self-help* label and prefer to see the fellowship as providing *mutual* support.

The programme consists of studying and following the Twelve Steps which emphasize two general themes: *spirituality* – belief in a 'higher power', which is defined by each individual and which represents faith and hope for recovery and *pragmatism* – doing 'whatever works' for the individual (Emrick, 1999).

Group meetings are one of the best known aspects of NA/AA. In groups, members share their experiences, achievements, their fears and their failures with peers whose advice supports the achievement

and maintenance of abstinence as well as the learning of new, pro-social behaviours (Brown *et al.*, 2001). Role modelling can be further assisted by the sponsor. NA/AA also provides a structure for the member's free time and evening meetings may provide a supportive activity during a high-risk time of day. In these respects, NA/AA can serve as an effective aftercare resource (Ouimette *et al.*, 1998).

In many countries, residential rehabilitation programmes are one of the longest established forms of treatment and in some countries, they remain one of the dominant treatment modalities. Many are based upon the principles of the Therapeutic Community (TC). With TCs the interaction between the individual and the community is itself seen as the treatment process, and the treatment ingredients are the programme structure, and the daily activities and social interactions in the TC. The primary staff members in many residential programmes are often recovering addicts who have themselves been rehabilitated in therapeutic communities.

The basic goal for residents in TCs in particular (but also in residential treatment programmes in general) involves a complete change in lifestyle involving abstinence from drugs, avoidance of antisocial behaviour, the development of prosocial skills and personal honesty. The specific objective of the TCs has been described as the treatment of individual disorders, 'but their larger purpose is to transform lifestyles and personal identities' (De Leon, 2000). Three psychological determinants of change within TCs are social role training, vicarious learning and efficacy training (see 'Self-efficacy and health').

At one time, traditional TCs worked with planned durations of stay of 2–3 years. Recent changes have led to modified residential TCs working with 6- to 9-month programmes, and short-term programmes with a 3- to 6-month programme (De Leon, 2000). Relatively short-stay, residential 'chemical dependency' programmes ('Minnesota Model', 'Hazelden' or 'chemical dependency' treatments) are often based upon the Twelve Steps. These programmes typically provide a highly structured 3–6 week package of residential care involving an intensive programme of daily lectures and group meetings designed to implement a recovery plan.

In an evaluation of Twelve-Step, cognitive-behavioural or combined Twelve-Step plus cognitive-behavioural treatments provided in 3–4 week inpatient programmes, all three treatments appeared to be effective in reducing substance use and psychological symptoms, and in reducing post-treatment arrests and imprisonment (Ouimette *et al.*, 1997; Moos *et al.*, 1999).

Pharmacotherapies

The most widely used form of pharmacotherapy involves methadone treatment. At the beginning of the 21st Century there were probably about half a million patients in methadone treatment worldwide. Methadone treatments are extremely diverse and programmes differ in doses prescribed, provision of counselling services, treatment policies and in drug use outcomes (Gossop & Grant, 1990; Ball & Ross, 1991; Stewart *et al.*, 2000). In a meta-analysis of methadone treatment evaluations, Marsch (1998) reported consistent findings of reductions in illicit opiate use, HIV risk behaviours and crime. Methadone treatments are rarely restricted merely to the provision of methadone pharmacotherapy (Strain & Stoller (1999)) and additional counselling, medical and

psychosocial services leads to improved efficacy of treatment compared to methadone alone (McLellan *et al.*, 1993).

Detoxification is a clearly delineated phase of treatment designed to eliminate or to reduce the severity of withdrawal symptoms when the physically dependent user stops taking drugs. The heroin withdrawal syndrome has been treated by methadone, other opioid agonists, clonidine, lofexidine, buprenorphine, opioid antagonists, as well as by hypnotic, anxiolytic, antidepressant and anti-psychotic drugs. Among the most commonly used treatments is gradually reducing doses of oral methadone.

Although there have been descriptions of withdrawal disturbances among regular stimulant users, the existence of a specific cocaine or amphetamine withdrawal syndrome is still uncertain (Lago & Kosten, 1994). Antidepressant drugs are sometimes given to counter dopamine depletion during cocaine withdrawal. Despite the theoretical rationale, the superiority of these drugs over a placebo in cocaine withdrawal has not been established (Kosten *et al.*, 1992). The use of substitute drugs for treatment of stimulant dependence is uncommon and of unknown effectiveness.

Opiate antagonist drugs such as naltrexone are also sometimes used to speed up withdrawal treatments or to help prevent relapse after detoxification. These substances bind to opiate receptors but without producing opiate type effects. They compete with opiate agonists such as heroin in such a way that opiates produce little or no effect. Antagonists appear to work well with highly motivated patients and when used under supervision (O'Brien, 1994). Because of their specific affinity for opiate receptors, such drugs have not been evaluated in the treatment of stimulant dependence.

Other interventions

The health risk behaviours of drug users have been the focus for various harm reduction activities. Dissemination of information about the transmission of HIV and other blood-borne infections is one of the least controversial prevention responses. This has been widely used and in some circumstances may be effective (Selwyn *et al.*, 1987).

Needle and syringe exchange schemes have been more controversial, though these have now been established in many countries (Stimson *et al.*, 1990). Many injecting drug users share needles, syringes, or other injecting equipment because of the lack of availability of sterile equipment.

Syringes have been supplied to users in a number of ways. Some services provide needles and syringes but make no requirement for the return of used equipment. The best known system involves the provision of needles and syringes to injectors on an exchange basis. This addresses public health concerns about used and possibly infected needles being left in public places, or disposed of in ways that may put others at risk. Attendance at exchange schemes has been found to be associated with reduced levels of sharing as well as increased contact with other treatment services (Stimson *et al.*, 1990).

Drug users may also be at risk through their sexual behaviour (see 'Sexual risk behaviour'). Many drug users engage in unprotected sex, often with multiple partners. Rates of prostitution tend to be higher among drug users (Hart *et al.*, 1989; Gossop *et al.*, 1993). Some drug users may be exposed to both drug risk and sexual risk through

having a sexual partner who injects drugs. Women may be at particular risk in this way (Gossop *et al.*, 1994a). In the United States, women infected with HIV by a drug using partner are the second largest group of women with AIDS (see also 'HIV and AIDS').

Since the earliest days of the HIV epidemic it has been known that homosexual activity may carry high risks of HIV transmission. Drug users may also be exposed to this form of risk. Gossop *et al.* (1994b) found that the factor most strongly associated with HIV seropositive status among a sample of heroin users was men having sex with men. Conversely, the strongest predictor of hepatitis infection was a drug risk factor, the number of years injecting drugs.

Treatment outcome

Early reviews of the effectiveness of treatments for addiction problems were often pessimistic about the impact of treatment upon outcome (e.g. Einstein, 1966; Clare, 1977). Such pessimism is no longer warranted. There is now an impressive accumulation of evidence to show that even people with severe dependence upon drugs can recover from their addictions and that treatment can play an important role in assisting recovery.

Large-scale, prospective, multi-site treatment outcome studies have played an important role in improving our understanding of treatment effectiveness (Simpson, 1997). Studies from both the United States and the UK have shown that patients who receive drug misuse treatment make improvements across a range of outcome measures (Simpson & Sells, 1990; Hubbard *et al.*, 1989, 1997). The results from the National Treatment Outcome Research Study (NTORS) showed substantial reductions after treatment in use of heroin, non-prescribed methadone and benzodiazepines, reduced injecting and sharing of injecting equipment, improvements in psychological health and reductions in crime, with improved outcomes still evident at 5-year follow-up (Gossop *et al.*, 2003).

However, a word of caution may be appropriate. For the therapist in the treatment setting it may be tempting to over-estimate the impact of treatment factors. The psychology of the individual and the social setting in which the individual lives exert powerful influences upon outcome. Hubbard *et al.* (1989) note that 'the role of treatment is to change behaviours and psychological states and to direct clients to community resources during and after treatment', and that 'programmes have no direct control on behaviour after clients leave treatment. Rather, treatment should influence post-treatment behaviour indirectly through changes in psychological states and behaviour during treatment' (p. 35). Effective treatments for drug problems look beyond the clinic to maintaining change in the real-life social environment.

There is broad agreement that many treatment and other factors may be related to outcome. Relatively little is known about what these factors are or how they affect outcome. An important question for clinicians and researchers is how to assess the impact of specific treatment process variables and identify 'active' and 'inert' components of treatment. The important developments in addiction treatments during the next decades may occur, not as a result of radical new discoveries, but through the improvement of existing interventions and through improved provision of treatments.

Drugs: beta-blockers

Sari D. Holmes and David S. Krantz

Uniformed Services University of the Health Sciences

Beta-blockers are a class of drugs that selectively compete for and inhibit binding at the beta-adrenergic subset of receptors of the sympathetic nervous system (Middlemiss *et al.*, 1981; Patel & Turner, 1981). Beta-adrenergic receptors are primarily located in the heart and in the smooth muscle of the blood vessels and the lungs, but also exert metabolic and other effects. The beta-blockers are structurally similar to the body's adrenergic neurotransmitters, norepinephrine and epinephrine, and they exhibit their greatest effects during periods of intense sympathetic nervous system (SNS) activation. Therefore, the most common clinical use of these drugs is for the treatment of cardiovascular disorders, including hypertension and manifestations of ischaemic heart disease such as angina pectoris and cardiac arrhythmias (Frishman, 1980; Patel & Turner, 1981; Weiner, 1985).

However, since the introduction of these drugs and their wide therapeutic use, a variety of both desirable and unwanted psychological effects have been observed. One of the most frequently noted beneficial effects has been the reduction of reported anxiety by individuals in certain acutely stressful situations (e.g. performing before an audience or dental surgery) that are normally accompanied by several somatic manifestations of arousal (Frishman *et al.*, 1981; Noyes, 1982; Elman *et al.*, 1998). There have also been some reports that chronic beta-blocker therapy might lessen anger and irritability or 'coronary-prone' behaviour pattern (Schmeider *et al.*, 1983; Krantz & Durel, 1983; Fedorets *et al.*, 2004). In addition to these psychological effects (some of which may be considered beneficial) unwanted psychological and behavioural effects of beta-blockers have also been noted. These include side effects such as fatigue, depression, nightmares and disturbances of sleep and sexual function (Patel & Turner, 1981; Moss & Procci, 1982; Weiner, 1985; Head *et al.*, 1996; Keller & Frishman, 2003). This chapter will provide a brief overview of the psychological and behavioural effects of beta-blocking drugs.

Psychological effects

Reduction of chronic anxiety

The anxiolytic (anxiety-reducing) effects of beta-blockers in chronically anxious patients were first reported by Granville-Grossman and Turner (1966) for the drug propranolol. Beta-blockers have been shown to be effective in reducing symptoms of generalized anxiety disorder (Swartz, 1998), panic disorder (Hirschmann *et al.*, 2000), social anxiety disorder (Elliott & Reifler, 2000), obsessive compulsive disorder (Dannon *et al.*, 2000) and post-traumatic stress disorder (PTSD) (Taylor & Cahill, 2002; Vaiva *et al.*, 2003). In some studies beta-blockers were effective as adjunctive therapy

with benzodiazepines or antidepressants (Dannon *et al.*, 2000; Hirschmann *et al.*, 2000), whereas other studies demonstrated the anxiolytic effects of beta-blockers alone (Swartz, 1998; Vaiva *et al.*, 2003).

Effects during situational stress

Considerable evidence has shown that beta-blockers can be useful in decreasing anxiety in certain acute stress situations. In healthy subjects, and in patients with cardiovascular disease, these drugs blunt the increases in cardiovascular activity and anxiety that accompany certain stressful activities such as public speaking, musical performance, parachute jumping, performing surgery and emotional upset (Middlemiss *et al.*, 1981; Neftel *et al.*, 1982; Benschop *et al.*, 1996; Elman *et al.*, 1998; Culic *et al.*, 2004). Anxiolytic effects have been reported for a variety of beta-blockers regardless of whether they have pharmacological properties that enable them to readily cross the blood-brain barrier. When situational stress leads to a decrement in performance, which in turn, increases anxiety further (e.g. tremor experienced by some musicians during public performance), reduction of anxiety or tremor by beta-blockade apparently leads to improved performance (Neftel *et al.*, 1982).

Other effects

In addition to their effects on anxiety, beta-blockers have been shown to influence depressed mood, anger, irritability and drug withdrawal. Reports of adverse mood state changes as a result of beta-blocker use have been confirmed, such that levels of tension, depression and total mood disturbance were higher on propranolol as compared to placebo (Head *et al.*, 1996). However, there is also evidence indicating that short-term, high-dose augmentation with pindolol is effective in SSRI (selective serotonin re-uptake inhibitor)-refractory patients (Brousse *et al.*, 2003; Sokolski *et al.*, 2004) and in reducing negative emotional states (Blumenthal *et al.*, 1988). Several studies (Schmeider *et al.*, 1983; Krantz *et al.*, 1982; Krantz & Durel, 1983; Fedorets *et al.*, 2004) suggest that, among patients with hypertension or coronary disease, chronic administration of beta-blockers may reduce anger and irritability or so-called 'coronary-prone behaviour' (see 'Hostility, Type A behaviour and coronary heart disease'). More recent studies suggest that these effects may be confined to beta-blockers that penetrate the brain, and are only evident among a sub-set of individuals (Krantz *et al.*, 1988). Furthermore, beneficial effects of propranolol have been found for cocaine dependence treatment, such that patients on the drug had lower cocaine withdrawal symptom severity than those on placebo (Kampman *et al.*, 2001).

Mechanism of beta-blocker effects on anxiety

It is not entirely clear whether the anti-anxiety effects of beta blockers result from their direct effects in the central nervous system or whether these effects result from the peripheral effects of these drugs. A central site of action is often assumed, especially when effects on mood or behavior are associated with a beta-blocker that readily penetrates into the brain (Cruickshank, 1980; Beversdorf *et al.*, 2002). Recent reported effects of beta-blockers relevant to SSRI efficacy (Brousse *et al.*, 2003; Sokolski *et al.*, 2004) and cocaine withdrawal (Kampman *et al.*, 2001) would be consistent with such an interpretation. However, various drugs in this class vary in the extent to which they penetrate the CNS, and anti-anxiety effects in acute stress situations are evident even for those beta-blockers that do not readily penetrate the brain (Nefitel *et al.*, 1982).

It has been suggested that the peripheral effects of beta-blockers are sufficient to account for their anxiolytic effects, and that this involves the role of information processing concerning peripheral sympathetic responses on the subjective experience of emotion (Tyrer, 1976; Durel *et al.*, 1985). Peripheralist views of emotion (e.g. James–Lange, Schachter–Singer) suggest that the subjective experience of anxiety is a result of a sequence of physiological events beginning with sympathetic nervous system stimulation leading to arousal manifestations, such as palpitation and tremor. The perception, cognitive interpretation, or automatic processing

of these responses acts to heighten the psychological aspects of anxiety based on this interpretation, beta-blockade inhibits peripheral psychological responses (e.g. rapid heart rate, tremor), interrupts the somatic psychic interaction, and thus reduces anxiety (Tyrer, 1976; Durel *et al.*, 1985; Elman *et al.*, 1998).

When compared with other anxiolytic drugs such as the minor tranquilizers (e.g. benzodiazepines), beta-blockers are probably most effective in patients whose anxiety is characterized by bodily complaints (Tyrer, 1976). In other words, when patients experience their anxiety more in terms of palpitations and tremor than as worry or mental tension, their anxiety is likely to be reduced by a beta-blocker. When psychic symptoms predominate, beta-blockers are considered much less effective than benzodiazepines.

Summary and conclusion

Beta-adrenergic blocking drugs, such as propranolol and atenolol, have utility in reducing the peripheral manifestations of anxiety and acute stress. These beneficial effects are most pronounced among individuals with somatic manifestations of anxiety. Effects of these drugs on mood are less consistent, and chronic use of these medications have occasionally been associated with unwanted side effects such as fatigue and depression.

Drugs: psychotropic medication

Andrew Scholey¹, Andy Parrott² and David Kennedy¹

¹Northumbria University

²University of Wales Swansea

Introduction

Psychopharmacology offers a range of psychotropic medications to the medical practitioner. The decision to administer such medicines should be made in the context of evidence-based, realistic risk–benefits assessment and sound clinical judgement. With many psychotropics there is a potential for dependence. This can be manifest in two ways; tolerance, where an increased dose is required to produce the same effect, and withdrawal where negative psychological and/or physical consequences are associated with drug discontinuation. Such effects have been characterized in detail from studies of opiate addiction (see ‘Drug dependency: opiates and stimulants’). The following sections summarize specific health aspects of selected ‘recreational’ and prescription psychotropic agents.

Tobacco

Cigarette smoking leads to around 130 000 deaths annually in the UK. Part of the addictive potential of cigarettes lies in the delivery system; inhaled tobacco smoke generates a nicotine ‘hit’ within 10 seconds of inhalation, although nicotine dependence is also evident from other routes such as chewing tobacco. The behavioural

effects are due to nicotine binding nicotinic acetylcholine receptors and in regular smokers cholinergic neuroadaptations probably underlie nicotine cravings during abstinence. These are transiently relieved by nicotine administration: indeed there is now strong evidence that while the regular smoker relieves negative effects of nicotine withdrawal they do not gain anything positive (Parrott *et al.*, 2004). Historically it was believed that smoking relieved stress: however there is now strong evidence that nicotine dependence itself causes stress (Parrott, 1999). This and other health risks associated with smoking are dramatically reduced following successful withdrawal from nicotine, which can be aided by the use of nicotine replacement systems (patches, inhalers, gum etc). The success of attempts to give up smoking is influenced by various factors (see meta-analysis by Viswesvaran & Schmidt, 1992). The highest abstinence rates are achieved when nicotine substitution is combined with appropriate social support. (See also ‘Tobacco use’.)

Alcohol

One in every 13 adults in the United Kingdom regularly drinks more than the recommended weekly levels of (21 units/week for males

and 14 units/week for females) Alcohol use also increases in parallel with the use of psychoactive substances such as MDMA/ecstasy, amphetamine and cannabis (Parrott *et al.*, 2001).

Following consumption, alcohol is distributed throughout the body but is more rapidly supplied to tissue that is dense in cells and has a good blood supply, such as the brain. Alcohol intoxication is associated with a number of detrimental behavioural effects including impaired memory, increased errors, disinhibition and a state sometimes described as ‘alcohol myopia’ (Steele & Josephs, 1990).

The terms alcohol abuse and alcohol dependence describe different levels of alcohol-related psychological problems (based, for example, on the DSM-IV criteria). For alcohol abuse one or more of the following criteria should have occurred for over a year: role impairment; hazardous use; legal problems related to alcohol use; social or interpersonal problems due to alcohol. To meet the criterion for alcohol dependence three of the following should have occurred for over a year: tolerance; alcohol withdrawal; drinking more than intended; unsuccessful attempts to cut down on use; excessive time related to alcohol; impaired social or work activities due to alcohol; use despite physical or psychological consequences.

Problem drinkers risk psychological dysfunction including anxiety and depression, and may experience physical withdrawal symptoms. There are also numerous medical problems related to heavy, chronic alcohol consumption including increased risk of coronary heart disease, liver cirrhosis, impotence and infertility, cancer and stroke. It is estimated that alcohol plays a part in up to 33 000 deaths per year in the UK (Department of Health, 2001). This represents 15.8 deaths per 100 000 for men and 7.6 per 100 000 in women. These figures are comparable with those for the United States and other European countries, although there is geographical variability within and between member states of both. In Europe there is traditionally a higher rate of alcohol-related mortality in areas such as Finland and the former East Germany with relatively fewer in countries such as The Netherlands and Sweden. Within the last year 1 in 4 adults in the UK will have experienced loss of memory following an alcoholic binge, injured themselves or another, or failed to carry out some task (National Statistics, 2001). Alcohol dependence may be treated by a number of behavioural and pharmacological interventions, the latter include acamprosate, ondansetron and sertraline. (See also ‘Alcohol abuse’.)

Benzodiazepines

Like alcohol, benzodiazepines act as CNS (central nervous system) depressants; unlike alcohol they have been (and are) used as prescribed drugs for a range of disorders. The Royal College of Psychiatrists lists several psychiatric conditions that may respond to short-term benzodiazepine therapy (either as a primary or secondary treatment) including anxiety disorder, sleep disorder and depression. However they also warn against over-prescription of the drugs due to their potential for dependence and withdrawal, although some reviews have highlighted the inconsistency in the characterization of benzodiazepine dependence (e.g. Linsen *et al.*, 1995). The cognitive impairment experienced while taking benzodiazepines has been well documented (e.g. Thompson *et al.*, 1999).

There is also evidence that cognitive dysfunction is a feature of long-term benzodiazepine use (Curran *et al.*, 1994). Such function may be restored, though possibly not completely, following successful discontinuation and withdrawal (Barker *et al.*, 2004). (See also ‘Drug dependency: benzodiazepines’.)

Antipsychotics

The clinical aspects of schizophrenia include ‘positive’ symptoms such as auditory hallucinations, paranoid delusions and thought disorder, while ‘negative’ symptoms include social isolation and withdrawal (Walker *et al.*, 2004). Traditional antipsychotic drugs such as chlorpromazine and haloperidol relieve positive symptoms in 70–80% of those with a diagnosis of schizophrenia. Recent years have seen the emergence of several newer antipsychotics, including risperidone, olanzapine and clozapine (Serretti *et al.*, 2004). An advantage of these newer ‘atypicals’ is that they can often relieve negative symptoms, not only reducing the incidence and severity of hallucinations and delusions, but also facilitating greater social integration (Serretti *et al.*, 2004). They also cause fewer adverse side effects, including dry mouth and Parkinsonian motor symptoms. Hence they are now the drugs of first choice, although the older typicals still remain widely used (Parrott, 1991; Parrott *et al.*, 2004).

For clinical and health psychologists, the main function of antipsychotic drugs is to facilitate psychotherapeutic intervention. It has been confirmed that attempting therapy with unmedicated clients can be overarousing, and may lead to a heightening of ‘positive’ symptoms (Parrott *et al.*, 2004). Since the advent of effective antipsychotic drugs, cognitive behavioural therapy, individual psychotherapy and many other forms of psychosocial intervention are now available (Marcinko & Read, 2004). Pharmacotherapy may reduce aberrant cortical and subcortical information processing. By reducing the incidence and/or severity of cortical hallucinations and delusions, new social–interpersonal skills can be learnt. This does however need a genuine psychotherapeutic programme and with therapeutic assistance (not necessarily by a professional), the client can become receptive to new ideas and suggestions on how to relearn and improve their social and interpersonal skills.

Antidepressants

Whereas schizophrenia affects 1% of the population, clinical depression occurs in 5–20%, depending upon definitions of severity and frequency. The majority are treated by an antidepressant, either a first generation drug such as imipramine or amitriptyline, or by a more modern psychopharmaceutical such as the Selective Serotonin Reuptake Inhibitor (SSRI) e.g. fluoxetine, or the Selective Noradrenaline Reuptake Inhibitor (SNRI) reboxetine (Parrott *et al.*, 2004). Clinical guidelines for the therapeutic interventions in depression have been devised by Ellis (2004). In severe depression with psychosis, either electroconvulsive therapy (ECT) or a combination of antidepressant and antipsychotic drug, should be the first line of approach. The advantages of ECT are its rapid speed of action (via sub-chronic alterations in neurotransmitter activity), and higher overall clinical efficacy. Its main drawback is adverse cognitive–memory side effects. Transcranial Magnetic Stimulation may prove to offer clinical efficacy without adverse cognitive sequelae

(Lisanby, 2003). In moderate depression, cognitive behaviour therapy, interpersonal psychotherapy and antidepressant drug therapy, each demonstrate similar efficacy, but vary in availability and cost (Ellis, 2004). With mild depression, various psychological approaches might be attempted initially (e.g. book reading groups, exercise/jogging, hobbies, group sports). Any regular activity which reduces psychosocial isolation and increases feelings of self-efficacy, is likely to reverse the feelings of pressure and worthlessness which have become endemic to modern life.

Beta-blockers

Beta-blockers act by inhibiting the effects of noradrenaline at beta-adrenoreceptors which are present in a number of tissues, including the heart and smooth muscle of the bronchi and blood vessels. Their primary effect is to block activation of the sympathetic nervous system (the part of the autonomic nervous system responsible for preparing for 'fight-or-flight'). Thus they decrease heart rate and relax blood vessels, lowering blood pressure. These effects are seen primarily during heightened sympathetic activity (e.g. during exercise or stress) rather than at rest (Rang *et al.*, 1995). Beta-blockers are generally avoided in treating those with asthma and diabetes as their effects can exacerbate or mask the symptoms of

these disorders (National Institute for Clinical Excellence guidelines 2001). (See also 'Drugs: beta-blockers'.)

Allergies to drugs and drug-drug interactions

Whilst adverse drug reactions are relatively common, including for psychotropic medicine, only 6–10% of these events are attributable to allergic reactions (Gruchalla, 2003). One of the major factors that characterizes allergic drug reactions is that they are generally unpredictable, and most often unrelated to the pharmacology of the drug in question. Theoretically, drug-related allergic reactions can be classified into one of four groups depending on immune system mechanisms involved (Coombs & Gell, 1975). However, a lack of knowledge of the mechanisms involved makes this identification process difficult in practice in many cases.

A related problem is that of drug-drug interactions. Presentation with co-morbid psychiatric problems is not uncommon and the specific combinations of drugs (e.g. mood stabilizers, antidepressants and antipsychotics) may produce unpredictable and unwanted interactions which the practitioner needs to be aware of and monitor vigilantly. (See also 'Allergies to drugs'.)

Dyslexia

Christine M. Temple

University of Essex

Dyslexia is a developmental disorder in the acquisition of reading skills, in children of otherwise normal intelligence, which cannot be explained on the basis of educational deprivation or sensory impairment. The child may have fluent speech and good communicative skills, yet has difficulty in mastering the formal written code employed for reading.

Historical perspectives

At the end of the nineteenth century, the term 'word blindness' was coined, first to refer to acquired disorders of reading resulting from brain damage, and then to refer to reading disabilities which occur developmentally. The angular gyrus was damaged in many cases of acquired word blindness and there was speculation that a congenital aplasia of the angular gyrus might underlie problems in learning to read. Early discussions of congenital word blindness can be found in Hinshelwood (1917).

Labelling

Throughout the twentieth century, there has been disagreement regarding the labelling of the disorder. This continues today, with the term 'developmental dyslexia' being accepted in most academic and medical settings but not in educational circles, where the terms 'specific reading disability', 'specific reading difficulty' and 'specific learning difficulty' are employed.

Incidence

Lewis and colleagues (1994) tested the population of 9- and 10-year-olds in a single education authority district in England, finding 6.2% with specific reading disabilities. It remains unclear whether these children represent a distinct group from the main distribution, or the lower tail of a normal distribution. Lewis *et al.* (1994) also reported a male to female ratio of 3.2:1, though Smith *et al.* (1991) suggest a lower ratio of 1.7:1–1.3:1.

Biological foundations

It has become evident that dyslexia is a heritable neurobiological syndrome. The concordance rate for dyslexia is 68% in monozygotic twins and 38% in dizygotic twins (De Fries & Alcaron, 1996). It is likely that several genes may be involved in the transmission of dyslexia with three possible sites implicated: chromosome 15q21 for single word reading (Smith *et al.*, 1983; Marino *et al.*, 2004),

chromosome 6p21.3 for phonemic segmentation and possibly single word reading (Cardon *et al.*, 1994; Grigorenko *et al.*, 1997; Gayan *et al.*, 1999) and chromosome 18p11.2 (Fisher *et al.*, 2002). Linkage has also been suggested to chromosomes 1, 2, 3 and other regions of 6 and 13.

Electrophysiological AEPs (auditory evoked potentials) at birth for speech and non-speech syllables discriminated those who eight years later would become dyslexic (Molfese, 2000). Specific EEG (electroencephalography) abnormalities have been reported, which have greater focus in temporo-parietal areas in some cases and in frontal areas in other cases (Duffy & McAnulty, 1985). Post-mortem analyses have revealed cyto-architectonic abnormalities, in the form of foci of ectopic neurons and microgyria, constellated in the left hemisphere (Galaburda *et al.*, 1985). A series of studies using PET and fMRI neuroimaging has demonstrated reduced activation of the left temporo-parietal region in adults with dyslexia, when carrying out rhyming and non-words reading tasks (e.g. Hagram *et al.*, 1992; Brunswick *et al.*, 1999). Reduced temporo-parietal activity has also been reported in fMRI studies of children with dyslexia doing a letter-rhyming task (Temple *et al.*, 2001) and MEG study of children reading (Simos *et al.*, 2000 *a,b*).

Cognitive neuropsychological analyses

Surface dyslexia

Cognitive neuropsychological analyses of the developmental dyslexias have delineated several different forms of the disorder, each of which is explicable in relation to models of normal reading. In developmental surface dyslexia (e.g. Coltheart *et al.*, 1983; Hanley *et al.*, 1992; Temple, 1997), words that conform to spelling-to-sound rules (e.g. beach) are read more easily than those that are not consistent with those rules (e.g. yacht). Errors indicate the application of a rule-based system (e.g. bear → 'beer'; subtle → 'subtill'). There is also homophone confusion, affecting words with the same pronunciations but different spellings (e.g. pane defined as 'something which hurts').

Surface dyslexia can be explained in relation to stage models of normal reading development, in terms of arrestment at an alphabetic stage, within which there is emphasis upon the use of letter-sound rules, with failure to progress to later orthographic/hierarchical stages, which incorporate context sensitivity and analyses based upon meaningful sub-components of the target word.

In relation to models of normal adult reading, surface dyslexia reflects over-reliance upon a non-lexical, phonological reading route, which translates graphemes or letter clusters to phonemes or phonological segments and blends these to produce an integrated

output (e.g. Coltheart *et al.*, 2001). The over-reliance upon the phonological reading route, leads to adequate ability to read non-words, but difficulty in reading irregular words. Homophone confusions arise because meaning is activated after the activation of pronunciation. Connectionist models, which represent relationships between orthography and phonology in a series of distributed connection weights, are also able to produce parallels to surface dyslexia, with emergent superiority in reading regular words. Early versions had difficulty in modelling the degree of accuracy in non-word reading (Seidenberg & McClelland, 1989). This was resolved in the subsequent dual route connectionist model of Plaut *et al.* (1996).

Possible underlying difficulties have been explored in surface dyslexia. Surface dyslexics have neither phonological difficulties nor general difficulties with visual memory (Castles & Coltheart, 1996) but have slower response times in reading (Seymour, 1986) and may have difficulties with rapid naming (Wolf & Bowers, 2000). Children with weak reading comprehension also demonstrate surface dyslexia (Nation & Snowling, 1998). Castles and Coltheart (1993) showed that 30% of developmental dyslexics display a surface dyslexic reading pattern. The syndrome has also been described following an early left occipital lesion in a child (Samuelsson, 2000).

Phonological dyslexia

In contrast to surface dyslexia, the major characteristic of developmental phonological dyslexia is a selective impairment of phonological reading processes. The term was first adopted by Temple and Marshall (1983) to refer to a teenage girl, who had significant difficulty in reading non-words aloud (e.g. *zan* → 'tan'; *chait* → 'chart'... 'trait'). Reading errors included many paralexical responses (word substitutions), including morphological paralexias (in which the base morpheme is correct but an ending is altered, e.g. *image* → 'imagine'; *sickness* → 'sicken'). Phonological dyslexia has now been described in many languages.

Phonological dyslexia cannot be explained in relation to stage models of reading development. Orthographic skills are mastered, despite failure to master alphabetic skills, yet the acquisition of alphabetic skills is supposed to precede orthographic skills. One alternative is that there are different pathways to the acquisition of reading. Phonological dyslexia is explained with relative ease in relation to models of normal adult reading as follows. There is impaired development of the phonological reading route, but relatively normal development of lexico-semantic and direct reading routes, enabling recognition of a whole word and thereby activation of its meaning and then pronunciation, or its pronunciation directly. Both Coltheart *et al.*'s (2001) dual route cascade model and Plaut *et al.*'s (1996) dual route connectionist model can account for phonological dyslexia.

Some children with mixed dyslexia have impaired development of both reading systems, having difficulty with both non-words and irregular words.

Phonological processing

It has been suggested that a basic phonological processing deficit underlies many cases of developmental dyslexia though surface dyslexics have intact phonological skills. There is also dispute as to whether impaired phonological awareness causes or is a consequence of dyslexia, for example, Hatcher *et al.* (1994) reported that remediation, involving training in phonological awareness, only generalized to a significant improvement in reading when training in reading had also been involved. Other theories of single factor causes of developmental dyslexia include impaired magno-cellular pathways, impaired automatization linked to cerebellar abnormality and impaired ocular dominance. None of these theories has yet proved convincing in accounting for the evidence.

Eating disorders

Eric Stice and Heather Shaw

Oregon Research Institute

Eating disorders include a variety of psychiatric disturbances involving abnormalities in eating behaviours, maladaptive efforts to control shape and weight and disturbances in self-perception regarding body shape. The three eating disorder syndromes are anorexia nervosa, bulimia nervosa and binge eating disorder. This chapter will review research on the aetiology, prevention and treatment of these disorders.

Aetiology of eating disorders

Aetiological theories of anorexia nervosa have implicated numerous factors, including norepinephrine abnormalities, serotonergic abnormalities, childhood sexual abuse, low self-esteem, perfectionism, need for control, disturbed family dynamics, internalization of the thin-ideal, dietary restraint and mood disturbances (Wilson *et al.*, 2003). However, few prospective studies investigating factors predicting onset of anorexic pathology or increases in anorexic symptoms, and no prospective tests of multivariate aetiological

models have been conducted. Prospective studies are essential to determine whether a putative risk factor is a precursor, concomitant or consequence of eating pathology. The only prospective study that tested predictors of onset of threshold or sub-threshold anorexia nervosa found that girls with the lowest relative weight and with extremely low scores on a dietary restraint scale at baseline had increased risk for future onset of threshold and subthreshold anorexic pathology; non-significant effects were observed from early puberty, perceived pressure to be thin, thin-ideal internalization, body dissatisfaction and depressive symptoms (Stice, Presnell, & Bearman, 2004). All other studies collapsed across anorexic and bulimic pathology (e.g. McKnight Investigators, 2003). Thus, surprisingly little is known about the risk factors for anorexic pathology or how they work together to promote this pernicious eating disturbance.

Greater strides have been made toward understanding the risk factors for bulimic pathology. The sociocultural model posits that internalization of the thin-ideal for females combines with direct pressures for female thinness (e.g. weight-related teasing),

promoting body dissatisfaction and increasing the risk for initiating dieting, negative affect and consequent bulimic pathology (Cattarin & Thompson, 1994). Body dissatisfaction is thought to lead females to engage in dietary restraint in an effort to conform to this thin-ideal, which paradoxically increases the likelihood of the initiation of binge eating. Dieting also entails a shift from a reliance on physiological cues to cognitive control over eating behaviours, resulting in vulnerability to over-eating when these cognitive processes are disrupted. Body dissatisfaction is also theorized to contribute to negative affect, which increases the risk that these individuals will turn to binge eating to provide comfort and distraction from these negative emotional states. Consistent with this model, thin-ideal internalization, perceived pressure to be thin, body dissatisfaction, dietary restraint and negative affect have been found to increase the risk for future onset of bulimic symptoms and bulimic pathology. Experiments have confirmed that reducing thin-ideal internalization, body dissatisfaction and negative affect produced decreases in bulimic symptoms, but have failed to support the dietary restraint model (see Stice, 2002 for a review).

To date there has been relatively little theory regarding the aetiological processes that promote binge eating disorder, and theories that have been developed have conceptually overlapped with theories of bulimic pathology. Prospective studies suggest that initial elevations in body mass, body dissatisfaction, dietary restraint, negative affect and emotional eating increase the risk for future onset of binge eating (Vogeltanz-Holm *et al.*, 2000; Stice, 2002).

It is likely that genetic factors also contribute to the development of eating disorders, although conflicting findings make it difficult to draw any firm conclusions. For example, in twin studies heritability estimates ranged from 0.0% to 70% for anorexia nervosa and from 0.0% to 83% for bulimia nervosa (Bulik *et al.*, 1998; Fairburn *et al.*, 1999). Further, one study found that the concordance rate for monozygotic twins was greater than for dizygotic twins (Treasure & Holland, 1989), but another had opposite findings (Walters & Kendler, 1995). Similarly, studies attempting to identify specific receptor genes associated with eating disorders have produced highly inconsistent results that have not been replicated (e.g. Hinney *et al.*, 1998, 1999). The large range in parameter estimates suggests fundamental problems with sampling error resulting from small samples, the reliability of diagnostic procedures, or statistical models used to estimate genetic effects.

These aetiological findings should be interpreted with some caution given several gaps in the literature. First, there appear to be no prospective studies testing whether any biological variable predicts onset of eating disorders, making it impossible to determine whether biological abnormalities are a cause or consequence of eating pathology. Second, very few studies have predicted onset of anorexic pathology, bulimic pathology, or binge eating disorder, or focused on comparing and differentiating the risk factors for these three classes of eating disorders. Without these types of studies, it is impossible to differentiate the aetiological processes that lead to eating disorders.

Prevention of eating disorders

Although initial eating disorder prevention programmes met with limited success, the effects from more recent trials are more

promising. A recent meta-analytic review of 32 prevention programmes found that 53% of the programmes produced significant reductions in risk factors for eating pathology and that 25% produced significant effects for eating pathology (Stice & Shaw, 2004). For example, one intervention reduced the rate of threshold/sub-threshold eating pathology from 15% in the control condition to 6% in the intervention condition (Stice *et al.*, 2004). The meta-analysis also identified several factors associated with larger intervention effects. Programmes which were directed at high-risk individuals, interactive (vs. didactic), targeted female adolescents over 15 years of age, had multiple sessions and used validated measures all produced larger effects. Programme content was less important than participant characteristics and research design in predicting intervention effects, though programmes with psychoeducational content were less effective. Results also suggested that the prevention programmes were more effective when they are not described as eating disorder prevention programmes per se (e.g. when they are described as body acceptance classes); in fact, 10 of the 15 prevention trials that significantly affected eating pathology were not presented as eating disorder prevention programmes.

Advances in eating disorder prevention programmes have been hindered by certain limitations, however. For instance, most prevention programmes have not been designed to reduce established risk factors for eating pathology; instead, most primarily provide information regarding eating pathology. In addition, a large proportion of prevention trials did not include a control group and therefore cannot disentangle true intervention effects from the effects of passage of time, regression to the mean, or measurement artifact. Moreover, because virtually no prevention trials have used placebo control conditions, it is not possible to rule out the possibility that any apparent intervention effects are due to demand characteristics or participant expectancies.

Treatment of eating disorders

There have been numerous randomized controlled trials of psychotherapy and pharmacotherapy in bulimia nervosa, and to a lesser extent binge eating disorder, but the research on the treatment of anorexia nervosa is very limited. Below, a brief overview of the treatment literature for each of the major eating disorders is provided. A more comprehensive overview can be found elsewhere (e.g. Wonderlich *et al.*, 2003).

Generally two approaches have been used to treat adolescents with anorexia nervosa: individual psychodynamic therapy and family systems therapy (Wilson *et al.*, 2003). There is an emerging consensus that family therapy is the best treatment option at this time for adolescent girls (Eisler *et al.*, 1997). A type of family therapy, known as the 'Maudsley method' involves three stages: re-feeding the patient; negotiating a new pattern of relationships and adolescent issues; and termination (Lock *et al.*, 2001). It appears to be most beneficial for anorexic individuals under age 19 who have been ill for a relatively short time (Wilson *et al.*, 2003). Individual therapy for adult patients has also been used, and there is some research to support the notion that adult anorexic individuals benefit more from individual psychotherapy than from family therapy (Eisler *et al.*, 1997). A variety of pharmacologic agents has also been evaluated in the treatment of anorexia nervosa, but due to the limited

understanding of the biological basis of this disorder, trials have not been adequately grounded in aetiologic and maintenance theories and have therefore proven to be relatively ineffective (Steinglass & Walsh, 2004). Unfortunately, the consensus in the field is that treatments for anorexia nervosa have limited efficacy in reducing anorexic symptoms and behaviours. Clearly, there is a strong need for large scale, multi-centre trials for anorexia nervosa so that effective treatment strategies can be identified.

In contrast, great strides have been made in understanding both psychotherapeutic and pharmacotherapeutic treatments for bulimia nervosa. Cognitive behaviour therapy (CBT) (see 'Cognitive behaviour therapy') is considered the treatment of choice for bulimia nervosa (Wonderlich *et al.*, 2004), due to its relatively rapid action and wealth of evidence suggesting reasonable efficacy. CBT focuses on decreasing restrictive dieting, addressing dysfunctional thoughts about shape and weight, interrupting binge-purge behaviours and enhancing self-esteem. Over 20 controlled trials of individual or group CBT for bulimia nervosa suggest that it is superior to minimal or wait list controls, as well as other interventions including behaviour therapy, psychodynamic therapy, supportive psychotherapy and pharmacotherapy (Wonderlich *et al.*, 2004) (see also 'Behaviour therapy' and 'Psychodynamic psychotherapy').

Several other psychotherapeutic treatments for bulimia nervosa also appear promising, including interpersonal therapy targeting relationship issues and avoiding body shape and weight topics (Agras *et al.*, 2000), and dialectical behaviour therapy (Safer *et al.*, 2001). Trials of pharmacologic agents for bulimia nervosa have been more promising than similar trials for anorexia nervosa. However, it appears that adding drug therapy to CBT provides uncertain benefit beyond psychotherapy alone (Wilson *et al.*, 2003).

Several psychotherapeutic treatments have also been used to treat binge eating disorder including CBT (e.g. Agras *et al.*, 1997), interpersonal therapy (e.g. Wilfley *et al.*, 2002) and dialectical behaviour therapy (Telch *et al.*, 2001). All three of these psychotherapeutic approaches have been quite efficacious in reducing binge eating and promoting abstinence. The major limitation of these studies is that binge eating disorder subjects, who tend to be obese, do not lose substantial amounts of weight over long-term follow-up, even after reducing binge-eating behaviours. However, individuals who

attain abstinence from binge eating are most likely to avoid further weight gain in longitudinal studies (Agras *et al.*, 1995).

Binge eating disorder subjects have also been treated with simple dieting strategies, which have been slightly more effective in achieving weight loss than psychotherapeutic strategies, and have demonstrated a significant reduction in binge eating frequency (Goodrick *et al.*, 1998). This is noteworthy, given predictions that dietary restriction in binge eating individuals would promote binge eating, rather than reduce it (Polivy & Herman, 1985). Low calorie diets have also been found to reduce bulimic symptoms (Presnell & Stice, 2003). These findings suggest that there may be fundamental problems with the restraint model of eating disorders.

Numerous pharmacologic therapies have also been tested in the treatment of binge eating disorder. However, similar to the evidence for bulimia nervosa, studies suggest that the addition of drugs adds little to CBT in treating binge eating disorder, and that drugs alone are not significantly more effective than placebo (Grilo *et al.*, 2002).

Conclusions

Overall, it appears that anorexia nervosa is the least understood of the three eating disorders, and is in greatest need of studies that delineate risk factors that can be targeted in prevention programme and maintenance factors that can be targeted in treatment programmes. In contrast, more is known about the aetiology of both bulimia nervosa and binge eating disorder, as numerous studies have examined the individual and combined effects of various risk factors. Moreover, relatively effective treatments have been developed and evaluated for these latter two eating disorders. Nonetheless, a major priority for future research will be to investigate whether biological variables are risk factors for future onset of eating disorders and to investigate how biological and psychosocial factors work in concert to promote and maintain eating disorders. It is likely that increased understanding in these areas will yield major advances in terms of prevention and treatment programmes for these pernicious disorders.

Eczema

David J. de L. Horne and Elizabeth A. Coombes

University of Birmingham and Cancer Centre

Introduction: prevalence and prognosis

Atopic eczema has been defined as ‘an inflammatory disease, characterized by an itchy, erythematous, poorly demarcated skin eruption, which has a predilection for the skin creases’ (Williams, 1994, cited in Charman, 1999). Symptoms include intractable itching, skin damage and soreness. Where it lasts into adulthood it becomes a lifelong disease where the typical pattern is of a labile course resulting in some uncertainty and insecurity. Eczema or atopic dermatitis (AD) is a common childhood condition. It usually presents during the first year of life (Barnetson & Rogers, 2002) and in 60–70% of

cases clears up during teenage years, although relapses may occur (Charman, 1999). The remaining sufferers are older children, adolescents and adults with a chronic skin condition. Symptoms can be mild or severe, and if severe can have both physical and psychological repercussions for the sufferer and the whole family.

Eczema is probably the most common of the atopy diseases to come to the attention of psychologists and psychiatrists for treatment and may co-exist with other atopy disorders in up to 48% of cases (Diepgen & Fartasch, 1992). Eczema affects 15–20% of children in the United Kingdom and 2–3% of adults (Charman, 1999), with a rising trend of incidence of twofold to threefold over the past three

decades (Barnetson & Rogers, 2002). A large cross-sectional survey of 715 033 children and adolescents, in 56 countries, revealed a range of prevalence rates from less than 2% in Iran to over 17% in Nigeria. When ethnicity was controlled for, environmental factors appeared to be of major importance (Williams *et al.*, 1999). There are difficulties, however, in accurately estimating prevalence due to a lack of consistency in measures of eczema, the use of varying age-groups and different sampling procedures (Charman, 1996).

Prognosis of eczema has been examined, mainly, via cross-sectional studies of risk factors, plus a limited number of longitudinal or follow-up studies. Vickers (1980) carried out a major study on 2000 children for 2 to 21 years, with excellent response rates to his surveys. He found that that eczema cleared up in about 90% of cases and only recurred in about 7%. Such factors as severity, birth order, method of infant feeding, ichthyosis, rhinitis or urticaria seemed to have no prognostic value. Conversely, early onset, seborrhoeic pattern and being male seemed to be good prognostic signs. Late onset, 'reversed pattern' (eczema in the antecubital and popliteal fossae, on the knees and elbows and perhaps the dorsum of the wrists and hands), co-morbid asthma and poor social environment seem to adversely affect prognosis. Why this should be so is not immediately apparent, and no adequate theoretical framework has been developed to account for such findings.

Specific features of the typical eczema patient on presentation are the itch, the erythema and sleeping problems. Itch is the main parameter and its effective control is a major prognostic sign. Various events, immunological and non-immunological, can affect the itch threshold. The scratching response has been well studied by Jordan and Whitlock (1974) who demonstrated that eczema sufferers develop conditioned itch-scratch responses more readily than controls and these responses were slow to extinguish. Emotional stress may initiate or exacerbate the itch-scratch cycle and stress management and relaxation techniques may be useful interventions (Koo & Lebwohl, 2001).

Sleep disturbances may be an issue in 'resistant' or 'severe' eczema and, certainly, itchy patients do tend to have a pattern of light, broken sleep. There has been debate as to why this is so. It can be argued that scratching behaviour itself (in response to the itch?) arouses eczema sufferers from deeper stages of sleep (Aoki *et al.*, 1991). On the other hand, the sleep pattern described is similar to that associated with depression and general inability to express a range of emotions (Tantum *et al.*, 1982) (see 'Sleep and health').

Causes of eczema

The causes of the eczema remain poorly understood (Williams, 1995). Certainly, both environmental factors (e.g. air pollution, smaller families with less exposure to infection, more pets, food allergies) and possible genetic factors (e.g. family history of atopy in two-thirds of cases (Rajka, 1986)) play significant roles.

Severity of eczema has been related to such factors as such as immunological status, level of cortisol, growth patterns, sleep patterns, family coping style, personality, etc. (e.g. Koblenzer & Koblenzer, 1988, in children; White, Horne & Varigos, 1980, in adults). Despite the difficulties in defining and quantifying

psychological stress there is some evidence linking it to exacerbation of conditions such as eczema (Koo & Lebwohl, 2001) and families with eczema sufferers have been reported as having more problems, regardless of number of life events, and a perceived lack of personal coping resources (Charman, 1996) (see 'Stress and health').

Psychological factors

Some eczema patients seem to 'over-value' some symptoms, e.g. a red face and some may describe their skin as though it had a 'mind of its own!' The need for control and frustration at the skin's unwillingness to respond may be significant factors in psychological treatment. Some patients may have difficulty in accepting that their emotions may affect the condition of their skin, but paradoxically, they may be hypersensitive to emotional issues, displaying higher levels than normal of anger (e.g. White *et al.*, 1980).

Self-monitoring of correlates with the condition of the skin is usually poor in both patients and their families, and hence recall of events associated with flare-ups can be scanty. However, recurrences are often coincidental with significant transition points in the lifespan, e.g. commencing school, marriage, a period of grief, etc. These stressful experiences may result in a reduction of the immunological system's ability to cope (e.g. Teshima *et al.*, 1982), and hence an increase in symptom severity.

Psychological variables may maintain, exacerbate or result from eczema. As a chronic disease, eczema has psychosocial implications. Having eczema, requiring special skin care can limit a child's ability to interact with peers (through restrictions or limits on physical activities such as sport or swimming). Sufferers can also feel unattractive and experience problems with self-image (Barnetson & Rogers, 2002). A general attitude of negative affectivity can make it difficult to develop and maintain rapport and adherence to treatments.

Little is known about protective factors. Why do so many young children get better (up to 90% by the age of 5 years) but a minority do not? Few, if any, medical explanations are proffered, but some psychological research suggests being male and absence of atopy in either parent may act as protective factors. Psychological factors may also influence adherence to treatment regimes. If a family is not familiar with eczema or chronic, illness they may be more inclined to attempt to actively seek treatment for eczema (e.g. Charman, 1996). Psychological considerations include maturational factors which may enable individuals to comprehend both how their disease is manifested and also how to learn better ways of coping with stress in their environment.

Medical treatment

Medical treatment (Charman, 1999) is multi-faceted and includes the use of both oral and topical steroids (sometimes in combination with antimicrobial steroids), emollient creams, wet dressings, phototherapy and allergen avoidance (e.g. dietary manipulation, or control of house-dust mites). Steroids are effective in the short-term but prolonged use is a problem because of unwanted side effects, such as general immunosuppression and damage to the skin.

However treatments are palliative rather than curative; and although around three-quarters of children may be clear of eczema by their teens, relapses do occur (McHenry *et al.*, 1995).

Psychological interventions

At this stage of our knowledge, the impact of psychosocial issues in terms of disease complexity and utilization of health facilities is limited, but they could be critical in determining effective long-term treatment (Charman, 1996).

Having eczema involves living with a chronic disease/illness, coping with the physical and emotional impact of unpleasant and aggressive treatment regimes, impact on family, self-image and ability to lead a 'normal' life. The challenge for psychology is to tailor interventions to the individual to address some or all of these phenomena.

There is beginning to be evidence that combining psychological interventions with conventional medical treatments can certainly ameliorate symptoms and enhance quality of life. However, most of the reported research has involved small groups of sufferers and lacks adequate controls.

A systemic perspective can consider factors relevant to where and when a patient opts to attend for treatment, probable compliance with treatment regimes and potential co-morbidities. Those who attend hospital-based specialty clinics and seek additional services have been reported as experiencing more stress, less emotional support and significantly more depression, anger, anxiety and subjective distress than those attending a general dermatology clinic or private practitioner.

Cognitive-behaviour therapy has been reported as useful in several studies of eczema sufferers (Halford & Miller, 1992; Horne *et al.*, 1989). Interventions include the use of biofeedback, relaxation, habit-reversal and so on (see 'Biofeedback', 'Cognitive behaviour therapy' and 'Relaxation training'). More recent research has shown that training in self-monitoring of symptom severity and change associated with environmental effects (both internal, such as the patient's own feelings (especially of itchiness) and thoughts; and external such as specific stressful situations at work or home) combined with habit-reversal (e.g. closing hands for three minutes to prevent scratching when feeling itchy) can be effective (Borge, 1994) (see 'Self-management'). Relaxation training also seems to be of benefit, especially when combined with self-monitoring and habit-reversal. One of the authors (DH) has used these three elements regularly in treating adult eczema patients and has found that patient-induced relaxing imagery of a soothing scene, such as a gentle breeze over water (such as a lake or the sea) can be more effective than relaxation without such autogenic imagery (Horne *et al.*, 1999).

Successfully counteracting the itch-scratch habit seems to be a key factor, especially for children. Sleep disturbance may trigger other physical, emotional and social problems and lead to irritability, poor concentration and less energy for play and other social activities (Fennessy *et al.*, 2000).

Some sufferers may have more profound emotional problems; for example, childhood sexual abuse. These effects may last into adulthood and require more intensive therapy (Horne *et al.*, 1989).

Family intervention may be effective to reduce the child's scratching behaviour by, for example, activity scheduling and non-contingent attention. Gil *et al.* (1988) found that parent responses, i.e. contingent physical touching and/or contingent attention to scratching behaviour in children, were important predictors of scratching behaviour even after controlling for demographic and medical status variables (see 'Behaviour therapy').

Psychological intervention allows patients to gain an important understanding of the relationships between stressors in their lives and flare-ups in their skin. This combined with the effective prevention of scratching the skin through habit-reversal, does seem to allow eczema patients to both lower their baseline levels of scratching and to take immediate, effective ameliorative measures when a flare-up does occur with consequent reduction in both oral steroid and more topical treatments (Horne *et al.*, 1989).

Recognition of the impact of psychosocial issues on eczema sufferers is a welcome step forward. But more good quality research is needed to explore the social, material and emotional impact of eczema on patients of all ages. Good communication between health professionals and patients is a key starting point. In addition, psychological interventions seem to have much to contribute: however, the majority of studies are small-scale and lack good controls.

Conclusions

Clinical judgements of disease severity tend to be contaminated by other clinical observations, based upon the patient's age, gender and estimated compliance. These judgements seem to influence decisions about treatment.

The first step in psychological therapy is to reassure the eczema sufferer that they have a real bodily illness with real discomfort, but also to help them realize that their thoughts, emotions and behaviours can be both a reaction to the illness but also influence its course.

Self-monitoring of factors leading to increased itchiness and scratching appears to be effective in increasing awareness of symptoms and their relationship to the patient's life. The addition of habit-reversal and relaxation training (particularly incorporating relaxing imagery), once a self-monitoring baseline has been established, appears to be an effective therapeutic intervention. However, for patients who do not respond to this 'package', more intensive psychological treatment may be warranted.

The role of psychological factors in understanding and treating people with eczema and other skin disorders has made some progress in recent years but generally the research is limited to case studies or small group studies, often with inadequate controls.

(See also 'Children's perceptions of illness and death' and 'Skin disorders'.)

Acknowledgements

The authors wish to acknowledge the ongoing collaboration and encouragement provided by Dr. George Varigos, the Senior Dermatologist at the Royal Melbourne Hospital, Australia, and also of Dr. Denise Charman of the Victoria University of Technology, Melbourne, Australia, whose Ph.D. studies greatly contributed to this chapter.

Endocrine disorders

Eric A. Storch and Gary R. Geffken

University of Florida

Psychiatric symptomatology related to endocrine disorders

Psychiatric symptoms are commonly present during the course of endocrine disorders, which complicates diagnostic decisions. Common symptoms across endocrine diagnoses include affective disturbances (e.g. depression, anxiety), cognitive dysfunction, dementia, delirium and psychosis. This article provides a review of the psychiatric morbidity within endocrine disorders. Conditions associated with dysfunction of the pituitary, thyroid, parathyroid, adrenals and gonads are reviewed, as well as diabetes mellitus.

Disorders of the thyroid

Hypothyroidism

Hypothyroidism is the most common pathological hormone deficiency and can be classified on the basis of its time of onset (congenital or acquired), level of endocrine dysfunction responsible (primary or secondary) and severity (overt or mild). Overt hypothyroidism has been associated with symptoms such as energy loss, weight gain, slowed reflexes, cold intolerance, weight gain, constipation, dry skin, bradycardia, hoarseness and slowed cognitive processing. However, as many as 60–70% of newly diagnosed patients

do not experience significant symptomatology (Ladenson *et al.*, 1997). Those with mild hypothyroidism also often do not have symptoms.

Psychiatric and neurological manifestations can include depression (Ladenson *et al.*, 1997), anxiety (Sait Gonen *et al.*, 2004), psychosis (Alp *et al.*, 2004), ataxia (Price & Netsky, 1966), seizures (Woods & Holmes, 1977) and coma (Nicoloff & LoPresti, 1993). Overt hypothyroidism commonly manifests itself with cognitive impairment and depression. Psychiatric symptoms progress in a gradual course of neurocognitive deficits beginning with mental slowing followed by cognitive disturbances (e.g. short-term memory problems) and depression. In most instances, psychiatric symptoms remit with thyroid hormone replacement, although improvement may take weeks or months.

Hyperthyroidism

Excessive amounts of circulating thyroid hormone result in thyrotoxicosis. Thyrotoxicosis may result from thyroid gland hyperactivity, ingestion of high levels of thyroid hormone or secretion of thyroid hormone for an ectopic site (Greenspan, 1997). Diffuse toxic goiter, also known as Grave's disease, is the most common form of hyperthyroidism. Generalized anxiety states, as well as symptoms similar to panic disorder, have been observed in hyperthyroidism (Sait Gonen *et al.*, 2004). There are also links with mania and hypomania, depression, obsessive-compulsive symptoms and organic states such as delirium, although these presentations tend to be infrequent (Radanovic-Grguric *et al.*, 2003). Other clinical manifestations include restlessness, fatigue, tremor, weight loss, irritability, emotional lability and insomnia (see also 'Hyperthyroidism').

Disorders of the parathyroid

Hyperparathyroidism

Primary hyperparathyroidism, a common cause of hypercalcaemia due to hypersecretion of parathyroid hormone (PTH), is typically linked to hypophosphatemia and elevated serum chloride levels. Hyperparathyroidism may also be secondary to renal failure. Symptomatic presentations of this disorder are characterized by the presence of kidney stones, bone disease and neuromuscular weakness (Bilezikian & Silverberg, 2004). However, as many as 60% of patients are asymptomatic (Takami *et al.*, 2003). Weakness, fatigue, intellectual weariness, poor memory, decreased attention and depression, all of which are often difficult to detect or are mistaken for having different aetiologies, may present as initial signs of the disorder (Silverberg, 2002). Psychotic symptoms (e.g. paranoid delusions, hallucinations) and delirium have also been reported (Papa *et al.*, 2003).

The type and severity of psychiatric symptoms have been related to serum calcium levels (Leigh & Kramer, 1984). Mood and cognitive symptoms have been linked to serum calcium levels of 12 to 16 mg/dL (normal levels range from 8.9 to 10.1 mg/dL). Delirium and psychotic symptoms are linked to levels of 16–19 mg/dL, and somnolence and coma develop in levels exceeding 19 mg/dL.

Hypoparathyroidism

The causes of hypoparathyroidism vary, representing disruptions of one or more of the steps in the development and maintenance of

parathyroid hormone secretion. Injury to or removal of the parathyroid glands during neck surgery is the most common cause of acute or chronic hypoparathyroidism, although familial and autoimmune links have been reported (Marx, 2000). Dementia has been reported in cases of hypoparathyroidism (Levine & Gaoni, 1990). Cognitive disturbances and intellectual impairment have been reported as well (Kowdley *et al.*, 1999) (see also 'Dementias').

Disorders of the adrenal system

Hypercortisolism

A chronic excess of glucocorticoids causes Cushing's syndrome. The pathogenetic mechanisms of Cushing's can be divided into corticotropin (adrenocorticotrophic hormone)-dependent (from a pituitary or ectopic source) and corticotropin-independent (Boscaro *et al.*, 2001). 'Cushing's disease', which accounts for 60–90% of the cases, is generally due to an over-production of corticotropin from a pituitary adenoma. As many as 85% of patients present with psychiatric symptoms and/or cognitive dysfunction. Common conditions include depression (Sonino & Fava, 2001), generalized anxiety disorder and panic disorder (Loosen *et al.*, 1992). Bipolar disorder, including manic and hypomanic episodes, has been reported in 30% of patients with Cushing's syndrome (Sonino & Fava, 2001). Approximately 60% of patients have varying degrees of diffuse bilateral cerebral dysfunction, with overt impairment in nonverbal, visual-memory and graphomotor abilities (Mauri *et al.*, 1993). Difficulties with concentration, forgetfulness, reasoning ability, comprehension and processing of new information have been also reported (Forget *et al.*, 2000).

Hypocortisolism

The mechanisms involved in the development of hypocortisolism are unclear. Alterations on several levels of the hypothalamic-pituitary-adrenal (HPA) axis may contribute to the presence of hypocortisolism. Other factors, such as genetics, gender or early stress experiences, may also contribute to its development. Hypocortisolism for patients who have experienced a traumatic event and subsequently developed post-traumatic stress disorder has been reported (Yehuda, 1997). Hypocortisolism has also been reported in healthy individuals who endured ongoing stress (Caplan *et al.*, 1979). Hypocortisolism has also been reported for patients suffering from bodily disorders, such as burnout with physical complaints, chronic fatigue syndrome, fibromyalgia and asthma among others (Demitrack *et al.*, 1991; Crofford *et al.*, 1994) (see 'Post-traumatic stress disorder', 'Chronic fatigue syndrome' and 'Asthma'). Other clinical symptoms include weakness, fatigue, loss of appetite, depression, apathy, irritability, anhedonia, poverty of thought and social withdrawal (Brown, 1975). Although psychotic symptoms and delirium have been reported, some psychotropic medications tend to exacerbate hypotension symptoms and thus, are contraindicated (Stern & Prange, 1991).

Diabetes mellitus

Diabetes mellitus (DM) is a highly prevalent, chronic disease with a prevalence of diagnosed and undiagnosed cases to be approximately 16 million cases (Harris *et al.*, 1998). Of these people, approximately 90–95% have Type II diabetes (Harris, 1995). DM is a complex and

challenging disease due to the necessary integration of daily medical tasks (e.g. blood glucose monitoring) and lifestyle modifications. The stress of having a serious chronic illness, taken with the rigorous nature of the diabetic treatment protocol, predisposes some to adjustment difficulties (Cox & Gonder-Frederick, 1992) (see 'Diabetes mellitus').

Although some inconsistencies exist, studies have generally shown an increased psychiatric morbidity among individuals with Types I and II diabetes (see Geffken *et al.*, 1998 for a review), particularly with regard to individuals in poor metabolic control (Lustman *et al.*, 1986). The most common psychiatric diagnosis is depression, with reports in adults estimating rates between 8.5% to 27.3% (Goldney *et al.*, 2004). However, the aetiological nature of this condition is unclear and it is probably multi-determined. Anxiety disorders, particularly specific phobias (e.g. needle phobia), are also commonly found (Dantzer *et al.*, 2003). Again, anxiety is likely due to multiple causes, including neuronal and structural damage secondary to hypoglycaemia (Auer, 1986), classical conditioning (Sheehan & Sheehan, 1982) and stress related to chronic disease management.

Disorders of growth

Growth hormone (GH) is produced by the anterior pituitary gland and impacts physical stature. In children, GH excess is linked to gigantism, whereas deficiency produces short stature or dwarfism. In adults, GH excess causes acromegaly; GH deficiency is not linked to specific physical stigmata.

In childhood clinic-referred samples, numerous psychological problems have been related to short stature, including low self-esteem (Csapo, 1991), increased rates of externalizing (e.g. impulsive, easily distracted, attention-seeking; Storch *et al.*, 2005) and internalizing behaviours (e.g. anxiety, somatic complaints; Holmes *et al.*, 1985) and poor social competency (Downey *et al.*, 1997). Among non-referred children, however, data have failed to support the hypothesis that short stature is related to psychosocial adjustment (Downie *et al.*, 1997). The effects of short stature are thought to extend to later life as adults who were diagnosed with short stature during childhood report greater psychological

problems (e.g. depression, social withdrawal, social phobia; Stabler *et al.*, 1996) and academic, occupational and social impairment related to their short stature (Crowne *et al.*, 1990). Pituitary gigantism has been linked to depression by some (Margo, 1981), but not others (Abed *et al.*, 1987).

Reproductive disturbances

Hyperprolactinaemia

Hyperprolactinaemia is a common endocrine disorder of the hypothalamic-pituitary axis (Petty, 1999). Common causes of hyperprolactinaemia include pituitary adenomas, chronic renal failure primary and dopamine receptor antagonists such as antipsychotic drugs. There are a range of clinical consequences of chronic hyperprolactinaemia including, sexual dysfunction (e.g. diminished libido, decreased arousal, orgasmic dysfunction, impotence), reproductive dysfunction (e.g. anovulation, irregular menstrual cycles, subfertility, decreased oestrogen, decreased testosterone) and psychiatric and cognitive symptoms including depression, memory deficits and psychosis. Hyperprolactinaemia development and exacerbation has been linked with the use of conventional antipsychotic medications (Kinon *et al.*, 2003) and risperidone (Tran *et al.*, 1997) (see also 'Sexual dysfunction').

Gonadal dysfunction

Hypogonadism in men can be of a primary (directly involving the testes) or secondary (involving the hypothalamic-pituitary axis) nature. Prior to puberty, hypogonadism is linked to failure to develop male sex characteristics; after puberty, it may result in decreased libido, muscle mass and sexual dysfunction. Klinefelter's syndrome, the most common cause of primary gonadal failure, has been associated with a range of psychiatric disturbances including personality changes, and mood and psychotic disorders (Wakeling, 1972). Turner's syndrome, a sex chromosome abnormality with a female phenotype, has been linked with factors that may interfere with healthy psychosocial adjustment (e.g. short stature, sexual infantilism) (Downey *et al.*, 1989) (see also 'Chromosomal abnormalities').

Enuresis

Martin Herbert

Exeter University

Diagnosis

The term 'enuresis' is used when a child, beyond the age of anticipated bladder control and socially correct toileting behaviour, urinates into clothing or other inappropriate places. The defining age is usually considered to be five years. Whether the urinating is intentional or involuntary is not relevant to the general diagnosis. However, involuntary urination during the night, in a child who has never ceased to wet the bed (or has lost a previously acquired skill) is referred to as 'nocturnal enuresis', and colloquially as 'bedwetting'. Nocturnal enuresis is one of the commonest reasons for families seeking help from primary care physicians. The problem was referred to as early as the sixteenth century in *The boke of chyldren* by Thomas Phaire, in a chapter entitled 'Of pissing in the bedde'.

'Diurnal enuresis' is the term for involuntary daytime urination. It occurs in approximately 1 in 10 of the children with nocturnal enuresis. A distinction is also made between children who are 'regular' and those who are 'intermittent' bedwetters. Most enuretic children have what is called 'primary' nocturnal enuresis, meaning that they have wet their beds since toddlerhood. 'Secondary' enuresis is the term applied to children who revert to bedwetting after a sustained period of dry beds. Although urinary tract infections or diabetes may play a role in secondary enuresis, it is often impossible to identify any specific medical cause. It may, however, be associated with psychological causes such as problems at home (e.g. a divorce) school (e.g. bullying), or other life stresses that precipitate a regression.

Assessment

Although most children with enuresis are physically normal, they will usually (and preferably) be physically examined by a primary care physician or paediatrician to exclude medical conditions. The doctor may arrange for urine tests to check for infections or other abnormalities, if any disorders are suspected. Constipation is sometimes associated with enuresis, occasionally involving soiling of underwear ('encopresis') in serious cases. Usually, mild constipation is remedied by simple dietary measures, but severe cases of constipation may require intensive treatment before the enuresis can be tackled. Primary enuresis may be associated with other disorders such as attention deficit hyperactivity disorder (ADHD) and sickle cell anaemia (Herbert, 2003) (see 'Hyperactivity' and 'Sickle cell disease').

Children with enuresis are at risk of having, or developing emotional and behaviour problems. Clinical psychologists have the particular behavioural skills that are needed for assessing and treating

enuresis, and (if required) encopresis. Some cases continue (if untreated) into late adolescence and even adulthood.

Toilet training: incidence of bedwetting

A child might be considered toilet trained when s/he is able to use the toilet (or potty) reasonably independently, perhaps with assistance over adjusting clothing. There is much variation in the age at which children achieve control between and within different cultures. Knowledge of the norms (averages) in typical development, while bearing in mind that there is a wide range of individual differences, might help parents feel more relaxed about the 'implicit' timetable for the development of continence. There is no one age at which children cease to wet the bed (see Murphy & Carr, 2000).

Control of the bowels is attained before bladder control. The developmental sequence is generally as follows:

1. bowel control at night
2. bowel control during the day
3. bladder control during the day
4. bladder control at night.

The sequence may vary for children; some achieve bowel and bladder control 'simultaneously'. Girls tend to be quicker than boys in becoming continent. Lack of control is frequently seen in children in residential establishments.

Causation

Causation in enuresis is multifactorial, involving medical, developmental, psychosocial, or genetic causes factors (see Butler, 1998; Clayden *et al.*, 2002):

1. *Medical causes* of enuresis might include (*inter alia*), urinary tract infection, diabetes, urinary tract obstruction, or neurogenic bladder (i.e. a bladder with impaired nerve function). Physiological causes may involve small functional bladder capacity, or a deficit in the amount of antidiuretic hormone (ADH) produced. The presence of this hormone concentrates urine and prevents the bladder from filling up during sleep. Among uncommon physical causes are chronic renal or kidney disease, diabetes, tumours and seizures. Such potentially important causes should make an expert physical examination a matter of routine.
2. *Developmental influences*: some enuretic children suffer from developmental delays other than incontinence; also an above average likelihood of a learning disability. (Herbert, 2003). A high level of 'skill' is needed before the bladder can be controlled

during sleep, so it is perhaps not surprising that some children do not achieve it with ease, especially when disabled or under stress.

3. *Psychosocial causes* (see Herbert, 2003): enuresis may have its origins in faulty learning. Some cases of enuresis are related to toilet training that was begun too early, or carried out in a very forcible manner. Young children lack a sufficiently mature signalling mechanism between the bladder and the brain to become aware of a full bladder. Consequently, they fail to wake up and wet the bed. Punishment is inappropriate. In fact, children with enuresis are most likely to have their toilet training initiated late. Enuresis may be an adjustment problem (notably in the sensitive period when the child is trying to learn control) as a result of high levels of life-stress. Both harsh 'pressurizing' of the child, or (conversely) complacent neglect of training, may lead to the failure of this development. Parents who are very controlling and quick to find fault may also trigger problems with bladder control (Table 1) (Herbert, 1996). Emotional problems may be superimposed when the child is made to feel acute shame at his or her 'babyish' ways. Children at risk of becoming bedwetters (mainly girls) tend to come from lower socioeconomic groups, and from large families living in overcrowded conditions. Mothers who give birth as teenagers constitute a further predisposing factor. In most cases, the causal mechanisms that underlie the risk factors (causal associations) are not known.
4. *Genetics*: enuresis often runs in families. Of children with nocturnal enuresis, 70% have a parent who was late in becoming dry. About twice as many boys as girls suffer from enuresis. The concordance rate for identical twins is 68% and 36% for fraternal (non-identical) twins. Molecular genetic evidence has not yet implicated a single gene. The most likely conclusion in our present state of knowledge is that the genetic influence in nocturnal enuresis is heterogeneous. (Clayden *et al.*, 2002).

Enuresis in adults

Nocturnal enuresis in adulthood is probably related to a nerve problem that affects bladder function, or a problem with the hormonal secretion by a gland at the base of the brain. A urological examination is likely to include an evaluation for a structural (anatomic) abnormality. There are medications (depending upon the cause of the problem) that can remedy the incontinence, treatment that may possibly have to be taken for a lifetime in order to remain effective. Young adults (teenagers) with enuresis often have a parent who had the same problem at about the same age.

Table 1. Frequency of bedwetting

Age in years	Approximate number of children in every 100 who wet the bed
2	75
3	40
4	30
5	20
6–9	12
10–12	5
15	1–2

Treatment

The treatment of enuresis falls into three categories: counselling; behavioural methods; and medication. Often, more than one treatment is used at the same time (see reviews of methods and their effectiveness by Butler, 1998; Clayden *et al.*, 2002; Doleys, 1977*a,b*; Murphy & Carr, 2000; Ondersma & Walker, 1998; Shaffer, 1994; Walker, 1995). The evidence suggests that:

- (i) counselling; alone this is rarely effective.
- (ii) behavioural treatments are generally effective; these include:
 - a. incentives (tangible and symbolic rewards) for achieving bladder control;
 - b. bladder training such as graduated delay of bladder emptying to increase bladder control;
 - c. conditioning methods, such as a urine alarm that wakens the child when s/he wets a pad to which it is connected;
 - d. decreasing fluids taken at night;
 - e. teaching the child to attend and respond to bladder sensations at night.

The most successful treatments available are the 'urine alarm' and 'dry bed' systems. The urine alarm system attaches a moisture sensor attached to the child's night-time underwear, and a small speaker on a bedside table or on the shoulder of the child. A very small amount of urine activates a loud alarm that causes the child to tense reflexly, thus inhibiting the flow of urine. The parent escorts the younger child to the toilet in order to complete the urinating. Adherence to this programme should produce a positive outcome, with the child waking up 'unprompted' after 4 to 6 weeks of treatment. Reliable bladder control is usually achieved after around 12 weeks of training. At such a time the backup alarm is no longer required. Many clinicians prefer to begin treatment with the use of incentive sticker (reward) charts, adding a urine alarm if the child does not respond to this so-called 'operant method'.

The evidence for the superiority of the urine alarm method (with rates of remission between 80 and 90%) over no-treatment and other-treatment control procedures, is well documented for nocturnal enuresis (e.g. Doleys, 1977*a,b*). Although there was an average relapse rate of 40%; nearly 60% of these returned to continence after booster sessions. In another study of 127 enuretic children (Van Londen *et al.*, 1995), 97% in a urine alarm programme which was supplemented with immediate contingency (operant/rewards) management, were continent compared with 84% of the group that received delayed contingency management and 73% who received a routine enuresis alarm programme. Only 8% of the first group had deteriorated after two-and-a half years (see 'Behaviour therapy').

A meta-analysis of 78 studies by Houts *et al.* (1994), while reporting that the highest success rates for psychological programmes were those using urine alarms, also found the alarm method to be no more effective than the medical treatments (tricyclics and desmopressin) at post-treatment. However, they were significantly superior at follow-up.

- (iii) medication: Tricyclic drugs (somewhat out of favour because of adverse side effects and poor results) and desmopressin are used in the treatment of enuresis. Desmopressin is available as a nasal spray administered before bedtime. Continence is

achieved relatively quickly in 70% of children; another 10% show significant improvement. It is only effective while the child is on medication; relapse occurs when it is discontinued. Children require a behavioural intervention before they can be taken off desmopressin.

Medication alone is often the first treatment of choice by physicians, a preference not supported by the evidence. Clayden *et al.* (2002, p. 804) state, in an extensive review, that 'it is puzzling that medication is so often preferred to the alarm when the latter is more effective, safer and less expensive'. It has to be said that despite the potential of urine alarm methods, problems of a technical nature can reduce their success. For example, sweat may trigger the alarm; batteries go flat; the child's clothing and bedding are not prepared properly; inconsistency on the part of exhausted parents; insufficient expert monitoring of the programme; premature withdrawal of therapy and so on. Butler (1998) provides an excellent review of the advantages of the enuresis alarm, and some of the practical difficulties that can hinder the usual expectation of success.

Conclusions

The findings on enuresis reviewed above suggest that:

- (i) Urine alarm-based methods (the so-called 'bell-and-pad' apparatus) is the most effective treatment for enuresis.
- (ii) A contingency management programme, where children obtain rewards for avoiding bedwetting (see 'Behaviour therapy') can be effective used alone, but is more successful when applied in combination with the urine alarm procedure.
- (iii) Such programmes require a psycho-educational element so that parents (of necessity involved in their implementation) receive adequate explanations and rationales for the procedures, as well as painstaking instructions for their correct use.
- (iv) To meet these objectives, a detailed guide describing behavioural and combined methods of treating nocturnal and diurnal enuresis has been prepared for practitioners and parents (by Herbert, 1996).

Epilepsy

Graham Scambler

University College London

Definition, prevalence and incidence

An epileptic seizure is the result of an abnormal paroxysmal discharge of cerebral neurones. Epilepsy itself is often defined as a continuing tendency to epileptic seizures. The form of the seizure depends on the site of the neuronal discharge in the brain. There

are as many causes of epilepsy as there are seizure types. Rare genetic disorders like Tay-Sachs disease, congenital malformations, anoxia, trauma, brain tumours, infectious diseases, acquired metabolic diseases, degenerative disorders and chronic alcoholism can all lead to epilepsy. There is evidence too that a low convulsive threshold can be inherited.

If the neuronal discharge remains confined to one part of the brain, the resultant seizure is described as 'partial'. If the discharge begins in one part of the brain but subsequently spreads to all parts, the seizure is said to be 'partial with secondary generalization'. Sometimes the abnormal discharge originates in the mesodiencephalic system and spreads more or less simultaneously to all parts of the brain, in which case the reference is to a 'primary generalized' seizure. Since it is generally understood that all partial seizures arise from some focal area of structural abnormality in the brain, all partial seizures, plus those seizures which are secondarily generalized from some focal onset, can be described as 'symptomatic epilepsy'. Primary generalized epilepsy is never symptomatic of underlying brain damage, and can thus be described as 'idiopathic epilepsy'.

Epilepsy is more common than many realize, although rates depend on the definition used and on case ascertainment. The prevalence of epilepsy is generally estimated to be between 5 and 10 cases per 1000 persons, and the overall incidence to be about 50 cases per 100 000 persons. The highest incidence is at the two extremes of life, with 50% of cases being under age 1 or over age 60. The prognosis varies with such factors as number of seizures at presentation, seizure type and use of anti-epileptic drugs (AEDs). In one recent review of the evidence (Bell & Sander, 2002), four prognostic groups were identified:

1. Excellent prognosis (20–30%): usually only a few seizures occur and spontaneous remission is the rule.
2. Good prognosis (30–40%): seizures are easily controlled by AEDs and, once remission is achieved, it is usually permanent.
3. AED-dependant prognosis (10–20%): AEDs suppress seizures and remission may be achieved, but relapse is likely if AEDs are stopped.
4. Bad prognosis (up to 20%): AEDs are palliative rather than suppressive of seizures. A few might respond to novel AEDs or surgery.

The mortality rate is slightly but significantly increased in those with epilepsy. In newly diagnosed epilepsy, death is commonly attributed to the underlying pathology, while in chronic epilepsy a familiar cause of death is Sudden Unexpected Death in Epilepsy (SUDEP) (the rate of sudden unexpected death being 20 times higher in those with epilepsy than in the general population).

Epilepsy services

In a contemporary survey of evidence-based standards of care for adults with epilepsy (Rajpura & Sethi, 2004), the authors conclude that although epilepsy services appear to be fairly standard throughout the UK, there is a need for more methodologically robust studies to determine the most clinically effective model of service provision for people with epilepsy. The existing quality of care, they add, is generally poor. Contributions to the World Epilepsy Day Symposium in November, 2004 established that the situation in the UK is the norm rather than the exception. In fact it is estimated that 70–90% of people with epilepsy in developing countries are not receiving any treatment or are not treated effectively (Ahmad, 2005). In a systematic review of specialist epilepsy services

in the UK (Meads *et al.*, 2002), no evidence was found either that specialist epilepsy clinics improved outcomes when compared with general outpatient neurology clinics, or that specialist epilepsy nurses improved outcomes when compared to usual care in an inpatient, outpatient or primary care physician/general practice (GP) setting. There was good evidence, however, that the 'process' of treatment and care was enhanced in the epilepsy nurse groups. In a study of the management of people with epilepsy in general practice, Goodwin and colleagues (2002) highlighted a number of deficiencies. Of the 116 participants, 71 were identified as requiring specialist review: 31 of these had experienced no seizures for five years. The authors judged that many were taking unnecessary medication and suffering unnecessary side effects.

Psychosocial sequelae of epilepsy

Approximately one in three people with epilepsy experience difficulties in addition to the physical impact of their conditions, including cognitive and psychosocial problems. Herman and Whitman (1986) have assessed the evidence for causal linkages between sets of 'neuroepilepsy', 'medication' and 'psychosocial' variables and measures of impairment. The results reflect the funding research bias towards neuroepilepsy and medication variables. Neuroepilepsy variables thought to be associated with psychiatric or psychological impairment include age at onset, aetiology, seizure control, duration of epilepsy, multiple seizure types, type of aura and neuropsychological status. Medication variables coming into this category are polypharmacy, serum levels of AEDs, type of medication and folic acid levels. The list of psychosocial variables is longer but each is less well researched: fear of seizures, perceived stigma, perceived discrimination, adjustment to epilepsy, locus of control, life events, social support, socioeconomic status and childhood home environment. The relative neglect of psychosocial factors in research is ironic given the *prima facie* plausibility of causal links between these and impairment. The psychosocial factors can be discussed under four subheadings.

Professional care

It is the physician who is empowered to make the diagnosis of epilepsy and to apply the diagnostic label. To communicate a diagnosis of epilepsy is to transform a 'normal person' into 'an epileptic' (Scambler & Hopkins, 1986). There is clear evidence that this new, unwanted status or identity can be more distressing and disruptive of lives than the anticipation or fact of recurrent seizures (see 'Coping with chronic illness').

However, if the communication of the diagnosis is often the most dramatic episode in relationships with physicians, it is generally but one moment in relationships beginning with the initial consultation and ending only with the cessation of AEDs or death. During these relationships people look to physicians, and increasingly to specialist epilepsy nurses, to replace uncertainty with expert accounts of tests, aetiology, therapy and prognosis. They also aspire to be treated effectively and with consideration of the full range of psychosocial sequelae of epilepsy. Occasionally their demands may be unrealistic: for all the lapses exposed by the growing number of audits, it remains the case that many of the uncertainties

surrounding epilepsy cannot be alleviated, given the current state of medical knowledge. But, interestingly, one common finding in Britain and in the United States relates to physicians' 'disinterest' in the day-to-day problems of coping with epilepsy (Schneider & Conrad, 1983; Scambler, 1989).

Personal identity

People perceive the status or identity of 'epileptic' to be discrediting through their association of epilepsy with stigma (Scambler, 2004) (see 'Stigma'). Often it is accompanied by a sense of shame and, more saliently perhaps, a fear that others will reject, exclude or otherwise discriminate against them. This fear of discrimination has been termed 'felt stigma', and actual discrimination 'enacted stigma'. Felt stigma can predispose people to conceal their condition if they can, this being the strategy of choice for many, within as well as outside their families. Nor is felt stigma a function of seizure frequency, as is commonly supposed. Concealment reduces opportunities for enacted stigma; paradoxically, felt stigma typically causes more distress than enacted stigma. Other strategies than concealment include minimizing risks through avoidance of others; pragmatic or selective disclosing; or, more rarely, a defiant 'avowal of normality'. Strategies in fact vary by role and over time.

Family management

Epilepsy often begins in childhood, and children's understanding of their circumstances is conditioned by parents' explanations and behaviour. Parents, like doctors, may act as 'stigma coaches', training their offspring to feel ashamed and apprehensive about their epilepsy, prescribing concealment by advice or example (Schneider & Conrad, 1980). This is a form of over-protection, and over-protection is a key source of anger and resentment among young people with epilepsy, which may be associated with behavioural and adjustment problems later.

In adolescence and adulthood felt stigma typically leads to concealment (see also 'Children's perceptions of illness and death'). Boy-or girlfriends tend not to be told, and even engagements may not provoke openness. The same fear of rejection that proscribes mention of the word 'epilepsy' makes for a persistent sense of unease in case one day a seizure or other cue might lead to or precipitate exposure. There is little evidence that open disclosure, or even unwitting 'exposure' (e.g. a witnessed seizure), are likely to

be followed by the termination of relationships, although it can happen. Uncertainty and bewilderment and occasionally conflict, tend to be succeeded by new, 'negotiated' equilibria (Scambler, 1989).

Work opportunities

Epilepsy is still associated with higher than average rates of unemployment and under-employment, although it must be borne in mind that epilepsy is sometimes one symptom of conditions much more disabling. Estimates of the proportion of British adults with epilepsy experiencing employment problems vary from 25–70%, depending on the criteria used. Difficulties may be the product of either enacted stigma or more legitimate forms of discrimination, for example banning driving. Felt stigma too can lead to disadvantage: people occasionally avoid or withdraw from the labour market, or decline opportunities for advancement, through felt stigma.

A wide range of studies have shown that felt stigma also leads to policies of non-disclosure to employers, at least when seizure frequency renders this strategy viable. While concealment reduces the prospects of meeting with enacted stigma or legitimate discrimination, it can prompt severe daily anxiety and tension in 'information management'.

Conclusions

There are implications here for improved quality of care. There is a need for patients' own perspectives to be elicited and taken seriously. Typically these perspectives are characterized by: (1) 'felt stigma': the perception of epilepsy as stigmatizing and a social and psychological burden; (2) 'rationalization': an urge to make sense of what is happening in order to restore cognitive order; and (3) 'action strategy': a need to develop ways of coping with epilepsy and its concomitant psychosocial problems. Doctors tend to be interested in those aspects of rationalization which facilitate diagnosis and management, but not in the process per se. Neither felt stigma nor action strategy tend to make it onto medical agendas for consultations, and are often handled badly when raised by patients. Physicians do not merely need to manage, inform and advice, but also to listen, which can be therapeutic in its own right. These are qualities which research studies are beginning to reveal in specialist epilepsy nurses.

Epstein–Barr virus infection

Rona Moss-Morris¹ and Meagan Spence²

¹University of Southampton

²The University of Auckland

The Epstein–Barr virus (EBV) is a tumorigenic herpes virus that has been implicated in a wide range of human illnesses such as Hodgkin's disease and B lymphoproliferative disease; however it most commonly causes infectious mononucleosis (IM) often referred to as glandular fever (Macswain & Crawford, 2003). Primary infection with EBV typically occurs subclinically between the ages of one and six, after which the virus latently inhabits B lymphocyte cells. Previous infection with EBV is indicated by the presence of EBV antibody titres in the serum, while lack of these antibodies indicates vulnerability to EBV infection (Kasl *et al.*, 1979). In the Western world, a second peak of EBV infection occurs between 14 and 20 years of age. Estimates suggest that 90% of the world's population are seropositive for EBV by the age of 30 and carry the virus as a lifelong latent infection (Papesch and Watkins, 2001).

Epstein–Barr virus and infectious mononucleosis

When people get infected with EBV, a number seroconvert without developing the clinical signs of IM. Those who develop the clinical syndrome experience an acute illness characterized by fatigue, sore throat, tender lymph nodes and fever, which usually resolves within two to four weeks (Rea *et al.*, 2001). The puzzle is why some infected individuals develop clinical IM while others do not.

In an attempt to answer this question, Kasl and colleagues (1979) investigated 432 young American cadets over a four-year period. They monitored when the cadets became infected with EBV for the first time and found that those who had a high level of motivation combined with poor academic achievement were significantly more likely to develop clinical IM than those who did not. These results suggest that the development of clinical signs following infection with EBV is dependent in part on psychological factors. More work is needed to investigate other possible

psychological risk factors and the biological sequelae associated with these factors.

Psychoneuroimmunology and elevated Epstein–Barr virus titres

A larger body of research within the area of psychoneuroimmunology has investigated antibody titres to EBV as a measure of immune system competence. Psychoneuroimmunology (PNI) is the study of how psychological factors may impact on the immune and neuroendocrine systems (see 'Psychoneuroimmunology'). Because EBV infection is largely ubiquitous and the virus remains in the body in a latent form, levels of elevated titres of EBV antibodies are seen to reflect a possible reactivation of the latent virus associated with a down regulation of cellular immunity (Van Rood *et al.*, 1993). Studies have shown that higher antibody levels to EBV are associated with a range of diverse stressors such as divorce, loneliness, marital dissatisfaction, care giving for a relative with Alzheimer's disease, space flight and university exams (Burlison *et al.*, 2002; Kiecolt-Glaser *et al.*, 1988; Sarid *et al.*, 2001; Stowe *et al.*, 2001). Personality and coping styles including high levels of emotional suppression, defensiveness and trait anxiety have also been significantly linked to elevated EBV antibody titres (Esterling *et al.*, 1993) (see 'Personality and health' and 'Emotional expression and health'). In addition, psychological interventions designed to reduce stress have significantly decreased these antibody titres (Van Rood *et al.*, 1993).

The relationship between stress and raised antibody titres may not be as straightforward as these early results suggest, however. Glaser and colleagues (1999) compared antibody levels in a homogeneous population of students attending a military academy before and after basic training, during a semester break and during examination week and found that only during the exam week were levels significantly raised. These results suggest that certain stressors may

have a more profound effect on the down regulation of the immune system than others.

Are elevated Epstein–Barr virus antibody titres clinically relevant?

Although elevated EBV antibody titres have been taken as a measure of the down regulation of the immune system, how, or if, this relates to clinical outcome remains a moot point. In the 1980s, elevated antibody titres were implicated as causal factors in conditions such as depression and chronic fatigue syndrome (CFS) and received much media attention (Moss-Morris & Petrie, 2000). Subsequent well designed studies comparing depressed and CFS patients with matched healthy controls found no significant differences in EBV antibody titres between these groups (Buchwald & Komaroff, 1991). Longitudinal studies have also failed to find sustained evidence of EBV infection in CFS patients, and improvement in symptoms and the clinical features of the disorder appear unrelated to changes in EBV titres (Buchwald & Komaroff, 1991; Matthews *et al.*, 1991).

Infectious mononucleosis as a risk factor for the development of chronic fatigue syndrome

The weight of evidence suggests that elevated EBV titres play little role in CFS. However, the clinical manifestation of EBV (i.e. an acute episode of IM) appears to be a relevant risk factor. A number of prospective studies have tracked the natural history of IM in order to determine the likelihood of developing chronic problems such as fatigue, fibromyalgia and depression. Estimates of fatigue post-IM range from 9–22%, in comparison with 0–6% of patients who experience fatigue six months after an upper respiratory tract infection (URTI) (White *et al.*, 1998). A study of the incidence of fibromyalgia following IM, however, found no greater risk of this condition than would be found in the general population (Rea *et al.*, 1999). With regard to depression, White and colleagues (2001) found that whilst new episodes of depression were triggered in the acute stages of IM, six months post-illness there was no greater incidence of depression than was found before onset of IM. We can conclude then, that for a group of predisposed individuals, the experience of IM places them at greater risk of developing chronic fatigue, but not other related conditions such as fibromyalgia or depression (see ‘Chronic fatigue syndrome’).

Patients with an acute episode of IM therefore provide an ideal group with which to prospectively examine other factors which may interact with the virus in causing the onset of chronic fatigue. White and colleagues (White *et al.*, 2001) followed patients who had experienced either IM or an URTI. At six months they compared those who had developed fatigue with those who had recovered on a large number of demographic, clinical and laboratory factors and on a range of psychosocial measures. They found that the most reliable predictors of fatigue at six months were: IM as opposed to URTI; a lower extroversion score; and lower laboratory tested physical fitness at two months post-illness.

Another study found that of 150 patients with IM, 12% reported significant ongoing fatigue and disability six months later (Buchwald *et al.*, 2000). These patients were more likely to be female, to have

experienced more life events in the six months prior to IM, and to have received greater family support during their illness (see also ‘Life events and health’). Candy and colleagues (2003) demonstrated that female gender and negative illness beliefs most reliably predicted fatigue cases six months post-IM. Finally, Spence and Moss-Morris (in preparation) followed up a large cohort of people who had experienced a severe acute infection; including 758 people with *Campylobacter* gastroenteritis and 260 with IM. Whilst IM was a significant predictor in the development of fatigue at three months, this was not the case at six months, with a similar proportion of gastroenteritis patients developing fatigue as IM patients. A number of psychological predictors were significantly related to chronic fatigue at six months, including anxiety, depression, somatization, perfectionism, negative illness beliefs and ‘all-or-nothing’ behaviour. Multivariate analysis indicated that the strongest predictor of fatigue six months post-IM was negative perceptions of the initial acute illness (see ‘Lay beliefs about health and illness’ and ‘Symptom perception’).

Commonalities emerge from the findings of the IM studies. Each has confirmed IM as a significant risk factor for the development of chronic fatigue in the short term; however, the extent of this influence may be less significant from six months post-illness. All found that their predictors differed according to the time point that outcome was measured; with biological predictors, such as higher levels of atypical lymphocytes (Katon *et al.*, 1999) and activated CD4 and CD8 (Candy *et al.*, 2003), perhaps more likely to predict fatigue at two or three months, whilst psychological predictors become more significant at six months post-illness.

The psychological factors shown to predict chronic fatigue or CFS following IM provide some support for the cognitive–behavioural model of this illness (Surawy *et al.*, 1995). Levels of psychopathology, such as anxiety and depression, together with personality characteristics, such as perfectionism and low extroversion, may act as predisposing factors. When such individuals are faced with needing to ease back from their commitments because of IM, they may respond in characteristic ways which help to perpetuate their fatigue. Initially, they may take some time off to recover. However, inactivity conflicts with their need to achieve in order to feel good about themselves or to please others, so they rush back to their commitments before they are fully well. This generates more symptoms as well as stress; the symptoms are interpreted as signs of the original illness, rather than signs of stress or recovery, and they return to bed. If this cycle continues, patients may develop the belief that they have a serious ongoing illness which does not seem to go away. They may develop a pattern of accommodating to their symptoms, which ultimately results in deconditioning and ongoing fatigue.

The fact that studies have shown that negative illness beliefs, ‘all-or-nothing’ behaviour in response to symptoms, and lack of physical fitness predict chronic fatigue post-IM, provide good support for the cognitive–behavioural aspects of the model (Candy *et al.*, 2003; Spence and Moss-Morris in preparation; White *et al.*, 2001). Furthermore, a simple behavioural intervention during the recovery phase of IM, where patients were encouraged to slowly, but surely, increase their levels of activity was shown to reduce the incidence of CFS post-IM (Candy *et al.*, 2004) (see ‘Behaviour therapy’ and ‘Cognitive behaviour therapy’).

In summary, the EBV provides intriguing avenues for the exploration of the relationship between psychology and biology. Psychological factors have been shown to predict who develops clinical signs of IM after EBV infection, and who goes on to develop

ongoing fatigue after IM. The latent nature of the virus means that antibody titres can be used to measure activity of the immune system and how this may be influenced by factors such as stress.

Facial disfigurement and dysmorphology

Nichola Rumsey

University of the West of England

Disfigurement

Introduction

The UK Office of Population Censuses and Surveys (OPCS) (1988/1989) has defined a disfigured person as someone who 'suffers from a scar, blemish or deformity which severely affects (their) ability to lead a normal life'. Macgregor (1990) has described facial disfigurement as a 'psychological and social death'. Disfigurement can result from many causes including congenital conditions (e.g. a cleft of the lip), from trauma (e.g. burns), surgical intervention (e.g. treatment for cancer), strokes and skin conditions (e.g. acne). Current estimates suggest that 10% of the population have some kind of facial 'difference' that sets them apart from the norm (Changing Faces, 2001). Recent research, however, suggests that the extent to which a visible difference results in social disability involves a complex interplay of psychological and social factors (Rumsey & Harcourt, 2004) (see also 'Disability').

The importance of the face in social interaction has long been recognized in the academic disciplines of psychology, history and anthropology. In a society that places a high premium on physical attractiveness and 'wholeness', it is not surprising that a sizeable research literature attests to the benefits of having a physically attractive facial appearance. When compared with the first impressions formed of those with an unattractive facial appearance, good-looking people are perceived to be more intelligent, popular, honest and socially desirable. Research also indicates that attractiveness is positively related to expectations of future success, happiness and marital satisfaction (Thompson *et al.*, 1999). Relatively little research and funding has been devoted to examining the effects of having an unattractive or disfigured facial appearance. However, common themes emerge from the research and writings that are available.

Difficulties experienced by disfigured people

Facial disfigurement can have far-reaching psychosocial consequences. The most common problems experienced by those with facial disfigurements, whether congenital or acquired, involve negative self-perceptions and difficulties in social interaction, with problems particularly apparent at times of change, for example, moving to a new neighbourhood, starting new school, or beginning a new job (Rumsey & Harcourt, 2004). First encounters can be problematic, with difficulties reported in situations such as meeting new people, making friends, developing relationships and succeeding in job interviews.

Many disfigured people attribute the problems they experience to the negative reactions of others, complaining that they are avoided

or rejected by the general public. Studies of the process of social interaction have shown that avoidance does occur. However, this avoidance is not necessarily the result of 'rejection' (Rumsey & Harcourt, 2005). A first meeting with a facially disfigured person is potentially problematic, as the normal rules of social interaction may not apply. The other party may be concerned that conventional patterns of non-verbal communication will be misconstrued (for example, eye contact might be interpreted as staring). Avoidance can feel preferable to the risk of embarrassment for either or both parties. Social encounters may also be thrown off-balance by the behaviour of the person with the disfigurement. Unconventional verbal or non-verbal communication can result from the inability to use facial musculature in the usual ways. Anticipating negative reactions from others, the affected person may adopt a shy or defensive interaction style (Macgregor, 1990), increasing the likelihood of negative reactions from others. Spirals of unhelpful emotions (e.g. social anxiety), maladaptive thought processes (e.g. fear of negative social evaluations), unfavourable self-perceptions (e.g. lowered self-esteem) and negative behaviour patterns (e.g. excessive social avoidance) may result.

Lansdown *et al.* (1991) characterized a visible difference as an underlying stressor throughout the lifespan, maintaining that life is likely to be appreciably harder for those with a face which is out of the ordinary. For children and adolescents, the majority of problems focus on teasing by others, on fear of going to new places and on problems associated with negative feelings about the self (Frances, 2003). However, disfigurements in children are not associated with any identifiable personality pattern, reports of delinquency, raised incidence of bad behaviour or lack of educational success (see also 'Children's perceptions of illness and death'). The intensified focus on physical appearance during adolescence can present difficulties. Image counts in the dating game, and joining social groups can be difficult if social confidence is eroded. Lansdown (1990) and others believe that problems in adolescence and adulthood are under-reported, as most data are collected in response to questions asked in medical settings, when the atmosphere is frequently not conducive to open discussion of social and psychological issues. Research involving older people is scarce: however, Spicer (2002) found that compared with middle-aged and younger adults, a smaller proportion of older adults affected by skin conditions reported high levels of appearance concerns, yet many still experienced considerable distress.

Factors playing a part in adjustment

Although the evidence suggests that people with facial differences are at risk for psychosocial problems, not all are equally affected.

Rumsey *et al.* (2002) found levels of anxiety, depression, social anxiety and social avoidance and perceptions of quality of life were unfavourable compared to published norms in 33–50% of a sample of over 600 outpatients attending for treatment of a variety of disfiguring conditions. What factors account for the differences in distress? Contrary to the expectations of many, the extent, type and severity of a disfigurement consistently fail to predict levels of adjustment. A person's subjective perception of how noticeable their difference is to others has been found to be a better indicator of psychological disturbance than an 'objective' rating provided by others (Rumsey *et al.*, 2004). In some cases, the cause of the disfigurement can exacerbate distress. As an example, the circumstances surrounding a burn injury may engender a variety of negative emotions such as guilt or blame in those affected (see 'Burns'). However, generalizations based on broad aetiological categories of disfigurement, (e.g. congenital as opposed to acquired) have limited utility as predictors of adjustment and distress and should be avoided (Newell, 2000).

Despite the common assumption that females experience more distress as the result of disfigurement than men, findings relating to gender effects are mixed (Rumsey & Harcourt, 2004). The considerable impact of social factors such as the current societal obsession with physical appearance and the prevailing images of attractiveness in all forms of media have been widely noted (see for example, Thompson *et al.*, 1999), however, the nuances of experiencing disfigurement in different cultural contexts remain largely uninvestigated.

Models of adjustment, (see for example, Newell, 2000; Kent, 2002) have placed increasing emphasis on cognitive processes to explain variations in adjustment. These include the emphasis placed on physical appearance in self-perceptions (e.g. self-esteem, body image), biases in information processing (e.g. vulnerability to media messages relating to attractiveness), the processing of social information (Moss & Carr, 2004) and processes of social comparison. In recent years, there have been calls to move away from an exclusive focus on the problems and difficulties associated with disfigurement, towards a broader research agenda that includes the strengths of people who cope well (Strauss, 2001). Research relating to protective factors is still in its infancy: however mounting evidence suggests that these include effective social interaction skills, good quality social support and a positive family environment which stresses the importance of a broad range of personal qualities (other than appearance) in self-esteem and self-worth (Rumsey & Harcourt, 2004).

Endriga and Kapp-Simon (1999) have highlighted the multiple domains of risk and protection in adjustment to craniofacial conditions. Researchers are only just beginning to unravel the complex interplay of factors affecting adjustment to disfigurement, motivation to seek treatment and responses to the outcome of treatment (see 'Reconstructive Surgery').

Meeting the needs of people with facial differences

Expanding the biomedical model of care

The assumption underlying treatment offered within the UK National Health Service is that improvements in physical appearance will reduce psychological distress and improve quality of life. Normalizing a person's appearance can clearly offer

benefits: however, the problems experienced by facially disfigured people are predominantly social and psychological. Although changes in appearance may be beneficial for many, they rarely provide the complete answer (Wallace & Lees, 1988; Hughes, 1998; Sarwer, 2002). Given the multifaceted nature of adjustment, the prevailing biomedical model of care needs to be expanded to include psychosocial support and intervention as routine adjuncts or alternatives to appearance enhancing treatment.

Interventions are likely to be particularly appropriate at key points, including following the birth (or prenatal diagnosis) of an infant with a disfiguring anomaly, times of transition during childhood, adolescence and adulthood (for example, starting or changing school; changing neighbourhoods or social groups; seeking and starting a new job) (Hearst & Middleton, 1997). Ideally, in order to promote a preventive rather than a reactive approach, and to avoid the stigmatizing nature of a referral for psychological 'treatment', support and intervention should be offered as part of routine care.

Providing information and support

If full multidisciplinary care cannot be offered, alternative methods of support should be explored. Clarke and Cooper (2001) have reported that many healthcare professionals would like to address the concerns of their patients, but feel they lack the appropriate training to deal with the psychosocial consequences of disfigurement. In response, the authors described the development and successful implementation of condition-specific information packs and training courses. An appreciation of common psychosocial difficulties should be achieved by all members of the care team, and routine screening for psychosocial difficulties should be implemented (see Rumsey *et al.*, 2002). Information and specialist resource materials should be readily available (see Changing Faces www.changingfaces.org.uk). Appropriate referral routes for more complex difficulties should be identified.

Cognitive-behavioural interventions

Kleve *et al.* (2002) reported significant improvements following an average of six individual cognitive-behavioural therapy sessions on measures of social anxiety, appearance-related distress, general anxiety and depression in adults with a range of disfiguring conditions. These improvements were maintained six months post-intervention. As many of the problems associated with facial disfigurement are associated with social interaction, some researchers have focused their attention on packages that aim to develop effective social interaction skills. These have been used successfully with children and adolescents with craniofacial conditions (Kapp-Simon, 1995), burns (Blakeney *et al.*, 2005) and with adults with disfigurements resulting from a variety of conditions (Robinson *et al.*, 1996). However, the relative efficacy of the many components of these interventions has yet to be clarified (see 'Cognitive behaviour therapy').

Conclusion

Facial disfigurement can have far-reaching social and psychological consequences. To date, insufficient resources have been devoted either to understanding the consequences of the pressures exerted by the tidal wave of media and societal attention on physical

appearance, or to developing healthcare provision to more closely meet the needs of those affected.

Dysmorphology

Definition and typical features

The term dysmorphobia comes from *dysmorfia*, a Greek word meaning ugliness, specifically of the face. In body dysmorphic disorder (BDD), the affected person experiences excessive self-focused attention and a preoccupation with an imagined defect, or exaggerates a minor physical anomaly, often of the face, hair or skin (Phillips, 2002). The feature is felt to be unbearably ugly and is regarded with loathing, repugnance and shame (Birtchnell, 1988). In DSM-IV (Diagnostic and Statistical Manual of Mental Disorders, 4th edn.), BDD is classified as a somatoform disorder, with its delusional variant considered to be a psychotic disorder. Associated behaviours are time-consuming, and typically include frequent mirror checking (though some avoid mirrors altogether), avoidance of social situations and excessive camouflage. There are high levels of co-existing conditions including depression, suicidal ideation, obsessive compulsive disorder and social phobia. Social, academic and occupational functioning are frequently impaired. In a study of 188 patients with BDD, Phillips and Diaz (1997) found that more than 25% had been completely housebound for a minimum of a week, nearly 30% had attempted suicide and more than half had been hospitalized at least once.

The origins of BDD are thought to be multifactorial and to include neurobiological, genetic, sociocultural and psychological factors.

The exact prevalence of BDD is unknown. Estimates of 0.7% in the general population, rising to 12% of those attending dermatology clinics have been reported (Phillips, 2002). However, as the condition involves both secrecy and shame, these figures are likely to be under-estimates. The age of onset is typically from early adolescence through to the late twenties, and the condition is often chronic. Research findings relating to gender differences in incidence are inconsistent (Veale, 2004).

Treatment decisions and intervention

Uncertainty about the aetiology of BDD is reflected in the diversity of recommendations for treatment, which include antidepressant medication, psychotherapy, cognitive-behavioural therapy and cosmetic surgery (Veale, 2004) (see 'Cognitive behaviour therapy' and 'Reconstructive surgery'). Evidence for the effectiveness of interventions is currently limited. In the first instance, people suffering from BDD will probably approach a plastic surgeon, maxillofacial surgeon or dermatologist for treatment, highlighting the need for collaboration and a skilful assessment of psychological factors involved in requests for surgery. Although the majority of people with BDD believe surgical alteration is the only way to effectively address their problems, expectations of outcome are often unrealistic. Surgery, if performed, is often perceived by the patient as unsuccessful, leading to further requests for operations, or the shifting of dissatisfaction to another part of the body. The consensus in the literature is to avoid surgical intervention, referring sufferers instead for psychiatric assessment and treatment.

Fetal wellbeing: monitoring and assessment

Peter G. Hepper¹, James C. Dornan² and Dan McKenna²

¹Queen's University

²Royal Jubilee Maternity Service

The main aim of obstetric practice is to ensure that mothers and babies remain healthy during pregnancy and birth. A variety of techniques may be employed to monitor and assess fetal health. This chapter concentrates upon techniques available to assess the health of the fetus. However it should be noted that the mother's health and wellbeing is inextricably linked to that of the fetus and a key element of antenatal care is the careful monitoring and management of the mother's health (see 'Antenatal care').

Key issues in assessing fetal wellbeing

The high-risk fetus in the low-risk population

Some mothers are classed as high-risk, i.e. at increased risk of having a baby with a problem due to some known factor, e.g. maternal age and Down's syndrome. Such mothers are relatively easy to identify and offered tests to assess the condition of their fetus (see 'Screening: antenatal'). However the majority of fetal problems arise in the low-risk population of mothers, who present no obvious signs of having a fetus with an abnormality. A reduction in the incidence of fetal problems rests with advances in

identifying the high-risk fetus in the low-risk population (McKenna *et al.*, 2003).

Screening and diagnosis

Diagnostic techniques, whilst providing a definitive answer regarding the presence of a particular problem, can be expensive in time and money and carry a serious risk to the fetus, e.g. amniocentesis, which may result in a miscarriage. These tests are thus unsuitable for widespread use with the low-risk population. This has led to the development of screening tests that do not carry a risk to the fetus. Such tests do not definitively indicate the presence of a particular problem but rather assess the probability that the fetus is affected. Where a fetus is identified as having a high probability of an abnormality, further, diagnostic, tests can be offered. Screening tests are not without their problems. Mothers have to interpret the risk factor, e.g. 1 in 50, to determine whether they will avail themselves of further testing. Some mothers consider 1:50 a low risk, whereas others consider 1:5000 a very high risk (see 'Risk perception'). Screening tests also create significant anxiety. For a risk of 1:50, 49 of the mothers who undergo further

testing will not have a fetus with that problem. It is essential that mothers are supported through these tests and the limitations of the test explained.

Validation of screening tests

A number of screening tests have been developed to assess elements of fetal health (NICE, 2003). However there has been little examination of their efficacy and thus decisions on their routine application during pregnancy await appropriate trials.

Improving fetal health

Whilst new techniques and screening tools are developed, effective treatments for the 'abnormal' fetus are scarce. For many years the only option, and still the main option, to deal with fetal compromise was early delivery. However, new possibilities for treatment are being developed. Pre-conceptually, taking folic acid as a dietary supplement reduces the incidence of neural tube defects (Fraser & Fisk, 2003). Fetal surgical techniques have been developed to treat diagnosed conditions, e.g. spina bifida (Olutoye & Adzick, 1999) but research is needed to assess their success. The future will undoubtedly witness pioneering techniques to 'treat' diagnosed problems in the fetus.

Assessing fetal health

What can be monitored or assessed?

There are a number of different measures that can provide information on the status of the fetus. These are:

- fetal cells – for chromosomal and genetic analysis
- fetal growth – comparison against norms
- physical structure – presence, absence or deformity of body parts or organs
- biochemical products – e.g. human chorionic gonadotrophin as part of screening test for Down's syndrome
- fetal environment – amniotic fluid volume
- fetal heart rate and circulation
- fetal behaviour.

Technology to monitor the fetus

The oldest 'technology' is that of palpation of the abdomen and this still has a role in assessing fetal health. Ultrasound provides detailed pictures of the fetus enabling assessment of fetal size, structure, environment and behaviour. Ultrasound also offers the means for monitoring fetal heart rate and Doppler assessment of the circulatory system. MRI (Magnetic resonance imaging) scans have been used to obtain pictures of the fetus (Glastonbury & Kennedy, 2002) but this technology is not routinely used to monitor the fetus.

Routine fetal monitoring

The health of the low-risk fetus is routinely assessed using a combination of ultrasound, and screening tests offered for Down's syndrome and the presence of specific diseases.

At the first antenatal visit, usually before 14 weeks gestation, ultrasound is used to assess gestational age and fetal viability, to detect multiple fetuses and gross abnormalities. Screening tests based on a maternal blood sample are offered to assess, e.g. rhesus and rubella status, anaemia, hepatitis B virus, HIV and syphilis. Screening for Down's syndrome will be offered. It is recommended (NICE, 2003) that screening for Down's syndrome uses the 'integrated test' based on measurement of pregnancy associated plasma protein A; human chorionic gonadotrophin; alpha-fetoprotein; unconjugated estrodiol; inhibin A obtained from a maternal blood sample; and the measurement of nuchal translucency (the subcutaneous space between cervical spine and skin) observed by ultrasound. It is essential that the woman is given full information about the particular test and her right to accept or decline the test should be made clear (see 'Informed consent' and 'Screening: general issues').

Women will be offered an anomaly ultrasound scan between 18–20 weeks gestation. The role of a scan at this gestation is now well established. In the hands of trained operator and with a modern ultrasound machine 98–99% of open neural tube defects will be detected (Smith & Hau, 1999).

The size of the fetus is assessed at each antenatal visit, usually by ultrasound guided measurement. Fetal growth occurs almost linearly in normal pregnancy. Of particular concern is the fetus whose growth slows down during the course of pregnancy (intra-uterine growth restriction, (IUGR)): such fetuses are considered compromised and may require early delivery.

Clinical assessment in late pregnancy determines whether the fetus is in the correct and safe position to deliver normally and is undertaken by abdominal palpation.

Monitoring during labour

It is customary to monitor fetal heart rate during labour. If the fetus is low-risk, i.e. singleton, at term (37–42 weeks), cephalic presentation, appropriately grown, in spontaneous labour with clear liquor and no major antenatal events having occurred and the mother is healthy, the fetal heart rate may be auscultated. If antenatal complications have occurred or the mother has a medical condition, e.g. pre-eclampsia, diabetes or a problem has arisen during labour such as unexpected bleeding, then, electronic monitoring of the fetal heart rate (cardiotocography) is traditionally applied. The fetal heart rate trace is assessed for its rate, the presence of long-term and short-term variability, accelerations and decelerations. If the decelerations occur after the contraction has reached the nidus they are known as late decelerations and are indicative of impending fetal compromise. In these situations a blood sample may be obtained from the fetal scalp and a pH of <7.2 may be indicative of severe hypoxia and warrant timely delivery.

Non-routine assessment of fetal health

The majority of pregnancies are uneventful and require little intervention. Indeed it is important to recognize the normality of this physiological event. In some cases, however, the fetus may be considered at high risk of an anomaly, e.g. Down's syndrome in women over 35, or routine monitoring reveals an abnormality. In these cases additional tests may be offered to monitor the fetus's health.

Chromosomal and genetic analysis

Women may be offered amniocentesis or chorionic villus sampling to obtain a sample of fetal cells for chromosomal or genetic analysis. Usually undertaken before 18 weeks gestation these tests provide a definitive diagnosis on the presence of chromosomal or genetic defects.

Fetal heart rate monitoring

Antenatal cardiotocography (CTG) is used to assess the health of the fetus at a specific instant in time. A heart-rate trace showing a normal rate, the presence of accelerations of fetal movement, variability of >5bpm and absence of decelerations is usually indicative of a healthy fetus at that moment in time. A CTG alone is not however predictive of how the fetus may be beyond 12 or 24 hours.

Umbilical artery waveforms measured using Doppler

Blood flow through the arteries and veins in the umbilical cord can be measured using ultrasound to provide an assessment of the fetal circulatory systems. Abnormalities in blood flow assessed by Doppler can predict IUGR, and the absence of end diastole flow is indicative of severe compromise (Baschat *et al.*, 2000). Doppler ultrasound of the fetal middle cerebral artery revealing increased blood flow may be indicative of fetal compromise (Bahado-Singh *et al.*, 1999).

The biophysical assessment of the fetus

Eight biophysical features, identifiable on ultrasound, are commonly observed in the high-risk pregnancy. Four reflect the acute wellbeing of the fetus: movements; tone; breathing; and changes in heart-rate patterns. Four reflect the chronic state of the fetus: umbilical artery Doppler measurements; placental architecture; amniotic fluid volume; and fetal weight estimation. Although some of these tests have not been subjected to rigorous scientific or clinical scrutiny, emerging evidence suggests that ultrasound assessment of the fetus's environment and growth should become part of the 'routine' antenatal visit. In one study, 2000 low-risk patients were randomized to receive traditional antenatal care or traditional antenatal care *plus an ultrasound examination* at 30–32 weeks and at 36–37 weeks gestation (McKenna *et al.*, 2003). The ultrasound scan assessed placental maturity, amniotic fluid volume and estimated fetal weight. This study showed that the introduction of an ultrasound scan increased antenatal intervention, did not increase admissions to neonatal intensive care, and importantly reduced the chances of delivering a growth restricted fetus by about a third. The perinatal mortality rate in growth-restricted fetuses is four to ten times higher than that of normally grown infants (Chiswick, 1985). Furthermore, growth restricted fetuses

that do not die in utero are more likely to suffer other complications e.g. birth hypoxia, neonatal complications in the neonatal period, impaired neurodevelopment and cerebral palsy in childhood and non-insulin-dependent diabetes and hypertension in later life (Barker *et al.*, 1993). In light of this evidence, the routine ultrasound assessment of the fetal environment in British obstetric practice may soon be considered the norm. It is already part of routine obstetric practice in North America.

Neurobehavioural assessment of the fetus

Whilst ultrasound may be used to visualize structural abnormalities, assessment of fetal CNS functioning has remained elusive to traditional obstetric techniques. Recent attention has focussed on the behaviour of the fetus as a means of assessing neural integrity. Since behaviour is a reflection of neural functioning and it has been argued that the assessment of the fetus's behaviour will provide information on its wellbeing. Fetal behaviour, observed using ultrasound, may be defined as any action or reaction of the fetus and may be divided into two main categories; spontaneous (under the volition of the fetus) or elicited (contingent upon the presentation of a stimulus, e.g. sound). Both have been used to assess wellbeing.

Differences in behaviour have been found in fetuses with abnormalities, e.g. anencephaly (Visser *et al.*, 1985), Trisomy 18 (Hepper & Shahidullah, 1992*a*), maternal diabetes (Mulder *et al.*, 1987). Environmental influences may also be observed, e.g. low doses of alcohol alter the fetus's startle behaviour (Little *et al.*, 2002).

The fetus's response to an auditory stimulus has been developed as a prenatal test of deafness (Shahidullah & Hepper, 1993). One technique which may prove useful in assessing neural integrity is that of habituation (Hepper & Leader, 1996). Differences in habituation have been observed in fetuses with Down's syndrome (Hepper & Shahidullah, 1992*b*). Fetal habituation performance has been found to predict postnatal development as assessed on Bayley's scale of neurobehavioural development (Ratcliffe *et al.*, 2002*a,b*).

Summary

It is unlikely that a single test will provide a complete assessment of fetal health. A combination of the above approaches will enable a comprehensive assessment of fetal wellbeing but much work needs to be undertaken to evaluate the effectiveness of individual tests and new tests need to be developed to further advance our ability to monitor and assess the health of the fetus.

Gastric and duodenal ulcers

Paul Bennett

University of Cardiff

Gastric ulcers are ulceration of the lining of the stomach. As their name suggests, duodenal ulcers occur in the duodenum, which is the part of the small intestine immediately following the stomach in the gastrointestinal tract. Collectively, they are referred to as peptic ulcer disease. Their most common symptom is abdominal discomfort or pain. These symptoms typically come and go for several days or weeks, occur two to three hours after eating, and are relieved by eating. Symptoms may at their worst during the night, when the stomach is empty following a meal. Other symptoms include poor appetite, weight loss, bloating, nausea and vomiting. If the disease process is not treated, the ulcer may erode through the entire stomach wall, resulting in the potentially fatal outflow of its contents into the abdomen.

Until relatively recently, peptic ulcers were thought to be the result of stress, which was thought to increase acid secretion within the stomach and hence also the duodenum. More recently, this psychological explanation has been largely superseded by a biological model. This suggests that a bacterium known as *Helicobacter pylori* (*H. pylori*) is responsible for the disorder. *Helicobacter pylori* infection is thought to weaken the protective mucous coating of the stomach and duodenum, allowing acid to get through to the

sensitive lining beneath. Both the acid and the bacteria irritate the lining and cause the ulcer. This biological model of ulceration has increasingly been seen as the primary model of ulceration (e.g. Centers for Disease Control and Prevention: <http://www.cdc.gov/ulcer/md.htm>), although there remains the possibility of other routes to ulcers, including stress.

The stress hypothesis has drawn on a number of strands of evidence (see Levenstein, 2000). These suggest, firstly, that while the evidence for *H. pylori* as a casual factor is strong, there is no reason to assume that it is the only factor which may contribute to the development of ulcers. Secondly, there is consistent evidence that stress may increase risk for ulcers in both animals and humans, prolong their duration and that reductions in stress may result in improvements in disease status. Stress therefore does seem to be involved in the aetiology of ulcers. One principal way in which stress may influence disease is through its impact on gastric acids. An alternative pathology in which stress mediates the immunological response to *H. pylori* infection has not been investigated. However, given our present understanding of psychoneuroimmunology, this possibility cannot be excluded (see 'Psychoneuroimmunology'). Stress may also have an indirect role by stimulating other behaviours known to

effect ulceration, including cigarette smoking (e.g. Shigemi *et al.*, 1999), lack of sleep (Segawa *et al.*, 1987) and increased alcohol consumption (Levenstein *et al.*, 1997)

More than *H. pylori*

The first evidence supporting the possibility of alternative routes to ulceration lies in findings that most people who carry the *H. pylori* bacteria never have ulcers, and that *H. Pylori* infection is not present in all cases of ulcers. Ciociola *et al.* (1999) calculated that 29% of duodenal ulcer patients have no active *H. pylori* infection. The most frequent alternative route is through the ingestion of non-steroidal anti-inflammatory drugs, but other causes cannot be excluded.

Stress as a precipitating factor

A number of well designed and executed studies have shown a relationship between stress (defined in a variety of ways) and ulceration. The National Health and Nutrition Epidemiologic Survey (Anda *et al.*, 1992), for example, found a 60% additional rate of medically confirmed ulceration among people with high stress in comparison with those with low stress. Individuals in the highest quintile for stress were nearly three times as likely to develop peptic ulcers than those reporting low levels of stress even after adjustment for ulcer-related factors, including aspirin use and smoking. In the Alameda County Study longitudinal study (Levenstein *et al.*, 1997), participants with high levels of distress at baseline were over twice as likely (odds ratio, 2.2) to develop ulcers over a nine-year period than those with low levels of distress after adjustment for levels of smoking, alcohol consumption, skipping breakfast and lack of sleep. The raw odds ratio between high and low distress groups was 2.8. In a second longitudinal study using confirmed diagnoses, Medalie *et al.* (1992) followed a cohort of 8458 men aged over 40 years with no history of ulcers for 5 years. Multivariate logistic regression revealed a significant independent association between radiologically confirmed duodenal ulcers and baseline measures of family problems (odds ratio, 1.6), low levels of intimacy and social support (odds ratio, 2.06) and internalization of negative affect (odds ratio, 1.89). By comparison, the odds ratio between smokers and non-smokers was 1.64. Animal studies confirm the role of stress in the aetiology of ulcers with stressors such as early separation from mothers, cold water immersion and bodily restraint all being associated with the high levels of ulceration (e.g. Ackerman *et al.*, 1975; Kim *et al.*, 2002).

Stress as a maintaining factor

Once peptic ulcer disease has been diagnosed, stress may impede ulcer healing. Hui *et al.* (1992), for example, followed a total of 122 endoscopically validated duodenal ulcer patients either in the active or remission phase for a period of 6 months. Patients who experienced a relatively high number of adverse life events or who remained stressed over the follow-up period were less likely to heal than those whose stress remitted. In a much larger population of over 2000 duodenal ulcer patients, Holtmann *et al.* (1992) found

healing rates and relapse were significantly associated with physician ratings of patient stress over a one-year period. In a further longitudinal study of 75 patients with endoscopically confirmed duodenal ulcer Levenstein *et al.* (1996) found that over a period of 14 months, a poor prognosis was predicted by low-status occupation, low education, depression, stressful life events. Of note were their findings that factors including smoking, alcohol consumption, use of anti-inflammatory drugs and *H. pylori* levels did not predict outcome.

Treating stress improves prognosis

Perhaps as a result of the rapid response to medical treatments (often using a combination of antibiotics and drugs which inhibit the production of stomach acid), studies of the psychological treatment of peptic ulcers are rare. However, the evidence they provide does bear on the stress-ulcer relationship. Despite its low number of participants ($n=22$), the study reported by Brooks and Richardson (1980) remains the key study of this approach. They randomly allocated patients with radiologically confirmed diagnoses of duodenal ulcers into either an intensive psychological intervention comprising an educative phase, relaxation training, cognitive restructuring and coping injury or an attention placebo condition (see 'Cognitive behaviour therapy' and 'Relaxation training'). All participants received antacid medication. Over a follow-up period of 60 days, patients in the active intervention experienced significantly fewer symptomatic days, and consumed less medication, although X-rays revealed similar levels of healing in both groups. It was in the longer term follow-up, however, that the strength of the intervention proved most beneficial. Significantly fewer participants in the active intervention (1 in 9) than in the placebo group (5 in 8) reported a recurrence of the disorder. Participants in the active intervention also attended hospital less frequently and none required surgery, compared to two in the placebo intervention. Without radiological or endoscopic confirmation of differences in disease state, these differences should be treated with some caution. However, they admit the possibility that changes in stress may influence disease processes.

Stress mechanisms

Not only is there empirical evidence of a role of stress in peptic ulcer disease, there are also plausible disease mechanisms. The most frequently cited psychobiological mechanism suggests that stress increases levels of gastric acids, which in turn increase erosion and ulceration of the gut wall. The model gains support from a number of relatively small naturalistic studies that have found stress and gastric acid levels to co-vary. In one study, Feldman *et al.* (1992) found that gastric acid output is correlated with levels of psychological distress, measures of tension, conflict and anxiety, in individuals with no ulceration. In addition, personality traits such as impulsivity and social isolation are also implicated in more labile acid secretion rates. Ocktedalen *et al.* (1984) followed a group of men participating in an intensive five-day training programme, involving heavy exercise and sleep deprivation. Levels of acid output rose by 300% among participants not given drugs to reduce acid secretion among whom there was no increase in

acid secretion. A second pathway that has received even less research involves the interaction between *H. pylori* and stress. One study in humans suggested the possibility that stress may moderate immunological responses to *H. pylori* infection. Levenstein *et al.* (1995) found that among patients with peptic ulcers, levels of *H. pylori* antibodies were lower among anxious patients than among less anxious individuals, suggesting stress may suppress the production of these antibodies and adversely influence levels of *H. pylori* within gut. By contrast, Kim *et al.* (2002) found *H. pylori* and stress were independent predictors of ulceration in rates exposed to *H. pylori* and water immersion-restraint stress (see also 'Stress and health').

Conclusions

Helicobacter pylori infection appears to be the most frequent cause of peptic ulceration, and its treatment the most effective way of curing the condition. However, stress may also be implicated in its development and maintenance either as an independent factor, one which influences other risk behaviours such as smoking or alcohol consumption, or through moderating effect on levels of *H. pylori* within the gut. Accordingly, some people with peptic ulcers may still benefit from interventions designed to reduce stress, particularly in the longer-term, where this reduction may have a preventive role.

Growth retardation

Michael Preece

Institute of Child Health

Definition

Variation in the growth of children occurs in two dimensions. The easiest to understand is the simple variation in height at any given age including full maturity. Less obvious is the variation that occurs in the timing of events during the growth process such as the

age at which puberty commences or adult height is reached: this is usually referred to as tempo.

In the case of boys, the average age of attaining adult height is 18 years but this may vary by as much as three years in either direction. Thus a perfectly healthy boy may not stop growing until 21 years of age and this would be an example of growth retardation

(Preece, 1998). In the case of girls, the same degree of variation is seen, but, on average, adult height is achieved some two years earlier than for boys.

Once the child reaches mature height, tempo has no more effect and the variation in height amongst adults is not dependent upon it. The major influence on adult height, assuming the individuals are all healthy, is heredity with a typical correlation coefficient between the mid-parental height and the height of the subject being 0.7 (Tanner, 1966). This is in keeping with a polygenic mode of inheritance for stature. During childhood the hereditary element still applies but variation in tempo will also contribute to the total variance in height. For example, a child of parents of average height might be relatively short simply because of delayed tempo of growth; this is more commonly referred to as growth retardation. It should be clear that growth retardation should not be used to describe short stature unless there is clear evidence of delayed tempo.

Using the above strict definition, it is possible for growth retardation to be present in a child of normal height. This would apply when the child has tall parents, but the delayed tempo makes the child appear shorter than would be expected from the parents. This effect is temporary and resolves as maturity is reached and the influence of the delayed tempo ends and, unless the delay is very severe, seldom leads to clinically relevant problems.

Clinical indicators

Short stature for a given chronological age will usually be part of the clinical picture unless the child is from a very tall family. In a child of peripubertal age there will be evidence of delay in other milestones such as the events of puberty. In many cases there will be as much concern about the latter as about the short stature. Similarly to the attainment of adult height there is a range of normal variation of about three years either side of the average age of attaining each stage of puberty. It is a convenient quirk of nature that the standard deviation of the age of attaining most pubertal events is one year (Tanner, 1962) and therefore a total range of six years around the average should include about 99% of healthy individuals.

In younger children, the assessment of tempo is much more difficult on clinical grounds although dental maturation can sometimes be used. If clinically relevant, skeletal maturation can be assessed from an X-ray of the left hand and wrist and provides a useful tool. From this a 'bone-age' is calculated which is equal to the chronological age of a healthy child with the same physical appearance on the X-ray. Thus a 10-year-old patient with tempo delayed two years will have a bone-age of eight 'years'. Using this technique a reasonable estimate of mature height may be obtained.

Clinical relevance

Some degree of growth retardation is very common and is responsible for a large number of referrals. It appears to be much more common in boys than in girls, but it is not clear whether this is due to a truly lower incidence in girls or whether it reflects social attitudes to height or a combination of both these factors. In many cases there is a combination of delayed growth and familial short stature which presumably reflects a selection bias, in that children who are delayed and from short families are more likely to cause concern and present clinically. In contrast, those from tall families will only present if the delay is extreme such that they appear short when compared to their peers or that the delay in puberty is sufficient to cause distress in its own right.

The importance of the condition lies in the psychological distress that can result. This is not usually a great problem before the age when adolescence usually commences (about 10 years in girls and 11 years in boys) and is not usually a permanent problem if handled sympathetically (Voss & Mulligan, 1994; Sandberg, & Voss, 2002). However, adolescence is a time of much anxiety even when it proceeds uneventfully, and children with severe pubertal and growth delay experience many additional problems particularly in their relationships with their peers (Gordon *et al.*, 1982). For this reason the condition needs serious treatment and sympathy even though it is effectively an extension of normal development and by its nature, temporary. Management generally involves reassurance along with active intervention to accelerate the attainment of puberty and the adolescent growth spurt. The latter is usually achieved with a short course of low dose anabolic steroids (Stanhope & Preece, 1988).

Haemophilia

Ivana Marková

University of Stirling

'Haemophilia' is a term referring to a group of genetically transmitted life-long blood clotting disorders which are caused by a defect in one or more of the plasma clotting factors. The most common are sex-linked recessive disorders, haemophilia A (classic haemophilia) and haemophilia B (Christmas disease), which are due to an isolated deficiency of the clotting activity of factor VIII or of factor IX, respectively. People with these disorders suffer bleeding into soft tissues, for example, joints, muscles or internal organs, which can happen after trauma or spontaneously. These bleeds can be very painful, and repeated episodes lead to weakening and crippling of joints. Bleeds into internal organs and the brain can be life-threatening. There is no cure for haemophilia.

Another common blood disorder is von Willebrand's disease or vascular haemophilia. It is an autosomal dominant genetic disorder, i.e. it is not sex-linked and affects both men and women. It is due to a combination of an abnormal factor VIII molecule with abnormal platelet function. Many problems related to treatment and its complications, as well as social and psychological problems are similar to those found in haemophilia A and B.

Genetics and clinical manifestation

Haemophilias A and B are genetically transmitted as follows: an affected woman carries a defective gene on one of her X chromosomes, which she can pass to any of her children. This means that there is a 50% chance that any of her sons will have haemophilia and a 50% chance that any of her daughters will be a carrier. None of the sons of a haemophilic male will have the disease but all of his daughters will be obligatory carriers. In the majority of families with haemophilia (approximately 70%) the evidence of transmission of a defective gene can be established and family trees indicating such transmission can be constructed. In the remaining 30% of families, haemophilia might have been transmitted for generations through female carriers who themselves did not suffer the disease, or it might have occurred as a result of a spontaneous mutation (see also 'Screening: genetic').

The clinical manifestations of haemophilias A and B are identical and only blood tests can differentiate between them. Haemophilia affects approximately 1 in 5000 of the male population; it can be found in all human races and also in a variety of animal species. The incidence of haemophilia B is approximately 1/6 to 1/10 of that of haemophilia A.

Haemophilia occurs in different degrees of severity and these are related to the level of deficiency of the relevant clotting factor(s) in the blood. It is common to classify the disease as mild (more

than 5% of the normal activity of the factor), moderate (between 1–2% and 5%) and severe (less than 1–2%). People with mild haemophilia usually need special care only when having surgery, while those with severe haemophilia may bleed spontaneously, either for no obvious reason or after emotional trauma. If haemophilia is known to be in a family, it can be diagnosed prenatally from a fetal blood sample (see 'Screening: antenatal' and 'Fetal wellbeing: monitoring & assessment'). Alternatively, it will be diagnosed in the child as a result of bruising, cutting teeth, surgery or injury. Mild haemophilia might not be diagnosed until adulthood.

Treatment of haemophilia

Haemophilias A and B are treated by replacing the missing clotting factor. During the last 50 years there has been a systematic technological effort to simplify and purify the treatment. Treatment by transfusion of full blood was replaced in the 1920s by injecting blood plasma and this was a standard treatment until the late 1960s. The patient had to go to hospital for this treatment and, if necessary, stay there over a period of time. Technological advancements in the late 1960s led to the production of various kinds of factor concentrates. As these products became safe and stable, they could be kept in home freezers. Programmes of home treatment were introduced enabling self-infusion or infusion to be given by a suitably trained relative or friend. Since this treatment can be administered either prophylactically or immediately after the bleeding occurs, it reduces long-lasting crippling of joints and painful bleeding. Thanks to the introduction of home treatment people with haemophilia have regained their independence and can take part in various kinds of physical activity without constant worries about injuries.

Since factor concentrates are blood products, there has always been a danger of viral contamination. While in recent years there have been tremendous advances in the development of pure and safer plasma-derived concentrates, simultaneously, genetically engineered recombinant DNA factors VIII and IX have been developed and are used as a treatment for children. The latest development in the treatment of haemophilia involves the possibility of gene therapy, now being in the stage of clinical trials. This treatment, which involves introducing a normal copy of the defective gene into a cell, produces the protein that was missing or defective. This, again, is a treatment of the affected individual but not a cure; the individual will pass the defective gene to the next generation. As with any genetically based treatments today, gene therapy

for haemophilia is widely discussed and controversial due to its perceived ethical and psychological concerns.

Treatment and care of people with haemophilia remains highly specialized and is carried out, in wealthy countries, in specialist haemophilia centres. Monitoring of the progress in treatment and of all haemophilia related issues in national haemophilia organizations is made through the World Federation of Hemophilia, which was founded in 1963 and has headquarters in Montréal, Canada.

There are two types of specialized centres. First, there are comprehensive care centres, which provide a broad range of medical and related services offering a wide range of diagnoses and treatments. Their staff consists of specialists with high expertise, like haematologists, dentists, nurses, physiotherapists, orthopaedic surgeons, geneticists and counsellors. People with haemophilia should be registered with, and regularly reviewed at, a comprehensive care centre. Secondly, there are haemophilia centres, which tend to have a smaller number of patients and do not offer the comprehensive range of services. They provide care, information and support for patients and their families.

The World Federation of Hemophilia also offers haemophilia training programmes and care workshops in developing countries. Moreover, people with haemophilia and local centres can consult the World Federation of Hemophilia website, which provides the news, advice and support.

Treatment-related complications

While the treatment by factor concentrates introduced in the late 1960s has led to a dramatic improvement in the quality of life of patients and their families, by the mid-1970s it was apparent that chronically treated patients had developed a variety of serious complications (e.g. inhibitors to treatment, hepatitis and chronic liver disease). Inhibitors to treatment are caused by the inability of the body to distinguish between treatment clotting factors and harmful foreign invaders, e.g. bacteria. As a result, the body produces antibodies, i.e. inhibitors that destroy the clotting factor which is supposed to treat the bleeding. Inhibitors constitute a long-term clinical problem for up to 20% of people with severe haemophilia A, and they are less of a problem for people with haemophilia B.

Other treatment-related problems are due to several hepatitis viruses transmitted through blood products and causing liver disease. Among these, hepatitis C is of particular concern, as there is not as yet a vaccine for hepatitis C. Hepatitis C affects most people with haemophilia who received clotting factor concentrates before 1986, that is, before effective heat treatment was first introduced in wealthy countries of the world, including the UK.

Finally, in the 1970s and early 1980s many people with haemophilia were infected with HIV through contaminated blood products. Unfortunately, by the time the problem came to awareness, in some parts of the world as many as 90% of severely affected patients with haemophilia B, and a small percentage of those with haemophilia A, had become infected and many have died. In order to alleviate suffering of patients affected by HIV, the World Federation of Hemophilia and national haemophilia organizations launched substantial efforts to speed up blood donation

screening and to physically treat blood and blood products. Moreover, governments of wealthy countries approved plans for financial assistance to patients who were infected by HIV during the epidemic (see also 'HIV and AIDS').

By the mid-1980s, blood donors were screened for the presence of HIV, and concentrates of clotting factors used for the treatment of bleeds, were heat-treated to destroy HIV. In order to destroy any harmful viruses, apart from being heated, concentrates are now treated in a number of other ways during manufacture, e.g. by adding to them solvent and detergent mixtures. All patients are vaccinated against hepatitis A and B.

Psychosocial problems of haemophilia

Throughout history, haemophilia has always presented a wide spectrum of psychological and behavioural challenges to patients, carriers and their relatives. The nature of these challenges keeps changing with the advances in diagnosis and treatment and with dealing with treatment complications. All these changes have a profound effect on social and psychological problems of patients and their families, as well as on social representations of haemophilia in the general public.

Haemophilia, like other chronic disorders, is a family matter. Moreover, being a sex-linked genetic disorder, it imposes different kinds of trauma on women and men and on the related family decisions. Prospective parents must decide whether to undergo diagnostic procedures in order to discover whether the fetus is affected with haemophilia and, if it is, whether they wish to undergo a termination of the pregnancy (see 'Screening: antenatal' and 'Abortion'). No matter how accurate and safe fetal diagnosis may become, it is perception and acceptance of such procedures and ethical concerns of the involved individuals that determine the subsequent course of action. There are several stages in bringing up a child with haemophilia that parents may find particularly difficult: coping with the diagnosis, teaching the pre-school child to look after himself, overcoming anxiety about the child's starting school and solving the problem of the child's career. The parents might find it difficult to strike a balance between the necessary and unnecessary restrictions imposed on the child. With the development of factor concentrates in the last four or five decades, the aim for a person with haemophilia at school, at work and in the family, has been 'to be as normal as possible'. However, adults with haemophilia, attempting to find employment, are faced with the problem of whether or not to tell their future employers about their disease. This of course also depends on how severe their haemophilia is. Getting life assurance has always been a problem for severely affected patients, and this problem has been aggravated as a result of haemophilia's association with AIDS.

The psychosocial impact of HIV and AIDS on patients and their families has been unprecedented and they have experienced two main kinds of problem. First, there is the problem of coping with the physical and mental trauma due to HIV and AIDS. While HIV infection in men with haemophilia is no longer due to blood products, new cases of HIV infection include women infected by their spouses and children who were infected by HIV presumably during pregnancy.

The second problem is related to the general public's social representations of haemophilia and HIV/AIDS. Throughout history, haemophilia has always been surrounded by mysteries of bleeding as well as by misconceptions, e.g. that a person with haemophilia can bleed to death from a needle prick. Misconceptions on the part of the general public, the fear of stigma and the fear of being rejected by employers or by intimate friends have often led to patients concealing their haemophilia (see 'Stigma'). The problem of HIV/AIDS

has only amplified these problems. The public misunderstanding of haemophilia and misconceptions about the transmission of HIV/AIDS in people with haemophilia has been experienced as a double stigma. While public education is essential to diminish social and psychological problem experienced by people with haemophilia and their families, equally important to consider are the rapid technological advancements in treatment and eventually for 'cure' of haemophilia which offer good prospects for the future.

Head injury

Erin D. Bigler

Brigham Young University

Head injuries are generally divided into two types: closed and open or penetrating (Graham *et al.*, 2002). In open or penetrating injuries, the skull is breached, most commonly struck with violent force by foreign objects during an assault or from a gun shot or as a result of the head impacting some part of the vehicle in a motor vehicle accident (MVA). Part of the damage from penetrating injuries often includes bone fragments and other debris associated with the trauma that directly injures the brain. In addition to the mechanical damage to brain tissue, there is typically local haemorrhaging that also damages the brain, since the forces that penetrate the brain usually tear blood vessels in the region of penetration. The pathological consequences of open or penetrating injuries to the brain are most likely to produce focal brain injuries, although often generalized damage may also occur. Open head injuries are less common than closed and some, like gunshot wounds (GSW) to the head, are associated with very high mortality.

The most common head injury associated with survival is a closed head injury (CHI), where the brain is injured by the mechanical, concussive and movement forces within the cranium, secondarily

through impact to the head and/or acceleration/deceleration forces. Either regional or global, such forces place what are referred to as tensile or shear-strain effects throughout the brain. These effects have the potential to stretch neural tissue, particularly axons, which in turn damages either their structure or function. Because of the vulnerability of the axon in CHI, the effects of trauma are often thought of in terms of a diffuse axonal injury (DAI, Graham *et al.*, 2002). These same shear-strain forces may also damage, disrupt or shear blood vessels, which may also be a major source of residual damage from trauma. This is often referred to as a haemorrhagic shear injury and can often be readily visualized by neuroimaging techniques (Tong *et al.*, 2004) (see 'Brain imaging and function'). Obviously, anything that disrupts the integrity of the vasculature has the potential to damage brain tissue either directly or through the secondary effects of disrupting blood flow; the brain has no capacity to store oxygen or glucose and needs a constant blood supply. Another aspect of brain injury is referred to as the neurotoxic cascade (Hatton, 2001; Kaminska *et al.*, 2004). As brain cells are injured, there is often an abnormal release of

neurotransmitters or a disruption in synaptic function which can result in biochemical changes that damage or kill brain cells. As brain cells die, volume loss occurs, resulting in either focal or generalized reduction in a specific brain region or in the brain overall. In CHI, generalized cerebral atrophy, as measured by neuroimaging, is proportional to the severity of injury and relates to outcome (Bigler, 2005).

Because it is the most common, this chapter will focus primarily on CHI, review current definitional standards, epidemiology, how to assess and treat brain injury and the long-term outcome.

Definition of brain injury and brain injury severity

Brain injury is defined by some alteration or impairment in normal neurological homeostasis or presence of a distinct abnormality caused by trauma, such as experiencing a brain contusion in a fall as shown by neuroimaging studies (Bigler, 1990) (see 'Brain imaging and function'). The mildest form of injury is that which results from a concussion, wherein the mildest form is but a brief, transient disruption in neurological function as described in Table 1. The most well-studied concussions are those associated with sports injury, the majority of which are likely to have a benign course (Guskiewicz *et al.*, 2003; McCrea *et al.*, 2003). As the level of concussion increases so do the potential sequelae, particularly after what is referred to as a complicated concussion, where, for example, there is neuroimaging evidence of a brain contusion or presence of a skull fracture. Severity of head injuries are often graded by the Glasgow Coma Scale (GCS, Teasdale & Jennett, 1974), which is a scale from

Table 1. Concussion grading systems

Grade	Cantu	Colorado	Roberts	American Academy of Neurology
0			'Bell ringer'; no LOC; no PTA	
1	No LOC; PTA <30 min	No LOC; confusion without amnesia	No LOC; PTA <30 min	No LOC; transient confusion; concussion symptoms or mental status abnormality resolve in <15 min
2	LOC <5 min; PTA >30 min and <24 h	No LOC; confusion with amnesia	LOC <5 min; PTA >30 min and <24 h	No LOC; transient confusion; concussion symptoms or mental status abnormality last >15 min
3	LOC >5 min or PTA >24 h	LOC	LOC >5 min or PTA >24 h	Any LOC, either brief or prolonged

LOC = loss of consciousness; PTA = post-traumatic amnesia
Adapted with permission from Leclerc *et al.* (Leclerc, Lassonde, Delaney, Lacroix & Johnston, 2001).

3 (deep coma, unresponsive) to 15 (no alteration in level of consciousness). Typically, GCS scores in the 13–15 range are considered mild; 9–12 is moderate, while 8 and below are moderate-to-severe traumatic brain injuries (TBI). Two other defining characteristics of brain injury are duration of loss of consciousness (LOC) and post-traumatic amnesia (PTA). Memory is the most commonly disrupted cognitive function in TBI and the length of time between the accident and the re-establishment of continuous memory for immediate past events, or the degree of PTA is predictive of outcome (Dikmen *et al.*, 2003; Katz & Alexander, 1994). As shown in Figure 1 regardless of which measure of injury severity is examined, duration of LOC, length of PTA or level of GCS are all associated with the development of cerebral atrophy.

Epidemiology

Bruns and Hauser (2003) review the epidemiology of TBI wherein estimates vary, depending on the minimal definition used to define TBI, but safely conclude that the annual incidence rate in North American and Europe exceeds 200 per 100 000 population (see also Center for Disease Control website: www.cdc.gov for up-to-date epidemiological statistics). This makes TBI one of the leading causes of death and disability in the world.

Assessment

Brain injury and its severity are defined by the events that cause the injury and by clinical findings during the initial medical assessment of the patient after the injury. As already stated, presence and duration of LOC and/or PTA, as well as GCS, define the severity of injury and some of its sequela. Most patients with moderate or worse CHI will be hospitalized, whereas those in the mild range are less likely to be hospitalized other than to be assessed in the accident and emergency department/emergency room. The majority with grade II or less concussion (see Table 1) may not even be initially medically assessed. The Diagnostic and Statistical Manual, 4th edn (DSM-IV) of the American Psychiatric Association (1994) as shown in Table 2, lists the common core neurobehavioural sequelae associated with head injury.

From the perspective of evaluating the cognitive and neurobehavioural deficits in the patient who has sustained a head injury, there are typically three general areas of assessment; neuropsychological, neuropsychiatric and neuroimaging. Each will be addressed below.

Neuropsychological

From a neuropsychological standpoint, the most common neurocognitive changes occur in the domain of short-term memory, attention/concentration and executive function (i.e. novel problem-solving skills, planning, organizational abilities, etc.). Guidelines by Lezak *et al.* (2004) provide a framework to assess these types of deficits. Neurobehaviourally, the changes that typically occur do so within the framework of mood- and anxiety-based disorders as well as potential changes in personality and temperament (Silver *et al.*, 2005), although damage to frontal and temporal brain regions often results in significant personality changes, the so-called frontal lobe

Fig 1 (A) Day-of-injury computerized tomography (DOI CT) scan taken within an hour of this patient sustaining a severe head injury when a delivery truck collided with the patient's vehicle. Her head struck the door frame and computerized tomography (CT) imaging shows a prominent cerebral haematoma with underlying contusion (bruising) to the brain. Two years after injury, magnetic resonance imaging (MRI) studies show generalized atrophy of the left hemisphere in the MRI sequences shown in (B) and (C). Atrophy is indicated by increased amounts of cerebral spinal fluid visualized on the surface of the brain. (D) represents the results of single photon emission tomography (SPECT) imaging where the darker image involving most of the left hemisphere (see arrows) represents less perfusion or uptake of the radiopharmaceutical as shown. Finally (E), the three dimensional (3-D) image of the patient's brain shows where the greatest amounts of cerebral atrophy could be detected.

Table 2. Research criteria for post-concussional disorder

-
- A. A history of head trauma that has caused significant cerebral concussion.
Note: The manifestations of concussion include loss of consciousness, post-traumatic amnesia and less commonly, post-traumatic onset of seizures. The specific method of defining this criterion needs to be established by further research.
- B. Evidence from neuropsychological testing or quantified cognitive assessment of difficulty in attention (concentrating, shifting focus of attention, performing simultaneous cognitive tasks) or memory (learning or recalling information).
- C. Three (or more) of the following occur shortly after the trauma and last at least three months:
1. becoming fatigued easily
 2. disordered sleep
 3. headache
 4. vertigo or dizziness
 5. irritability or aggression on little or no provocation
 6. anxiety, depression, or affective lability
 7. changes in personality (e.g. social or sexual inappropriateness)
 8. apathy or lack of spontaneity
- D. The symptoms in Criteria B and C have their onset following head trauma or else represent a substantial worsening of pre-existing symptoms
- E. The disturbance causes significant impairment in social or occupational functioning and represents a significant decline from a previous level of functioning. In school-age children, the impairment may be manifested by a significant worsening in school or academic performance dating from the trauma.
- F. The symptoms do not meet criteria for Dementia due to Head Trauma and are not better accounted for by another mental disorder (e.g. Amnesic Disorder due to Head Trauma, Personality Change due to Head Trauma).
-

From DSM-IV-™, pp. 705–6. Diagnostic and Statistical Manual of Mental Disorders 4th edn. (American Psychiatric Association, 1994).

syndrome (Cato *et al.*, 2004). (See 'Neuropsychological assessment' chapter for more information.)

sequela listed in Table 2 may be amenable to various pharmacotherapies following neuropsychiatric assessment.

Neuropsychiatric

As mentioned above, disorders that centre on changes in personality, mood and emotional regulation are commonplace in TBI and are the primary reason behind neuropsychiatric consultation and treatment of the patient with a head injury (Silver *et al.*, 2005). Large-scale epidemiological studies of neuropsychiatric outcome have clearly shown the increased lifetime prevalence of depression and anxiety-based disorders in those who have sustained a TBI (Dikmen *et al.*, 2004; Fann *et al.*, 2004; Holsinger *et al.*, 2002; Jorge *et al.*, 2004; Oquendo *et al.*, 2004). Some of the neurobehavioural

Neuroimaging

Tremendous advances in neuroimaging have provided various methods for detailed analyses of structural and functional deficits associated with brain injury (see Bigler, 2005). Figure 1 shows what residual damage from a severe TBI looks like on initial computerized tomography (CT) and on follow-up magnetic resonance imaging (MRI) in a patient who sustained a significant head injury. A consequence of this more lateralized left hemisphere damage, as visualized on the imaging studies, was that the patient had significant language and memory deficits on neuropsychological testing,

as well as requiring neuropsychiatric treatment for post-TBI depression. Additional details of the type of neuroimaging possible are provided in the chapter 'Brain imaging and function'.

Treatment

Depending on the residual neurological and neurobehavioural deficits and brain regions injured, a variety of potential treatment options exists for the individual who sustain a CHI. When neuropsychological tests demonstrate cognitive deficits; various cognitive rehabilitation strategies may be available (see Borgaro *et al.*, 2003; Miller *et al.*, 2003) (see 'Neuropsychological rehabilitation'). Likewise, cognitive behaviour therapies and other forms of psychotherapy may be beneficial in treating a variety of behavioural changes which accompany head injury (Salmond *et al.*, 2005) (see 'Cognitive behaviour therapy'). Additionally, psychotherapeutic techniques may help address adjustment and stress related problems that often attend an individual with a brain injury. In concussion, the mildest form of TBI, immediate educational and psychotherapeutic intervention may minimize the occurrence and development of the so-called post-concussive syndrome (Millis *et al.*, 2001). Also, medications for memory, mood, sleep and related functions may be necessary. As shown by Annegers and Coan (2000) there is a significant increase in the incidence of post-traumatic epilepsy and anticonvulsant medication may be part of the treatment regime (see also 'Epilepsy'). There is considerable psychiatric morbidity associated with having a head injury (Fann *et al.*, 2004; Holsinger *et al.*, 2002; Jorge *et al.*, 2004), as already discussed.

Long-term outcome

Moderate-to-severe TBI is associated with increased levels of impaired social, personal and vocational outcome (Colantonio *et al.*, 2004). Individuals who have experienced a significant TBI have an increased risk of dementia later in life (Plassman *et al.*, 2000) (see 'Dementias'). As already mentioned, having a TBI also increases the risk of post-traumatic epilepsy (Annegers & Coan, 2000) and a variety of neuropsychiatric disorders. There is greater psychosocial stressors in families where an individual has sustained a TBI and individuals with moderate-to-severe TBI are more likely to be disabled (Colantonio *et al.*, 2004).

Summary

Cognitive and neurobehavioural sequela are commonplace in head injury, especially in moderate-to-severe injury where high levels of permanent disability exist. Significant improvements in the assessment and treatment of head injury have occurred over the last decade, particularly in the area of neuroimaging findings in detecting brain abnormalities associated with trauma.

Headache and migraine

Bjørn Ellertsen

University of Stavanger

Introduction

Headache is one of the most common nuisances known to man. The pain may be secondary, as in fever or hypertension, or primary, as in migraine. It has been estimated that about 30% of people in the western world suffer from one or more severe headache episodes per year. In the UK, more than 3 million workdays are estimated lost per year due to headache. The majority of headache patients have migraine, tension-type headache (TTH) or combinations of these. About 65% of the patients seen in headache clinics suffer from migraine, 25% from TTH and about 10% from other types of headache. Although such samples are selective, the relative proportions of types of headache are probably representative of the population. The causes of headache syndromes like migraine, cluster headache and TTH are largely unknown. However, knowledge about clinical, physiological, biochemical and psychological characteristics is substantial.

The definitions of headache syndromes lacked precision in the past, making it problematic to compare studies. Therefore, the International Headache Society (IHS) formed a Classification Committee which published diagnostic criteria in 1988 (IHS, 1988). Most research published after 1988 adheres to these criteria.

Pathophysiology

In the field of psychophysiology, psychological variables are manipulated while physiological variables are measured as dependents. The field has yielded important information about the pathophysiology of headache. When reviewing the literature on response characteristics of patients, it becomes evident that the earlier distinction between migraine as vascular, and TTH as myalgic is oversimplified. Abnormal vasomotor responses have been observed in migraine patients in a number of studies. In general, data suggest labile autonomic nervous system activity. In an early study, non-medicated female migraine patients were found to show slower habituation to strong auditory stimuli than controls. They also showed more pronounced pulse wave amplitude reduction in the temporal arteries during stressful stimulation, and a pronounced pulse wave amplitude increase while resting afterwards (Ellertsen & Hammerborg, 1982). Surface EMG levels in the frontal muscles were higher in migraine patients than controls. In non-medicated TTH patients, significantly less pronounced heart rate responses were observed, as compared with controls. Further, TTH patients showed pulse wave amplitude increases in response to stimulation, whereas controls showed a slight decrease (Ellertsen *et al.*, 1987a).

TTH patients showed significantly higher frontal EMG levels than controls, but not higher than migraine patients. Thus, vascular abnormalities occur in both types of headache but they appear to have different vascular response patterns.

There is by now no doubt that central nervous processes play a central part in migraine attacks. The vascular hypothesis of migraine has been superseded by a more integrated theory which involves both vascular and neuronal components. It has been demonstrated that the visual aura experienced by some migraine sufferers arises from cortical spreading depression (CSD), and that this neuronal event also may activate perivascular nerve afferents, leading to vasodilatation and neurogenic inflammation of the meningeal blood vessels and, thus, throbbing pain (Silberstein, 2004). There is compelling evidence accumulated to support the concept that CSD is responsible for migraine aura (Parsons, 2004). Thus, it has been demonstrated that migraine attacks are associated with both paroxysmal vascular and electrical changes, caused by centrally triggered brainstem mechanisms. The electrical changes have been studied using both evoked potentials (EP) and SCP. Measurement of SCP in migraine patients has indicated a habituation deficit caused by brainstem-related dysfunction. Habituation shows systematic variation around a migraine attack. After an attack, habituation is normal (Kropp *et al.*, 2002). Many patients with migraine develop more chronic TTH over the years and TTH patients are often seen to develop more severe and short-lasting migraine type attacks. It is therefore always important to look into the history of each headache patient when diagnosing and planning treatment.

Personality and psychopathology

The question of psychopathology and characteristic personality traits in patients with recurring or chronic headache has been discussed in a number of publications (e.g. Philips, 1976; Adler, Adler & Packard, 1987; Ellertsen, 1992; Mongini *et al.*, 2000; Lanzi *et al.*, 2001; Waldie & Poulton, 2002; Huber & Henrich, 2003; Mongini *et al.*, 2003). A review of this literature on migraine and TTH shows that a main area of discussion revolves around the question of cause and effect. Although most studies report an increased prevalence of emotional and psychological disturbances, the question of predisposing personality factors remains unanswered. Waldie and Poulton (2002) reported from a 26-year longitudinal study and concluded that migraine and TTH seem to be distinct disorders with different developmental characteristics. Migraine was associated with maternal headache, anxiety symptoms in childhood, anxiety during adolescence and stress reactivity personality traits at the age of 18. TTH was associated with neck or back injury before the age of 13. More prospective studies are needed in order to shed light on these important questions, but there are few truly longitudinal studies available (see also 'Personality and health').

The Minnesota Multiphasic Personality Inventory (MMPI and the revision MMPI-2) has been used in a number of studies of headache patients. One issue is whether MMPI profiles obtained in pain patients actually reflect neurotic traits, since items concerning bodily symptoms contribute to the scales in question. However, affirmative responses to MMPI items concerning bodily symptoms are insufficient to drive any clinical MMPI scale into the

abnormal range. Prognosis and planning of treatment is dependent on a number of variables. Some of these are undoubtedly reflected in the MMPI and other personality measures. Most MMPI studies of headache patients have demonstrated characteristic profiles in these groups. In general, patients show 'neurotic' MMPI profiles, where the clinical scales reflecting health concerns, depression and somatization are elevated.

In their classic study, Kudrow and Sutkus (1979) found that patients with 'vascular headache' (migraine and cluster headache) scored lowest, TTH and 'combination headache' intermediate and post-traumatic and 'conversion' headache patients highest on the neuroticism scales of the MMPI. One possible interpretation of these data is that a continuum of increased stress and pressures, or an interaction between stressors and predisposing personality characteristics, was reflected in the MMPI. It has been maintained that the relationship between certain personality traits and headache becomes more pronounced as the chronicity of the headache problem develops. DeDomini *et al.* (1983) found that MMPI elevations were more pronounced in patients with 'daily headache', as compared with patients with headache attacks. Thus, combinations of intensity, severity and duration of pain problems seem to be strongly related to the degree of neuroticism found in personality tests. Zwart *et al.* (1996) found normal MMPI-2 profiles in migraine and cluster headache patients. Significant depression and somatization was found in TTH and cervicogenic headache patients. When all groups were analysed together, there was a strong relationship between headache duration per month and scale elevations. Comparable personality data from boys with migraine, using the Personality Inventory for Children (PIC), yielded no significant differences between patients and controls. (Ellertsen & Troland, 1989). There was, however, a relationship between duration of headache problems and PIC factor scales indicating social withdrawal and social incompetence within the patient group.

Significant lowering of MMPI scales has been reported in groups of migraine and TTH patients who responded favourably to biofeedback treatment (see 'Biofeedback'). In one study, MMPI profiles were compared in female migraine before and after biofeedback treatment in a 2-year follow-up study (Ellertsen *et al.*, 1987c). There were no differences between most and least improved patients before start of treatment. However, the least improved group showed unchanged profiles, whereas most improved patients showed significant changes on 5 MMPI scales. Decreased somatic complaints, less tension, improved interpersonal relationships and more energy was indicated. Similar changes in MMPI profiles after therapeutic intervention were reported by Fan *et al.* (1999). They concluded that management of migraine should include psychological intervention. In summary, the research discussed shows that depression, anxiety and somatization are found in chronic headache syndromes, whereas mild anxiety levels seem to be characteristic in recurring headache.

Applied psychophysiology

Hand temperature biofeedback has been used routinely in treatment of migraine patients since Sargent and Green (1972) first published their promising data on this method. The objective is to achieve learned control of peripheral vasomotor tonus, which in turn is assumed to contribute to normalization of autonomic lability,

and hence reduced headache problems. Electromyographic (EMG) biofeedback treatment of TTH was originally described by Budzynski *et al.* (1970). Obviously, the two different treatment approaches were inspired by the aetiological distinction between vascular and muscular mechanisms in the headache syndromes. Few biofeedback studies have combined clinical trials and psychophysiological evaluation. In one study, heart rate and pulse wave amplitude response patterns predicted biofeedback treatment outcome (Ellertsen *et al.*, 1987). This pointed to a potential utility of psychophysiology in identifying patients who respond favourably to this type of treatment. Migraine patients showing most pronounced clinical improvement also showed a normalization of pulse wave amplitude response patterns after treatment (Ellertsen *et al.*, 1987).

Biofeedback treatment effects are well documented in adult and child migraine patients (Hermann & Blanchard, 2002;

Andrasik, 2003). In general, meta-analyses of clinical trials show that biofeedback, relaxation training and hypnosis treatment all yield effects comparable to prophylactic medication, i.e. an average reduction of attacks around 45%, as compared with 14% placebo effects (e.g. Holroyd & Penzien, 1990) (see 'Biofeedback', 'Relaxation training' and 'Hypnosis'). More recent treatment of migraine using EEG biofeedback (neurofeedback) has yielded promising results. Thus, it has been demonstrated that migraine patients can learn to control their SCPs and learn to habituate through the use of neurofeedback, which in turn leads to a reduction in the numbers of attacks (Kropp *et al.*, 2002).

In summary, the fields of psychophysiology, abnormal psychology and applied psychophysiology have made important contributions to our understanding of headache syndromes and also contributed to improved diagnostic and treatment procedures.

Herpes

John Green

St. Mary's Hospital

Background

Genital herpes is an extremely common infection caused by one of the two related Herpes simplex viruses, HSV-1 and HSV-2. HSV-1 is the cause of cold sores around the mouth but can infect the genitals and be transmitted either oro-genitally or by genital-genital contact. HSV-2 is mainly a genital infection although orolabial infection can occur. Both viruses establish lifelong infections in the nerve roots and can be periodically reactivated causing recurrent episodes. During episodes small blisters appear which are itchy or painful and which break down in about a day to leave an open sore, which usually heals in about a week in those who are immunocompetent. However inapparent lesions are common and asymptomatic shedding, production of virus in the absence of lesions, also occurs in the absence of frank episodes. Most infections are believed to result from inapparent lesions or asymptomatic shedding since avoidance of sex during obvious episodes is common.

Genital recurrence rates are higher on average for HSV-2 than for HSV-1. Some individuals have only a single obvious episode, others can have episode rates up to one per fortnight. While episodes usually diminish in frequency over the years there is considerable variation. Infection is lifelong and cannot be eliminated. Treatment is by antivirals which, when used on a continuing basis, largely or completely suppress episodes during active treatment but do not affect natural history.

Most people with genital herpes have never been diagnosed and are unaware that they are infected. Estimates of incidence are based on serology but are limited because they are based on HSV-2 antibodies only. Orolabial HSV-1 infection is very common and serology cannot distinguish the site of infection. Since in many countries HSV-1 accounts for half or more of clinical cases, as a rough rule of thumb rates for HSV-2 might be doubled to estimate overall genital infection rates. On this basis the incidence of genital infection with the HSV viruses in the USA and Europe in adults under 35 is probably in the 15–25% range with some populations showing rates in excess of 50%. HSV infection is a common cause of genital ulcer disease in developing countries. Rates are rising worldwide, particularly rapidly for HSV-1.

Fortunately the disease causes little in the way of long-term physical morbidity. The main risk is transmission to the neonate at birth where disseminated herpes of the neonate can cause blindness, brain damage or death. Transmission to neonates is unusual except where the mother is infected late in pregnancy. Cases of disseminated herpes of the neonate are rare in Western Europe although they are more common in areas of social and relationship instability, for instance some inner city areas of the USA.

Risk of transmission can probably be reduced by antiviral treatment of the mother (RCOG, 2002). Caesarian section is sometimes used where risk of transmission is thought particularly high. Otherwise the main problem is psychological morbidity and reduced quality of life.

Psychological effects

Psychological morbidity is very common at the time of diagnosis with half of patients being clinically anxious and about a tenth clinically depressed on the HADS (Carney *et al.*, 1994). In those who do not get an (apparent) recurrence these symptoms usually resolve over a few months. In those with recurrences, psychological distress remains high for several months or even years. Distress does usually resolve eventually and by 5–6 years most patients report that their sexual and interpersonal function are similar to before they were infected and their levels of anxiety and depression are not different from population norms (Brookes *et al.*, 1993; Cassidy *et al.*, 1997). A few patients however fail to adjust over many years.

There is little systematic information on non-adjusters. There is no way at present to predict who will have difficulty in adjusting. Such evidence as is available suggest that non-adjusters are more likely to be women, although not exclusively so. Possibly this is in part because episodes are usually more painful in women. Frequency and severity of episodes are related to level of psychological distress and hence those with higher levels of reported distress might be more likely to be women. Higher initial levels of distress might be associated with more problems adjusting, although this is not established. However the infection may also feed into negative societal stereotypes of women's genitalia as 'contaminated'. Additionally there is some evidence that even amongst adjusters the experience of a chronic condition outside the patient's control may have a broader impact on the patient's thinking about the world (Green & Kocsis, 1997).

Data on the impact of antiviral treatment on psychological well-being is surprisingly limited as most early drug trials used episode frequency as their endpoint. However available evidence suggests that suppression of episodes can reduce psychological distress and improve quality of life. (Carney *et al.*, 1993; Patel *et al.*, 1999). Clinical experience suggests that the effects may persist after treatment cessation, possibly because stopping episodes allows patients space to adjust psychologically.

While many patients report unfounded concerns about casual household transmission and transfer to other sites on their own bodies (very rare and then probably only shortly after infection)

and concerns surrounding pregnancy their main concern is usually how to deal with current and future sexual relationships.

Genital herpes can lead to suspicion between partners. Diagnosis may be delayed and misdiagnosis outside specialist clinics is not uncommon. A tenth or more of 'first' episodes are actually recurrences of infection that may in some cases have been acquired some time prior to current relationship. Infection can occur from an apparently uninfected partner by asymptomatic shedding or during inapparent episodes. Orogenital transmission, particularly by HSV-1 from asymptomatic shedding in the saliva is probably common. It can be difficult to establish who gave it to whom and under what circumstances and, in the case of HSV-1 transmission, the source partner may have acquired orolabial infection non-sexually and then passed it on through oral sex.

Herpes is a heavily stigmatized disease which has received extensive, grossly misleading press coverage. Consequently many of those who are infected are unwilling to confide in friends or family. Most patients, at the time of diagnosis, are unable to think of anyone they know who has the disease, leading to a sense of loneliness and having been 'picked out' (see 'Stigma').

While standard advice is to disclose to sexual partners before first intercourse most patients delay informing partners until they are sure of the relationship, often when moving in with a partner or otherwise making a psychological commitment (Green *et al.*, 2003). There are also practical reasons for delayed disclosure at this time. It can be difficult to hide recurrent infection or ongoing treatment when living with someone. The usual tactic adopted by those planning to disclose to a partner is to 'test out' their attitudes to the disease before disclosure. Depending on the response disclosure may or may not occur. Individuals frequently fail to inform casual partners, in part because of fears that they may tell others.

Condoms provide some protection against transmission but this is less than for bacterial infections. Antiviral medication reduces but does not eliminate infectivity (Corey *et al.*, 2004). It is thought likely that individuals usually become less infectious over time, at least those whose episodes decline in frequency, and that the chances of transmission in a discordant couple reduce with length of relationship. Unfortunately transmissions can, and do, occur in couples who have engaged in unprotected sexual intercourse for many years without any problem.

There has been considerable interest in the utility and psychological impact of type-specific antibody tests for HSV (Mullan & Munday, 2003; Page *et al.*, 2003). The availability of type-specific antibody tests for genital herpes has meant that it is possible to establish whether couples where one partner has episodes and the other does not are truly discordant, or whether the partner without episodes is infected but asymptomatic. The tests are acceptable to most couples under these circumstances since they

have implications for their use of prophylaxis to prevent transmission. Under these circumstances serological tests do not appear to have a high incidence of adverse psychological sequelae. Discussion of the issues with the couple prior to testing is, however, likely to be important in clinical practice. The tests are also acceptable to many, but by no means all, patients as a routine screen for possible infection in genitourinary medicine (GUM) clinics, although the utility of serological tests for an infection so common in the general population and where there is no obvious treatment is uncertain. There have been suggestions in some countries that population screening, for instance in young people, might be appropriate as a measure to control spread. However existing tests do not have perfect specificity and sensitivity and there are grounds for concern over the likely proportion of false positives in low incidence populations.

A great deal of effort has been expended on trying to establish whether there is a link between stress and recurrences, as many patients believe. In part this has been motivated by the idea that the disease might be a good model on which to test psychoneuroimmunological hypotheses, although in fact the disease is probably a poor model since it would recur anyway regardless of stress and ongoing recording of episodes and asymptomatic shedding is fraught with practical difficulties. Green and Kocsis (1997) found the evidence for stress causing recurrences unconvincing. The issue is complicated because the episodes cause stress in themselves and because higher levels of distress may affect recognition of, and retrospective reporting of, episodes as happens in ocular herpes infections (Kip *et al.*, 2001). Additionally viral replication starts some days prior to the frank episode and it is possible that the immunological response to replication in itself may raise stress levels, generating a spurious apparent linkage.

There have been a number of studies seeking to intervene psychologically in individuals with recurrent genital herpes. In most the target has been to reduce the frequency of episodes rather than to encourage adjustment. With few exceptions these studies have been small and have had methodological problems, particularly the use of retrospective accounts of episode frequency, which can make them difficult to interpret. Although demonstrating a reliable and consistent impact of psychological interventions on recurrences would be of considerable theoretical interest it is not clear how achievable this is. Antivirals already offer considerable control over episodes. Demonstrating an improvement in the speed and extent of psychological adjustment through psychological intervention would seem of greater practical importance currently, and clinical experience and what is known about psychological aspects of the disease suggest that this is likely to be an achievable goal.

HIV/AIDS

Michael H. Antoni and Adam W. Carrico

University of Miami

Individuals infected with Human Immunodeficiency Virus (HIV) endure a chronic disease which requires behaviour changes and psychosocial adaptation (see 'Coping with chronic illness'). Health psychologists are in a position to make a unique contribution to the care of HIV-infected persons by designing and implementing behavioural interventions capable of facilitating these adjustments. Here we review many of the challenges facing HIV-infected persons as well as highlight potential targets for behavioural interventions.

A revolution with HAART

Due to the substantial reductions in morbidity and mortality associated with the advent of Highly Active Anti-Retroviral Therapy (HAART), HIV infection is now commonly conceptualized as a chronic illness (Bangsberg *et al.*, 2001). By directly suppressing HIV replication, HAART-treated individuals may attenuate T-helper (CD4+) cell decline and delay the onset of Acquired Immune Deficiency Syndrome (AIDS). However, not all HIV-infected patients treated with HAART display adequate viral suppression which may be due in large part to suboptimal adherence as well as the emergence of drug-resistant strains of the virus (Bangsberg *et al.*, 2001; Tamalet *et al.*, 2003). Questions also remain regarding the appropriate time to initiate HAART in HIV-infected patients due to variability in the extent immune reconstitution, increased incidence of opportunistic infections in the months following initiation and reports of profound drug-related toxicities (Yeni *et al.*, 2002). As a result, the current state of medical treatment

for HIV infection dictates that healthcare providers take into account the dynamic interplay among contextual, patient-related and treatment-related factors in order to deliver the best possible patient care.

HAART is a demanding regimen that requires unprecedented levels of patient adherence, greater than or equal to 95% to maximize the clinical benefits. Further complicating adherence to HAART are the special indications (e.g. taking medications with food) which accompany many medications in order to attenuate the severity of side effects, maximize bioavailability and ensure a constant therapeutic dose. Much of the research in this area continues to focus on what methods are most reliable and valid in the measurement of patient adherence to antiretroviral medications. Drawing upon a larger existing literature in a variety of medical populations, adherence has been examined using numerous methods including physician ratings, pharmacy refills, measuring medication levels in peripheral venous blood samples, patient self-report and electronic monitoring (Dunbar-Jacob *et al.*, 2002). It is likely that patient-reported HAART adherence is an over-estimate on average. On the other hand, more 'objective' measures (i.e. medication event monitoring system; MEMS) may underestimate adherence due to the lack of fit between the technology and the patient lifestyle factors (Samet *et al.*, 2001). As a result, investigations of adherence to HAART should employ multiple measures that utilize different methods of assessment (Llabre *et al.*, 2006). Investigations that employ the MEMS should also include assessments of participant experiences using this technology, and those that utilize only self-report measures of adherence to HAART would do well to examine the influence of

socially desirable responding. Finally, regardless of the chosen measure(s), investigations should establish validity by examining the relationship of adherence with HIV viral load and HIV medication resistance genotyping where possible (see also 'Adherence to treatment').

Adherence to HAART is influenced by a host of variables such as experiences with the treatment regimen, access to resources, patient psychosocial functioning and social/cultural factors (Fogarty *et al.*, 2002). One treatment-related factor which appears to be a significant obstacle to continuing HAART is the side effects many patients experience. In fact, medication intolerance is the most commonly cited reason among patients for termination of HAART (Park *et al.*, 2002). Greater knowledge of possible side effects from antiretroviral medications, younger age and prescription of four or more antiretroviral drugs with Ritonavir have also been associated with premature termination of HAART (Park *et al.*, 2002). In addition, a number of psychosocial factors such as depressed mood and poor emotional functioning have been related to non-adherence to HAART (Catz *et al.*, 2000). The effects of psychosocial factors on HAART adherence and subsequent HIV disease progression are especially salient given the illness experience of persons living with HIV/AIDS.

Psychosocial adjustment to HIV/AIDS

In the face of social stigma, HIV-infected persons must manage the multiple demands of a life-threatening illness as well as financial hardships, bereavement and other personal losses (see also 'Stigma'). Possibly due to the high prevalence rates of these stressors, HIV-infected individuals are at increased risk for developing an affective or adjustment disorder across the disease spectrum (Bing *et al.*, 2001). In fact, results from a meta-analysis of 10 published studies indicate that the risk of developing major depressive disorder is two times higher in HIV-infected samples when compared with HIV-negative peers (Ciesla & Roberts, 2001). While increased levels of distress may be observed across the HIV disease spectrum, patient illness burden has been identified as a potent predictor of psychosocial adjustment as AIDS develops (Lyketsos *et al.*, 1996) and progresses (Siegel *et al.*, 1997).

To varying degrees, patients with an AIDS-related condition (ARC) are subject to elevated levels of stigma/discrimination, grapple with existential concerns, must cope with the physical disfigurement or disability (see 'Facial disfigurement' and 'Disability') and experience greater treatment burden associated with a 'disease within a disease' (De Moore *et al.*, 2000). Thus, the emergence of various ARCs may have dramatically different implications for patient psychosocial adjustment depending on the extent of illness burden and stigma experienced. For example, unlike many other ARCs, Kaposi's Sarcoma (KS) lesions may be readily visible and are commonly recognized (particularly in the gay community). As a result, individuals with KS may experience discrimination across a number of domains as well as increased levels of depression, anxiety and social isolation when compared to other individuals with AIDS. These observations are supported by qualitative data indicating that fear of KS ranks as high as fears of death, neurological deficits and pain among HIV-infected patients (Bor, 1993). In addition, physical disfigurement may

be a common concern in patients with KS (De Moore *et al.*, 2000). Thus, there is compelling clinical and qualitative evidence to indicate that examining distress and illness-related concerns within AIDS-defined populations will provide a deeper understanding of the diverse experiences of individuals living with AIDS.

A number of investigations have examined the role of depressed mood in CD4+ cell decline, progression to AIDS and mortality (Leserman, 2003). Because of observations that clinically significant changes in HIV viral load (Kalichman *et al.*, 2002) and increased symptom burden have both been associated with reactive depressed mood, the directionality of the relationship between depression and HIV disease progression has been hotly debated. Therefore, longitudinal investigations with repeated measurements of psychosocial and immunologic data provide the most reliable findings examining the role of depression in HIV disease progression. Future investigations examining of the putative mechanisms will undoubtedly lend further support to the role of depression in HIV disease progression.

Depressed mood may influence HIV disease progression via a number of pathways. First, depressed mood may be associated with increases in a variety of health-risk behaviours (e.g. non-adherence to HAART, substance use and sexual risk-taking) that in turn impact HIV disease progression. In particular, research examining the mediational role of HAART adherence remains an area for further study (Leserman, 2003). Neuroendocrine dysregulation represents another plausible pathway whereby depressed mood influences immune status and longevity. Elevations in cortisol and catecholamines (e.g. norepinephrine; NE) are commonly observed in depressed persons, and have been demonstrated to impact HIV replication, immune function and disease progression (Leserman *et al.*, 2000). Cortisol influences maturational selection of CD4+ cells in these lymphoid organs (Norbiato *et al.*, 1997), facilitates HIV infection of CD4+ cells (Markham *et al.*, 1986) and is associated with high rates of apoptosis in CD4+ cells and accessory cells in the lymphoid tissue (Clerici *et al.*, 1997). Release of NE at sympathetic nervous system terminals provides opportunities for this catecholamine to influence the progression of HIV infection at the primary site of viral replication. By binding with beta-2 adrenergic receptors on the lymphocyte membrane, NE induces cellular changes via the G protein linked adenylyl cyclase-cAMP-protein kinase A signaling cascade. In vitro data have observed that cellular changes of this nature are associated decrements in interferon-gamma and interleukin-10 which in turn are associated with elevations in HIV viral load over an 8-day period (Cole *et al.*, 1998). Taken together, it is likely that both behavioural and neuroendocrine mechanisms make unique contributions to HIV disease progression.

Although a number of investigations have examined the association between psychosocial adjustment and HIV disease progression (Cole & Kemeny, 2001; Leserman, 2003), there is a general consensus that these effects have not been reliably observed (Kopinsky *et al.*, 2004). These discrepancies may be due in large part to the heterogeneity of patient populations across samples and utilization of multiple outcome measures as indicators of HIV disease progression. Researchers have indicated that this literature may benefit from investigations that examine patient subgroups at both extremes of the disease spectrum. Specifically, the most

vulnerable populations may hold promise for future investigations of the effects of psychosocial factors on HIV disease progression. Examining a more homogenous group of patients with respect to HIV disease stage may also provide useful information regarding the putative mechanisms of the effects of psychosocial variables on HIV disease progression and may provide some interesting data on the most beneficial time frame(s) for psychological intervention (Kopinsky *et al.*, 2004). We propose that investigations of persons living with KS appear to meet these criteria and provide unique opportunities to examine the dynamic interactions among psychosocial factors, viruses, glucocorticoids, cytokines and angiogenesis that are relevant to this ARC (Miles, 2000) (see also 'Psychoneuroimmunology').

Behavioural interventions

A variety of behavioural interventions have been developed as adjuncts to medical treatment for HIV-infected persons at various disease stages to decrease distress, enhance coping skills and encourage health-promoting behaviours with the hope of enhancing quality of life as well as slowing disease progression (Antoni, 2003). Components of these treatments such as

relaxation, cognitive restructuring and coping skills may account for some of the psychosocial, neuroendocrine and immunologic changes observed (Antoni, 2003) (see 'Cognitive behaviour therapy' and 'Relaxation training'). Although it appears that conducting these interventions in a group format may offer optimal efficacy and cost-efficiency, future work needs to address the various components of these multi-modal interventions to better understand their mechanisms of action. By gaining a better understanding of the most potent mechanisms of change in these treatments, a new generation of interventions can be developed that more effectively capitalizes on these factors to maximize the benefits derived by patients. It is also plausible that different stress management components are more efficacious in different populations. However, the ultimate test of the efficacy of these interventions will require long-term follow-up to assess effects on ongoing psychosocial adjustment and clinical health course. Ultimately, by understanding those factors influencing psychosocial adjustment to HIV infection, behavioural interventions may be refined to address the array of challenges that are experienced by persons living with HIV/AIDS.

Hormone replacement therapy

Christine Stephens

Massey University

With an unprecedented number of women living beyond midlife in western countries, the impact of menopause is an important public health issue. Middle-aged women are one of the largest single age groups in these populations, and every middle-aged woman must inevitably experience menopause. Since the 1950s, exogenous hormones known as hormone replacement therapy (HRT) have been increasingly prescribed to women to counteract adverse symptoms at menopause (McPherson, 2004). More recently it was suggested that long term HRT was beneficial and use by middle-aged women in Britain, increased substantially, from under 5% in the 1980s to 33% in 1998 (Kmietowicz, 2000). In the US, 38% of menopausal women were taking HRT in 2002 (Minelli *et al.*, 2004). In New Zealand, HRT use among middle-aged women increased from 12% in 1991 to 20% in 1997 (North & Sharples, 2001). However, the findings of the Women's Health Initiative (WHI) study (Rossouw *et al.*, 2002) received much media attention, changed perceptions of the risks and benefits and were associated with an immediate change in use. In the United States, Haas *et al.* (2004) reported a drop in use among women undergoing mammography of 18% per quarter. In New Zealand, 58% of 998 women initially stopped taking HRT (Lawton *et al.*, 2003). These dramatic changes reflect the problems involved in making a decision about HRT for many women. Generally, the decision making issues focussed on by medical and psychological research, are understandings of the changing knowledge about benefits and risks of HRT use, and the broader social context in which women must make their decisions about HRT.

Medical benefits and risks

Physical and psychological symptoms of menopause

HRT has been prescribed for middle-aged women to alleviate menopausal symptoms such as hot flushes, night sweats, atrophy of the vagina and skin changes. Hot flushes are the most common experience, occurring in up to 75% of menopausal women (Joffe *et al.*, 2003). In the 1990s, the benefits of oestrogen in reducing the incidence of osteoporosis and heart disease were emphasized (McKinney & Thompson, 1998). This change in focus, from the treatment of specific menopausal symptoms to prophylactic and possibly long-term treatment, changed the potential role of HRT in middle-aged women's lives, and added to the complexity of decision making about HRT. In 2002 the WHI reported that the effects of oestrogen plus progestin (for women with intact uteruses) on healthy post-menopausal women increased risk of breast cancer, CHD, stroke and venous thromboembolism and, despite decreased risk of hip fracture and colorectal cancer, concluded that this combination is not suitable for prevention of chronic diseases (Rossouw *et al.*, 2002). These and other recent findings support previous evidence of the risks of HRT such as breast cancer, the benefits in regard to osteoporosis and completely counteracted previous epidemiological findings that suggested cardiovascular benefits.

Depressed mood is often cited as a symptom of menopause, and the use of HRT to treat dysphoria has been widely accepted (Barlow, 1992). It is clear that hormone changes are not related to major depressive disorder (Schmidt & Rubinow, 1991), and

extensive research has provided only equivocal support for an association between hormones and mood. Clinical trials have provided some support for enhancement of mood through the administration of oestrogen to healthy non-depressed women (e.g. Klaiber *et al.*, 1997; Derman *et al.*, 1995). However, others (e.g. Girdler *et al.*, 1999) found that HRT was not associated with changes in mood. Prospective studies of HRT in surgically menopausal non-depressed women have also demonstrated a positive effect (e.g. Sherwin & Gelfand, 1985) but Phillips and Sherwin (1992) also found no effect of HRT on mood. It has been suggested that clinical samples are biased and certainly, population studies of menopausal women generally indicate that emotional wellbeing is not affected by menopause (Hunter, 1990). Studies using population samples to examine psychological distress or mood have shown no differences between HRT users and non-users in Australian (Slaven & Lee, 1998) and New Zealand (Stephens & Ross, 2000) samples. The WHI trial included a sample of 1511 women randomly assigned to oestrogen plus progestin or placebo. After three years there were no differences in depressive symptoms, mental health or vitality. In the light of such findings, alternative treatment strategies are being explored for mood disturbances that occur in menopausal women (Joffe *et al.*, 2003).

Cognitive functioning and hormones

Changes in cognitive functioning, particularly memory problems, are also complained of by women at menopause. Basic research indicates that oestrogen has multiple effects on brain function (Cutter *et al.*, 2003) and, among middle-aged women, the most promising effect of oestrogen has been observed on verbal memory. Observational and experimental studies have found a positive relationship between oestrogen and verbal memory, in both post-surgical and naturally menopausal women. However, there have been studies of equal merit which have failed to find such a link (Stephens *et al.*, 2003). Oestrogens are also implicated in Alzheimer's disease (Waring *et al.*, 1999) but the most recent findings of clinical trials (e.g. Mulnard *et al.*, 2000) show that HRT treatment of older women has no effect on the progress of such neuropsychological disorders. Again, the findings of the WHI trials have added weight to these conclusions. Among women over 65 it was found that random assignment to oestrogen had no effect on mild cognitive impairment, but the group taking HRT was actually at higher risk of developing dementia (Shumaker *et al.*, 2003).

Thus, information that is available to middle-aged women from multiple sources (such as primary care physicians, pharmaceutical companies, literature or the Internet) is rapidly changing, and often conflicting in regard to the risks and benefits of HRT use and the nature of menopause (Breheny & Stephens, 2001; Daley, 1999). These factors contribute to the difficulties for women deciding about HRT (Stephens *et al.*, 2001), without taking into account the wider social context in which these decisions must be made.

The social context of HRT decision-making

Lay understandings of health

The information presented to women about disease risks and benefits is inclined to cause extreme anxiety or confusion, or may

be simply ignored as outside everyday concerns. It is difficult for women to see their 'self' in terms of risk ratios provided by medical research (unless they see themselves as candidates for disease, for example because of a family history). Some explanation for this difficulty comes from research showing that medical discourses are part of, but do not encompass all of, understandings of health. Firstly, attitudes towards menopause have been found to predict HRT use more strongly than experiencing symptoms (Breheny & Stephens, 2001). Furthermore, narrative researchers such as Blaxter (1993) demonstrate how health is understood in terms of biography and social relations. Work with middle-aged women has shown that it is this wider social world, beyond medical discourse, that enables women to position themselves as users of HRT or not (Stephens *et al.*, 2004) (see also 'Lay beliefs about health and illness' and 'Risk perception').

Competing constructions of HRT

Our social world includes controversy over virtually every aspect of HRT use. The last few decades have seen publicly contested changes in the meanings of menopause (e.g. Bell, 1987; Goldstein, 2000). The construction of menopause as a deficiency disease requiring medical treatment has been strongly contested in sociological literature (Griffiths, 1999) and this debate carried into the media where constructions of menopause as a medical or natural change compete (e.g. Lupton, 1996). When analyzing women's talk to identify the use of these discourses in practice, Hunter and O'Dea, (1997) determined that biomedical discourses do not include the complexity of women's experiences, and Griffiths (1999) highlighted contradictions in women's talk about HRT. Women resisted the medicalization of menopause and were critical of doctors, yet made use of a medical model of risk to make their decisions about HRT. Stephens *et al.* (2004) noted that women drew upon a common range of discourses which construct HRT in different ways (such as support for a threatening change, as a biomedical aid, as a 'drug' to be avoided by the virtuous or as unnatural). The women used different constructions according to the social function of their talk at the time, like accounting for their use of HRT or to discuss concerns about the choices available to them. The researchers concluded that different contexts such as a doctor's surgery or discussion with a friend, would lead to the use of different (apparently contradictory) constructions.

Embodied experience

Such analyses highlight the discursive aspects of the social world but can neglect the importance of embodied experience. Goldstein (2000) described women's distress in the face of constructions of menopause which dismiss the very somatic nature of their experiences. An emphasis on the psychosocial aspects of bodily changes is not helpful to women who are suffering from heavy bleeding, sleepless nights or incontinence. To understand the complexities of having and being a body in a social world, Stephens (2001) used women's accounts to show the importance of physical experiences such as hot flushes in terms of their experiential and social meanings together. For example, the discomfort of a flushed face has quite different import at home or at work, in the company of males or females or among those of different social status.

The experience of symptoms also has important moral meanings in a social world in which it is virtuous to 'get on with it', or the use of HRT is seen as a crutch for the weak (Breheny & Stephens, 2003). Women would benefit from understandings, applied in medical settings, which include the complex interactions of the physical and social aspects of menopause and HRT use.

Clinical implications

Although longitudinal studies have somewhat clarified the medical risks and benefits of HRT, the difficulties of the decision have not been ameliorated for women and many questions are unresolved (Rymer *et al.*, 2003; Wang-Cheng & Rosenfeld, 2003). The current results are already being subjected to various interpretations, and although most recommend that HRT is beneficial for immediate symptoms and unsuitable for long-term use (e.g. Minelli *et al.*, 2004), other commentators are pointing to the low real risk ratio, the benefits for osteoporosis or to remaining questions about the prophylactic use of oestrogen (McPherson, 2004). All women should have access to accurate unbiased information about the benefits, risks and side effects of using HRT. However, the ongoing problem is multiple conflicting interpretations and the personal relevance of risk/benefit ratios (Bond & Bywaters, 1998). Current recommendations have also brought to the fore the problem of when and how to cease HRT use; an issue commonly discussed by women on Internet sites. When we also consider the social and moral milieu in which women experience menopausal changes or use HRT, the dilemmas for women are clearly ongoing. It is apparent that the HRT decision

should be made on an individual basis in discussion between a woman and her doctor (Griffiths, 2003).

These sorts of recommendations accord well with shared decision making in medical practice (Griffiths, 1999; Mort, 1996). One result is that women are being offered increasing levels of personal responsibility with which they may not be comfortable (Budge *et al.*, 2000) and this aspect deserves more attention. McLellan (2002) asked women about their preferred decision making style and most wished for a shared final decision. However, this balance changed across the decision process during which many women preferred that the doctor decide about providing information, and wanted their doctors' help when considering their choices (see also 'Patient-centred healthcare').

Conclusion

The results of research in regard to the positive and negative aspects of HRT use continue to be a source of confusion to women who expect to take more personal responsibility for such decisions. Health practitioners who are responsible for prescribing HRT must be aware of the complexities of the decision for each woman and the importance of the social context, beyond the medical consultation, in which she must cope with her physical experiences or account for her use of pharmaceuticals. It is important to develop our understandings of how the medical information may be integrated with the psychosocial implications of making these decisions.

Hospital acquired infection

Jan Stygall and Stanton Newman

University College London

Any infection not present or incubating at the time of admission into hospital is classified as a nosocomial infection and is often referred to as a hospital acquired infection (HAI). Approximately 1 in 10 patients acquire an infection after admission into hospital of which it has been estimated that 30% or more could be prevented (Gastmeier, 2004).

Urinary tract infection (usually catheter-associated), surgical-site infection, bloodstream infections and pneumonia (usually ventilator-associated) account for more than 80% of all HAIs. The most frequently occurring infections are urinary tract accounting for approximately 35% of HAIs however they are associated with the lowest mortality and cost (see 'Urinary tract symptoms'). Surgical-site infections account for around 20% and are third in cost whereas bloodstream infections and pneumonia are less common, explaining about 15% each; however these are linked with much higher mortality and costs. While the rates of both urinary tract and surgical-site infections have recently declined slightly, bloodstream infections and methicillin-resistant *Staphylococcus aureus* (MRSA) infections are rapidly rising. Patients in intensive care units account for 25% of HAI cases with nearly 70% being attributed to micro-organisms that are resistant to one or more antibiotics (Burke, 2003).

Among the factors that promote HAI are underlying diseases and decreased patient immunity, invasive diagnostic and therapeutic techniques, widespread antimicrobial resistance, lack of infection control measures and environmental hygiene (Lazzari *et al.*, 2004). However, the exact extent to which the environment plays a part is largely unknown. Recently concerns have been raised regarding the perceived falling standards of cleanliness in hospitals in the UK, which has been linked with the rise in HAIs. However, Dancer (2004) argues that although there may well be a connection between dirty hospitals and HAI, there is, at present little evidence to confirm this claim. Evaluating the quality of 'cleanliness' is not an easy task and usually, unless an infection has already occurred, the only method employed is visual assessment. Dancer (2004) suggests there are internationally agreed microbiological standards for air, water and food preparation surfaces in the food industry, which should be mirrored in hospitals. A recent World Health Organization consultation on the 'Prevention and Control of HAI' called for an international strategy to establish standards, procedures and methods for HAI surveillance, prevention and control and to promote their implementation at a national level.

As organisms have to be transmitted from the environment to the patient one likely route is via the hands of healthcare workers (HCWs). It has been argued that hand hygiene is the simplest and most effective measure for preventing hospital-acquired infections. Hand hygiene behaviour includes both handwashing and hand rubbing with alcohol-based solutions. Recommendations have been

issued to guide HCWs practice, however adherence with hand hygiene recommendations is usually estimated at below 50%. Another method of transmission via the hands is the misuse of gloves. Girou *et al.*, (2004) in a study of 120 HCWs found improper gloving in 64.4% of instances and in 18.3% of contacts gloves were not removed before performing strict aseptic precautions. This non-adherence is seen in a wide range of different types of HCW, e.g. nurses, doctors, physiotherapists etc. (Jenner *et al.*, 2002). There is also evidence that adherence rates vary not only with type of HCW, i.e. nurses have higher adherence rates than physicians, but also by speciality such as doctors in anaesthetics, accident and emergency etc. (Pittet *et al.*, 2004) (see also 'Healthcare work environments').

Although guidelines regarding hand hygiene are widely available, a survey reported in 1999 found that in 90% of infection control programmes handwashing education was not provided (see McGuckin *et al.*, 2001). In common with other health behaviour intervention studies, providing information only, appears to have limited effect on behaviour with various studies reporting little relationship between knowledge and hand hygiene (e.g. Kennedy *et al.*, 2004). The most frequently implemented intervention has been education and training where HCWs have explained to them why and when hand hygiene should be practised and also shown the appropriate techniques to adopt. Studies involving education have also been shown, however, to have minimal long-term effects on handwashing behaviour although, there is an indication that surveillance and feedback to HCWs of infection rates can enhance adherence to policies (e.g. Stone *et al.*, 2000). There is also evidence that different types of HCWs respond differently to differing methods of education (Seto, 1995). Pillet *et al.* (2004) suggest that infection control professionals should learn from the behavioural sciences and become 'agents of change'. They identified multiple predictors of handwashing hygiene, and therefore suggested a move away from the purely knowledge-based programmes of infection control to a more behavioural approach which may incorporate a variety of different methods.

O'Boyle *et al.* (2001, p. 352) suggest 'although the hand hygiene procedure itself is simple, HCW's behaviour related to hand hygiene is a complex phenomenon that is not easily understood, explained or changed'. Various barriers to adhering to hand hygiene have been suggested such as: skin irritation; inaccessibility of hand hygiene supplies; interference with HCW-patient relationship; patient needs perceived as priority; wearing of gloves; forgetfulness; lack of knowledge of guidelines; insufficient time for hand hygiene; high workload; understaffing; and lack of evidence of impact of hand hygiene on infection rates.

The handwashing hygiene of other HCWs, especially those perceived as role models, has been shown to impact upon handwashing

behaviour both positively and negatively. Perceived role models who show good handwashing behaviour will elicit good behaviour from other HCWs; conversely a senior member of staff who takes little notice of handwashing procedures can produce the opposite effect (e.g. Jenner *et al.*, 2002; Pittet *et al.*, 2004).

Although theoretical models have often been employed to examine the impact of beliefs on various health behaviours, very few studies have applied these models to investigate HCW's perceptions regarding infection control. O'Boyle *et al.* (2001) used the Theory of Planned Behaviour (TPB; Ajzen & Fishbein, 1980) as an explanatory model for adherence to hand hygiene recommendations in a longitudinal study involving 120 nurses (see 'Theory of planned behaviour'). Although the TPB motivational variables predicted 'intention to handwash' and intention was related to 'self-reported adherence' the TPB model did not predict actual adherence. Actual adherence was predicted by nursing activity which included type of ward, shift, patient to nurse ratio etc. Jenner *et al.* (2002) also using TPB included the concept of 'barriers' from the Health Belief Model (HBM; Rosenstock, 1966) with a single item as a measure of 'personal responsibility' to explore health behaviours of 104 hospital-based HCWs in relation to hand hygiene (see 'Health belief model'). They found that attitudes and personal responsibility were significant predictors of intention with perceived behavioural control and intention being significant predictors of behaviour. Two barriers to hand washing (availability and number and location of sinks) were found to correlate with both behaviour and perceived behavioural control. Barriers were also found to significantly influence infection control adherence in two other studies employing the HBM (Osbourne, 2003; Williams *et al.*, 1994). Levin (1999) examined TPB, TPB plus perceived risk and Theory of Reasoned Action (TRA; Ajzen & Fishbein, 1980) in identifying predictors of HCWs' intention and self-reported use of gloves. They found that intention, attitude

and perceived risk were significant predictors of behaviour. Intention was the best predictor of glove use with perceived control contributing most. Although the predictive potential of 70% using TRA in relation to HCWs' reported glove use could not be improved by either TPB or TPB with perceived risk, the authors argue that these variables provided an important insight into HCWs' intention regarding the use of gloves.

A patient education behavioural model was employed in studies by McGurkin and colleagues. In their UK study conducted in 2001, patients were requested to ask 'Did you wash your hands?' of any HCW who had direct contact with them. Adherence to the programme was measured by soap/alcohol usage and handwashing per bed. Handwashing increased on average by 50%. However, HCWs washed their hands significantly more often when dealing with surgical patients than with medical ones. Sixty-two per cent of patients felt at ease when asking HCWs if they had washed their hands. Seventy-eight per cent of HCWs said they had washed their hands. Interestingly all patients asked nurses, but only 35% asked doctors. Similar findings were reported in an earlier study conducted by McGuckin *et al.* (1999) in the USA with 57% of patients reporting they had asked the HCW about handwashing and soap usage increased by 34%. Another study conducted in the UK (Sen *et al.*, 1999) found that patients were reluctant to enquire whether HCWs had washed their hands. However, the major difference between these two studies was that the patient participants in the McGuckin *et al.* study were told specifically that the HCW would expect to be asked about handwashing and that the HCWs were supportive of the study.

Most research into the study, and enhancing, of infection control practices have concluded that future programmes need to employ both an integrated and multidisciplinary approach.

Huntington's disease

Maurice Bloch

University of British Columbia

Huntington's disease (HD) is a genetic disease which is transmitted as an autosomal dominant trait. It is a chronic degenerative disease of the CNS characterized by movement disorder, cognitive deterioration and personality change. While found in all parts of the world HD is most commonly found in Caucasians of whom about 1:10 000 individuals are affected. Onset is subtle and insidious and occurs most frequently between 30 and 50 years of age. Juvenile onset is seen in about 10% of cases and about 20% have onset at over 50 years of age with diagnoses as late as the eighth decade reported. The disease progresses inexorably, culminating in death usually 15 to 25 years after observed onset. Late onset HD tends to progress more slowly than early onset forms of the disease. There is thus far no effective treatment or cure for the disease.

HD is commonly known for its jerky, dance-like (choreic) movements. Movement may, however, also be rigid, especially in the juvenile form and the later stages of the adult form. Cognitive deficits (dementia) commonly associated with HD include difficulty with memory (primarily a retrieval problem), attention and concentration. While the dementia of HD is primarily subcortical and is non-aphasic, it includes many additional cognitive functions such as cognitive speed and fluency verbal fluency, difficulty persisting with, or initiating, a task and with change of set (see also 'Dementias').

Becoming affected with HD may have a tremendous impact on the psyche. Organic change is compounded with psychological trauma. High rates of schizophrenia, anxiety disorders, alcoholism and other psychiatric illnesses are reported. Irritability, poor impulse control, angry and hostile behaviour are observed in many sufferers of HD during circumscribed periods of the illness. While insight and orientation remain relatively intact throughout the illness, judgement is often impaired. This may be observed in bad business decisions, inappropriate sexual behaviour and impaired social judgement. Depression is the most common psychiatric illness seen in HD and is associated with a higher rate of suicide. Harper *et al.* (1991) have surveyed the literature and have found studies reporting suicide rates which range between 0.5% and 12.7%.

It is difficult to separate out the aetiology of a mental illness when biological, psychological and social factors are all contributing.

This is the case with affective disorders associated with HD. There is, however, growing evidence that affective disorders are related to the pathophysiology of HD. A prevalence rate of affective disorder, of between 9% and 44% has been reported (Harper *et al.*, 1991). Peyser and Folstein (1990) found that about 10% of all HD patients have manic episodes, some have delusions and hallucinations. Many respond to appropriate pharmacological treatment. Affective disorder is more common in some families, in persons of Caucasian ancestry and in those with later onset.

Irrespective of the aetiology of the psychiatric problems or of the dyskinesia and dementia associated with HD, the impact on the individual and the family is profound. However, textbooks on HD (Folstein, 1989; Harper *et al.*, 1991) in citing over 500 publications related to HD rarely refer to the psychosocial impact of the disease.

The psychosocial adaptation of the individual living at risk for HD and to the onset and diagnosis of the disease is described in a Model of Psychological Response Stages (Bloch *et al.*, 1993). During the warning stage, asymptomatic individuals become aware of their risk status for HD and develop adaptive psychological defensive strategies. In response to the early signs and symptoms of HD (incipient stage) unconscious working through of this realization occurs while it is kept out of conscious awareness. When symptoms can no longer be ignored, the possibility of diagnosis of HD is acknowledged (break-through stage). After the delivery of the diagnosis short- and long-term adaptive responses to living with HD occur (adjustment stage).

Living with an individual affected with HD will have serious ramifications for family members, for their roles and for the family system. The caregiver may take over the role functions of the affected person while maintaining his/her previous roles and at the same time providing care for the affected person. In the case of a genetic disease the caregiving spouse lives with the awareness that any number of the children may have inherited the gene and may develop the disease. The burden is multiplied for those families in which multiple members are concurrently affected. The caregiving spouse, who has no genetic loading for the disease, is pivotal in maintaining the integrity of family functioning. The needs of the caregiver are, however, often neglected. Time taken

to fulfil social and personal needs is frequently accompanied by strong feelings of guilt. Attrition over the years wears the caregiver down and may culminate in family breakdown or increased vulnerability to mental health problems.

The attitude of the affected person and of the caregiver toward the disease may have substantial influence on the attitude to the disease of any children in the family. Children are more likely to view the disease as catastrophic if the parents treat it as such (see 'Children's perceptions of illness and death'). This will happen in those families where the affected individual is perceived as not accepting the disease, is rejected by the family or behaves in ways destructive and embarrassing for family members. A less threatened and more wholesome relationship to the disease is more likely to develop in those families where there is a positive attitude of challenge and struggle in a context of love and support. Nevertheless, the child too must bear a great deal. The burden of being thrust, perhaps, into a quasi-parenting role vis-a-vis the affected parent and the negative impact of the shadow of this incurable disease hanging over the at risk children may be immense. Anxiety and uncertainty must be borne and may influence important decisions about marriage, childbearing and career.

In 1983 a polymorphic DNA marker for the HD gene was discovered (Gusella *et al.*, 1983). This led to the offering of predictive testing for HD using linkage analysis. Ten years later the cloning of the gene for HD was reported (The Huntington Disease Collaborative Research Group, 1993). The mutation in the HD gene was identified to be an unstable CAG-trinucleotide expansion. Persons affected with HD have a CAG repeat length over 36 and are considered at 'increased risk' for developing HD should they live long enough. However, some individuals with repeat lengths between 36–41 may never develop HD in their lifetime. CAG repeats between 27–35 are referred to as intermediate alleles and will not result in the development of clinical HD in their lifetimes. However, the CAG expansion is unstable and may lead to an expansion in the progeny of the carrier of the intermediate allele especially if this carrier is a male (Goldberg *et al.*, 1993).

There is a significant inverse relationship between CAG repeat length and age of onset of HD. A greater CAG expansion is associated with an earlier age of onset. However, caution must be exercised when predicting age of onset for a particular CAG repeat length as the precision of predictions is relatively low, with wide confidence limits. (Langbehn *et al.*, 2004).

The discovery of the HD gene has overturned some of the previous dogma about HD. It is now accepted that new mutations of the HD gene are not uncommon (Falush *et al.*, 2001); that the penetrance of the HD gene is not complete and that, in particular, there is a range of trinucleotide repeat sizes at which the disease may or may not manifest (Goldberg *et al.*, 1993). There is evidence that not all apparent HD phenotypes are caused by an abnormality in the HD gene (Goizet *et al.*, 2002). Consequently direct gene testing has become important not only to provide testing for at risk individuals and to definitively diagnose late onset cases where the symptoms may be more subtle and the diagnosis more difficult to ascertain but also as a definitive diagnostic test for individuals with no family history of HD.

Earlier linkage testing was less than 100% accurate and could not be carried out at all if blood (DNA) was not available from crucial family members. It is now possible to offer predictive testing by direct gene analysis, at a level of much greater accuracy, and testing

can now include persons for whom the previous linkage test had been uninformative or who did not have any blood samples from crucial family members. Direct testing also allows persons at less than 50% risk (such as grandchildren of affected persons) to be tested even while their parent (at 50% risk) is still alive. This creates the dilemma of indirectly providing predictive testing for the parent when the CAG expansion is detected in the child (Creighton *et al.*, 2003; Lindblad, 2001; Brinkman *et al.*, 1997). Questions concerning the use of the test for the purposes of testing minor children must be addressed. (Bloch & Hayden, 1990) (see 'Screening: genetic').

In surveys undertaken prior to the availability of the predictive test 57–84% of at risk individuals indicated an interest in the test (Evers-Kieboom *et al.*, 1987; Kessler *et al.*, 1987). Actual uptake of the test worldwide, at between 5–24% has been significantly lower than anticipated (Creighton *et al.*, 2003). The reasons for this may include the cost of testing in countries where the test is not covered by universal health plans; the increasing hope for future treatment in the context of a late onset disease; the perceived burden of the disease in the family; and fear of discriminatory practices in areas of insurance or employment.

The uptake of prenatal predictive testing has been very low (Simpson & Harper, 2001; Maat-Kievit *et al.*, 1999; Creighton *et al.*, 2003). This low uptake may be attributed to the emotional trauma of abortion and to the hope that there would be a cure for the child in the future (see also 'Screening: antenatal').

The impact of predictive testing on individuals has been extensively reported. In a worldwide study of 4527 individuals who had undergone predictive testing the frequency of catastrophic events (defined as suicide, suicide attempts and psychiatric hospitalization) was estimated to be 0.97% (Almqvist *et al.*, 1999). Half of these individuals were noted to already be affected with HD. An increased risk result, psychiatric history prior to the predictive testing and being unemployed were identified as factors associated with an increased likelihood of a catastrophic event following predictive testing. A five-year follow-up study identified persons who had experienced a clinically significant adverse event since receiving their predictive test result (clinical depression; psychiatric hospitalization; planned, attempted or successful suicide; marked increase in alcohol consumption; breakdown of a primary relationship or scoring significantly high level of distress on the Global Severity Index of the Symptom Checklist 90(R) reported a frequency of 6.9% (14 of 202 individuals) (Almqvist *et al.*, 2003). The most frequent adverse event was clinical depression (6 individuals) and attempted suicides (3 individuals). The study found that psychological distress was significantly reduced for both the increased and decreased risk groups after receiving predictive test results.

HD is the first disease for which a test to modify genetic risk has been available. The counselling protocols developed for HD predictive testing have been adopted as a blueprint for counselling persons entering genetic testing for other diseases such as breast cancer and polycystic kidney disease. The basic protocol includes at least two sessions of pre-results counselling, the preference that a supportive companion accompany the candidate to the results session and that ongoing follow-up be provided and be available on demand. (Went, 1994). Nevertheless predictive testing has created new counselling challenges, ethical and moral dilemmas. Issues of third party interest, social cost and patient confidentiality have arisen (see also 'Screening: general issues').

Hyperactivity

Bjørn Ellertsen and Ine M. Baug Johnsen

University of Stavanger

In 1902, a paper published in *The Lancet* pointed to the fact that 'abnormal physical conditions in children' could be caused by diseases of the central nervous system (CNS). This conclusion was based

on observations of children developing hyperactive, antisocial behaviour after encephalitis (Still, 1902). Kahn and Cohen further discussed the clinical picture in 1934, introducing the concept

'organic drivenness' (Kahn & Cohen, 1934). Bradley (1937) reported clinical efficacy of CNS stimulants in hyperactive children a few years later.

The concept of minimal brain dysfunction (MBD) was used for many years to describe children with hyperactivity and attention problems. However, this concept was used differently both between and within countries, thus making comparison of research reports problematic and clinical evaluations different. Accordingly, the MBD concept has been abandoned in clinical practice and research, whereas Attention Deficit Hyperactivity Disorder (ADHD) has become the internationally accepted term and diagnosis for the group of children described as MBD or hyperactive in older publications (APA, 1994).

Hyperactivity is regarded as a predominant symptom in ADHD children, but the relative importance of this symptom has been discussed extensively over the years. In *The Diagnostic and Statistical Manual-III* of The American Psychiatric Association (DSM-III), the syndrome was subdivided into attention deficit disorder with or without hyperactivity. The DSM-III revision broke this down into ADHD only, thus demanding that hyperactivity should be present in order to diagnose ADHD. In the DSM-IV (APA, 1994), the sub-division reappeared (predominantly inattentive, predominantly hyperactive or both). It is important to underscore that hyperactive behaviour also occurs as part of other clinical syndromes than the typical ADHD syndrome and therefore must be excluded through differential clinical evaluation. It is equally important to be aware of the high proportion of co-morbidity between ADHD and other developmental disorder such as learning disabilities (Ghelani *et al.*, 2004) and developmental coordination disorder (DCD) (Kaplan *et al.*, 1998; Kadesj & Gillberg, 2003).

Hyperactive children diagnosed as ADHD in present clinical practice seldomly present a history of encephalitis or other CNS diseases. Genetic factors have been found to play a central role in the syndrome (Swanson & Castellanos, 2002), as well as prenatal factors. Reported findings from multiple methods of brain imaging suggest that specific abnormalities may be associated with ADHD. These abnormalities seem to affect neural networks related to attention, information processing, alerting, orienting, working memory and executive functions (Swanson & Castellanos, 2002). There are, however, no biological diagnostic markers of ADHD. The diagnosis is based on behavioural characteristics only. Hyperactivity has been vividly described in a large number of publications and textbooks. The DSM-IV requires that a minimum of 6 out of 9 symptoms of hyperactivity-impulsivity have persisted for more than 6 months, and to a degree that is maladaptive and inconsistent with developmental level. In addition, at least 6 out of 9 symptoms of inattention are required.

The hyperactivity symptoms include behaviours such as fidgeting, leaving the classroom seat when inappropriate, running about or climbing in situations where this is inappropriate, difficulties in playing quietly, often 'on the go' as if 'driven by a motor', excessive talking, blurting out answers before questions are completed, difficulties in awaiting turn and interrupting or intruding on others. When evaluating behaviours like these, it is of crucial importance to take into account the chronological and mental age level of the child (APA, 1994). The clinician must therefore be trained both in normal developmental psychology as well as psychopathology. The incidence of ADHD has ranged considerably

between epidemiological studies, depending on diagnostic criteria employed, but international consensus seems to place it between 3 and 5% in school-aged children when the DSM-IV criteria are employed (Barkley, 1998). The picture becomes far more complicated when 'pure' Attention Deficit Disorder (ADD) is added and it may be argued that clinical and diagnostic criteria and procedures regarding ADD, with no hyperactivity, are in need of further thorough clinical research. As it is now, the question of ADD is often raised in children, adolescents and adults where other psychopathology is obvious. This is, however, not the topic of the present chapter.

An extensive evaluation is required with regard to ADHD. The evaluation should comprise clinical observation, paediatric neurological and psychiatric examination, neuropsychological assessment, motor coordination evaluation and personality testing, in order to sort out the individual problem profile in ADHD. In cases where the referred child does not meet the criteria for ADHD, this extensive and multi-disciplinary evaluation usually provides sufficient information to arrive at alternative diagnoses and treatment planning. Important differential diagnoses are mental retardation, anxiety disorders, depression, coping failure, Tourette's syndrome, psychopathology and side effects of medication. A number of rating scales and observation guides are available for ADHD (e.g. Barkley, 1998).

Co-morbidity may be the rule rather than the exception in children with ADHD. Up to 44% of ADHD children may have at least one other psychiatric disorder, 32% two others and 11% at least three (Barkley, 1998). Psychiatric co-morbidities in question are oppositional and defiant behaviour, aggressiveness, conduct disorder, anxiety and mood disorders. There is also a well established co-morbidity between ADHD and DCD (Harvey & Reid, 2003; Kadesj & Gillberg, 2003; Kaplan *et al.*, 1998). For this reason it is important that all children assessed for possible ADHD also are assessed with regard to motor coordination difficulties. The motor coordination problems in question should be assessed using standardized and norm-based methods, such as the Movement-ABC test (Henderson & Sugden, 1992). Children who are found to have such problems may show significant and long-lasting improvement after high-dosage, task-specific motor training (Iversen *et al.*, in press). There is also co-morbidity between ADHD and reading/writing problems. Such problems will, however, normally be identified by the school system and are not further discussed here.

The clinical efficacy of CNS stimulant treatment, such as methylphenidate, in children with ADHD is indisputable. In spite of this well established fact, this type of intervention is repeatedly and at times heavily debated. Ignorance about the pharmacological and clinical effects of the medication is one reason for this, and less than optimal diagnostic procedures leading to incorrect treatment another. However, we advocate that other treatment procedures are tried out before medication is considered. The reasons for this go back to the co-morbidities, particularly the defiant and conduct dimensions. One useful approach is to use behaviour modification programmes as the first step in ADHD children with such co-morbidities in order to see how many ADHD problems 'are left' after such intervention (see 'Behaviour therapy'). There are a number of studies of the efficacy of behaviour modification procedures in ADHD. Hinshaw *et al.* (2002) present a discussion of findings from such studies and conclude that multimodal treatment, combining intensive behavioural intervention with well delivered

pharmacological agents, typically ranks better than either treatment component alone. A similar discussion regarding the treatment of adolescents with ADHD, for which there is far less research data, has been presented by Barkley (2004). Central stimulants can contribute by facilitating effects of behavioural modification procedures, but there is always a risk of state dependent learning. Learning that took place on medication may deteriorate when medication is withdrawn. In any case, we advise against pure pharmacological treatment.

The question of prognosis in ADHD is controversial. Until the late 1980s, ADHD was generally considered a childhood disorder that was typically outgrown by adolescence and always by adulthood.

A number of studies have shown that this is not the case. It has been demonstrated that from 50% to 80% continue to experience significant ADHD symptoms into their adult lives (Murphy & Gordon, 1998). Although many cope with this, there is reason to believe that the symptoms may cause self-medication, problems holding a job, marital distress, juvenile delinquency and adult criminality. In addition, co-morbidities such as mood disturbances are also present in adult ADHD. There is reason to believe that there is a significant proportion of untreated ADHD among adult substance abusers and criminals. Thus, early intervention and proper treatment is of great importance in order to prevent such developments.

Hypertension

Katherine Joeques and Sandra N. Boersma

Leiden University

The term ‘essential hypertension’ is used when there is no clear identified medical reason for raised blood pressure. Blood pressure (BP) is determined by cardiac output (i.e. blood ejected by the left ventricle of the heart), peripheral resistance (i.e. force against which

blood moves during circulation) and blood volume. An increase in one of these factors will give rise to increased BP if the other influences remain constant. Systolic blood pressure (SBP) is associated with contraction of the heart, whilst diastolic blood pressure (DBP)

refers to the force between contractions. Most experts agree on the definition of hypertension, i.e. above 140 mm Hg SBP and/or above 90 mm Hg DBP. Hypertension is a known risk factor for stroke and other cardiovascular events, as well as end-stage renal disease (see Coronary heart disease chapters and 'Stroke'). In the western world approximately 20% of middle-aged adults suffer from hypertension, with higher prevalence in the elderly (80% of >65-year-old group) and in Afro-Caribbeans (50% in middle age). Hypertension is asymptomatic, and therefore often remains undetected and untreated. In the UK, the state-run health service spent around £840 million (\$1.5 billion) in 2001 on prescriptions for antihypertensive drugs, nearly 15% of the total annual cost of all primary care drugs (NoEHGDG, 2004). Certain psychological and behavioural factors have long been associated with the aetiology of hypertension. In fact, only 30%–60% of the variation in essential hypertension in the population can be accounted for by genetic factors (Levy *et al.*, 2000). In addition to pharmacotherapy, psychological and behavioural interventions tend to be aimed at prevention or aiding reduction of existing hypertension.

Aetiology of hypertension

Physiological mechanisms have been proposed linking psychological factors with long term BP regulation. The mechanisms are thought to involve a complex interaction between central and sympathetic nervous system activity and neurohormonal regulation. One of the models that has received much attention in recent decades focuses on cardiovascular reactivity to stress (Lovallo & Gerin, 2003). It has long been recognized, both from animal and human research, that acute stress provokes raised BP (Obrist, 1981). Studies of laboratory stressors (reviewed by Treiber *et al.*, 2003) supply reasonable evidence that cardiovascular reactivity to stress can predict increased risk for the development of hypertension. Care should be taken not to simply extrapolate findings from laboratory studies to 'real life' stressors. One area of research that has tried to overcome this shortcoming has focused on occupational stress. For example, Ming and colleagues (2004) followed air traffic controllers for a period of 20 years, and identified that increased BP reactivity in response to job stress was associated with long term risk of hypertension, after controlling for age, body mass index and baseline BP readings. It remains unclear, however, to what extent moderating or confounding variables (e.g. age, gender, pre-existing disease, health behaviours or genetic characteristics) play a role (see 'Stress and health'). These findings, combined with the fact that descendants of hypertensives tend to show greater cardiovascular reactivity to stress than children whose parents do not suffer from hypertension (Fredrikson & Matthews, 1990), intimate that cardiovascular reactivity is partly genetically determined. This would mean that prolonged stress is only a risk factor for hypertension for those people who are predisposed to respond with greater cardiovascular reactivity. The availability of ambulatory BP monitors has provided further insight into the relationship between 'real life' job stress and elevated BP which may result in long term hypertension (Schnall *et al.*, 1998).

Psychological factors other than stress have also been linked with hypertension. In a quantitative review of 15 prospective studies,

Rutledge and Hogan (2002) found moderate support that psychological factors such as anger, anxiety and depression predicted hypertension development in the long term. Although these authors are critical of the various measures used to assess psychological factors and BP, they conclude that these overall findings have clinical relevance. Schum and colleagues (2003) identified similar findings regarding a positive relationship between trait anger and raised ambulatory BP in a meta-analysis. It is not immediately obvious how these studies relate to the findings cited above with respect to cardiovascular reactivity to stress. An underlying mechanism has been suggested, namely perseverative cognition, such as rumination and worry. This would be responsible for prolonged duration of cardiovascular reactivity to a discrete stressor, as well as for the psychophysiological activation associated with negative emotional states, including anger, anxiety and depression (Brosschot & Thayer, 2004) (see also 'Hostility, Type A behaviour and coronary heart disease'). Further to the psychological factors, issues related to behaviours such as diet, obesity, exercise habits, and alcohol abuse have shown stronger links with development of hypertension (Shapiro & Goldstein, 1982). It is likely that physiological, psychological and lifestyle factors operate interactively rather than independently to promote hypertension.

Assessment

Within both clinical and research settings the use of ambulatory or home BP monitoring is now recommended for the assessment of sustained hypertension, in favour of solely clinic based measures. These methods deal with the common 'white-coat' hypertension phenomenon, which is the presence of BP values higher than normal when measured by a physician in the medical environment (Celis & Fagard, 2004).

Psychological and behavioural interventions aimed at prevention and reduction of hypertension

Psychological or behavioural components have been added to interventions aimed at the prevention or reduction of hypertension through enhancing adherence to anti-hypertensive medication, reducing stress or encouraging health behaviour change.

The main treatment for hypertension consists of pharmacotherapy. However, Benson and Britten (2004) found that four in five people had reservations about taking antihypertensive medication, and nearly one in five suffered adverse side effects. These findings, in combination with the asymptomatic character and lifelong nature of hypertension, may explain the high levels of non-adherence with antihypertensive medication. Adherence (also called compliance) is estimated to be around 50%, which has serious implications for BP control (Kroesel-Wood *et al.*, 2004) (see also 'Adherence to treatment'). In a review of 58 different interventions aimed at enhancing adherence, explored in randomized controlled trials, Schroeder and colleagues (2004) identified that interventions which contain motivational or behavioural components show promising, albeit modest, results. Further to this, interventions related to hypertension can be aimed either at changing health behaviour or stress management. Considering the role of stress in the development of hypertension,

there were high hopes for stress-reducing interventions in the 1970s, including meditation, relaxation, biofeedback and cognitive-behavioural therapies (see 'Biofeedback', 'Cognitive behaviour therapy' and 'Relaxation training'). On reviewing such interventions, however, they have generally not been effective in the management of high blood pressure (Dubbart, 1995; Blumenthal, 2002), although an individualized stress management programme has shown more promising results (see Blumenthal, 2002). Although it is suggested that stress management might usefully supplement other behavioural interventions (e.g. aiding behaviour modification such as smoking cessation), it is no longer seen as a viable single approach to reducing BP.

Being overweight, high-sodium diets and alcohol abuse are known risk factors for the development of hypertension, and to a lesser degree lack of exercise and smoking (No EHGDG, 2004). All these behaviours are susceptible to change, and have been the targets of simple or complex interventions. When reviewing these behavioural factor individually, the benefits of weight loss on BP reduction are most clear cut, with reductions of 7–10 mmHg SBP and 6–7 mmHg DBP following weight loss of around 8–10 kg in both normotensive and hypertensive individuals who are overweight, whilst sodium reduction and increased exercise show smaller effects (Blumenthal *et al.*, 2002). Behaviour change interventions will implicitly make use of psychotherapeutic strategies. Explicit use of such strategies in behaviour change interventions has also been examined. In a review of patient-centred behavioural interventions, Boulware and colleagues (2001) located 15 studies which offered,

in addition to the usual pharmacotherapy, either self-monitoring of BP, counselling or structured training courses. The latter two generally focused on multidimensional lifestyle changes (i.e. weight loss, healthy diet, exercise and tobacco cessation). They conclude that adding counselling to usual care produced additional reductions of 5–6 mmHg in both SBP and DBP. Although the mechanisms for this improvement are not immediately obvious (did the intervention improve health behaviours, or did it improve adherence to medication, patient awareness, regular check-ups?) this review does suggest the potential benefits of such behavioural interventions. A recent randomized controlled trial aimed at achieving behaviour modification in a healthy population with above optimal BP (including borderline hypertensives) consisted of a combination of counselling and behavioural strategies without pharmacotherapy. They found promising results, with improvements in health behaviours and associated reduction in BP after six months, and 30–35% of the participants returning to optimal BP levels (Writing Group of the Premier Collaborative Research Group, 2003).

It can be concluded that behaviour-related lifestyle factors, in particular being overweight, lead to hypertension. Furthermore, individuals who respond to prolonged stress with greater cardiovascular reactivity are also at risk of suffering from elevated BP. Psychological and behavioural interventions aimed at preventing or reducing hypertension may primarily strive towards increasing adherence with antihypertensive medication and facilitating healthy lifestyle.

Hyperthyroidism

Nicoletta Sonino¹ and Giovanni A. Fava²

¹University of Padova

²University of Bologna

The term 'hyperthyroidism' refers to disorders which result from overproduction of hormone by the thyroid gland. The term 'thyrotoxicosis' is broader and denotes the clinical, physiological and biochemical findings that occur when the tissues are exposed to, and respond to excess thyroid hormone, thyroxine (T₄) and triiodothyroxine (T₃), not necessarily originating from the thyroid gland. Common symptoms include nervousness, sleep disturbances, tremors, frequent bowel movements, excessive sweating and heat intolerance. Weight loss is usual despite a normal appetite and food intake. Graves' disease, also known as Basedow's disease, is the most common form of hyperthyroidism in patients younger than 40 years. It is a disorder which has a complex pathogenesis (with involvement of autoimmune factors) and is characterized by these major manifestations: thyrotoxicosis associated with diffuse goitre, ophthalmopathy and dermopathy. Other relatively common forms include toxic adenoma, toxic multinodular goitre and subacute thyroiditis.

A large body of literature on psychosocial aspects of hyperthyroidism is available

Life events

The notion that stressful life events may be followed by hyperthyroidism has been a common clinical observation. Bram (1927) reviewed 3343 cases of exophthalmic goitre. In 85% of cases he detected 'a clear history of psychic traumas as the exciting cause of the disease'. Several retrospective controlled studies (Winsa *et al.*, 1991; Sonino *et al.*, 1993a; Kung, 1995; Radosavljevic *et al.*, 1996; Yoshihuchi *et al.*, 1998; Matos-Santos *et al.*, 2001) have substantiated these clinical observations. All these studies used valid and reliable methods for life events collection. In controlled studies, stressful life events have been found to be significantly more frequent in the year preceding the onset of Graves' disease than in controls

and patients with non autoimmune thyrotoxicosis (toxic nodular goitre). Daily hassles were also associated with hyperthyroidism and were found to affect the short-term outcome of anti-thyroid drug therapy (Yoshihuchi *et al.*, 1998) (see also 'Life events and health'). Stress may affect the regulatory mechanism of immune function in a number of ways (see 'Psychoneuroimmunology'). Within the complex pathogenesis of autoimmune thyroid hyperfunction, these studies emphasize the role of emotional stress.

Psychological disturbances

Hyperthyroidism is commonly associated with depression, anxiety and irritability. Major depression is a common complication. It was reported to occur in about a quarter of patients with untreated Graves' disease (Kathol & Delahun, 1986; Sonino *et al.*, 1993b). Psychomotor agitation, weight loss and insomnia were found to be common symptoms (Demet *et al.*, 2002). The association between hyperthyroidism and bipolar disorder (with occurrences of mania) has been also described (Nath & Sagar, 2001). Anxiety disorders (and particularly panic attacks) are another common manifestation of hyperthyroidism (Kathol & Delahun, 1986).

A survey study of neuropsychiatric complaints of patients with Graves' disease (Stern *et al.*, 1996) found that irritability was the most frequent symptom, occurring in nearly 80% of patients. Anti-thyroid treatment leads to a significant improvement in depressive and anxiety symptoms in most patients (Kathol *et al.*, 1986). Affective disturbances may be precipitated by hyperthyroidism but may also antedate its clinical manifestations or predispose to its onset.

Quality of life

Functional capacity (the ability to perform daily life activities, social interactions, intellectual and cognitive function and economic

status), perceptions (levels of wellbeing and illness attitudes) and effects of symptoms of disease (with resulting general impairment, which are often subsumed under the rubric of quality of life) have become the focus of increased attention in hyperthyroidism (see also 'Quality of life'). Psychiatric symptoms (and particularly depression) may considerably affect quality of life and influence how the endocrine disease process is experienced. However, psychological wellbeing is not simply a lack of distress, and a compromised quality of life may occur also when significant psychopathology does not occur (Sonino & Fava, 1998). Graves' ophthalmopathy has attracted particular attention as a source of compromised quality of life in patients with hyperthyroidism (Terwee *et al.*, 1998).

Psychological symptoms following treatment

An improvement in psychological disturbances and quality of life frequently occurs with successful endocrine treatment. However, this is not always the case. In a recent study (Sonino *et al.*, 2004), a sample of patients with remitted endocrine disease (including hyperthyroidism) was found to present high prevalence

of psychological distress. Quality of life may thus also be compromised when the patient is apparently doing well from a hormonal viewpoint. Indeed, long-term residual complaints and psychosocial sequelae were found to be common after remission of hyperthyroidism (Fahrenfert *et al.*, 2000). Over one-third of patients with a full-time job were unable to resume the same work after treatment.

Clinical implications

Many patients with hyperthyroidism are in need of psychological support. Patients have become more aware of these issues. Their difficulties in coping with thyroid disease have led to the development of several patients' associations (Wood, 1998). Normalization of thyroid hormones values does not always result in re-establishment of a satisfactory quality of life.

Psychological help appears to be particularly important after endocrine treatment has been provided, to facilitate changes of lifestyle and maladaptive attitudes which may hinder recovery.

Hyperventilation

David K.B. Nias

University of London

Hyperventilation is over-breathing or breathing in excess of metabolic requirements. It usually involves rapid high thoracic rather than diaphragmatic breathing. Typically it occurs during an asthma attack or when a predisposed person is feeling anxious or in a state of shock such as following surgery or severe injury (see also 'Asthma'). From a clinical perspective it is important to distinguish between acute or transient over-breathing and chronic or persistent hyperventilation. It is the latter type that has generated a lot of interest especially in connection with anxiety disorders. Controversially the chronic form has even been given the status of a syndrome, namely hyperventilation syndrome or HVS. Attempts have been made to attribute it as a cause of various disorders and panic disorder in particular. Clinical accounts, together with proposed treatments, have appeared for more than 100 years. This history provides a good example of the interaction of physical (e.g. asthma) and mental (e.g. anxiety) factors and the inherent difficulty of differentiating between cause and effect.

Over-breathing occurs as part of the classic 'fight or flight' response as the body involuntarily prepares for action (see 'Stress and health'). Such breathing soon removes sufficient carbon dioxide from the lungs to lead to a significant fall in the blood level of carbon dioxide, a state known as 'hypocapnia'. There is also a loss of carbonic acid that leads to buffer depletion as the body compensates. These changes set in train a number of somatic sensations that typically are misinterpreted by the patient as serious, such as sudden chest pain. Paradoxically there is also a sense of breathlessness that, combined with the resulting emotional arousal, leads to more over-breathing and so the symptoms tend to continue (Barlow, 2002).

Historical perspective

The immediate or acute effects of over-breathing were demonstrated to the Physiological Society in 1908, when selected members of the audience were asked to deliberately over-breathe. Many and varied symptoms (such as muscle spasm) soon became dramatically apparent. It was recorded that 'even observers became distressed'. A good example of the possible relevance of psychological factors in aetiology was highlighted in a widely publicized account of an over-breathing epidemic in a girl's school in the 1960s. Following a three-hour school parade in which some girls had actually fainted, many complained the next day of 'feeling dizzy and peculiar'. By the afternoon, 85 girls had been taken to hospital and the school closed; a similar pattern occurred as soon as the school was reopened. Physical examinations at the hospital were essentially negative, and detective work at the school ruled out food poisoning and leaking gas. Conversion hysteria was considered because of altered sensations in the limbs (e.g. pins and needles), but in the end it was

claimed that hyperventilation was to blame (Moss & McEvedy, 1966).

Because of the 'downward spiral' mechanism of anxiety, over-breathing, somatic symptoms and then more anxiety, chronic over-breathing has been proposed as having aetiological significance in the development of both physical and psychological disorders. Links with physical disorders have ranged from heart disease to spontaneous pneumothorax (collapsed lung). Links with exhaustion and 'battle fatigue' were made during World War I. Similarly it has been linked with many psychosomatic conditions such as hypochondriasis, conversion disorder (somatization type) and chronic fatigue syndrome (see 'Psychosomatics' and 'Chronic fatigue syndrome'). Most research has been directed at the link with panic disorder, a condition often associated with rapid breathing. However, although over-breathing can worsen or even bring on symptoms, it is now regarded more as a reaction to or a symptom of an underlying physical or psychogenic condition. Even if it is not a fundamental cause of other disorders, what is becoming apparent is that treatment for hyperventilation can help as part of a broader programme for other disorders generally.

Symptoms and diagnosis

Patients who habitually over-breathe complain of a variety of symptoms and are often referred for numerous tests before an experienced clinician recognizes the abnormal breathing. Instead of obvious signs such as rapid breathing it is more subtle respiratory signs, such as yawning, that are characteristic of habitual over-breathing. Neurological signs include dizziness and headache; gastrointestinal signs include dry throat and acid regurgitation; musculoskeletal signs include tension and weakness; and cardiovascular signs include palpitations and chest pain. The latter naturally are often of extreme concern to patients. Psychological symptoms include anxiety, anger and associated problems such as sleep loss and fatigue, all of which can in turn lead to a worsening of symptoms (Lum, 1987).

Although acute attacks may be obvious, chronic hyperventilation is difficult to diagnose and its prevalence is unknown with estimates ranging up to a quarter of patients who have been tested for this chronic form of the condition. It is particularly common in patients with panic and other anxiety disorders. Hyperventilation often comes to light only after extensive testing for other symptoms that patients typically present with such as fatigue or chest pain. Acute over-breathing, as may occur in a panic attack, is usually obvious when the characteristic rapid breathing is accompanied by the symptoms of hypocapnia. Chronic hyperventilation, as may occur in patients who present with a variety of symptoms, is much harder

to diagnose. Because of their various somatic complaints, patients may be referred to different specialists before attempts are made to test for hyperventilation. Although a variety of breathing tests can be given, including vital capacity, there is no critical diagnostic test in spite of many attempts to find one.

Because of buffer depletion, people who chronically hyperventilate find it difficult to hold their breath and so one test is 'breath holding time'. Such people are found able to hold their breath comfortably for only a few seconds. Another is the 'voluntary' or 'hyperventilation provocation test' in which people are asked to over-breathe and then to rate any symptoms experienced. At the same time, levels of blood carbon dioxide can be measured by the non-invasive technique of a rapid infrared carbon dioxide analyser. A variation is the 'imagery' or 'think' test in which people are asked to recall episodes of emotional arousal (e.g. anger) while testing for hypocapnia. Similarly, an exercise test in the form of a cycle ergometer is used to test how soon hypocapnia develops following leg ache. However, when rigorously researched these various tests, whether conducted in response or at rest, give inconclusive and unreliable results (Lindsay *et al.*, 1991).

In a double-blind trial of the 'hyperventilation provocation test', patients with suspected hyperventilation tended to recognize their symptoms during both this test and during a placebo condition in which carbon dioxide levels were maintained by manual titration. A sub-group of patients also underwent ambulatory monitoring and was found to over-breathe after rather than before spontaneous symptom attacks (Hornsveld, *et al.*, 1996). This latter finding, in particular, was put forward as casting doubt on the validity of hyperventilation as a syndrome. Instead it provides evidence that hyperventilation is a consequence rather than a cause of anxiety and related disorders.

Treatment

One of the simplest and best known techniques for sudden attacks of over-breathing is the 'paper bag' method. Using a paper bag, patients are instructed to re-breathe the air they have just breathed out. By taking in less oxygen this helps to restore their blood level of carbon dioxide. When there is also a reduction in their symptoms,

patients can be reassured that their symptoms are associated with (if not caused by) over-breathing and not something more sinister. However, carbon dioxide levels may increase too quickly causing problems and so this method is not recommended for general use. Also while it can work for acute attacks (it also helps for hiccups), it is of limited use in chronic cases. Controlled trials for the paper bag method, and indeed other techniques, aimed at correcting habitual breathing patterns have been disappointing with little more than a placebo effect being apparent (Garssen *et al.*, 1992). This is consistent with hyperventilation being a manifestation, albeit a complex one, of an underlying disorder rather than a syndrome in its own right.

More advanced techniques have been researched with the finding that a combination of methods works best. For example, medication (e.g. beta-blockers) is often prescribed in combination with relaxation training (e.g. autogenic training or yoga, see 'Relaxation training'). Even better is to combine such methods with *in vivo* exposure to the circumstances that lead to over-breathing. Graded desensitization to the events that typically trigger over-breathing for that individual seem to help. Similarly, in another study patients with panic disorder experienced how their symptoms could be created or made worse by deliberately over-breathing. They were then encouraged to re-attribute the cause of these symptoms using a cognitive therapy approach (Clark *et al.*, 1985) (see 'Cognitive behaviour therapy'). Applications of the biofeedback method, such as how to recognize tension and over-breathing, have also been developed with promising results (Meuret, Wilhelm & Roth, 2004) (see 'Biofeedback'). Finally because slow breathing is better than rapid, exercises to develop slow diaphragmatic breathing are a useful part of an overall treatment programme.

Interest in this topic has helped in our understanding of how mental and physical factors interact. Research has helped to improve the management of acute attacks of over-breathing, such as in cases of severe shock or head injury (Diringer, 2002). For chronic cases of hyperventilation, it is apparent that treatment should focus on the underlying cause (what is causing the over-breathing in the first place) as well as on other symptoms (such as anxiety). Training in how to develop normal breathing patterns is then more likely to help.

Hysterectomy

Susan Ayers

University of Sussex

Introduction

Hysterectomy is the most common major gynaecological operation in the UK and the USA. Prevalence rates vary in different countries and range from 8% in France, 10% in the UK and 22% in Australia to approximately one-third of women in the Netherlands and the USA. Hysterectomies are usually carried out for benign conditions, such as abnormal menstrual bleeding, fibroids and endometriosis and are therefore elective operations. In the USA, for example, approximately 90% of hysterectomies are elective operations. However, approximately 10% of hysterectomies are carried out for malignant conditions such as cancer of the cervix or uterus (see 'Cancer: gynaecological').

There are three main types of hysterectomy: a subtotal hysterectomy, in which only the uterus is removed; a total hysterectomy, in which both the uterus and the cervix are removed; and a radical hysterectomy, in which the uterus, cervix, surrounding tissue, upper vagina and sometimes the pelvic lymph nodes are removed. Radical hysterectomies are usually only done in extreme circumstances such as cancer of the uterus or cervix. In addition, some women will have their fallopian tubes and ovaries removed at the same time, which initiates menopause. In these cases women have to decide about whether or not to use hormone replacement therapy (see 'Hormone replacement therapy'). Currently, the most common hysterectomy carried out is the total hysterectomy, which is thought to be preferable for benign conditions because it avoids later complications with the cervix such as cervical cancer. However, recent evidence suggests that total hysterectomies are associated with more physical complications, a longer recovery time and poorer sexual functioning compared to subtotal hysterectomies, although this remains contentious (Thakar *et al.*, 2002).

Preparation for hysterectomy

Hysterectomy is a major operation and, as such, women are likely to be anxious and benefit from psychological preparation, which can improve postoperative recovery (see 'Stressful medical procedures' and 'Surgery'). Research looking more specifically at preparation for gynaecological procedures indicates that women judge procedural information to be most important but prefer a combination of procedural, sensory, coping and reassuring information (Wallace, 1984).

Psychosocial impact of hysterectomy

In common with many other medical procedures, the psychosocial impact of hysterectomy often bears little relationship with the

medical assessment of the severity of the symptoms which warranted the hysterectomy. A number of explanations for the impact of hysterectomy on women have been put forward and focus on different contributory factors. For example, biological explanations emphasize the role of hormonal changes or disruption to pelvic anatomy. Psychodynamic explanations emphasize the symbolic role of the womb in women's self-concept. Cognitive-behavioural approaches emphasize the role of information, anxiety, stress and illness behaviour. These different explanations are not necessarily conflicting and may be more or less important in individual cases. However, they have obvious implications for intervention, which will be discussed.

Research into the experience and psychosocial impact of hysterectomy has looked at a range of outcomes; primarily physical recovery, mood, psychiatric disorder, sexual function and quality of life. There are many inconsistent findings, which can be attributed to methodological differences. Early cross-sectional, or retrospective, research found that hysterectomy was associated with sexual problems, emotional problems and decreased quality of life. For example, early research looking at mood and psychiatric disturbances established that a higher proportion of women who have had a hysterectomy suffer from mood disturbances or psychiatric disorders compared with women of a similar age in the general population (Richards, 1974). However, later prospective studies showed that these problems are present in women before hysterectomy and that, following hysterectomy, there is either an improvement or no change in psychological wellbeing (Khastgir *et al.*, 2000). The outcome of hysterectomy therefore needs to be placed in the context of the symptoms that precede it, as well as individual, interpersonal and social factors both before and after hysterectomy. This is consistent with the diathesis-stress approach to life events and illness (see 'Stress and health'). This makes the outcome of hysterectomy difficult to examine in practice, as it requires large prospective studies of women with gynaecological problems in order to measure a wide range of clinical and psychosocial factors. A few well designed prospective trials have been carried out in the last two decades and this chapter briefly summarizes findings from some of these trials with reference to mood, quality of life and sexual functioning.

As previously mentioned, women with symptoms which warrant hysterectomy already have a higher prevalence of mood disorders than comparative norms. The most common mood disorder is depression with up to a third of women having clinical depression before the hysterectomy. For example, a prospective study of 1101 women in the USA found that 28% of women who undergo hysterectomy are depressed before the operation (Rhodes *et al.*, 1999). The prevalence of clinical depression after hysterectomy varies

widely in different research studies. However, there is evidence to suggest that over a half of women with psychiatric morbidity before hysterectomy no longer fulfil criteria for psychiatric disorder after hysterectomy (Gath *et al.*, 1995). Despite the recovery of a substantial proportion of women, depression prior to hysterectomy is associated with poorer outcomes in terms of physical symptoms (e.g. pain), quality of life (e.g. activity limitation, social functioning) and sexual functioning (see 'Sexual dysfunction' and 'Quality of life'). For example, Hartmann *et al.* (2004) found that women with preoperative depression were three to five times more likely to have impaired quality of life, physical functioning, mental health and social functioning two years after the hysterectomy.

Studies of quality of life following hysterectomy find a similar pattern to the effect of hysterectomy on mood. Quality of life is generally improved after hysterectomy compared with preoperation levels (Hartmann *et al.*, 2004), but remains poorer than population norms for women of a similar age group (Thakar *et al.*, 2004).

The impact of hysterectomy on sexual function has been increasingly studied in recent decades, with inconsistent results. This is unsurprising when it is considered that sexual function is also associated with age, ethnicity, mental health, relationship problems and a range of socioeconomic conditions (Laumann *et al.*, 1999). Reviews of research into sexual function after hysterectomy have concluded there is either no change or an improvement in frequency and quality of sexual function for the majority of women after hysterectomy (Farrell & Kieser, 2000; Katz 2002; Maas, Weijnenborg & ter Kuile, 2003). Individual studies suggest that sexual function after hysterectomy is predicted by sexual functioning before the operation (Rhodes *et al.*, 1999), emotional wellbeing and relationship with partner (Bancroft *et al.*, 2003). Physical aspects of sexual function, such as arousal, vaginal lubrication and orgasm are poor predictors of sexual functioning post-hysterectomy.

Intervention

When looking at psychosocial interventions for hysterectomy there are a number of issues that need to be considered, such as what type of intervention is most appropriate, when should it be applied (pre- or post-operatively), efficacy and effectiveness. The type of intervention provided is partly dependent upon the explanation one adopts

for the psychosocial outcome of hysterectomy. For example, if a biological explanation is adopted then HRT may be the preferred form of intervention (see 'Hormone replacement therapy'). If a cognitive-behavioural explanation is adopted then the intervention may comprise of information provision, techniques to reduce anxiety or increase adaptive coping strategies (see 'Cognitive behaviour therapy').

There is, however, little research on the provision of psychological intervention specifically for women with hysterectomy. Research that has been done tends to focus on the provision of preoperative information and coping techniques, which are usually found to have a positive effect on outcome. For example, Miro and Raich (1999) carried out a controlled trial of the provision of relaxation techniques preoperatively and found this was associated with less reported pain after surgery and with more activity three weeks after surgery compared with controls. The chapter on 'Surgery' gives more information on psychological preparation for surgery in non-specific surgical groups. As yet, little research has looked at provision of psychotherapy to women before or after hysterectomy, despite the higher than usual prevalence of psychiatric morbidity in women at these times. Some researchers have suggested that psychotherapy before hysterectomy could serve as a 'clinical filter' to identify patients for whom psychotherapy may be more useful than hysterectomy (Kincey & McFarlane, 1984). In addition, it seems likely that psychotherapy could be a useful adjunctive therapy for women undergoing hysterectomy who have psychiatric morbidity.

Conclusion

Women undergoing hysterectomy have increased psychiatric morbidity, decreased quality of life and poorer sexual function than women of a similar age in the population. Prospective studies have now established that after hysterectomy mood, quality of life and sexual function improve for the majority of women although levels still remain worse than norms. Intervention studies have concentrated on provision of information and coping techniques preoperatively, with largely beneficial results. Psychotherapy interventions have not been examined but may be useful in cases of psychiatric morbidity.

Immunization

Roger Booth

The University of Auckland

Overview

Immunization is designed to stimulate immune responses against antigens of infectious agents (e.g. bacteria or viruses) and generate specific immunological memory such that successfully immunized individuals, when exposed to the infectious agent later in life, will respond with protective immunity. When this response was first being elucidated, the cellular and molecular interactions involving T and B lymphocytes (main cells of the immune system), antibodies (antigen-specific effector molecules) and cytokines (immune regulatory hormones) were thought to operate virtually autonomously within the body, influenced predominantly by the internal state of the immune network and the characteristics of antigens (foreign shapes derived from infectious agents). However, individual differences in susceptibility to infection and effectiveness of immunity following vaccination, led to exploration of non-physiological factors.

Research using laboratory animals demonstrated that 'lifestyle' factors such as overcrowding (Edwards & Dean, 1977) and exposure to physically stressful conditions (Sheridan, 1998) reduced immune responses to immunization often to the point that the animals become susceptible to infection. Such studies extended into the human arena have confirmed that many aspects of human psychology affect immune responses to vaccination and should be considered as significant factors in vaccine effectiveness.

Research evidence

Stress and immunization

When healthy women were immunized with a novel antigen, keyhole limpet haemocyanin (KLH), those reporting more

stressful events had lower baseline and post-immunization lymphocyte proliferation (Snyder *et al.*, 1993) and anti-KLH antibody levels in their blood, while those reporting more social support had higher responses (Snyder *et al.*, 1990; Snyder *et al.*, 1993). In medical students immunized with KLH either at the time of an important examination or during examination-free term-time, the likelihood of developing delayed-type hypersensitivity (DTH) skin responses to KLH was reduced in the more distressed subjects independently of behavioural and demographic variables, but anti-KLH antibodies and the proliferation of KLH-specific T lymphocytes in culture were not related to levels of distress suggesting that, in this model, cellular rather than humoral immune responses appear susceptible to the influence of distress (Smith *et al.*, 2004).

Other research, has focused on clinically relevant vaccines. For example, hepatitis B vaccines administered to medical students at examination time yielded poorest responses in those students who were the most stressed and anxious, while those reporting greater social support demonstrated stronger vaccine-specific responses (Glaser *et al.*, 1992). In another study, anti-hepatitis B antibody concentrations were negatively related to stress scores but not to coping styles nor to loneliness during the first two months after immunization (Jabaaij *et al.*, 1993). Such stress effects early in the generation of the response may be due, at least in part, to effects on hypothalamic–pituitary–adrenocortical activity and sympathetic nervous system activation, as variations in levels of activation of these systems in response to an acute laboratory stress test (i.e. stress reactivity) was associated with individual differences in immune response to hepatitis B vaccine (Burns *et al.*, 2002b).

Several studies have found significant associations between psychological stress and responses to influenza virus vaccination.

Elderly people caring for relatives with dementia are considered to be living under conditions of chronic stress (consistent with activation of their hypothalamic–pituitary–adrenocortical axis, as measured by salivary cortisol was elevated (Vedhara *et al.*, 1999)). When groups of such people were immunized with influenza vaccine, their resulting anti-influenza antibody responses and antigen-specific production of various cytokines were significantly lower than age-, sex- and socioeconomically-matched control groups (Kiecolt-Glaser *et al.*, 1996; Vedhara *et al.*, 1999). Kohut and colleagues (2002) found that two weeks after immunization, anti-influenza antibody concentrations were greater in exercising elderly people than in a sedentary group, and perceived stress and optimism and social activity were predictors of immune cytokine levels.

Mild levels of daily perceived stress have also been found to influence responses to influenza vaccines in healthy young adults. Five months after immunization, participants who reported significantly more life events and perceived stress had lower levels of anti-influenza antibodies and were more likely to be in the ‘vaccine failure’ category (Burns *et al.*, 2003). The timing of psychological stress relative to immunization is also important as shown by the recent work of Miller and colleagues (2004). Stress ratings on the two days before the vaccine and the day it was given were not associated with antibody response, but ten days afterward appeared to shape the long-term antibody response.

Perceived stress effects are not confined to viral vaccines, and can also affect antibody responses to bacterial vaccines against pneumococcal pneumonia (Glaser *et al.*, 2000) and meningitis (Burns *et al.*, 2002a) (see also ‘Stress and health’ and ‘Psychoneuroimmunology’).

Negative affect, anxiety and depression

There are associations among stress reactivity, trait negative affect and antibody response to hepatitis B immunization in healthy young adults (Marsland *et al.*, 2001). In a double-blind study of rubella vaccination, low concentrations of rubella antibodies following immunization were predicted by high neuroticism scores, and by low self-esteem (Morag *et al.*, 1999). As outlined in the chapter ‘Symptom perception’, because negative affect is strongly associated with symptom reporting, Diefenbach and colleagues (1996) explored the relationship between these variables and symptom experience following immunization in a group of elderly volunteers before and after three inoculations (influenza, tetanus toxoid and KLH). Negative affect was related to cross-sectional symptom reporting as expected but not to increases in symptom reporting from before to after the symptom-producing inoculation procedure. In contrast, in elderly people following influenza vaccination, those with high anxiety or depression scores were more likely to suffer from side effects (Allsup & Gosney, 2002). Because depression is associated with enhanced production of inflammatory cytokines that influence various conditions associated with ageing, Glaser and colleagues (2003) assessed the relationship between depressive symptoms and changes in inflammatory response after an influenza virus vaccination. Even modest depressive symptoms appeared to sensitize the inflammatory system in older adults and to produce amplified and

prolonged inflammatory responses after infection and other immunological challenges, which could accelerate a range of age-related diseases.

Gulf War syndrome

Following the Gulf War, many soldiers claimed to be suffering from a wide variety of incapacitating symptoms (Jamal, 1998). During the conflict these soldiers were exposed to many potentially damaging risk factors including environmental adversities and multiple vaccinations. Multiple vaccinations in themselves did not seem to be harmful, but when combined with the stresses of Gulf War deployment, appeared to be associated with adverse health outcomes (Hotopf *et al.*, 2000). Although some investigators have questioned the validity of this finding (Shaheen, 2000; Bolton *et al.*, 2001), a large cohort study of Gulf War veterans concluded that ‘consistent, specific, and credible relations, warranting further investigation, were found between health indices and two exposures, the reported number of inoculations and days handling pesticides’ (Cherry *et al.*, 2001). Pertussis was often used as an adjuvant in the vaccines administered to soldiers and this, in combination with stress or neurotoxic chemicals, may have triggered neurodegeneration through sustained induction of the inflammatory cytokines in the brain (Tournier *et al.*, 2002).

Conclusions and clinical implications

Responses to immunization are influenced by a variety of factors – the vaccine itself, vaccination procedure, capacity of the recipient to respond to the vaccine (dependent on genetic factors, sex, age and nutrition), behaviour (sleep, smoking, substance abuse, diet) – as well as stress, anxiety, depression and negative affect. In a recent critical review, Cohen and colleagues (2001) concluded that there is a relationship between psychological stress and antibody responses to immunizations in humans (convincing in the case of secondary responses but less convincing for primary responses) and that more attention needs to be paid to the kinetics of stress and antibody response and their inter-relations. Moreover, health practices did not mediate relations between stress and antibody responses, but elevated cortisol levels among stressed individuals may play a role.

Because the inhibitory impact of perceived stress on responses to immunization can be partially predicted in individuals by acute stress reactivity (i.e. stress-induced sympathetic nervous system activation) (Marsland *et al.*, 2002), the opportunity exists for interventions to diminish the effect. As an example, Klingman (1985) assessed the effectiveness of a brief preparatory cognitive-behavioural intervention in a school population undergoing mass inoculation against rubella. Girls in the intervention group reported less anxiety and exhibited more cooperative behaviour during inoculation than did those in the control group. Whether there were also significant differences between the groups in immune response to the vaccine is an intriguing question yet to be investigated. Distress during childhood immunization is a common phenomenon and may affect the immune response. Consequently, identifying factors that influence or ameliorate this distress may well

improve the efficacy of childhood immunization. Moreover, interventions, such as exercise in elderly people undergoing influenza immunization (Kohut *et al.*, 2002) may also be more generally effective by reducing perceived stress and anxiety.

Finally, although most of the research into psychological factors relating to immunization have focused on immune compromise

associated with 'negative' psychological constructs, Hayney and colleagues (2003), studying a cohort of healthy individuals, found significant positive correlations between psychological wellbeing and quality relationships and the production of key cytokines one month after influenza and hepatitis A immunizations.

Incontinence

Siobhan Hart

Colchester General Hospital

Incontinence, that is the uncontrolled voiding of urine or faeces (or both), is a common problem which, contrary to many assumptions, is not restricted to the extremes of the lifespan. Amongst children it is more common in boys (see 'Enuresis'), but at all other ages it is more prevalent in women. Widely quoted UK figures put the prevalence of urinary incontinence at about 1.6% of men and 8.5% of women in the age range 15–64 while the corresponding figures for those aged over 65 are 6.9% and 11% respectively (Thomas *et al.*, 1980). Figures from a postal survey into faecal or double (i.e. faecal and urinary) incontinence carried out by the same team (Thomas *et al.*, 1984) suggest prevalences of 4.2% and 1.7% for men and women respectively in the age range 15–64 and 10.9% and 13.3% for men and women older than 64. However, precise figures are very difficult to obtain and many cases go unreported because of shame and embarrassment (incontinence has been dubbed 'the last taboo') or because many believe that some degree of incontinence is part of the normal ageing process or the inevitable consequence of childbirth. All too many cases only come to light during the course of investigation of some other condition that requires attention. Predictably the incidence of both urinary and faecal incontinence is very much higher amongst elderly institutionalized individuals. This is hardly surprising as incontinence is one of the major factors that leads to institutionalization in this section of the population.

Apart from its obvious implications for personal hygiene and general health, the psychosocial consequences of incontinence can be devastating for victims and their families, causing much personal distress, as well as disrupting patterns of everyday living and interpersonal relationships. Recent years have seen growing interest in documenting and quantifying these psychosocial consequences. A number of incontinence specific health-related quality of life questionnaires have been developed and their psychometric properties evaluated (Naughton *et al.*, 2004, Rockwood, 2004) (see 'Quality of life' and 'Quality of life assessment').

The causes of incontinence are many and complex and include congenital abnormalities, damage to the peripheral sensory and motor neural networks and/or to the complex urino-rectal musculature brought about by disease or physical trauma. In addition, incontinence can be caused by damage to the central nervous system, either to the spinal cord or to the brain. Psychological

factors can also play a causal role, perhaps most prominently in cases of juvenile incontinence, but also indirectly in adults where emotional distress, such as following bereavement, may serve as a trigger. Psychological distress, including that generated by incontinence itself can also serve to exacerbate the situation. It follows that the first step in treatment must be a detailed investigation to determine the relevant factors and their relative importance. Only then can the most appropriate intervention be determined. This may range from surgery through pharmacological treatment to psychological and behavioural management. Most often the treatment involves a combination of approaches.

This initial investigation must include the sensitive and empathic exploration of the broader psychosocial and contextual issues to establish the meaning of incontinence for affected individuals and their families as well as helping them develop realistic expectations regarding treatment procedures and their outcomes.

Successful applications of psychological interventions have been documented in a wide variety of client groups, including those with head injury, stroke, multiple sclerosis and neurodegenerative conditions (including those which lead to cognitive impairment and dementia) as well as individuals with learning difficulties (see Smith & Smith, 1987) (see also 'Head Injury', 'Stroke' and 'Dementias'). Treatment approaches include classical and operant conditioning, pelvic floor exercises, biofeedback, anxiety management, interventions to treat depression as well as approaches aimed at wider systemic issues which might be causing or compounding incontinence and leading to excess disability.

The use of classical conditioning is exemplified by the 'bell and pad' method of treating enuresis. An alarm triggered by urine release causes awakening and constriction of the sphincter muscle. After a number of nights the interoceptive cues of bladder distension that precede urine release come to be associated with the alarm and in time will trigger waking prior to urination. Originally developed as an intervention with children it has also proved effective with other client groups (see 'Enuresis').

Many successful treatments of incontinence have incorporated operant conditioning principles whereby behaviours which are positively reinforced tend to become more frequent while those which are not are gradually extinguished. Although specific details vary

from case to case such approaches generally share common elements. Firstly, complex sequences of behaviour, such as toileting, are broken down into their component parts. Secondly, detailed observation establishes the frequencies of various behaviours as well as determining their antecedents and consequences. Thirdly, specific target behaviours are identified and reinforcement schedules used to alter their frequency. Fourthly, the efficacy of the intervention is regularly assessed and the programme adjusted as necessary. Behavioural modification programmes are very resource intensive and require high levels of commitment from patients and their families. A key element in the success of any operant programme is the consistency of reinforcement schedules; something that is not always appreciated. While there is no doubt that behaviour modification techniques can significantly improve continence, surprisingly little work has been carried out to optimize treatments, identify those who are most/least likely to benefit or evaluate how well continence is maintained in the absence of intensive input from health professionals (Burgio, 2004, Goode, 2004, Whitehead, 2004) (see 'Behaviour therapy').

Pelvic floor muscle rehabilitation focuses less on voiding habits per se and instead concentrates upon improving the strength and control of pelvic floor muscles. Originally developed as a method of treating urinary stress incontinence, it has been successfully applied to other forms of urinary incontinence and indeed to faecal incontinence.

A number of studies have incorporated biofeedback techniques as a key element in pelvic floor muscle rehabilitation programmes. Essentially biofeedback techniques provide people with continence problems with information about pressure in the bowel or bladder, or about the activity in key muscle groups. This is presented in the

form of an audio or visual signal that changes as a function of changes in the physiological parameter being measured. It is particularly useful when the intrinsic kinaesthetic feedback is diminished or distorted. Although biofeedback has been used with considerable success there has been very little in the way of standardization of procedures or investigations aimed at optimizing the effectiveness of the procedure, especially when there are reports of alterations of physiological parameters that are only loosely coupled with improvements in continence (Tries, 2004). The choice of physiological parameter to be the signal source, the number and duration of treatment sessions would appear to be a matter of local custom and practice rather than being based on any theory or empirical evidence. Moreover evaluations must also take account of the contributions of other aspects of the treatment programme as biofeedback is generally only one element in a more extensive treatment package that will typically include relaxation techniques and patient/family education (see 'Biofeedback' and 'Relaxation Training').

Incontinence draws together many of the key themes that run through other chapters in this book, for example, the need to take a holistic approach that incorporates biological, psychological and social elements; the absolute necessity for good communication between healthcare providers and patients and their families; education; compliance; the need for theoretically driven approaches which identify key factors in specific cases and tailor treatment approaches to match these as well as the need for empirical evidence of efficacy. Incontinence is not the most glamorous aspect of healthcare. However it is always treatable even if it cannot be cured and there is usually much that can be done to improve the quality of life of those afflicted.

Infertility

Annette L. Stanton¹ and Julia T. Woodward²

¹University of California

²Duke University Medical Center

Introduction

The substantial majority of young adults intend to become parents, but not all achieve a goal of conceiving easily when pregnancy is desired. The 1995 National Survey of Family Growth interviews conducted with 10 847 women suggested that 7.1% of married couples (2.1 million) in the United States met criteria for infertility (i.e. no contraceptive use and no pregnancy for 12 months or more; Abma *et al.*, 1997), and 15% of women of reproductive age reported a past infertility-associated healthcare visit. In the United Kingdom, one in six couples has a fertility problem (Human Fertilisation and Embryology Authority, 2004). The American Society for Reproductive Medicine (ASRM, 1997) estimates that infertility affects females and males with almost equal frequency. Sources of female infertility commonly include ovulatory disorders and tubal or pelvic problems. Male infertility typically involves problems with sperm production (e.g. abnormal sperm density, motility or morphology) or impaired sperm delivery. Infertility remains unexplained following diagnostic work-up in approximately 20% of couples.

Approximately 44% of those with impaired fecundity (i.e. difficulty conceiving or carrying a pregnancy to term) seek medical services, with higher rates among those who are white, older, married, childless and more affluent (Chandra & Stephen, 1998). Over 50% of infertile couples who pursue treatment become pregnant (ASRM, 1997). Among the available infertility treatments, a dramatic rise in the use of assisted reproductive technology (ART; i.e. fertility treatments in which both eggs and sperm are handled in the laboratory) occurred in recent years, with a 66% rise in the number of ART procedures performed in the United States from 1996 to 2001 (Wright *et al.*, 2004). Although the high cost of ART has limited its use to a small minority of infertile couples, the live birth rate from ART also increased substantially during that time – from 28% in 1996 to 33% in 2001 for the most common ART procedure of using freshly fertilized embryos from the patient's own eggs (Wright *et al.*, 2004). These rates vary markedly, however, as a function of patient and treatment factors; for example, the 33% rate quoted above subsumed a 41% rate in women under 35 years of age and a 7% rate among women over 42 years. An escalation in multiple births has accompanied the increase in ART use. Infants conceived through ART accounted for 1% of total births in the US in 2001, but the proportion of twins and triplets or more attributed to ART were 14% and 42%, respectively (Wright *et al.*, 2004), posing greater health risk to mother and infant.

Research in psychology and related fields pertinent to infertility has centred on four questions: (1) can psychological and behavioural factors cause infertility or influence response to medical

treatment? (2) what is the impact of infertility on psychological adjustment? (3) can we identify psychosocial risk and protective factors with regard to the adjustment of infertile couples? (4) can psychosocial interventions alter the course of infertility or enhance adjustment?

Behavioural and psychological factors in the aetiology of infertility

A number of health behaviours and their consequences are involved in the aetiology of infertility. Unsafe sexual practices can transmit diseases (e.g. pelvic inflammatory disease) which are a frequent and preventable cause of infertility (see 'Sexual risk behaviour'). Both being overweight and underweight are associated with infertility in women (Rich-Edwards *et al.*, 2002), and a recent dietary intervention trial revealed significant weight loss and improvement in reproductive abnormalities in obese women with polycystic ovary syndrome who were seeking fertility treatment (Stamets *et al.*, 2004). Cigarette smoking, a behaviour practised by approximately 30% of reproductive age women and 35% of reproductive age men, also has been associated with a greater likelihood of infertility (with stronger evidence for women than men), as well as with lower conception rates in ART (The Practice Committee of the American Society for Reproductive Medicine, 2004). Provision of information regarding the link between smoking and infertility along with exhaled carbon monoxide monitoring, with or without a brief, stage-of-change intervention, were associated with an increased rate of maintained smoking cessation from 4% at baseline to 24% after 12 months in one trial with infertile women (Hughes *et al.*, 2000).

The contention that psychological features contribute to infertility has a long history, beginning with psychoanalytic views and continuing in much modified form in investigations of stress-related determinants of fertility problems and of response to infertility treatments. Strong experimental evidence demonstrates that a variety of stressors can induce reproductive problems in nonhuman animals (e.g. deCatanzaro & Macniven, 1992), and physical stressors, such as intense and enduring physical activity, can contribute to menstrual disturbances and compromised fertility in humans (Chen & Brzyski, 1999). The biological pathways through which stress might affect reproduction and response to infertility treatments, including neuroendocrine and autonomic routes, are increasingly well understood (Domar & Seibel, 1997). However, no comprehensive theory has been advanced to specify the relations among specific psychological and stress-related factors, biological

processes and reproductive outcomes. Further, research has not demonstrated that psychological factors play a definitive aetiological role in infertility, although interest in the role of stress and associated psychological variables in infertility treatment response has increased in recent years (e.g. see Gallinelli *et al.*, 2001; Klonoff-Cohen *et al.*, 2001) (see also 'Stress and health').

Psychological adjustment to infertility

Certainly, the experience of infertility can disrupt one's cherished life goals and affect multiple life domains; moreover, undergoing what are often invasive, prolonged and costly medical treatments for infertility, without a guarantee of the desired outcome, may compound the challenges of infertility. However, reviewers of the empirical literature on psychological adjustment to infertility find little evidence that global psychological functioning or marital satisfaction is impaired in infertile couples on average compared to fertile couples or normative data (e.g. Eugster & Vingerhoets, 1999; Greil, 1997; Stanton & Danoff-Burg, 1995). As an example, Edelman and Connolly (1998) followed couples upon referral to an infertility clinic and at seven months. Couples also completed weekly diary ratings of distress over 22 weeks during diagnosis and medical treatment. Little evidence of psychopathology, including depressive symptoms and anxiety, emerged. The weekly diaries also revealed a general lack of distress, although they evidenced wide inter-individual variation. As found in a number of other studies, women reported greater distress connected to infertility than did men. In general, findings in this literature reveal both the psychological resilience of most individuals who face infertility and the substantial individual variability in response. Such variation renders it important to identify risk and protective factors for adjustment to infertility.

Predictors of adjustment to infertility

The environmental, social and personal contexts, as well as situation-specific cognitive appraisal and coping processes, have been investigated with regard to their associations with psychological adjustment to infertility (see Stanton *et al.*, 2002, for a brief review and relevant citations). Several demographic factors (e.g. high socioeconomic status, having other children) and personality attributes (e.g. optimism, high self-esteem) have been associated with more favourable adjustment in infertile couples (see also 'Socioeconomic status and health' and 'Personality and health'). Research on relations of medical factors (e.g. diagnosed cause, infertility duration) with psychological function has yielded mixed results, but engaging in a greater number of medical treatments and incurring more expense are related to greater perceived stress from infertility.

Because a minority of couples experience infertility and because particular cultural influences can render not having children socially stigmatizing, infertility often presents social challenges. Couples undergoing infertility typically must attempt to manage questions from others regarding their own parental status and look on as multiple friends and family members get pregnant and have children. Interpersonal support, both within the dyad experiencing

infertility and from close others, is associated with more favourable psychological adjustment (see also 'Social support and health').

With regard to cognitive appraisals, couples typically perceive infertility both as carrying the potential for harm (e.g. loss of a desired role) and benefit (e.g. strengthening the marriage). Finding some positive meaning in infertility predicts better adjustment. Greater perceived control also is related to more positive adjustment, when the relevant life domain is indeed potentially controllable (e.g. pursuing medical treatment, managing negative emotions regarding fertility problems) (see 'Perceived control').

A consistent finding regarding coping processes is that coping through attempting to avoid thoughts and feelings surrounding infertility predicts poor adjustment. In contrast, such approach-oriented strategies as problem-focused coping and emotional expression regarding infertility predict more favourable psychological status. Further, one partner's coping has been shown to affect the other's adjustment.

Psychosocial intervention in infertility

Controlled intervention research targeting factors shown to predict infertility-related adjustment is accumulating. These experimental trials often test cognitive-behavioural techniques for stress management and typically are delivered to women (or couples) in a group format (see 'Cognitive behaviour therapy'). In general, findings are promising with regard to enhancing adjustment (e.g. reducing depressive symptoms; Domar *et al.*, 2000b; McQueeney *et al.*, 1997). Although findings require cautious interpretation, some evidence suggests that such interventions also are associated with increased pregnancy rates in the intervention versus the control group (Domar *et al.*, 2000a; Hosaka *et al.*, 2002). However, mechanisms through which psychosocial interventions might influence pregnancy rates have not been demonstrated empirically.

Directions for research and application

It is important to move beyond the descriptive, cross-sectional methodologies that characterize much of the psychosocial research on infertility to investigation of determinants of psychological and reproductive outcomes in individuals and couples with fertility problems within longitudinal and experimental designs. Both predictive research and randomized, controlled trials of psychosocial interventions are essential. Given that psychologists and other mental health professionals are working in infertility clinics to perform psychological evaluations of patients (e.g. gamete donors and those seeking donor services) and to provide psychological interventions, research is needed to establish the evidence base for the effectiveness of such services. In the light of the expanding use of ART, theoretically grounded research on decision-making, stress and coping in couples as they elect various medical procedures will be of value, as will studies that examine psychological and biological outcomes of these treatments. Study of the psychosocial implications of ethical issues surrounding ART also is warranted. Finally, psychosocial research in infertility primarily has involved women and couples who are married, relatively affluent, white and participating in specialized fertility treatments. Research is needed with individuals who do not or cannot elect specialized medical services, as are

studies to examine the generalizability of extant findings to diverse groups.

In their capacities as researchers and clinicians, psychologists certainly can play a valuable role in addressing the challenges of infertility. They can aid in identifying and intervening with biopsychosocial contributors to and consequences of infertility. For example, the area will benefit from development of effective

prevention programmes that target biopsychosocial contributors (e.g. smoking, unsafe sexual practices) to infertility and associated treatment outcomes. The demonstration of marked diversity in response to infertility implies that many individuals will not need psychological assessment or counselling, although psychosocial intervention may prove invaluable to the health and wellbeing of some individuals and couples who confront fertility problems.

Inflammatory bowel disease

Paul Bennett

University of Cardiff

Inflammatory bowel disease (IBD) refers to two disorders: Crohn's disease and ulcerative colitis. Both are remitting diseases, with alternating periods of exacerbation and remission with symptoms of pain, diarrhoea and anorexia. Ulcerative colitis usually affects the large colon and results from inflammation of its inner lining. Crohn's disease results from an inflammation of the entire thickness of the intestinal wall, and may occur anywhere in the gastrointestinal tract, although it most frequently occurs in the small intestine. Complications of both disorders include the development of fistulas and scarring which may lead to obstruction and distension and, potentially fatal, rupture of the bowel. Both are thought to result from immune dysfunction and carry a high risk for the development of cancer (see 'Cancer: digestive tract').

Aetiology and impact

Initial aetiological theories suggested both ulcerative colitis and Crohn's disease to be psychosomatic in origin (see 'Psychosomatics'). Early analytical work by Alexander provided clinical evidence of this relationship, while a number of uncontrolled studies found a high percentage of IBD patients to report adverse life events prior to symptom exacerbation. However, controlled studies have shown little consistent evidence that IBD patients experience more stress preceding exacerbation than is typically encountered by healthy controls. Indeed, Von Wietersheim *et al.* (1992) found the number of life events reported in the previous six months by ulcerative colitis patients to be lower than those reported by patients undergoing surgery for minor injuries. However, they listed more feelings of being under pressure.

More pertinent, however, may be studies examining the impact of daily hassles. Duffy *et al.* (1991) followed a large cohort of IBD patients for approximately six months, and found that major life events and daily strains independently prospectively contributed to the variance in both self-reported and medically verified symptoms of IBD. The combined stress and demographic variables explained a total of 47% of the variance in disease activity. In a smaller study involving a more fine-grain analysis, Greene *et al.* (1994) followed 11 patients for a period of one year. A daily diary of stress, coping and mood provided a measure of psychosocial stress and its emotional responses. Pooled time series analysis revealed a prospective effect of stress on the self-reported signs and symptoms of IBD. Daily and monthly stress were positively associated with disease activity.

The symptoms of IBD may also contribute to distress. Porcelli *et al.* (1996), for example, reported prospective data on a large

cohort of IBD patients, evaluating the relationship between psychological distress and disease activity. Patients were evaluated at baseline and six-month follow-up, and grouped as 'unchanged', 'improved' and 'worsened'. The clinical course of IBD affected the extent of psychological distress. An improvement in disease activity over time was related to a decrease in the anxiety scores. A worsening in disease activity over time was related to increase in anxiety scores.

Interventions

Interventions with IBD patients have been of two types: those targeted primarily at symptom reduction, and those at reducing distress resulting from symptom exacerbation. Unfortunately, few satisfactory studies of either type have been conducted, limiting the conclusions which may be drawn from the research. In one of the first such studies, Karush *et al.* (1977) allocated IBD patients to either medical treatment alone or in combination with supportive psychotherapy. Over the eight-year period of the study, patients in the combined treatment group experienced shorter and less severe exacerbations and longer periods of remission. However, the study was seriously compromised by non-random allocation to condition and a failure to control for the use of steroids and antibiotics. Subsequently, Milne *et al.* (1986) reported significant improvements on measures of symptomatology over a follow-up period of one year in patients assigned to a stress management protocol relative to those assigned to a standard treatment control group. No differential changes in medication which may explain these differences occurred. However, patients in the intervention condition reported significantly more symptoms and psychological stress at baseline, and their relative improvement on both types of measure may be attributable to regression to the mean. One final study examined the relationship between stress management and symptoms. Schwarz and Blanchard (1991) reported the only failure of IBD patients to benefit from psychological therapy in comparison to a symptom monitoring condition. Participants in the active condition reported significant reductions in five symptoms following an intervention comprising progressive muscle relaxation, thermal biofeedback and cognitive stress management techniques (see 'Biofeedback', 'Cognitive behaviour therapy' and 'Relaxation training'). Over the same period of time, patients in the symptom monitoring group reported decreases in all eight of the symptoms being monitored. When this group subsequently received the intervention, their symptoms increased.

More positively, a number of studies suggest that psychological distress resulting from symptom flare up may be reduced through

the use of psychological techniques. Despite the lack of symptomatic change, patients in the active intervention of Schwarz and Blanchard (1991) reported less symptom-related stress, less depression and less anxiety than those in the control group. Mussell *et al.* (2003) also found a cognitive behavioural group treatment to reduce levels of depression, and disease-related worries and concerns. Finally, Shaw and Ehrlich (1987) found evidence that psychological interventions may help patients cope better with the pain associated with IBD. They allocated 40 patients with IBD to either a relaxation training or attention control condition. Immediately following the intervention and at six-week follow-up, patients in the active intervention reported significantly less frequent and intense pain, and were more able to control their pain. In addition,

significantly fewer patients were taking anti-inflammatory drugs (see also 'Pain management').

Conclusions

There is some evidence of a modest relationship between everyday levels of stress and IBD symptomatology. It is not clear, however, whether psychological interventions can impact on the symptoms of IBD, although there is more evidence that such interventions may help patients cope better with them.

Intensive care unit

Christina Jones and Richard D. Griffiths

University of Liverpool

Overview

A critical illness is a major life event for patients and their relatives and happens within the confines of an intensive care unit (ICU). The ICU is where you will find some of the sickest patients in the hospital, with very intensive medical and nursing interventions and monitoring being undertaken around the clock. In the UK each patient has a dedicated nurse looking after them as they may require support for different failed organs, such as artificial ventilation, dialysis or drugs to raise their blood pressure.

The psychological impact of a critical illness is now recognized to go well beyond the confines of the ICU. The patients admitted to an ICU vary in age, illness type and severity and this differs

considerably between hospitals depending on the population they serve. Patients undergoing major surgery who know before they go to theatre that they will be admitted to ICU afterwards may experience a strong sense of security because they have been prepared for their admission beforehand (Shi *et al.*, 2003). However, for the many patients who develop an illness needing an admission to ICU as an emergency such preparation is simply not possible. The reasons for admission to ICU may vary greatly, from a major car crash to severe pneumonia. However the majority of these patients will be so ill that they will need a ventilator to do their breathing for them for varying periods of time, from hours to months. Their perception of their surroundings and comprehension of information may be clouded as they wake from the sedation and analgesia, which has been given

to keep them comfortable with the ventilator. Patients in ICU are completely emotionally and physically dependent on the staff looking after them. Keeping patients informed and giving them a sense of security and hope is a real challenge, but providing emotional support may be sufficient to help many patients cope with this dependence. A recent study found that feelings of vulnerability were reduced when patients were well informed; received care which was personalized to their own needs; and had a family member present (McKinley *et al.*, 2002).

In the past when patients left the ICU they were discharged to their admitting speciality, for example surgery, and follow-up was left to this team. This follow-up therefore had a tendency to concentrate on the problem as identified at admission. But since the introduction of formal follow-up and specialized ICU outpatient clinics, awareness of the longer-term psychological impact on patients of such a severe multi-system illness has been growing (Jones & Griffiths, 2002). Anxiety; depression; panic attacks; new phobias, such as agoraphobia, and high levels of symptoms of post-traumatic stress disorder (PTSD) have all been reported in ICU patients (see 'Post-traumatic stress disorder'). One particular challenge in this patient group is the fragmentary nature of patients' recall for their illnesses and the high incidence of delusional memories, such as hallucinations, paranoid delusions and nightmares. These delusional memories are described by patients as being very vivid, as if they really happened to them. Although patients may recognize intellectually that these memories cannot be true, the frightening emotional content make them hard to ignore.

Research evidence

In the past, the myriad of psychological and behavioural disturbances occurring within ICU have been unhelpfully called 'ICU psychosis or syndrome'. It is now recognized that most patients suffer delirium at some stage in ICU. This may or may not be accompanied by agitation but increasingly is recognized to be associated with delusions and hallucinations. It is not surprising, given the serious medical conditions, metabolic derangements and numerous drugs that the incidence of delirium varies considerably, dependent on the patient population. It is described ranging from between 19% (Dubois *et al.*, 2001) to over 80% (Ely *et al.*, 2001a) within intensive care. A validated, practical and reliable assessment tool to diagnose delirium in ICU is available. Called the Confusion Assessment Method for the ICU (CAM-ICU) (Ely *et al.*, 2001b) it is recommended for routine use by the practice guidelines for sedation of the American Society of Critical Care Medicine (Jacobi *et al.*, 2002). Further clues to the aetiology of delirium come from the recognition that neuropathological changes, especially during severe sepsis may be common (Sharshar *et al.*, 2003).

While the patient is in ICU and once the effects of sedation and illness have lessened, symptoms of anxiety and depression have been reported (Goldman & Kimball, 1987; Chlan, 2003; Bardellini *et al.*, 1992) but reliably establishing these diagnoses within ICU where patients cannot freely talk due to oral or tracheal intubations is contentious. The criteria used to assess depression, in particular, are somewhat unclear. A withdrawn patient may be labelled as depressed when they are actually delirious. In this case the administration of an antidepressant should be avoided until

clear diagnostic criteria are available as they may further cloud cognition in this acute setting.

Following serious illness, anxiety, panic attacks and depression are common in other patient groups (House *et al.*, 1995). ICU patients are no exception to this and anxiety and depression are common in both patients and their families after discharge. For close family members, high levels of anxiety symptoms are predictive of developing the symptoms of PTSD (Jones *et al.*, 2004). One large study involving 3655 patients reported problems with emotional behaviour, sleep and alertness, particularly with the younger patients aged between 30–50 years (Tian and Reis Miranda, 1995). The delusional memories that patients can recall from their stay in ICU can be vivid and can precipitate PTSD-related symptoms. The memory of patients may be disturbed with some suffering amnesia for the ICU stay (Jones *et al.*, 2000). Where delusional memories are the sole recollections of ICU, with no factual memories being recalled at all, the risk of developing high levels of PTSD-related symptoms is even higher (Jones *et al.*, 2001). In addition, there seems to be a strong correlation between symptom levels in family members and patients (Jacobi *et al.*, 2002). This may be because the patient and relatives are unable to support each other.

Although physical recovery can be improved by the use of a self-directed rehabilitation package, the ICU Recovery Manual, early in the convalescent phase, psychological recovery may not be as simple (Jones *et al.*, 2003). While depression may be improved, the self-directed package had less impact on anxiety and PTSD-related symptoms. This is particularly so when patients report having delusional memories, so emphasizing the importance of recognizing such patients and ensuring an appropriate referral for further treatment.

In addition to psychological distress critical illness can also have an impact on cognitive function, particularly on strategic thinking and memory, possibly reflecting frontal lobe problems. At this present time it is unclear if the cognitive deficits noted so far are permanent due to neurological damage or may recover with time (Ambrosino *et al.*, 2002; Hopkins *et al.*, 1999; Jackson *et al.*, 2003).

Clinical implications

For ICU treatment

It has been the tradition in the UK and many Northern European countries to sedate patients to ensure the patients' compliance with the ventilator. This practice has been defended in terms of the patients' comfort and to reduce anxiety while in ICU. Clearly such drugs have significant impact of the patients' cognitive function and may affect the ability to understand and remember information given to them (see 'Anaesthesia'). Research has not, until recently, been undertaken to examine the ideal depth of sedation to ensure that patients are not traumatized by their experience of ICU. Sedation may have a role to play in the formation of delusional memories by clouding cognition. In a recent retrospective study the impact of waking the patient daily while on ICU from their continuous sedation was evaluated in terms of their later psychological distress (Kress *et al.*, 2003). There was a trend towards those patients who were woken daily being less distressed and less likely to develop PTSD than those who were kept continuously sedated and only woken up to get them to breathe on their own without a ventilator.

This may have major clinical implication for the way patients are cared for on ICU.

Psychological services after discharge

At present, once ICU patients are discharged home, even where follow-up services exist, there may be little provision for counselling or referral to clinical psychology. A few hospitals around the UK have dedicated counsellors and/or clinical psychologists with sessional time for ICU. For the majority of patients the first person they may tell about their problems will be their GP (primary care physician). While some GPs now have counsellors attached to the surgery, the waiting list can be lengthy. Little research has been undertaken on particular therapeutic approaches to address psychological distress in this patient group.

Interventions

A simple intervention, which has been imported from Sweden and is well received by patients, is to keep a patient diary with photographs whilst on ICU (Bäckmann & Walther, 2001). This can be written by staff and family and is given to the patient afterwards. The language used is everyday and any medical words are explained. Periods of confusion or agitation are also written about with a possible reason for this. A small pilot study in Sweden showed that patients felt that

the diary helped them come to terms with their illness and recall what had happened (Bergbom *et al.*, 1999). For those who could not remember ICU, the diary seemed to fill in the lost time. This intervention needs formal evaluation to ensure that some patients are not made more distressed by reading a diary and seeing photographs of themselves in ICU.

Conclusion

Further research is needed to understand the processes behind the formation of delusional memories on ICU and to examine the impact of therapeutic interventions undertaken within the ICU, such as altering sedation practice, on later psychological health.

The growth of counselling services for patients diagnosed with cancer is in recognition of the psychological impact of severe illness. At present only about a third of ICUs in the UK follow up their patients in a dedicated clinic. The provision of counselling or psychology services specifically for this patient group is sparse. Psychological services for post-ICU patients are required so that each patient is appropriately assessed and given the necessary support. Physical recovery after critical illness is on the whole good, although it is a lengthy process. If psychological services are not available for some patients their optimal quality of life may never be achieved.

Intimate examinations

Penelope Cream

Royal Free Hospital

Any medical examination that involves unusually close contact with a comparative stranger may be termed intimate. The degree of intimacy is subjective, and may depend on factors such as previous experience of similar medical contact, cultural and social norms and related life events, such as abuse or childbirth.

Examinations that are generally described as intimate include breast, pelvic, genital and rectal or anal examinations. However, procedures such as urodynamic investigations (Shaw *et al.*, 2000) and physiotherapy treatment can also prove intimate for many patients, as can undressing for any type of medical examination. Nearly every specialty within medicine and surgery involves intimate examination, and particularly primary care, sexual health, gynaecology and obstetrics, gastroenterology, emergency medicine, genito-urinary medicine and dermatology. Even the less classically intimate specialties, such as cardiology, involve procedures such as femoral artery catheterization through the groin that may be embarrassing to the patient.

Psychological impact of intimate examination

There are significant clinical implications of negative reactions to examination. Patients may be less likely to seek help or delay treatment for health problems or fail to attend screening, such as for mammography, cervical smears or colonoscopy (see 'Delay in seeking help'). Patients may feel unable to disclose the full extent of their concerns or difficulties. The level of self-efficacy (Bandura, 1977), in this case the ability to recognize and act on the need to seek medical care, that a patient holds is an important factor in determining compliance with intimate examination (see 'Self-efficacy and health behaviour'). This helps the patient to overcome instinctive psychological reactions to the procedure, such as embarrassment, fear and anxiety (Marshall, 1994). Patients' health beliefs can be influenced by their examination experiences and a traumatic experience when young could have a long-lasting impact on a patient's future help-seeking behaviour (Bodden-Heidrich *et al.*, 2000).

Factors that affect comfort during intimate examination

Both clinician and patient comfort are important: embarrassment and anxiety tend to be 'contagious'. If the clinician can contain the patient's emotions and concerns, the examination will progress more easily and will be less likely to deter attendance at future appointments. In turn, the awkward or nervous practitioner may make a previously unembarrassed patient feel uncomfortable and worried.

Patient factors

The patient may experience a range of reactions on attending for an intimate examination. These include individual variation in characteristics such as coping style, shame, embarrassment and fear. Other factors include feelings of vulnerability, awkwardness, humiliation and pain. These are more likely to be present if the patient has had a distressing experience in a previous intimate examination, has suffered sexual abuse or feels unable to communicate effectively with staff. Patients attending for a routine test that they have had many times before are likely to be less affected by the procedure than those admitted as an emergency or who cannot understand what is happening to them, for instance. In this case the level of perceived control is an effective indicator of psychological discomfort; the more control the patient feels he or she has over the situation, the lower the embarrassment and anxiety tend to be (e.g. Stattin *et al.*, 1991) (see also 'Perceived control').

Cultural or religious factors play a part in the patient's level of comfort during the intimate examination (Dean, 1998). It may not be appropriate for a male clinician to examine women from certain ethnic backgrounds, for instance, nor to have male chaperones, interpreters or other observers present. Equally, the female practitioner should be mindful of whether a male patient finds it unacceptable to be examined by a woman.

Clinician factors

Sensitive and effective communication is of the utmost importance, and may facilitate both the examination itself and subsequent disclosure of other matters, such as digestive or sexual difficulties (Berman *et al.*, 2003), body image problems, abuse and trauma experiences (Wijma *et al.*, 2003), treatment compliance issues and psychological conditions. A considerable number of patients attending gynaecological clinics, for example, have been found to have co-morbid psychological difficulties (Byrne, 1984) and practitioners carrying out intimate examinations are well placed to elicit further information and prompt referrals for additional problems.

Factors that have been found to relate directly to communication include gender congruency, trust in the clinician and the patient's level of perceived control over the situation. Communication and education about the procedure work most effectively when tailored to the individual patient's coping style: some people prefer more or less information before the procedure, depending on whether they are avoidant or active copers (Miller, 1987). If they are very anxious, extra time may be needed to explain what is happening because of the slowing of the ability to take in information when anxious or under stress (see also 'Healthcare professional-patient communication').

Characteristics of the clinician contribute to the ease of examination. Embarrassment, awkwardness and shame can touch both parties in an examination; the sensitive practitioner can benefit by being aware of his or her own reactions to the nervous or embarrassed patient, and decide in advance how to reassure and normalize distress. Good interpersonal skills can alleviate discomfort considerably (Hall *et al.*, 1994). A lack of confidence on the part of the doctor or nurse can lead to awkwardness or mistrust for the patient. Training issues may contribute to this lack of confidence. In many medical schools it is difficult to find sufficient examination opportunities to feel proficient, and doctors have reported avoiding carrying out breast (Desnick *et al.*, 1999) and rectal examinations (Lurie *et al.*, 1998) because of a fear of causing pain or embarrassment to the patient. A lack of skill in perceiving patients' attitudes and feelings towards pelvic examination may influence how and whether the procedure is carried out (Fiddes *et al.*, 2003). This reluctance can result in unnecessary referrals to specialists (Turner & Brewster, 2000). Pilot schemes using lay teaching associates are being tested in the UK, and have already been found to be successful in Scandinavia, North America and Australia in increasing trainees' skills and examination opportunities (Pickard *et al.*, 2003).

Although respect for the patient is of the utmost importance in all medical settings, intimate procedures require particular care in both interpersonal and environmental terms to help the patients feel that they are retaining as much dignity as possible. Guidelines exist in many settings to guide intimate examination procedures. In the UK, the Royal College of Obstetricians and Gynaecologists (1997), for instance, suggests that a clinician should never comment on the patient's body or functioning while performing the examination, while research on shame and dignity indicates that fears of how

one's body appears to a doctor or nurse can contribute considerably to distress (Lazare, 1987).

Gender congruency effects have been found in the literature, although in certain populations these tend to be less important, such as with women who have had a child and who may have extensive experience of examination. Derose *et al.* (2001) found that women clinicians were perceived by both male and female patients as being more sensitive, more empathic and thought to possess better communication and technical skills than their male colleagues. However, patients who had had satisfactory examinations with a male clinician were happy to continue seeing a man and tended not to express a preference of practitioner gender when asked (Lodge *et al.*, 1997). The age of the patients has an effect on practitioner preference: young male patients undergoing genital examination in the US showed a strong preference towards having a female doctor (Van Ness & Lynch, 2000), while older patients tend to prefer a more senior doctor.

Some reports have shown that the position in which intimate examinations are carried out can influence patient comfort and reduce distress. Women's preference for either a supine or semi-sitting position has been found to be influenced by the gender of the examiner and previous experience of intimate examination, with semi-sitting position being linked to a reduction in anxiety with a male clinician. Women have been found to prefer a semi-sitting over supine position for pelvic examination if the clinician were male or if they were being examined for the first time (Seymore *et al.*, 1986). Research into male prostate rectal examinations has found that a variation in position can reduce pain associated with the examination but does not decrease embarrassment (Frank *et al.*, 2001).

The environment in which the examination is carried out is important in maintaining privacy and respect for the patient. Teaching environments need to be handled particularly sensitively, and consideration should be given to the effect of third parties, whether trainees, students, family members or chaperones. The majority of women in Webb and Opdahl's (1996) study indicated a preference for a chaperone if being examined by a male doctor; other studies have shown that female patients prefer to be alone with a female clinician. While the majority of patients prefer privacy when undressing, opinion is more divided on the necessity of a blanket or gown, although this depends on the nature of the procedure. Designs for new gowns for victims of sexual abuse have been trialled successfully, and have been found to reduce anxiety during the examination (Smith & Smith, 1999). One of the strongest factors in patient distress is a lack of privacy and a fear of or actual interruption during the examination, and this contributed considerably to dissatisfaction with the procedure.

Overall, the successful intimate examination or procedure depends on a combination of components: effective and empathic communication; privacy and mutual respect; dignity; and trust for both patient and clinician. These factors, together with clinical confidence and sensitivity, will help a potentially difficult and emotionally charged procedure to go smoothly, and facilitate help-seeking and screening behaviours in the future.

Irritable bowel syndrome

Paul Bennett

University of Cardiff

Irritable bowel syndrome (IBS) is a disorder of the large bowel. There are number of diagnostic criteria for diagnosis of the condition, but the Rome criteria (Drossman, 1999) are perhaps the most often used. These state that the disorder involves three months of continuous or recurrent symptoms of abdominal pain or discomfort that is relieved by defecation and/or associated

with a change in frequency of stool matter and/or associated with a change in consistency of stool. In addition, two or more of the following are present for at least three days a week: altered stool frequency; altered stool form; passage of mucous; and feelings of bloating or abdominal distension. These symptoms are relatively common, with estimates of the prevalence of IBS within the general

population varying between 3 and 18%, with women being about twice as likely as men to experience IBS symptoms (e.g. Drossman *et al.*, 1993)

Early aetiological models suggested IBS was a primary psychophysiological disorder. Latimer (1981) even suggested that its symptoms and aetiology are synonymous with those of anxiety, with symptom choice (anxiety or IBS) being determined by social learning. This strong theory is no longer tenable, and more support is given to a weaker 'stress' hypothesis, which suggests that IBS symptoms are multi-causal and can result from a variety of factors, including gut infection, food intolerance and stress (see 'Psychosomatics').

Linkages with stress

There is consistent evidence linking IBS to high levels of stress. Firstly, IBS patients have higher levels of co-morbidity with psychiatric conditions than among comparison groups. Walker *et al.* (1990), for example, found that 93% of IBS patients met the diagnostic criteria for at least one short-term psychiatric disorder. This compared with 19% of patients with inflammatory bowel disease. Secondly, IBS patients have higher levels of psychometrically measured stress than other populations. Schwarz *et al.* (1993), for example, reported IBS patients scored more highly than 'normal' controls on a variety of measures of depression and anxiety. Unfortunately, the dependence of these studies on patients who actively sought medical treatment for their symptoms renders interpretation of their findings difficult. Up to 80% of people with IBS do not consult a physician as a result of their symptoms. In addition, those who do visit their doctor more for other minor or vague symptoms than the average, and report higher levels of stress than non-attenders (e.g. Drossman *et al.*, 1988). Thus, the apparently high levels of psychological co-morbidity found among patients with IBS may be the result of studying people with high levels anxiety or depression who seek medical help more readily for relatively minor symptoms than people with lower levels of distress (see 'Symptom perception'). This process would inflate the apparent relationship between IBS and stress.

Despite this caveat, there is evidence to suggest that among IBS patient populations, levels of IBS activity do co-vary, to some extent, with levels of stress. Bennett *et al.* (1998) followed a cohort of 117 patients with IBS, and found that chronic life stress predicted 97% of symptom intensity between baseline and 16-month follow-up. No one exposed to even one chronic stressor improved clinically over the period of the study. All those who did improve, did so in the absence of such a stressor. Whitehead *et al.* (1992) reported another such study, examining the relationship between the occurrence of life events and IBS symptoms over a series of three-month periods in a group of 39 women. Changes in life events accounted for 10% of the variance in symptoms. In a third longitudinal study, Dancey *et al.* (1998) found that daily hassles contributed to increased symptoms up to two days following their occurrence.

Aetiology

Two pathways have been identified through which stress may influence the symptoms of IBS. The autonomic stress model of IBS

suggests that people with the condition respond to stressful events with high levels of gut motility as a result of either autonomic or enteric nervous system over-activity or the gut responds to similar levels of activity in a more vigorous manner than in people without the disorder. This may be compounded by decreased thresholds for pain and rectal sensations at times of stress (Murray *et al.*, 2004). Thus, people with IBS may have a gut that is highly responsive to stress, and from which there may be more sensations indicating a need to defecate, than other individuals. A second pathway may involve the onset of the disorder as a result of infection, for example, with the *Campylobacter* bacteria, with stress contributing to its maintenance. This may be the result of a stress-mediated inability to down-regulate the initial inflammatory stimulus efficiently (Barbara *et al.*, 2004) (see also 'Stress and health').

Stress is generally seen as external to the individual, but there is some evidence that some stress may be self-generated or be the result from past stressful experiences. Negative perfectionism may contribute to the symptoms. Somatic perceptions may also be cognitively exaggerated in some IBS patients, contributing to the perception of pain severity (Lackner *et al.*, 2004). Drossman *et al.* (1990) suggested that previous sexual or physical abuse may account for the high levels of distress among female patients with IBS. They found higher levels of pre-adolescent sexual and physical abuse among female patients with IBS disorders than among comparable female patients with organic gastrointestinal diseases. These findings, however, have not always been replicated (e.g. Hobbis *et al.*, 2002). Further, the theory does not explain the mechanisms through which such an association may be manifest.

Treating IBS

IBS may usefully be treated with drug medication including smooth muscle relaxants and bulking agents (see Poynard *et al.*, 2001). Dietary interventions involving supplementary dietary fibre may also be of value (Bijkerk *et al.*, 2004). However, here we focus on the impact of psychological interventions.

Perhaps the most widely used intervention to treat IBS involves the use of cognitive behaviour therapy, which seems to compare well with medical interventions (e.g. Bennett & Wilkson, 1985) (see 'Cognitive behaviour therapy'). In an interesting development of the potential interplay between medical and psychological treatments, Darnley *et al.* (2002) examined whether stress management could add to the effectiveness of medical treatment in non-responders to the initial intervention. All the people in her study were first given drug treatment. Those that continued to have IBS symptoms some six weeks later received either a stress management programme or continued on the drug regime, in the hope that additional time on the drug would improve their symptoms. Among the non-responders, patients in the cognitive behavioural programme fared best, reporting significant improvements in a variety of measures of IBS symptoms as well as reductions in measures of emotional distress. Data from Keefer *et al.* (2002), who found long-term reductions in abdominal pain, diarrhoea and bloating following instruction in meditation, suggests that even relatively simple interventions may be of benefit.

Although later studies have provided confirmatory evidence, the most substantial study of the effectiveness of psychotherapy remains that of Svedlund (1983). He evaluated the effectiveness of medication alone or in combination with an intervention comprising up to ten hours of sessions aimed at helping participants modify maladaptive behaviour, find new solutions to problems, and to cope more effectively with stress and emotional problems. In this, it appears very close to the cognitive-behavioural interventions previously described. At one-year follow-up, the combined treatment group maintained significantly greater improvements on a variety of measures of IBS symptoms, including pain and bowel dysfunction. Finally, Gonsalkorale *et al.* (2003) found 71% of IBS patients initially responded to hypnotherapy. Of these, 81% maintained their improvement over five years (see 'Hypnosis').

Conclusions

Although not all cases of IBS will be the result of stress, and some may result from a combination of stress and other insults to the gut, the role of stress in the aetiology of IBS is now well established, at least among the specific populations that attend medical clinics. Stress may influence gut motility, perceptions of gut activity and immunological changes in the gut that result in the initiation or maintenance of symptoms. It may also moderate emotional and cognitive responses to somatic sensations within the gut and rectum. People who do have stress-related IBS may benefit from a variety of interventions designed to moderate stress levels and change their cognitive content.

Lymphoedema

Anne Williams

Napier University

Lymphoedema, the chronic accumulation of fluid in the interstitial tissues, is due to an insufficiency in the lymphatic system (British Lymphology Society, 2001). Most commonly, it involves one or more limb/s but an oedema of the trunk, head and neck or genitalia may also occur. Lymphoedema affects over 1.33 per 1000 of the population (Moffatt *et al.*, 2003) and can have significant physical, psychosocial and economic implications. This chapter overviews relevant pathophysiology, outlines the causes of lymphoedema, explores the psychosocial impact and describes management strategies for lymphoedema.

Underlying pathophysiology

The lymphatic system is composed of a vast network of lymphatic vessels and over 700 lymph nodes, many of which are sited in regional groups at the neck, axillary and inguinal areas. The system transports excess fluid and proteins from the interstitial tissues to the blood circulation (Stanton, 2000) and also has an important immunological function. Networks of thin-walled lymphatic vessels lie in the dermis, supported by elastic fibres and anchoring filaments. Stimulated by local tissue movement, these lymphatics open, allowing fluid to pass into the system and drain via precollector and collector vessels through lymph nodes and into larger lymphatics, such as the thoracic duct, finally returning to the blood circulation (Földi & Földi, 2003). Lymph flow is influenced by contractions in the muscular wall of the collectors and ducts. Variations in local pressures due to pulsation of adjacent blood vessels and the skeletal muscle pump, along with changes in intra-thoracic and intra-abdominal pressures during breathing, also enhance lymph flow.

Table 1. Lymphoedema staging criteria

Stages of lymphoedema	Features of lymphoedema
Stage 0	Latent or sub-clinical stage that can exist for many years: impaired lymph transport occurs but swelling is not evident.
Stage 1	Excess volume is less than 20%; fluid accumulates but reduces with elevation.
Stage 2	Excess volume of 20–40%; initially skin is pitting but becomes non-pitting and swelling does not reduce on elevation.
Stage 3	Excess volume of >40%; non-pitting swelling with persistent skin and tissue changes.

The accumulation of protein-rich fluid leads to increased limb volume, changes in limb shape, skin and tissue damage and inflammation. The epidermis becomes stretched and dry. Eventually, the tissues become hard, fibrotic and vulnerable to recurrent infection or cellulitis (Table 1). A positive Stemmer's sign (an inability to pinch the skin at the base of the second toe) is a differential diagnostic sign for lymphoedema.

Epidemiology

Primary lymphoedema is characterized by lymph vessel aplasia (absence), dysplasia (reduction) or other intrinsic abnormalities in lymph vessels or lymph nodes; it may also be associated with genetic abnormalities (Burnand & Mortimer, 2003). The prevalence of primary lymphoedema is unclear although it affects around 8–12% of all patients referred to specialist lymphoedema clinics (Williams *et al.*, 1996; Sitzia *et al.*, 1998; Cleave, 2002).

Secondary lymphoedema results from damage to the lymphatic system due to various cancer- or non-cancer-related changes. Recent studies indicate that up to 38% of women experience problems such as arm swelling and restricted arm movement following breast cancer (Engel *et al.*, 2003; Querci della Rovere *et al.*, 2003), despite the use of more conservative treatment approaches. Lymphoedema has also been reported in 41% of those treated for invasive cervical cancer (Werngren-Elgstrom & Lidman, 1994) with a 29% incidence following lymph node dissection for malignant melanoma (Serpell *et al.*, 2003) (see chapters on 'Cancer').

Non-cancer-related causes of lymphoedema include trauma, limb dependency, chronic venous disease and infection. Oedema has been identified in 35% of those with leg ulceration (Moffatt *et al.*, 2004). Lymphatic filariasis, a tropical disease spread by mosquitos and caused by infection with the organism *Wuchereria bancrofti*, a worm that enters the lymphatic system, is the most common cause of secondary lymphoedema worldwide but rarely seen in the developed world (Bernhard *et al.*, 2003).

Psychosocial issues

The literature mainly focuses on breast cancer-related swelling. An early study of women with breast cancer-related lymphoedema reported greater psychological morbidity, impaired physical functioning and impaired adjustment to illness in those with lymphoedema as compared to a non-lymphoedema control group (Tobin *et al.*, 1993). Woods (1993) also described altered sensations in women with breast cancer-related lymphoedema and suggested that levels

of psychological distress were not directly related to severity of swelling. High levels of psychological, social, sexual and functional morbidity have been further identified in women with upper limb swelling, exacerbated by poor social support, pain and a passive and avoidant coping style (Passik & McDonald, 1998).

Johansson *et al.* (2003) interviewed 12 women with mild-to-moderate lymphoedema describing problem-focussed or emotion-focussed approaches to coping and highlighting their difficulties with the reactions of other people. Beaulac *et al.* (2002) used the FACT-B tool and identified lower scores in those with increased limb volume. Coster *et al.* (2001) have also described the validation of a quality of life scale based on the FACT-B questionnaire and incorporating additional questions pertaining to arm swelling.

Studies of other lymphoedema groups are limited. Ryan *et al.* (2006) studied 82 women with lower limb swelling related to gynaecological cancer, describing altered sensations in the swollen leg and identifying the impact on appearance, mobility and finances. A phenomenological study of people with various types of lymphoedema reported difficulties with self-image (Williams *et al.*, 2004) and highlighted the problems experienced by people with non-cancer-related lymphoedema in accessing treatment. In particular, it described their isolation, prolonged anxiety and feelings of depression due to misdiagnosis of the condition by health professionals.

The psychological morbidity of lymphoedema and its relationship with quality of life has not been adequately evaluated (Rietman *et al.*, 2003). The association between lymphoedema and other common physical symptoms such as pain, restricted movement and numbness and their influence on psychological distress also remains unclear. Problems with pain and discomfort in lower limb swelling have been reported (Sitzia & Sobrido, 1997; Moffatt *et al.*, 2003) but quality of life and psychological assessment tools for lymphoedema are inadequate (Sitzia & Sobrido, 1997; Poole & Fallowfield, 2002) and further validation of condition specific tools is required (see 'Quality of life' and 'Quality of life assessment').

Management strategies

Lymphoedema treatment aims to reduce swelling, improve limb shape, promote healthy skin and tissues and enhance quality of life. A comprehensive initial assessment is vital and provides the baseline for individualized treatment planning and long-term monitoring of this chronic condition. Detailed medical history and assessment is undertaken to include skin and tissue condition, physical difficulties, psychosocial and information needs and factors that may affect outcome. Limb circumferential measurements are used to calculate the volume of the limb and provide a comparison with the unaffected side in a unilateral oedema.

Of central importance is the need to maintain good skin condition and prevent complications through various measures:

- Keeping the skin supple and healthy with daily hygiene and moisturizing with bland emollients
- Avoiding any cuts, scratches, bites or burns; applying antiseptic if they occur and prescribing antibiotics to treat cellulitis
- Avoiding restrictive clothing, having blood pressure taken or injections on the affected limb

- Using the limb normally but avoiding heavy or repetitive activities that exacerbate swelling.

Treatment consists of a two-phased approach using a combination of treatment modalities. Phase one, often called intensive treatment or Decongestive Lymphatic Therapy (DLT), combines daily skin care, manual lymphatic drainage (MLD) massage, multi-layer lymphoedema bandaging (MLLB) and isotonic exercises over a 2–4 week period. A therapist (often a nurse or physiotherapist) provides the treatment, commonly as an outpatient.

Manual lymphatic drainage is a specialized massage following the Vodder, Földi, Casley-Smith or Leduc methods. It increases lymph drainage and enhances the uptake of proteins into the lymphatics, helping to establish collateral routes to redirect fluid to unaffected areas. It is specifically indicated for treating breast, genital and head and neck oedema.

Multi-layer lymphoedema bandaging is usually reapplied daily, after MLD, to reduce swelling and reshape the limb. The pressure from the bandages forces fluid towards the root of the limb. A stockinette lining and soft padding or foam are used to protect and reshape the limb prior to application of layers of short stretch bandages. The digits are often bandaged.

Phase two is a maintenance period of independent care and is suitable for those with those with mild lymphoedema or following intensive treatment. This requires a considerable degree of commitment and lifestyle adjustment, incorporating skincare, specific exercises, self-massage and the wearing of compression hosiery garments within the daily routine. Specialized lymphoedema compression garments are worn daily to prevent fluid accumulation and support the muscle pump. These should be measured and fitted by an experienced practitioner to ensure comfort and efficacy. Exercises are used to improve posture, develop muscle tone and enhance lymph drainage. Careful positioning of the limb and wearing of appropriate clothing and footwear are also important in optimizing mobility and function.

Treatments are modified depending on the severity of the lymphoedema, health and age of the patient. Additional problems such as recurrent cancer, cardiac or renal failure may complicate treatment outcome. Equally, care must be taken to ensure that quality of life is not unnecessarily compromised by the treatment regime.

Diuretics have limited use for lymphoedema and can lead to electrolyte imbalance in the long term. However, they may be used to treat co-existing conditions such as ascites or congestive cardiac failure (see 'Coronary heart disease: heart failure'). Intermittent compression pumps such as the 'floutron' should also be used with caution as they can produce a fibrotic band at the root of the limb and may increase the risk of genital oedema in people with lower limb swelling (Boris *et al.*, 1995).

Evidence base

The evidence base for lymphoedema treatment is developing. A randomized controlled trial of 83 patients with chronic limb oedema showed that 18 days of bandaging followed by hosiery achieved a significantly greater effect on limb volume than hosiery alone (Badger *et al.*, 2000). Manual lymphatic drainage

has also resulted in significant changes in limb volume and some quality of life domains, as measured by the EORTC QLQ-C30, in women with breast cancer-related lymphoedema (Williams *et al.*, 2002).

Other authors have reported significant improvements in quality of life following treatment (Mirolo *et al.*, 1995; Weiss & Spray, 2002; Mondry *et al.*, 2004) although further work is required to explore the efficacy and cost effectiveness of lymphoedema treatment in different groups.

Conclusion

Lymphoedema is an under-recognized condition that requires long-term intervention but can be successfully controlled. Assessment of quality of life and psychological changes is important in identifying those requiring additional support or referral, although valid and reliable tools are lacking. Individuals should be assessed by practitioners with appropriate knowledge and skills and may require referral for specialist lymphoedema treatment.

Malaria

Julie A. Carter

University College London and Kenya Medical Research Institute/Wellcome Trust Research Laboratories

Malaria is defined as an acute febrile illness with parasitaemia (presence of parasites in the blood), although this may not be detectable, depending upon local capability for parasitologic confirmation. Four species of protozoal plasmodia: *Plasmodium falciparum*; *P. vivax*; *P. ovale*; and *P. malariae* can cause human malaria, transmitted by the female *Anopheles* mosquito when biting for a blood meal. The clinical features of uncomplicated malaria, i.e. fever, diarrhoea, headache, generalized aching and vomiting are non-specific and describe the symptoms of a variety of febrile illnesses prevalent in malaria-endemic areas.

Overview

Over 40% of the world's population from more than 90 countries lives with the risk of malaria. The World Health Organization (WHO) estimates that there are over 300 million clinical cases of malaria each year, resulting in the deaths of over 1 million people, 90% of whom are children under 5 years in sub-Saharan Africa. An estimated 3 million children are admitted to hospital with malaria each year in endemic regions of sub-Saharan Africa, although this represents only a minority of clinical cases, as more than 80% of patients have no contact with formal health services. Many deaths from malaria occur at home, making the establishment of reliable health statistics difficult.

In endemic areas, almost every child is infected with the malaria parasite but most carry it asymptotically. Approximately 1–2% of clinical infections result in severe disease, which is characterized by the presence of life-threatening complications, operationally defined as any malaria syndrome associated with high mortality (>5%) despite appropriate hospital treatment (Newton & Krishna, 1998). The majority of severe disease and mortality is due to *P. falciparum*. Cerebral malaria (CM) is the most severe complication of the disease, presenting as a diffuse encephalopathy. Alterations in level of consciousness, ranging from drowsiness to deep coma, are often precipitated by seizures, which are reported in the histories of 50–80% of children (Molyneux *et al.*, 1989).

The morbid consequences of malaria have, until recently, been overlooked in the face of high mortality rates and the limited means of detecting such problems in many less developed countries. Children surviving severe falciparum malaria were traditionally

considered to make a full recovery. However, research in the past two decades has indicated that severe malaria is associated with persisting neurological and cognitive impairments in survivors. CM is the defined end of the spectrum of severe malaria: clinically discrete and comparatively easy to identify, it has been the subject of most studies, with up to 24% of African children surviving the disease reported to have neurological and/or cognitive deficits (Carter *et al.*, 2005a). Estimates of the prevalence of impairments have varied according to the definition of the disease, length of follow-up and nature of the assessment techniques. However, the data consistently suggest persisting impairments in a proportion of childhood survivors of CM.

The burden of severe disease is borne by children, so the majority of studies investigating neurological and cognitive impairments have involved this population group. Adults living in endemic areas with exposure to repeated malaria infections since birth generally attain a degree of immunity from severe disease. Conversely, travellers from non-endemic areas are highly susceptible to malaria: if the disease is contracted, the outcome depends on factors such as chemoprophylaxis (drugs taken to prevent malaria), exposure to mosquito bites and the genotype (genetic constitution) of the individual. The few studies involving adult survivors of severe malaria have reported that the risk of long-term neurological or cognitive impairment is minimal (Dugbartey *et al.*, 1998), although a study of Vietnam veterans reported some neuropsychological deficits (Richardson *et al.*, 1997).

Research evidence and clinical implications

Early studies

The first studies investigating impairments associated with CM generally used neurological discharge examinations to detect deficits up to 18 months after the acute episode. In consequence, they tended to identify gross deficits, most commonly, ataxia, paresis, cortical blindness and severe speech and language deficits (Bondi, 1992; Brewster *et al.*, 1990; Carme *et al.*, 1993; Meremikwu *et al.*, 1997; Molyneux *et al.*, 1989; van Hensbroek *et al.*, 1997). Children with severe neurological impairments such as spastic tetraparesis or vegetative states often die at home within months of discharge, thus do not present at follow-up (Newton *et al.*, 2000).

Impairments generally fall into two categories; transient and persisting. For example, ataxia is commonly reported at discharge but usually resolves rapidly. Cortical blindness and hemiparesis often improve within the first six months but may not completely resolve (see 'Blindness and visual disability'). Speech and language deficits are reported to be among the most commonly occurring impairments and may present as complete mutism at first, usually improving over time (Bondi, 1992; Brewster *et al.*, 1990). Neurological disorders such as epilepsy may develop after discharge (see 'Epilepsy'). A recent study reported that more than 9% of children assessed up to 9 years after recovery from CM had epilepsy (Carter *et al.*, 2004).

Risk factors

Neurological impairment following CM has been associated with prolonged or focal seizures (Bondi, 1992; Brewster *et al.*, 1990; Meremikwu *et al.*, 1997; van Hensbroek *et al.*, 1997); deep coma (van Hensbroek *et al.*, 1997); prolonged coma (Bondi, 1992; Brewster *et al.*, 1990; Meremikwu *et al.*, 1997; van Hensbroek *et al.*, 1997); raised intracranial pressure (Newton *et al.*, 1997); hypoglycaemia (Bondi, 1992; Brewster *et al.*, 1990) and severe anaemia (Brewster *et al.*, 1990), although the latter finding has not been replicated in other studies (Bondi, 1992). van Hensbroek and colleagues (1997) found that hypoglycaemia and lactic acidosis, strong predictors of fatality, were not independently predictive of neurological impairment. Depth and length of coma and multiple convulsions were the only independent risk factors for subsequent neurological deficits, suggesting that morbidity and mortality may not share a common pathologic pathway.

Studies of persisting impairments

By developing more detailed, culturally-appropriate assessment tools, researchers have started to investigate the prevalence of persisting or subtle impairments in the past decade, often concentrating on neuropsychological functioning (see 'Neuropsychological assessment'). Muntendam and colleagues (1996), in one of the earliest studies of this type, found no impairments in 36 Gambian children assessed an average of 3 years after hospitalization, except in the balance task of a sensory-motor development test. In a larger case control series, Holding and colleagues (1999) administered a detailed battery of cognitive and behavioural assessments, adapted from the Kaufman Assessment Battery for Children (K-ABC), and a brief language assessment to Kenyan children with a history of severe malaria with impaired consciousness. They found a significant sub-group (14%) with impairments in cognitive functions, language and behaviour. Group differences were found on measures of attention, syntax, articulation and behaviour, suggestive of possible impairments in higher order (executive) functions. Boivin (2002) also administered an adapted version of the K-ABC to 29 Senegalese children and matched controls but reported contrasting results, with group differences in performance on aspects of sequential and simultaneous processing, non-verbal performance and attentional capacity.

Carter and colleagues recruited a large, unselected group of Kenyan children with a history of CM and administered a broad spectrum of developmental assessments up to 9 years after the

initial insult. These children performed significantly poorer than children unexposed to severe malaria on measures of vocabulary, pragmatics, higher level language and non-verbal functioning (Carter *et al.*, 2005b). The presence of long-term epilepsy significantly increased the risk of problems in language, memory, attention, behaviour and motor skills. This study also suggested the existence of a group of children with particularly poor performance on assessments in which there was average group performance. Twenty-four per cent of children with previous CM had impaired cognition, behaviour, motor skills, hearing or vision, in comparison with 10% of the unexposed group (Carter *et al.*, 2005a).

Academic performance may be affected by repeated episodes of *P. falciparum* or *P. vivax*, particularly mathematical and language performance (Fernando *et al.*, 2003). Language deficits may cause particular difficulties at school, as much of what is taught is encoded in literate language and most basic academic skills are conveyed through verbal expression. Carter and colleagues concluded that the level of performance shown by children in their study suggested that they would have difficulties in an educational environment without specific support (Carter *et al.*, 2005a), although such support is rarely available in rural Africa. In addition, difficulties may only become apparent as children progress and face more complex cognitive and linguistic demands, both socially and educationally, raising the possibility that the number of children with problems may increase over time.

Impairments associated with other manifestations of falciperum malaria

Falciparum malaria produces a range of other neurological manifestations, such as multiple, prolonged or focal seizures with rapid recovery of consciousness after the seizure, which are more common than CM. Despite this, the prevalence and characteristics of acquired neurological impairment following such manifestations have received little attention. Children with a history of severe malaria with complicated seizures (either prolonged, repetitive or focal) have been found to have significantly reduced performance on measures of phonology, pragmatics and behaviour relative to children unexposed to severe malaria (Carter *et al.*, 2005b). Twenty-four per cent of children surviving severe malaria and complicated seizures are reported to have a neurological or cognitive impairment (Carter *et al.*, 2005a). These results suggest that severe malaria with complicated seizures may be associated with a different pattern of deficits than CM, yet may still cause problems for children, particularly in the educational environment.

Healthcare workers and educators working with children with neurological or cognitive impairments associated with any form of severe malaria should consider the other challenges these children may face, including stigma and reduced opportunities in education, marriage and employment (Kisanji, 1995) (see 'Children's perceptions of illness and death' and 'Stigma'). The negative consequences of impairments may also extend to the child's family, who rely on each family member for help in the home: for example, in most African homes, girls cook, clean the house and look after younger siblings as early as 7 to 8 years of age. On the other hand, Kisanji (1995) argues that children with impairments and their families experience fewer problems in less developed compared

to more developed countries, particularly in the extended family situation in which responsibility for care can be shared amongst family members.

Conclusions

The pattern emerging from research on neurological and cognitive impairments associated with severe malaria is of a problem affecting many more children than initially realized. Evidence of persisting deficits following CM and impairments associated with other neurological manifestations of severe malaria suggest a major public health problem in terms of education and development in malaria-endemic areas.

Mastalgia (breast pain)

Antonio V. Millet¹ and Frederick M. Dirbas^{2†}

¹Valencia School of Medicine

^{2†}Stanford University

Introduction

Most women consider premenstrual mild cyclic breast pain (mastalgia) lasting for one to four days as normal. For some, however, mastalgia can be moderate-to-severe and last over five days each month, causing a great discomfort. Women with mastalgia are generally reluctant to consult medical personnel and those who do will often report recent quantitative or qualitative increases in their pain (Dixon, 1999). Because of increased awareness of breast cancer, more women than ever before are seeking professional advice (Klimberg, 1998) (see also 'Cancer: breast'). Subjective by nature, mastalgia is difficult to quantify and, at present, few physicians adopt a systematic diagnostic approach. Available treatments are few and limited by low efficacy and multiple side effects.

Prevalence and classification

Mastalgia is the most common breast complaint for which women consult their healthcare providers: up to 70% of women under 55 years old experience it (Arona, 1998; Dixon, 1999). Many patients with mastalgia consult once (36%) or more (5%) (Ader & Shriver, 1997). Neither marital status, household income, education, nor race appears to influence these rates (Ader *et al.*, 2001). Breast pain is usually classified as cyclical mastalgia (CM) and non-cyclical mastalgia (NCM). CM occurs in a predictable pattern, often premenstrually, while NCM is described as a constant or intermittent breast pain with no relationship to menstruation. Chest wall pain accounts for 7% of the consulting women.

Natural history and impact on daily activities

Both CM and NCM run a chronic relapsing course: persistence over a decade is not infrequent (Davies *et al.*, 1998). Severe mastalgia accounts for important costs and interferes with sexual activity (48% of the patients), physical activity (36%), social activity (13%) and working/school activity (6%) (Ader & Browne, 1997; Ader & Shriver, 1997). Some patients with CM engage in some form of non-harmful self-medication (e.g. vitamin supplements) and others initiate self-treatments that may be associated with serious adverse effects such as dieting, using over-the-counter medication, diuretics (Ader & Browne, 1997). A higher use of mammography among women under 35 years with mastalgia has been reported (Ader & Browne, 1997; Ader & Shriver, 1997; Ader *et al.*, 2001).

Associated health and behavioural factors

Mastalgia has been associated with smoking, caffeine intake, low levels of physical activity and perceived stress although some of these associations are controversial (Ader *et al.*, 2001). However, nutrition and alcohol consumption are not associated with mastalgia (Ader *et al.*, 2001). Although CM is a well known component of premenstrual syndrome (PMS), over 80% of women with CM do not meet criteria for PMS in either retrospective (Ader *et al.*, 1997) or prospective studies (Ader *et al.*, 1999) (see 'Premenstrual syndrome'). Oral contraceptives have been found in some studies to decrease moderate-to-severe CM (RR 0,45) and somatic symptoms of PMS (Ader *et al.*, 2001; Unruh, 1996).

Attitudes of healthcare providers towards mastalgia

Healthcare providers consulted are commonly gynaecologists (72%), family physicians (10%) and nurses (10%). Responses to questions about pain are not associated with the specialty of healthcare providers (Ader & Browne, 1997). In general, when faced with chronic pain for which they are unable to identify any organic origin physicians tend to conclude that the pain is psychogenic, especially when patients are female (Unruh, 1996) (see 'Psychosomatics'). Common responses are that CM is 'normal' (58%) and due to 'fibrocystic changes' (14%) or 'hormone disturbances' (4%). Less than 10% of providers ordered tests, referred the patient to a breast clinic, advised breast self-examination, suggested avoiding caffeine (4%) or prescribed treatment (4%) (Ader *et al.*, 2001) (see also 'Attitudes of health professionals').

Risk of subclinical cancer

No increased risk of breast cancer has been clearly associated with mastalgia so far (Klimberg, 1998). Cancer has to be considered seriously in any patient with unilateral, localized and persistent mastalgia (Klimberg, 1998).

Mastalgia aetiology

Mastalgia is poorly understood and we can only speculate on its causes.

Histological abnormality

Most of the patients with mastalgia have also breast nodularity and tenderness. There is, however, no relationship between histology and symptoms and it is now accepted that fibrocystic changes are associated with normal breast involution.

Hormonal

Hormonal cause of CM is suggested by its natural history and it has been noted that women with CM are more likely to be premenopausal, nulliparous or be very young when they have their first baby. However, hormone levels are similar in women with and without mastalgia. An increased sensitivity to normal levels of hormones might account for CM but this hypothesis has not been proved.

Other physiological explanations

Mastalgia has been related to an upward shift in the circadian PRL profile, an increased PRL response to TRH and anti-dopaminergic drugs and to a loss of seasonal variations. In addition, there is some evidence suggesting that women with mastalgia have increased levels of saturated fatty acids and reduced proportions of essential fatty acids.

Neurosis

Recent studies have shown increased anxiety and depression among mastalgia patients compared to controls. In addition, women with severe breast pain have had a greater incidence of significant life events than women without severe mastalgia (Colegrave *et al.*, 2001). However, the data is cross-sectional so it is likely that emotional distress is a result of mastalgia rather than a cause. Somatic and emotional distress in patients with mastalgia is likely to influence the care they need (Colegrave *et al.*, 2001). Some people are unlikely to be helped unless their anxiety and fears (about breast cancer and others) are addressed (Colegrave *et al.*, 2001). In states of acute stress, prolactin release may form a physiological basis for mastalgia.

Management

History-taking and pain characterization

Any woman who presents with mastalgia should undergo a careful history-taking (enabling the physician to classify mastalgia) and a thorough physical examination. Prospective daily recording of pain characteristics for at least 2 months using scales such as the Cardiff Breast Pain Chart, or other visual analogue scales, provides the physician with very accurate data (Dixon, 1999; Klimberg, 1998; Ader *et al.*, 1999; Tavaf-Motamen *et al.*, 1998); 20% of the patients will find spontaneous remission of mastalgia (Ader, 2001). Although over-used in women with mastalgia, mammography should be considered in some patients (Ader & Browne, 1997; Ader & Shriver, 1997; Ader *et al.*, 1999; Dujim *et al.*, 1998; Goodwin *et al.*, 1997; Royal College of Physicians, 1998). After completion of

history-taking and PE/imaging, most patients can be reassured and only a few will require any other treatment (Barros *et al.*, 1999).

Lifestyle measures and dietary changes

Numerous lifestyle interventions have been proposed to relieve breast pain. Results must be interpreted with caution due to high rate of responses to placebo (20%) (Khanna *et al.*, 1997) (see 'Placebos').

For women who exercise vigorously, a well-fitting support bra can provide substantial pain relief (Abdel Hadi, 2000). Sedentary life has been reported in up to 80% of women with mastalgia: for them, increasing exercise levels may improve pain via release of endorphins (see 'Physical activity interventions').

The association between methylxanthine consumption (coffee, tea, chocolate, cola beverages) and mastalgia is controversial and results of methylxanthines avoidance are controversial (Goodwin *et al.*, 1997) but given the well-known health benefits of caffeine avoidance, a methylxanthine-restricted diet may be recommended.

Evening Primrose Oil (EPO) is rich in gamma-linolenic acid (GLA), a precursor of prostaglandin E1. It is a well tolerated and effective treatment of mastalgia, although mechanism of action is unknown (Goodwin *et al.*, 1997). Long courses (over 4 months) are recommended by most authors. EPO is considered the first-line treatment in young, potentially long-term, patients with milder symptoms as well as in those who desire pregnancy, who choose to continue using oral contraceptives (OC) or who want to avoid hormonal therapies (see also 'Complementary medicine').

Endocrine therapy

Bromocriptine, danazol and tamoxifen have been shown to be effective in treating cyclical mastalgia (Ader, 2001). With an unknown mechanism of action, Danazol is currently the only medication approved by the United States FDA for this indication. Low-dose regimens are recommended to minimize side effects. Unfortunately, relapse rates after termination of treatment are high (about 70%). It is not recommended as a first-line drug and should be reserved for patients whose pain is strongly affecting their lifestyle.

Use of tamoxifen (10 mg/day) is currently limited, under close supervision, to patients with severe symptoms and in whom all standard first-line therapies have failed. Success rates of tamoxifen in treatment of CM are around 80–90% (GEMB Group, 1997; Kontostolis *et al.*, 1997). Bromocriptine is used as a second line therapy when danazol is not tolerated; response rates to bromocriptine are about 50–65%.

Non-hormonal options

Analgesics taken when pain occurs are often effective (response rate: 90%) (Arona, 1998). Anxiety and other psychological disorders have been found to be more frequent among patients with mastalgia (Fox *et al.*, 1997). Although mastalgia does not represent a psychoneurotic problem, emotions can function as aggravating factors and some women are unlikely to be helped unless their anxiety is addressed. Whether distress is secondary to, or causal of,

mastalgia is part of the presenting problem and requires careful management. Psychiatric evaluation and a trial of antidepressants might be beneficial in patients who fail to respond to 'standard

pharmacological interventions'. If mastalgia is persistently localized to a small area, excision may be curative in exceptional cases. (See also: 'Pain management.')

Meningitis

Julie A. Carter

University College London and Kenya Medical Research Institute/Wellcome Trust Research Laboratories

Meningitis is an acute infectious disease, arising from infection of the membranes surrounding the brain and spinal cord by one of several microorganisms, such as bacteria, viruses, parasites and fungi. Recovery from meningitis has long been associated with severe neurological and/or cognitive deficits, including hearing impairment, epilepsy, motor impairments and learning disability. Those surviving without obvious or severe deficits have traditionally been considered to make a complete recovery. This view has recently been challenged by evidence that subtle cognitive, academic or behavioural problems may persist years after recovery from the disease.

Overview

Most research studies on impairments associated with meningitis have examined bacterial meningitis. Acute bacterial meningitis is one of the most common infections of the central nervous system (CNS). In more developed countries, *Streptococcus pneumoniae* and *Neisseria meningitidis* are the most common pathogens responsible for community-acquired bacterial meningitis. *Haemophilus influenzae* meningitis has almost been eliminated due to the Hib vaccination. Bacterial meningitis is 10 times more common in

children from less developed than more developed countries and the case fatality rate is higher, partly due to the prevalence of HIV infection, which makes children more prone to invasive bacterial infections (Molyneux *et al.*, 2003). In sub-Saharan Africa, the 'meningitis belt', an area stretching from Senegal in the west to Ethiopia in the east with a population of 300 million people, is also subject to recurring epidemics of meningococcal disease, primarily due to the serogroups *N. meningitidis* A, C and W135. A systematic review of 26 reports of neurological and cognitive impairments in survivors of bacterial meningitis indicated that up to 57% of children are left with deficits at least six months after recovery (Carter *et al.*, 2003).

Tuberculous meningitis is usually caused by the spread of *Mycobacterium tuberculosis* from the primary site of infection. In high-incidence geographic areas, tuberculous meningitis usually affects young children several months after primary infection, whereas in low-incidence areas, adults are more often affected, frequently after the reactivation of a dormant subcortical or meningeal focus. In sub-Saharan Africa, tuberculous meningitis is now the most common form of bacterial meningitis due to the impact of HIV/AIDS (Donald & Schoeman, 2004). Despite antituberculosis chemotherapy, tuberculous meningitis continues to cause death or severe neurocognitive deficits in more than half of those affected (Thwaites *et al.*, 2004).

Viral meningitis is the most common cause of acute aseptic meningitis. The most common causes are enteroviruses, herpes viruses, arboviruses and mumps and measles viruses. The disease is usually benign and self-limiting, making the prevalence difficult to estimate because many cases do not present to medical facilities. There are few data on impairments subsequent to aseptic meningitis: reports suggest it has the lowest rate of impairments of any form of meningitis, affecting between 2.2% and 9.1% of children (Carter *et al.*, 2003).

Other forms of meningitis such as fungal meningitis and parasitic meningitis are uncommon in more developed countries. However, *Cryptococcus neoformans*, which usually affects the immunocompetent, is now the second leading cause of death among HIV-positive patients worldwide. Neurological deficits, particularly severe visual impairment, are reported to be common in survivors (Day & Laloo, 2004). Eosinophilic meningitis may be caused by prolonged schistosomiasis infection or ingestion of raw or pickled fish, shellfish, snake or amphibian. Again, severe neurological deficits may occur in those who recover, related to the physical damage caused by the parasites (Day & Laloo, 2004).

Research evidence and clinical implications

The risk of neurological or psychological impairment in survivors of bacterial meningitis is correlated with factors such as age; time and clinical stability before effective treatment; type of micro-organism; bacterial load in the cerebrospinal fluid (CSF); intensity of the patient's inflammatory response and time elapsed to sterilize CSF cultures (Saez-Llorens & McCracken Jr, 2003). Patients at the extremes of age (neonates and the elderly) tend to have the poorest prognosis. Neonatal meningitis is commonly caused by Group B Streptococci and *Escherichia coli*. A prospective study from the USA reported impairments in 68% of survivors

(Franco *et al.*, 1992), although another study, in which data were derived from medical notes, reported a lower rate of 16% (Klinger *et al.*, 2000).

Bacterial aetiology has a substantial impact on the outcome of ABM: pneumococcal meningitis usually results in higher levels of impairment in children, followed by *Haemophilus* and meningococcal meningitis (Baraff *et al.*, 1993). Pneumococcal meningitis also has a devastating effect on morbidity in adults. Van de Beek and colleagues (2004a) reported a higher prevalence of cranial nerve palsy, aphasia, hemiparesis and quadriplegia in adult survivors of pneumococcal meningitis compared to meningococcal meningitis. Tuberculous meningitis is also associated with high levels of impairment in adults: 29% of survivors are reported to have cranial nerve palsy; 16%, hemiparesis and 7%, paraparesis (Thwaites *et al.*, 2004).

Hearing impairment is reported in 2% to 38% of children surviving bacterial meningitis, the variation in reported prevalence due to heterogeneity in study populations, baseline disease severity, methods of assessment, types of impairment investigated and duration of follow-up (Carter *et al.*, 2003). Cochlear dysfunction is considered to be the reason for the hearing impairment: Richardson and colleagues (1997) reported that all children with sensori-neural hearing loss as a result of meningitis failed to produce otoacoustic emissions. The cochlear dysfunction causing the hearing loss is generally thought to be the result of labyrinthitis or the effects of bacterial toxins or inflammatory mediators on the hair cells of the Organ of Corti. Other possible mechanisms include similar processes acting on the endocochlear potential, metabolic defects secondary to low CSF glucose and the effects of changes in intra-cranial pressure (ICP) transmitted through the cochlear aqueduct (Richardson *et al.*, 1997). Meningitic hearing loss has been found to be a risk factor for poor school progress but is not considered to be the cause of the academic and behavioural problems often reported in children following meningitis (Koomen *et al.*, 2003; see also 'Deafness and hearing loss').

Between 2% and 40% of children are reported to have a cognitive and/or language impairment at least six months after recovery from bacterial meningitis (Carter *et al.*, 2003). Deficits, listed in order of frequency, are described as learning disability, speech disorder or delay, developmental delay, language disorder or delay, poor speech or minimal brain dysfunction. Few studies provide information on the neuropsychological impairments underlying learning, speech or language problems. A recent study that investigated the neuropsychological profile of childhood survivors of bacterial meningitis reported generic problems in cognitive functioning, speed and motor steadiness, rather than impairments in specific neuropsychological domains (Koomen *et al.*, 2004a).

Behavioural deficits are reported in 2% to 18% of children, often in the areas of social and school adjustment (Carter *et al.*, 2003). Reported problems, again listed in order of frequency, include hyperactivity, school behaviour problems, irritability, nervousness and temper tantrums (see 'Hyperactivity').

Multiple impairments are reported in the most severely affected survivors: for example, 15% of children in Grimwood and colleagues' (1995) study had more than one impairment. These children often require high levels of rehabilitative and educational support.

At the other end of the spectrum of severity, it is becoming clear that even children who seem to have recovered completely may have residual problems. One-third of Dutch children who survived bacterial meningitis without severe impairments were found to have academic and/or behavioural problems an average of seven years later (Koomen *et al.*, 2004a). Parental reports highlighted problems in school achievement, concentration and mood. Academic limitations were in the areas of mathematics, reading and writing; a high proportion of children had repeated classes at school or had been placed in schools for children with special needs.

The cause of academic and cognitive deficits post-meningitis is still debated, with some suggesting that bacterial meningitis causes a developmental delay and others stating that the illness irreparably impairs cognition (Koomen *et al.*, 2004a). Koomen and colleagues (2004b) identified nine independent risk factors for impairment: sex; birthweight; father's educational level; *S. pneumoniae* as the causative pathogen; CSF leukocyte count; delay between admission and antibiotic therapy; dexamethasone use; anticonvulsant therapy for seizures; and prolonged fever. Risk factors for mortality or morbidity in adults are reported to be those indicative of systemic compromise, a low level of consciousness and infection with *S. pneumoniae* (van de Beek *et al.*, 2004a). A meta-analysis of clinical trials indicated that dexamethasone has a protective effect on hearing in pneumococcal meningitis if administered before the start of antibiotic therapy (McIntyre *et al.*, 1997). Conversely, its use is not reported to prevent severe deficits in adolescents and adults with tuberculous meningitis (Thwaites *et al.*, 2004). Adjunctive corticosteroid therapy has also been associated with a reduction in the frequency of neurological impairments in adult survivors of bacterial meningitis (van de Beek *et al.*, 2004b).

Neurological or cognitive impairments may be transient in nature. Pikis and colleagues (1996) state that five children with motor impairments and one child with hearing loss recovered, although four of the children were left with other impairments. Salih and colleagues

(1991) report a similar pattern with two children with hemiplegia recovering but later developing epilepsy. The prevalence of epilepsy after bacterial meningitis increases over time and may develop years after the initial insult (Pikis *et al.*, 1996; Pomeroy *et al.*, 1990; see also 'Epilepsy'). Health workers and educators need to remain aware of the child's medical history, even years after recovery.

Conclusions

Despite advances in treatment and improvements in mortality rates, the risks of long-term impairment following bacterial and tuberculous meningitis have not been greatly reduced. Survivors may have hearing deficits, cognitive deficits, behaviour problems or seizures. In less developed countries, the toll of meningitis will continue to be more pronounced because of the lack of prompt and adequate treatment and the impact of HIV/AIDS. Children with HIV are more likely to develop impairments subsequent to meningitis than children not infected with HIV, although the types of impairment are similar (Molyneux *et al.*, 2003).

There is increasing recognition of more subtle cognitive deficits in apparently unaffected survivors of meningitis (Grimwood *et al.*, 1995; Koomen *et al.*, 2004a). These deficits, although difficult to detect on formal assessment, may still adversely affect the child's social and educational functioning and suggest that the burden of impairment and disability as a result of meningitis, particularly in less developed countries, is probably much greater than has previously been recognized. With the increasing number of studies examining risk factors for impairment, it may in the future become possible to identify people at higher risk of developing deficits. This would enable more concentrated follow-up of this subgroup of survivors and early detection and adequate rehabilitation of impairments.

Menopause and postmenopause

Myra S. Hunter

King's College London

The menopause literally refers to a woman's last menstrual period occurring, on average, between 50 and 51 years of age. Cessation of menstruation is preceded by a gradual reduction in output of oestrogen by the ovaries and fewer ovulatory cycles (see Richardson, 1993). The menopause transition is characterized by hot flushes and night sweats, or vasomotor symptoms, which are experienced by between 50 and 70% of women in western cultures. For the majority of women these are not seen as problematic. It is estimated that between 10 and 15% of women find them difficult to cope with, mainly because of their frequency or their disruptive effects upon sleep. The average duration of the menopause transition, assessed by menstrual changes and hot flushes, is estimated to be four years but there is considerable variation between women (McKinlay *et al.*, 1992).

The menopause has for centuries been associated with emotional and physical pathology, and myths about its impact upon sexual function, femininity, ageing and women's sanity abound. Menopause was even once postulated to cause psychosis (involuntary melancholia) but there is no evidence to support this. The commonly used term 'change of life' reflects the view that the menopause is closely associated with general emotional and social adaptations of mid-life.

The development of hormone replacement or oestrogen therapy (HRT) has had a major impact upon definitions of the menopause and the development of health services. The menopause is now seen as a cluster of symptoms caused by hormone deficiency and treatable with HRT. While initially recommended for the treatment of hot flushes, HRT has been advocated for the alleviation of symptoms, as well as the prevention of osteoporosis, cardiovascular

disease and even dementia in postmenopausal women. However, claims for long-term health benefits have been modified by the results of recent prospective trials of hormone treatments, particularly the Women's Health Initiative (WHI) (Rossouw *et al.*, 2002) and the Million Women Study (MWS) (Manson *et al.*, 2003). Together these studies suggest that HRT does not protect against cardiovascular disease (and in fact was associated with small but increased risks of strokes and blood clots in the WHI trial) and is associated with a small but increased risk of breast cancer. Moreover, claims that HRT might protect against mild cognitive impairment or dementia were not supported (Tanne, 2004). These findings have impacted upon hormone therapy use, with many women discontinuing or reducing the doses of HRT (Hersh *et al.*, 2004) and an increased interest in non-medical treatments (see 'Osteoporosis' and 'Hormone replacement therapy').

Psychologists and other social scientists have attempted to understand the nature of changes across the menopause transition. Early studies suffered from methodological problems, such as reliance upon clinical samples and use of unstandardized measures. Cross-sectional studies produced mixed results, but several prospective studies carried out in the 1980s and '90s together provide fairly strong evidence that, on average, the menopause does not have a negative effect upon mood or wellbeing for the majority of middle-aged women (Avis *et al.*, 1994; Dennerstein *et al.*, 1999). Similarly, qualitative studies have revealed that the menopause can have benefits, such as the end of menstrual periods and the need for contraception, as well as challenges, such as hot flushes and night sweats and perceiving the menopause as a marker of ageing (Hunter & O'Dea, 1997; Busch *et al.*, 2003). Studies comparing

the experience of the menopause in different cultures tend to reveal a diversity of experience, suggesting that the meaning ascribed to it and women's reactions to it are, in part, culturally determined (Lock, 1986).

Psychologists have examined the influence of psychosocial factors such as life stresses, beliefs and expectations, as well as sociodemographic variables as predictors of menopausal experience. In general, psychosocial factors have been found to account for a greater proportion of the variation in measures of mood and psychological symptoms than stage of menopause. For example, predictors of depressed mood during the menopause include a history of depressed mood, low socioeconomic status, life stress (particularly that involving losses or exits of people from the social network) and negative beliefs, for example, that the menopause is likely to bring emotional and physical problems (Hunter, 1993). The results of a large prospective study of a cohort of women followed since birth in 1946 provides evidence of risk factors across the lifespan, such as parental divorce and prior experience of physical or emotional problems as adults, for psychological distress in midlife (Kuh *et al.*, 2002). Interestingly menopausal status was not associated with levels of distress. Women who have an early menopause, those who have severe hot flushes and those who have undergone surgical menopause have been found to be more likely to experience emotional reactions. Correlational studies have failed to find a significant relationship between oestrogen levels and depressed mood. However, it is possible that the rapid withdrawal of hormones, as occurs with removal of the ovaries, might have impact upon mood.

The implications of this research have been an increased awareness of the need to provide balanced information about the menopause, as well as the need to develop a choice of clinical interventions for those women who do experience problems during this time of life. For example, a health promotion intervention

offered to premenopausal women was found to increase knowledge and reduce negative attitudes to the menopause (Liao & Hunter, 1998). For menopausal symptoms, there is a growing interest in complementary therapies and herbal remedies but the evidence for their effectiveness to date is not very strong (Kronenberg & Fugh-Berman, 2002; Moyad, 2002). The extent to which the symptoms are perceived as a problem is less associated with hot flush frequency or duration, but more with cognitions (perceptions of ability to cope), mood (depressed mood, anxiety) and lower self-esteem (Hunter & Liao, 1996; Reynolds, 1997). There is growing evidence that treatments involving relaxation therapy can effectively reduce hot flushes (Stevenson & Delprato, 1983; Freedman & Woodward, 1992; Irvin *et al.*, 1996). A four-session cognitive-behavioural treatment (CBT) including relaxation has been developed that incorporated stress management, psychoeducation, moderating precipitants of hot flushes and relaxation (Hunter & Liao, 1996). Using a patient preference design (comparing no treatment (monitoring) vs. HRT vs. CBT), women experiencing hot flushes and night sweats during the menopause transition reported comparable improvements following either CBT or HRT. There were no significant changes in the monitoring group but both active treatments resulted in a 50% reduction in hot flush frequency (see 'Cognitive behaviour therapy' and 'Relaxation training').

Given that women who do seek help for menopausal problems tend to have higher levels of distress than non-attenders at clinics, it has been suggested that they may be attributing distress resulting from life problems to the menopause. Problem clarification using a biopsychosocial framework might enable a range of possible influences to be considered. There is some evidence to suggest that psychological interventions might be beneficial in helping women to find appropriate solutions to their problems (Hunter & Liao, 1995; Greene, 2003).

MMR vaccine

Emily Buckley

Staffordshire University

The MMR triple vaccine provides protection from measles, mumps and rubella (German measles). These diseases can have serious complications such as convulsions, temporary or permanent deafness, meningitis, brain damage and even death. However, since the introduction of the MMR vaccine in 1988, these once common diseases have become rare in the Western World.

In the United Kingdom, children are expected to receive two doses of the combined vaccine, the first at 12–15 months of age and the second between three and five years. In 1997/8 MMR vaccination coverage was at its highest level with 91% of all children being vaccinated by their second birthday. However MMR coverage is now at its lowest for over ten years with only 82% of all children being immunized with MMR in 2003, and in some areas such as London, uptake has fallen to only 72%. This is far below the current Government targets which advocate that 95% of all children should be immunized by the age of two in order to maintain herd immunity. In 2002 the UK had the first measles outbreaks for a decade (Office of National Statistics, 2004). Worldwide 890 000 children die as a result of measles each year, mainly in countries with poor immunization coverage (Owens, 2002), and as

such, the reasons for falling immunization rates need to be addressed.

Non-immunization has been attributed to a number of factors including parental attitudes to immunization (such as unfamiliarity with diseases) and unsatisfactory provision of services. Furthermore, media coverage of possible side effects of the MMR vaccine (namely Crohn's disease and autism, see 'Parental attitudes' section below for more details) has been credited with undermining the Governments position on the safety and efficacy of the vaccine (see also 'Immunization').

Parental attitudes

Public perception of the severity of diseases has changed substantially in recent years, largely as a result of the success of vaccination in reducing the morbidity and mortality of disease. In Western countries parents tend to be unaware of the risks that these diseases pose and often report differential opinions regarding the severity of the three diseases, with measles perceived to be far

more serious than mumps or rubella (Smailbegovic *et al.*, 2003). This belief in itself undermines parents' belief in the need for the combined vaccine in light of its potential side effects (see 'Risk perception').

However, the view that parents who refuse the MMR are ill-informed is not justified. Parents who have concerns about vaccination have often read widely in both medical and non-medical literature to try to settle their concerns (Aghley & Campbell, 1998). The majority of parents who refuse vaccinations have very strong views about vaccination, and appear to have received plenty of advice from professionals as well as other sources such as friends, family and the media before making their decisions (New & Senior, 1991).

Adverse publicity in the early 1990's (Wakefield *et al.*, 1993) which linked the MMR vaccine to Crohn's disease led to 2000 fewer children being vaccinated in the following three months. More recently, Wakefield *et al.* (1998) suggested links between the MMR vaccine and autism in children. Recent research has shown that as a result of media coverage, parents want more information to be available to them about the risks and benefits of MMR. Although a large number of studies have failed to find an association between the MMR vaccine and autism (Fombonne & Chakrabarti, 2001; Meldgaard Madsen *et al.*, 2002; Peltola *et al.*, 1998) and despite continued assurances by the Government, MMR uptake rates have continued to fall. Parents still feel that the information available to them about the diseases and vaccine safety is insufficient and unreliable, and that health professionals are not easily available to support them (Bond *et al.*, 1998; Gill & Sutton, 1998). Health professionals have a duty to provide accurate information to enable parents to make an informed decision about whether to have their children vaccinated, and parents' concerns should be treated seriously and sympathetically. Parental confidence in the Government and NHS positions on MMR has declined, and has resulted in great parental anxiety (Begg *et al.*, 1998), not only for the parents who refuse MMR immunization, but also in those who accept the vaccine (Roberts *et al.*, 2002).

Healthcare professionals and government

UK government policy dictates that payments to primary care practices for immunizing children are dependent upon the percentage of the practice immunized, in order to maintain high vaccination levels within the population. Many parents are sceptical of health professionals' motives as a result of this system of payment, and feel that they cannot trust health professionals' opinions due to a perceived vested interest (Evans *et al.*, 2001). Doctors are also becoming increasingly dissatisfied with this payment system, and are aware that it is undermining primary care physicians (GPs) in the eyes of their patients, and so they have requested that the Government changes the payment system.

Furthermore, there resides in the UK a general feeling of mistrust within the public regarding the Government's position on matters of public health which stems from the handling of the BSE (bovine spongiform encephalopathy) crisis (Kmietowicz, 2002).

The public were reassured on numerous occasions over a ten-year period that there was no risk to humans from consumption of meat products from BSE-infected cattle, until in March 1996 it was announced that BSE was likely to have been transmitted to humans causing a variant form of the neurodegenerative Creutzfeldt-Jakob Disease (Phillips *et al.*, 2000). The Government continues to maintain that the combined MMR vaccine is the safest and most effective way to protect children, and that harm will come to children if they do not receive two doses of MMR. However a substantial minority of people would like their children to receive three separate vaccines, and if faced with the option of the combined vaccine or none, will opt for none. The Department of Health's uncompromising position risks alienating the public by failing to respect parent's autonomy (Jewell, 2001).

The Government is in a difficult position because they do not want a repeat of the pertussis (whooping cough) debacle in the 1970's, when the media publicized a possible link between the pertussis vaccine and brain damage. An alternative vaccine was offered to parents, which led the public to believe that the Government had doubts about the vaccine's safety and coverage fell to 30% (Vernon, 2003).

Research also suggests that some health professionals may lack confidence in the need for MMR. Some health professionals are sceptical of the need for MMR in light of the media controversy, and this is likely to affect the advice that they provide to parents. Smith *et al.* (2001) found that the confidence of primary care physicians (GPs), practice nurses and health visitors in the MMR vaccine fell following the publication of Wakefield's two papers. Forty per cent of respondents were unsure about the need for a second dose of the MMR, and more than one in ten felt that a second dose was unnecessary. Providers of complementary and alternative medicine have also been shown to have negative attitudes towards the MMR (Schmidt & Ernst, 2003). These researchers argue that the reduced confidence in the safety of MMR and professional uncertainty about the need for MMR vaccination will have contributed to the decline in MMR uptake, and suggest that more professional as well as public education is needed.

Conclusion

MMR uptake rates have been falling since the early 1990s as a result of speculation regarding potential side effects of the vaccine, and rates will continue to fall if the public confidence in MMR is not restored. The majority of research suggests that parents want more information to be available to them, along with the opportunity to discuss concerns with health professionals, and that this is likely to result in an increase in MMR uptake if parents' anxieties are dealt with effectively. Many health professionals' confidence in MMR has also been undermined, and there is a need to re-educate professionals regarding the need for immunization, and to provide them with all available evidence regarding safety of the vaccine so that they can provide fully informed advice to parents (Smith *et al.*, 2001). Providing parents with more and better information, and involving them in decisions regarding vaccination, moving to a

policy of concordance rather than compliance, is likely to increase confidence in the vaccine, and lead to an increase in MMR uptake. (Bellaby, 2003). However, we must also acknowledge the fact that vaccination is not compulsory in the UK, and therefore parents have

the right to refuse to have their children immunized, whether it be for philosophical or scientific reasons. In the main, parents are acting conscientiously, and do what they perceive to be in the best interests of their children (Bradley, 1999).

Motor neurone disease

Laura H. Goldstein

King's College London

Introduction

Motor Neurone Disease (MND), is a terminal, progressive neurodegenerative disease of the central nervous system. The most common form of MND is amyotrophic lateral sclerosis (ALS) involving both upper and lower motor neurones (UMNs, LMNs). Less common are primary lateral sclerosis (involving only UMNs) progressive muscular atrophy (involving only LMNs) and progressive bulbar palsy (PBP) where there is predominant involvement of the motor systems of the brainstem (Leigh & Ray-Chaudhuri, 1994). Peak age at onset is in the sixth decade of life. Incidence is around 1–2: 100 000 per year and prevalence 5–6:100 000. Median survival in ALS is 3.5 years from diagnosis, death commonly resulting from respiratory failure. Disease progression is generally variable but prognosis is poorest in those presenting with bulbar signs (about 25% of cases). Typically the disease presents with limb muscle weakness. Overall 90–95% of cases are sporadic, but 5–10% are familial in nature. At present there is no cure for MND. However the glutamate release antagonist, riluzole, has been shown to improve survival at 18 months (Lacomblez *et al.*, 1996).

Psychological research concerning people with MND has predominantly involved investigations of the neuropsychological profile associated with ALS and of emotional and psychosocial issues (Goldstein & Leigh, 1999).

Neuropsychological aspects of MND

Increasing evidence that MND involves extra-motor cerebral regions is provided by findings of mild cognitive impairment occurring in up to 35–40% of non-demented patients with ALS, and by reports that a fronto-temporal dementia may also be seen in ~5% of sporadic cases (see 'Dementias'). Cognitive testing in MND patients, with or without dementia, may be complicated by the dysarthria or motor impairment associated with the disease. Whilst cognitive impairment is not exclusively associated with bulbar impairment, they may be associated (e.g. Abrahams *et al.*, 1997; Massman *et al.*, 1996).

MND without dementia

In non-demented MND patients, neuropsychological deficits have been elicited most consistently on executive function tests of orthographic or semantic verbal fluency (e.g. Abrahams *et al.*, 1997, 2000). Executive dysfunction has been shown in studies using the Wisconsin Card Sorting Test (e.g. Abrahams *et al.*, 1997; David & Gillham, 1986; Massman *et al.*, 1996), picture sequencing

(Talbot *et al.*, 1995) as well as measures of response inhibition and focussed attention (e.g. Abrahams *et al.*, 1997).

Memory deficits are more variable and are generally thought to reflect poor encoding. They may occur in tasks of word recognition, learning of object line drawings, recall of prose passages and verbal learning (Abrahams *et al.*, 1997; David & Gillham, 1986). Memory dysfunction may occasionally reflect the consequences of respiratory weakness and can respond to treatment (Newsom-Davis *et al.*, 2001).

Some non-demented ALS patients may demonstrate language impairments (e.g. Abrahams *et al.*, 2004; Rakowicz & Hodges, 1998) although data are contradictory (Abrahams *et al.*, 2000). It has yet to be determined how these cases relate to the dementia that may be associated with ALS (e.g. Bak *et al.*, 2001). In general, more posterior functions are intact.

MND-dementia

In ~5% of sporadic cases and ~15% of familial cases of MND (see Barson *et al.*, 2000 who suggest a higher prevalence rate), a frontal-type dementia occurs, characterized by a breakdown of social and personal behaviour and change in personality. Cognitive impairment usually precedes physical difficulties (e.g. Neary *et al.*, 1990). Where neuropsychological assessment has been possible, impaired abstract reasoning, mental inflexibility, reduced verbal fluency, poor response inhibition, impaired attention, deficient confrontation naming and a non-fluent dysphasia have been reported (e.g. Neary *et al.*, 1990). Memory is variably affected but visuospatial and posterior functions appear intact.

Psychological and psychosocial factors in MND

Mood

Studies have generally reported relatively low levels of anxiety and depression in people with MND (e.g. Goldstein *et al.*, 1998; Hogg *et al.*, 1994; Moore *et al.*, 1998; Rabkin *et al.*, 2000). Anxiety and/or depression scores on questionnaires are variably correlated with functional impairment (e.g. Goldstein *et al.*, 1998; Hogg *et al.*, 1994). Identifying the emotional concomitants of MND is important in view of the reported prognostic role of mood in this illness (Johnston *et al.*, 1999).

About 20% of MND patients experience pathological laughing and crying (emotional lability; EL) which is more common in patients with bulbar symptoms. Measures exist for its evaluation (e.g. Newsom-Davis *et al.*, 1999) and EL may be correlated with aspects of executive dysfunction (McCullagh *et al.*, 1999).

Quality of life (QoL)

Whilst illness characteristics may influence perceived QoL in people with MND (e.g. Nelson *et al.*, 2003), when measured in other than health status terms this has been found to have little direct relationship to illness severity, but more to factors such as social support, existential factors, everyday cognitive functioning and spiritual and religious aspects of the person's life (e.g. Ganzini *et al.*, 1999; Goldstein *et al.*, 2002; Simmons *et al.*, 2000). Studies investigating the impact and nature of caring for a person with MND indicate the need for psychological support to be provided for carers as well as people with MND (e.g. Goldstein *et al.*, 1998, 2000; Rabkin *et al.*, 2000; Trail *et al.*, 2003). Psychological and psychosocial factors may be important determinants of treatment choices (e.g. ventilation) and end-of-life options (Ganzini *et al.*, 2002; Trail *et al.*, 2003) (see Quality of Life).

Conclusions

As a progressive, disabling and life-limiting disease, MND poses several clinical challenges. Research is needed to describe how cognitive impairment impacts on the everyday functioning

and care of people with MND and how this relates to treatment choices and QoL. In addition psychological factors related to having the familial form of the disease require consideration. At present most of the care provided to patients and their families relates to the physical impact of the disease, but since existential issues are clearly important to people with MND, greater clarity concerning how best to address such matters within a medical and psychological setting would be of value. In addition the adoption of theoretical models of coping with illness would assist in both understanding the factors that influence people's adjustment to MND and how best to intervene when adjustment is poor.

Multiple sclerosis

Rona Moss-Morris¹, Kirsten van Kessel² and Emma L. Witt²

¹University of Southampton

²The University of Auckland

Multiple Sclerosis (MS) is a chronic disease of the central nervous system (CNS) for which there is no known cause or cure. The disease is characterized by the destruction of the myelin sheath surrounding the nerves resulting in the formation of plaques. These plaques disrupt the transmission of nerve impulses leading to the symptoms of the illness which include, but are not limited to, spasticity, loss of balance and co-ordination, blurred or double vision, numbness, speech distortions, bladder and bowel problems, fatigue and cognitive dysfunction (Robinson, 1988). Plaques can occur in a variety of different sites resulting in substantial variation in the type and nature of the symptoms across individuals.

The course of the illness is also highly variable and unpredictable (Robinson, 1988). A small percentage of patients have a relatively benign course, characterized by an abrupt onset, little disease activity and no permanent disability. The majority have either a relapsing-remitting or a relapsing-progressive course. Patients experience periods of partial or total remission where the illness is inactive, interspersed with symptom relapses. Finally, MS can have a chronic-progressive course, in which there is a progressive worsening of symptoms and disability. Patients may be initially diagnosed with one type of MS, but over time progress to another.

There is substantial variation in the worldwide distribution of MS, with prevalence rates greater than 100 cases per 100 000 of population identified in many areas of the United Kingdom, Europe and North America. In contrast, considerably lower prevalence rates are found in Africa, the Middle East and Asia (Compston, 1998). MS is more common in females than males, with a gender ratio approaching 2:1 (Compston, 1998).

The onset of MS is typically between 20 and 40 years of age. These relatively young individuals are faced with a lifetime of uncertainty and in a minority of cases, a shortened lifespan. They have to cope with an unpredictable illness, loss of function, alteration of life roles and the experience of a range of debilitating, changeable and sometimes embarrassing symptoms. Consequently, adapting to MS can be particularly arduous. A number of factors are associated with poorer adjustment in MS including the length of the prediagnosis period, illness uncertainty, cognitive impairment, remission status, incontinence and sexual dysfunction (Aikens *et al.*, 1997; Franklin *et al.*, 1988; Mushlin *et al.*, 1994; Rao *et al.*, 1991) (see ‘Coping with chronic illness’, ‘Incontinence’ and ‘Sexual dysfunction’). However, many of these factors are inherent within the illness and provide few indicators as to how health professionals may be able to assist patients in adjusting to MS. This chapter will focus on psychosocial factors which may provide potential avenues for assisting the adjustment process, and in some instances, possibly attenuate the disease process.

Emotional responses

Emotional states have been linked with MS onset or exacerbation throughout the history of the disease. In the late nineteenth century Charcot related experiences such as grief and anger to MS onset. In the early twentieth century it was widely held that an MS-prone personality increased susceptibility in the face of emotional stress (LaRocca, 1984). Although more recent research has found no

evidence of a premorbid MS personality profile (VanderPlate, 1984), the role of emotions in MS is clearly important.

MS patients report a range of emotions in response to experiencing an unpredictable, degenerative and debilitating illness including depression, anger and anxiety (Mohr & Cox, 2001). Emotional responses may also be associated with neurological changes and a small percentage of patients experience pathological laughing and crying and euphoria (Mohr & Cox, 2001).

Depression is the most commonly studied emotional state in MS. Around 50% of MS patients report a lifetime prevalence of major depression (Mohr & Cox, 2001). Depression may be due to a number of factors including the psychosocial consequences of the illness or the neurological changes associated with the disease process. In some instances, depression may be an iatrogenic effect of MS disease-modifying drugs.

Rates of anxiety also appear to be high with reported point prevalence rates ranging between 19% to 34% (Mohr & Cox, 2001). However, anxiety and other emotional responses in MS have received less attention in the literature. More work is needed in this area because not only do patients' psychological responses impact on their quality of life, but preliminary evidence suggests that they impact on the MS disease process itself. Psychological distress and depression has been shown to affect levels of T-helper cells implicated in the immune system's attack on the CNS, and to increase levels of the cytokine interferon-gamma (Mohr *et al.*, 1998; Foley *et al.*, 1992) (see 'Psychoneuroimmunology').

Stress

Further evidence that emotional states may play an important role in the exacerbation of MS disease comes from the stress literature. A meta-analysis of 14 studies found that stressful life events were associated with MS exacerbation, with a weighted average effect size of $d=0.53$. The results were not affected by differences in study design, method and sample characteristics, and were significant for exacerbation at onset and during the course of disease (Mohr *et al.*, 2004b). These results are particularly pertinent when one takes into account that interferon beta, the class of drugs used to moderate the disease process in MS, show an average effect size in exacerbation reduction of $d=0.36$, and this effect reduces after the first year (Filippini *et al.*, 2003).

How stress contributes to disease activity is less clear. One possibility is that stress impacts on the immune system, but to date there is no specific biological model to explain the effect of stress on individuals with MS disease. It is also not known whether different types of stressors have a differential impact on the disease process, or whether it is the nature of the emotional response to the stressor that is most important.

A model of stress and MS also needs to take into account a bi-directional relationship, where stress is both a result of living with the condition and a contributor to disease progression (Schwartz *et al.*, 1999). MS itself may be a source of considerable stress and adjustment to the illness has been shown to be related to disease characteristics (McReynolds *et al.*, 1999). However, there are a number of factors that may moderate the stressful effects of the illness such as the way in which patients cope with their illness, their social resources and their illness perceptions. These are discussed in turn.

Coping

Much of the work on coping in MS has adopted the Folkman and Lazarus (1984) coping framework, which suggests that the impact of a potentially stressful event is moderated by the person's appraisals of the event as threatening, their available coping resources and the actual strategies put in place to deal with the stressor (see 'Stress and health'). In support of this model is the preliminary evidence that coping strategies may moderate the relationship between stress and disease activity. Mohr and colleagues (2002) found that greater use of distraction was associated with less stress and fewer new brain lesions eight weeks later. Furthermore, coping strategies have been shown to be better predictors of adjustment to MS than level of physical impairment (McCabe *et al.*, 2004). Poorer adjustment has been consistently associated with a greater reliance on passive, avoidant emotion-focused coping (Mohr & Cox, 2001). Research on the use of problem-focused coping is more mixed, with some studies finding a significant correlation with better adjustment outcomes, and others reporting no relationship. It may be that certain problem-focused strategies are more effective at different stages of the disease (Mohr & Cox, 2001).

Social support

Social support is also important for adjustment to chronic illness. In MS, low levels of social support and less use of social support seeking are associated with higher levels of psychological distress and depression (Mohr *et al.*, 2004a). Peer support from other people with MS is often proposed as an effective means of reducing MS-related distress and is frequently used by MS support groups. However, intervention studies provide inconsistent evidence of a beneficial effect of peer support on adjustment (Messmer Uccelli *et al.*, 2004). It may be that peer support is more appropriate at certain stages of the disease process, and for coping with particular issues. Alternatively, it may be that the most beneficial effects of social support are experienced when people actively seek the type of support they need. Messmer Uccelli and colleagues (2004) suggest that social support interventions that aim to teach people with MS methods of accessing support, as well as coping skills, may be more effective in enhancing adjustment. Further research is needed on the roles and interaction between social support and coping strategies in adjustment to MS (see 'Social support and health').

Caregivers

Partners and family members often play a key caregiving or social support role to people with MS. This can be a demanding task as caregivers are often the main source of emotional and physical support, sometimes for many years. They may also face their own adjustment issues in relation to their partners' or family members' MS, including psychological distress, reduced social and recreational opportunities and financial strain. Caregivers of people with MS report less social support than the general population, with lower levels of support associated with greater distress (McKeown *et al.*, 2003). This suggests that caregivers should also

be considered when looking at interventions aimed at helping patients with MS adjust to their condition.

Illness and symptom perceptions

Although most of the studies investigating psychosocial aspects of adjustment to MS have focused on the coping literature, there is a growing body of evidence that patients' beliefs are also important in adjusting to MS. The illness representations framework refers to the thoughts and beliefs a person has about their illness, and the way he/she understands and makes sense of the disease (Leventhal *et al.*, 1997). Illness representations influence how someone will respond or behave, and in turn these behaviours affect adaptation to the condition.

Studies which have looked at illness representations in patients with MS have shown that believing a wide range of symptoms are associated with the condition and that MS has many negative effects on one's life is associated with increased social dysfunction, poor self-esteem, depression and anxiety, higher level of illness intrusiveness and greater impairment in physical functioning (Jopson & Moss-Morris, 2003; Vaughan *et al.*, 2003). These effects are independent of the severity of the illness itself. The only domain of adjustment more closely associated with the severity of the illness is physical dysfunction. There is also evidence of an association between illness beliefs and fatigue in MS, and that fatigue in MS may in part develop because of a feeling of helplessness in the face of symptoms and a tendency to focus unduly on bodily sensations (Jopson & Moss-Morris, 2003; Vercoulen *et al.*, 1996, 1998) (see 'Lay beliefs about health and illness' and 'Symptom perception').

Psychological interventions

The evidence reviewed above suggests that psychological interventions may be useful in helping patients to develop skills to cope with emotions and to adjust to the MS diagnosis and symptoms. To date, there have been few randomized controlled trials evaluating the efficacy of psychological interventions with MS patients. In their review of the empirical literature, Mohr and Cox (2001) note that most studies have focused on the treatment of depression in MS evaluating cognitive-behavioural therapies (CBT), relaxation, supportive group therapy and antidepressant medications (see 'Cognitive behaviour therapy', 'Relaxation training' and 'Social support interventions'). One recent comparative trial found that CBT and sertraline were more effective than supportive-expressive group psychotherapy at reducing depression in MS (Mohr *et al.*, 2001). However, only small numbers of patients made significant improvements, and the authors of this study recommend more aggressive strategies such as a combination of treatment modalities. Another study found that telephone-administered CBT decreased depressive symptoms in MS patients (Mohr *et al.*, 2000), offering an alternative treatment delivery method for patients who are unable to attend clinic appointments.

Future interventions for MS patients need to focus on a broader range of adjustment variables, such as coping with symptoms like fatigue and pain, levels of social adjustment and generalized distress. The fact that illness representations contribute to outcome suggests that it might be important to provide MS patients with skills to develop accurate beliefs about their illness and modify those illness cognitions that have been shown to relate to poorer outcome. Similarly, more work needs to be done on finding alternatives to passive coping strategies in MS and to test the efficacy of stress reduction techniques on slowing MS progression.

Myasthenia gravis

Ruth Epstein

Royal National Throat, Nose & Ear Hospital

Myasthenia gravis

Myasthenia gravis is a neurological disease which is characterized by abnormal muscle fatigability. It may affect any group of muscles; head and neck muscles are initially most affected, with extraocular muscles most commonly involved (Stell, 1987). The disease is relatively rare, with an incidence between 2 and 10 per 100 000 (Garfinkle & Kimmelman, 1982). This condition occurs in all ages, but is usually seen in young adults and is twice as common in women as men. Onset for females is reported in the third decade of life, while in males it is during the sixth decade (Garfinkle & Kimmelman, 1982). Aetiology is unknown, but current evidence suggests that it is an autoimmune disease attributed to a decrease in the number of acetylcholine receptors in the motor end plate (Fritze *et al.*, 1974).

Patients with myasthenia gravis tend to show bulbar symptoms, with the initial and most common being drooping of the eyelids or ptosis (Grob, 1961). They also report dysarthria characterized by hypernasality, reduced loudness, increased breathiness and articulatory imprecision (Aronson, 1990), dysphagia, diplopia,

weakness of the legs and blurred vision. The unique features of myasthenia gravis are fatigability, fluctuation of function and restoration of function after rest (Colton & Casper, 1990). Diagnosis depends on the typical clinical picture and can be confirmed by intravenous administration of edrophonium (Tensilon Test), laryngeal electromyographic measurements or detection of anti-acetylcholine receptor antibodies in the blood. If the patient is asked to count aloud, the voice gets progressively less distinct and more nasal.

A common diagnostic pitfall is the interpretation of symptoms of myasthenia gravis as being psychogenic, especially if the patient has a history of psychiatric illness. Furthermore, physical signs in early myasthenia gravis are often precipitated by emotional stress, accounting for the possibility of mistaking this disease for a conversion reaction (Ball & Lloyd, 1971) (see also 'Psychosomatics').

A number of recent studies have examined the psychosocial impact of myasthenia gravis. On the whole, the results suggest that patients with this condition experience depression at a higher rate than the general population and at a similar rate as patients with other chronic illnesses (Fisher *et al.*, 2003; Magni *et al.*, 1988;

Knieling *et al.*, 1995). Furthermore, patients with myasthenia gravis who attributed their illness to psychosocial factors proved to be more depressive, insecure and excitable at the time of diagnosis. Interestingly, six months later, they demonstrated a psychological stabilization and decreased depression, which was attributed to using an emotionally centred coping process (Knieling *et al.*, 1995).

Medical management of myasthenia gravis consists of administration of anticholinesterase drugs (e.g. pyridostigmine) with

steadily increased dosage, until the desirable effect is obtained. Steroids are used for severe cases (Smith & Ramig, 2003). The effectiveness of thymectomy (removal of the thymus gland) remains debatable.

Most remissions occur in the first few years of the disease, but relapses are common. Neonatal myasthenia is occasionally seen in infants of affected mothers, but usually resolve in a few weeks.

Neurofibromatosis

Rosalie E. Ferner

Guy's Hospital

Neurofibromatosis 1 (NF1) is a common autosomal dominant disease with an estimated birth incidence of 1 in 2500 and a prevalence of 1 in 4000 (Huson *et al.*, 1991). The principal and defining clinical features are café au lait patches, skinfold freckling, cutaneous neurofibromas (benign peripheral nerve sheath tumours), iris Lisch nodules (hamartomas) and characteristic bony dysplasia (Huson *et al.*, 1988; National Institutes of Health Consensus Development Conference, 1988) (Table 1). The majority of patients are diagnosed by the age of three years. NF1 arises as a spontaneous mutation in 50% of individuals and there is a wide variety of disease expression in patients with NF1, even within families. Neurofibromatosis 1 is clinically and genetically distinct from the rare condition neurofibromatosis 2, which is characterized by bilateral vestibular schwannomas (benign tumours of the eighth cranial nerve), schwannomas involving other cranial nerves, spinal nerve roots and peripheral nerves and by central nervous system meningiomas and gliomas (Evans *et al.*, 1992).

The gene for NF1 has been identified on chromosome 17q11.2 by positional cloning (Viskochil *et al.*, 1990; Wallace *et al.*, 1990) and

the protein product is neurofibromin, which has high levels of expression in the brain and acts as a tumour suppressor (Gutmann *et al.*, 1991). Neurofibromin reduces cell proliferation by promoting the inactivation of the protooncogene p21RAS, which has a major role in mitogenic intracellular signalling

Table 1. Diagnostic criteria for neurofibromatosis 1

Two or more criteria are needed for diagnosis:

- Six or more café au lait patches >15 mm in adults and >5 mm in children
- Two or more neurofibromas or one plexiform neurofibroma
- Axillary or groin freckling
- Lisch nodules (iris hamartomas)
- Optic pathway glioma
- A first degree relative with NF1
- A distinctive osseous lesion such as sphenoid wing dysplasia or thinning of the long bone cortex with or without pseudoarthrosis

Source: National Institutes of Health Consensus Development Conference, 1988.

pathways. Neurofibromin also has a function in adenylate cyclase control and microtubule binding, which could be crucial for normal brain function (Guo *et al.*, 2000; Xu, 1990).

The neurological complications of NF1 arise from tumours and malformations, as a result of deformities of the skull and skeleton and as a consequence of neurofibromas compressing peripheral nerves, spinal nerve roots and the spinal cord (Ferner, 1998). Cognitive impairment is a common and clinically important complication of NF1 and patients may present with low IQ, specific learning problems, behavioural difficulties or a combination of these manifestations (Ferner *et al.*, 1996; North *et al.*, 1997).

The majority of individuals with NF1 have an IQ in the low average range and the mean full scale IQ is between 89 and 94 (Ferner *et al.*, 1996; Legius *et al.*, 1995; North *et al.*, 1997). Profound cognitive deficit is unusual and an IQ less than 70 occurs in 4.8% to 8% of patients, only slightly higher than in the general population (North *et al.*, 1997). Some researchers have reported lower performance IQs than verbal IQs in children with NF1, but this discrepancy is not evident in most assessments of children or adults (North *et al.*, 1997). There is no indication that cognitive impairment in NF1 improves with age in either cross-sectional or longitudinal studies (Hyman *et al.*, 2003; Ferner *et al.*, 1996).

A child with a specific learning disability, fails to attain his or her academic potential, regardless of cultural or socioeconomic background and in the absence of overt neurological, genetic or general medical problems. The disorder may be evident despite a normal or more rarely, above-average intelligence. Specific learning difficulties have been documented in 30% to 65% of children with NF1 and include visual spatial impairment, incoordination, handwriting and language difficulties, poor reading, spelling and mathematical skills (Lorch *et al.*, 1999; Schrimsher *et al.*, 2003). Individuals with NF1 have slower reaction times and higher error rates on continuous attention and divided attention tasks, compared with matched controls (Ferner *et al.*, 1996).

Children with NF1 exhibit disruptive behaviour, misinterpret social cues and attention deficit hyperactivity disorder (ADHD) has been observed in 50% of young NF1 patients (Mautner *et al.*, 2002) (see 'Hyperactivity'). In a recent study on personality, NF1 children and adolescents were less conscientious and more emotionally unstable and irritable than their peers in the general population (Prinzie *et al.*, 2003). Poor social skills have been described in NF1 children, particularly those with ADHD. NF1 individuals have a reduced capacity for planning and organization, display inflexibility and have difficulty in selecting appropriate strategies to cope with unfamiliar and complex tasks, consistent with impaired executive function (Ferner *et al.*, 1996).

The aetiology of the cognitive deficit in NF1 has not been elucidated. Psychiatric problems including depression, anxiety, psychosis, alcoholism and anorexia nervosa have been observed. These problems do not account for cognitive dysfunction in NF1, but, as might be anticipated, patients with anxiety and depression have slower reaction times and motor coordination (Ferner *et al.*, 1996). Autism has been reported in NF1 individuals, but epidemiological studies do not indicate that this disorder occurs with increased frequency in NF1 (Mouridsen *et al.*, 1992). Socio-demographic factors, macrocephaly, age and gender differences do not contribute to learning problems (Ferner *et al.*, 1996; North *et al.*, 1997). The presence of neurological and/or medical complications is weakly

associated with a lower mean full scale IQ in NF1 patients (Ferner *et al.*, 1996).

A neuropathological study considered the anatomical basis of intellectual impairment and the authors hypothesized that cognitive problems in NF1 are related to underlying migrational abnormalities in the developing brain (Rosman & Pearce, 1967). Unidentified bright objects (UBOs) have been identified as focal areas of high signal intensity on T2 weighted MRI, predominantly in the basal ganglia, brainstem and cerebellum (Bognanno *et al.*, 1988; Ferner *et al.*, 1993; North *et al.*, 1997). The lesions do not cause obvious neurological deficit and develop in the majority of children with NF1, but tend to disappear in adulthood. Their nature and significance is unclear, but they may represent aberrant myelination or gliosis (Di Paulo *et al.*, 1995). There have been reports that the presence of UBOs is associated with cognitive dysfunction, and in some cases this was related to the site and volume of the UBOs (Joy *et al.*, 1995; Moore *et al.*, 1996). A recent study suggested that UBOs represent a marker for impaired fine motor performance in individuals with NF1 (Feldmann *et al.*, 2003). However, other studies have found no association between the number, size and sites of T2-weighted hyperintensities and cognitive problems in NF1 (Ferner *et al.*, 1993; Legius *et al.*, 1995). In a longitudinal study, a significant decrease in the number size and intensity of UBOs on brain MRI over an eight-year period, was not mirrored by a commensurate improvement in cognitive performance in NF1 children (Hyman *et al.*, 2003).

Mice with heterozygous mutations of the *NF1* gene have exhibited similar cognitive deficits to those encountered in humans. Visual spatial problems, impaired motor coordination and attention deficit have been documented and improve with remedial training (Silva *et al.*, 1997). Mouse models of learning problems in NF1 have suggested that the cognitive dysfunction is due to excessive Ras activity leading to impaired long-term potentiation, in turn caused by increased GABA-mediated inhibition (Silva *et al.*, 1997).

An increased frequency of structural brain abnormalities has been demonstrated in NF1 individuals with severe learning problems in whom there is a deletion of the whole *NF1* gene (Korf *et al.*, 1999). The authors conjecture that intellectual impairment in these patients arises from abnormal brain development as opposed to a defect of brain function associated with haploinsufficiency of the *NF1* gene product.

Currently there is no specific treatment for individuals with cognitive impairment and NF1. Prompt educational assessment is advocated with appropriate remedial help and one to one tuition where possible. Children with an ADHD profile respond to judicious treatment with methylphenidate and cognitive behavioural therapy is helpful in some instances (Mautner *et al.*, 2002) (see 'Cognitive behaviour therapy'). Recent research has demonstrated a reversal of cognitive deficits in mice when Ras activation is blocked by farnesyl transferase inhibitors (Costa *et al.*, 2002). Lovastatin, a specific inhibitor of HMG-CoA improves learning difficulties in a mouse model and has a potential therapeutic role in NF1 patients (Li *et al.*, 2005). These latest findings have brought us a step closer to an understanding of the molecular basis for cognitive impairment in NF1, and coupled with longitudinal clinical studies and functional imaging should prepare the way for future therapy in humans.

Non-cardiac chest pain

Christopher Bass

John Radcliffe Hospital

Introduction

Non-cardiac chest pain (henceforth referred to as NCCP) has attracted an enormous amount of both clinical and research interest in the last five years. This has been accompanied by the publication of a number of major reviews by gastroenterologists (Botoman, 2002) as well as psychiatrists and psychologists (Thurston *et al.*, 2001). More recently Accident and Emergency (A&E) physicians have also shown an interest in the topic (Goodacre *et al.*, 2002), whereas cardiologists have been more concerned with rapid access chest pain clinics (Wood, 2001). What has provoked the resurgence of interest in this topic?

There are a number of possible explanations. First, the establishment of rapid access chest pain clinics in the UK has revealed that between one-half and three-quarters of patients attending these clinics do not have coronary heart disease. Second, high rates of patients with 'undifferentiated' or non-cardiac chest pain have been detected in chest pain observation units established both in the USA and the UK. Finally, there is evidence that these patients are not only a significant economic burden (Eslick *et al.*, 2002) but also that certain interventions can reduce chest pain, consultation rates and disability (Mayou *et al.*, 1997).

In this chapter the prevalence, diagnosis, pathophysiology, economic burden and management of patients with non-cardiac chest pain will be discussed. It is important to emphasize that the cause of NCCP is often multifactorial and that eliciting the interaction between each patients' symptom experience and interpretation is a key part of the clinical interview.

Prevalence

Non-cardiac chest pain (NCCP) occurs frequently within the general population. A recent population based survey based in the USA found that 23% of adults aged 25–74 years had NCCP, (defined as 'those who reported chest pain but did not have a history of cardiac disease' Lock *et al.*, 1997). In an Australian population-based study of 672 residents aged 18 years or more asked to complete a validated chest pain questionnaire, 39% had experienced chest pain at some time. Of these, only 77% had a history of MI and 8% of angina (Eslick *et al.*, 1999). Of those classified as having NCCP, most (77%) had not presented for medical care in the past 12 months.

Non-cardiac chest pain accounts for 2–5% of all admissions to accident and emergency departments, although the proportion of patients with NCCP presenting to A&E departments depends to a large extent on referral criteria. Over 50% of patients referred to cardiologists with chest pain are diagnosed as having non-cardiac

chest pain (Mayou *et al.*, 2000). Significantly, these patients continue to report symptoms and disability six months after discharge from the clinics. More recent findings from rapid access chest pain clinics (RACPC) have revealed that between 50 to 75% of all patients seen in these clinics have NCCP. Furthermore, when RACPC is offered to all patients of any age there is a threefold increase in the patients assessed for chest pain. This suggests that increasing numbers of patients with NCCP are being referred to secondary care services.

Aetiology/pathophysiology

In all likelihood NCCP is the consequence of a combination of minor physical and psychological factors that interact. Most clinical accounts of NCCP include a variety of causes including musculoskeletal, gastro-oesophageal (mainly reflux and oesophageal dysmotility), 'micro vascular' angina and psychological causes.

Gastroenterological causes

It should be appreciated that a variety of common gastroenterological conditions usually associated with abdominal pain can occasionally present with chest pain. These include peptic ulcers, gallstones and irritable bowel syndrome (see 'Gastric and duodenal ulcers' and 'Irritable bowel syndrome'). If the history is suggestive these can be investigated using appropriate techniques (de Caestecker, 2002). This having been said, the oesophagus is the more usual focus of gastroenterological scrutiny.

Gastro oesophageal reflux remains the single commonest disorder resulting in atypical chest pain. Treatment with acid suppressive agents results in a significant improvement in chest pain in the majority of patients, and in a recent double-blind placebo controlled trial of omeprazole versus placebo a significant clinical response was noted in the patients receiving omeprazole (Achem *et al.*, 1997), although a large placebo effect was seen, common in therapeutic trials in patients with functional upper GI disorders (see 'Placebos').

Musculoskeletal disorders

There is no doubt that musculoskeletal disorders can cause chest pain but their overall prevalence is difficult to estimate. Musculoskeletal causes of chest pain have been implicated in 13 to 19% of patients with negative cardiac studies (Wise *et al.*, 1992). In this study 69 of 100 patients with chest pain but normal coronary angiograms had chest wall tenderness compared to none of the 25 control arthritic patients. Of particular interest in this study is that reproduction of typical chest pain occurred in only 16 of these patients. Furthermore, the exact origin of musculoskeletal pain

Box 1. Screening questions for panic attacks

In the past 6 months have you ever had a spell or an attack when you suddenly felt frightened, anxious or very uneasy?

In the past 6 months have you ever had a spell or an attack when for no reason your heart suddenly began to race, you felt faint, or you couldn't catch your breath?

If the answer is 'yes' to either question then continue:

Obtain description

Did any of these spells happen when you were not in danger or the centre of attention, such as in a crowd or when travelling?

How many times have you had these spells in the past month?

remains obscure, but it should be appreciated that chest wall tenderness may simply be a reflection of convergence of visceral and somatic nociceptors at spinal level, in a similar fashion to the well-recognized phenomenon of abdominal tenderness elicited in painful abdominal visceral disorders.

Cardiovascular factors

In some cases the cause of pain may be related to functional abnormalities of blood flow at a microvascular level, although the clinical relevance of these remains controversial.

Psychosocial factors

Although anxiety disorders (with or without panic attacks) have been shown to be associated with non-cardiac chest pain (Katon, 1996; Fig. 2), not all patients with non-cardiac chest pain have conspicuous psychiatric disorder. The importance of identifying panic attacks or panic disorder is that these patients tend to report persistent medically unexplained symptoms and place an undue financial burden on outpatient services and hospitals as well as have a negative impact on social and vocational function if the diagnosis is not made. There are a number of useful screening questions for panic attacks that should be asked. These are shown in Box 1.

The patient may report psychological problems such as abnormal health beliefs, e.g. exaggerated fears of death, marked conviction of disease despite negative findings and intense bodily preoccupation. These abnormal illness beliefs and worries can act as maintaining factors in patients with non-cardiac pain whatever the initial cause (see also 'Lay beliefs about health and illness' and 'Symptom perception').

Pathophysiological mechanism such as hyperventilation can also contribute to symptoms (Cooke *et al.*, 1996) and, in some patients, cardio-respiratory symptoms can be provoked by using simple provocation tests. For example the breath-holding test and hyperventilation provocation test (where the patient is asked to over-breathe for 60 seconds) can reproduce chest discomfort in some patients (see 'Hyperventilation').

In addition for looking for physical signs, such as chest wall tenderness, by palpating the chest wall, it is important to examine the patient for evidence of physiological arousal involving the respiratory symptom, such as gasping or sighing respirations as well as very short breath-holding time (less than 20 seconds).

When enquiring about psychological abnormalities it is important to ask patients about experience of distressing life events as precipitants of anxiety and depressive disorders. These should be routinely sought by physicians, i.e. asking about events signifying loss, threat and rejection in the six to nine months before the

onset on the symptoms. For example, asking questions such as 'tell me about any changes or set backs that occurred in the months before your symptoms began' are useful. A component of life stress; severe and chronic threat, has been shown to have a large and consistent effect on symptom intensity over time in patients with irritable bowel syndrome (Bennett *et al.*, 1998). This and other research (e.g. Bradley *et al.*, 1993) suggests that the experience of the stressor, and efforts to deal with it, constitute the primary link between prolonged exposure to threat and changes in symptom intensity and reporting (see also 'Life events and health' and 'Stress and health').

An interactive model

Research findings therefore suggest that a multitude of somatic factors interact to produce chest-localized sensations that it may act as a stimulus to misinterpretation and pain. Thus, gastro-oesophageal reflux and occasionally oesophageal spasm are common triggers, as are hyperventilation, chronic obstructive airways disease and intercostal muscle spasm. All these factors can cause chest discomfort. A crucial factor for determining the way in which these sensations are interpreted are previous experience, e.g. exposure to family members or others with heart disease, and previous illness experience, e.g. heart or lung disease as a child. Recent distressing life events may act as factors to provoke increased arousal and low mood, which may lead to physiological changes and bodily sensations such as palpitations and chest discomfort. These may then become a focus for somatic preoccupation and concern about underlying heart disease. Subsequent sensations of chest pain, from whatever cause, may then be interpreted by the patient as signs of disease, especially in the presence of adverse and ongoing psychosocial circumstances.

The importance of iatrogenic or physician-induced factors should never be underestimated. For example, in one-third of patients in one well-known study the discovery of a systolic murmur or tachycardia by physicians was ascribed incorrectly to heart disease, yet these patients with normal hearts were advised to restrict activity (Wood, 1941). Inappropriate treatment of non-cardiac chest pain with anti-anginal medication is also ill-advised, and it is worth noting that it is very difficult to 'undiagnose' angina (Dart *et al.*, 1983).

Management

The aim for early and effective intervention is crucial, but patients vary not only in terms of the frequency and severity of symptoms

and associated disability but also in their needs for explanation and treatment of their physical and psychological problems. For this reason management needs to be flexible. Patients may find a factsheet helpful (see Price *et al.*, in press).

Avoiding iatrogenic worries

A consultation for chest pain is inherently worrying. Inevitably, many patients assume that they have severe heart disease that will have major adverse effects on their life. These concerns may be greatly increased by delays in investigation, by comments or behaviours by doctors and by contradictory and inconsistent comments.

Communication

Problems in the care of patients with chest pain often arise from failures in communication between primary and secondary care. Lack of information and contradictory and inconsistent advice makes it less likely that patients and their families will gain a clear understanding of the diagnosis and treatment plan. It is important to make sure that information is passed on to and understood by patients and relatives (see 'Healthcare professional-patient communication').

Effective reassurance

Those with mild or brief symptoms may improve after negative investigation and simple reassurance. Further hospital attendance may then be unnecessary. Others with more severe symptoms and illness concerns will benefit from a follow-up visit four to six weeks after the cardiac clinic visit (or A&E/emergency room visit), which allows time for more discussion and explanations. This may be with either a gastroenterology or cardiac nurse in the outpatient clinic or with a doctor in primary care. It also provides a valuable opportunity to identify patients with recurrent or persistent symptoms who may require further help (see below) (see 'Reassurance').

Specialist treatments

Psychological and psychopharmacological treatment should be considered for patients with continuing symptoms and disability, especially if these are associated with abnormal health beliefs, depressed mood, panic attacks, or other symptoms, fatigue or palpitations. Both cognitive-behavioural therapy (Mayou *et al.*, 1997; van Peski-Oosterban *et al.*, 1999) and selective serotonin re-uptake inhibitors (Varia *et al.*, 2000) have been shown to be effective. A recent systematic review of psychological interventions in the management of non-specific chest pain suggested a modest benefit, particularly for those using a cognitive behavioural framework (Kisely *et al.*, 2005) (see 'Cognitive behaviour therapy').

Tricyclic antidepressants are helpful in reducing reports of pain in patients with chest pain and normal coronary arteries (Cannon *et al.*, 1994). However, patients often find them unacceptable in

the context of NCCP because of side effects, even at low dosage. Sertraline may be an effective alternative according to one randomized trial in NCCP and certainly appears to cause fewer side effects.

Organizing care

Because of the heterogeneity of the needs of patients with non-cardiac chest pain, a 'stepped' approach to care has been proposed. The cardiologist working in a busy outpatient clinic may require access to additional resources if he nor she is to provide adequate management for the large numbers of patients with non-cardiac chest pain, some of whom may have co-existing angina or be recovering from coronary artery bypass graft surgery. One way of doing this is to employ a specialist cardiac nurse who has received additional training in the management of these problems. The nurse can provide patient education, simple psychological intervention and routine follow-up in a separate part of the cardiac outpatient clinic. For those patients who require more specialist psychological help it is important for the cardiac department (possibly the cardiac nurse) to collaborate with the clinical psychology or liaison psychiatry service.

Some departments may prefer to offer treatment as an out patient using a group cognitive behavioural approach. In this way more patients can be managed with fewer treatment resources. Potts *et al.* (1999) demonstrated that a psychological treatment package (education, relaxation, breathing training, graded exposure to activity and challenging automatic thoughts about heart disease) was not only feasible, but also reduced pain, psychological morbidity and disability, and improved exercise tolerance.

Long-term management

In many patients the symptoms can become chronic and difficult to manage, and in this group psychological factors are likely to be important (Miller *et al.*, 2001). There is evidence that a strong clinician-patient interaction leads to not only greater compliance and satisfaction, but also to a reduced number of return visits for IBS-related symptoms (Owens *et al.*, 1995). A key component of this 'physician-patient interaction' is the physician's awareness of the patient's psychosocial history, which includes enquiry about relevant life events, exploring psychosocial history and eliciting patients' concerns. Moreover, patient's complaints improve more when they visit the same clinician throughout the outpatient consultations and when they are satisfied with the consultations (van Dulmen *et al.*, 1997). In some patients several consultations may be required to help them make tentative connections between psychological factors, life stresses and the pain (Guthrie & Thomson, 2002). Even in the absence of conspicuous mood disorder, low dose tricyclic antidepressants are effective long-term treatments in patients with functional chest pain (Prakash & Clouse, 1999).

Obesity

Jennifer J. Thomas and Kelly D. Brownell

Yale University

Introduction

A critical turning point in the history of human food consumption has become evident. With famine and undernutrition the central food issues for much of human history, we now face the opposite: overnutrition and obesity. The number of individuals who are overnourished now equals or exceeds the number undernourished (WHO, 1998), and the prevalence of obesity is increasing in every corner of the world. The percentage of individuals in the USA who are either overweight or obese rose from 55.9% in 1994 to 65.7% in 2002 (Flegal *et al.*, 2002; Hedley *et al.*, 2004) leading the Centers for Disease Control and Prevention to apply the word 'epidemic' (CDC, 2004).

The most widely used index of obesity is the body mass index (BMI), which is calculated as weight in kilograms divided by height in meters squared (i.e. kg/m^2). The World Health Organization defined obesity as a $\text{BMI} \geq 30 \text{ kg}/\text{m}^2$, given epidemiological data showing that mortality at this weight is increased by 30% (Manson *et al.*, 1995). Premature deaths associated with obesity are primarily attributable to cardiovascular disease, Type II diabetes and several cancers (Pi-Sunyer, 1993) (see chapters on 'Coronary heart disease' and 'Diabetes mellitus'). Obesity also carries many additional complications including hypertension, sleep apnoea, gall bladder disease and osteoarthritis (see 'Hypertension', 'Sleep apnoea' and 'Osteoarthritis'). Some, but not all, data suggest that obesity is associated with increased risk for psychological distress, including binge eating and depression. Because obese individuals are considered personally responsible for their condition, psychosocial complications include prejudice and discrimination in important areas of living such as education, employment and healthcare (Puhl & Brownell, 2001). The annual cost of obesity to society in the USA alone, calculating direct costs such as preventative and treatment services and indirect costs such as the value of lost wages due to disability and early mortality, is estimated to be \$70 billion annually (Colditz, 1999), which constitutes 9.4% of the national healthcare expenditure. Beyond these costs are the realities of human suffering produced by the physical and psychosocial impact of being overweight.

Aetiology: the toxic environment

Body weight is determined by a complex interaction of biological and environmental factors. Genetic predisposition makes weight gain more likely in some people than others, and helps account, to some extent, for a host of factors such as susceptibility to related diseases. Heritability estimates of obesity range from 25–40% (Bouchard, 1994; Price, 2002). A landmark study found that weights

of adult adoptees more closely resembled the weights of their biological than their adoptive parents (Stunkard *et al.*, 1986). Investigators have recently identified at least five single-gene defects which produce obesity in laboratory animals, perhaps most notably the leptin deficiency marked by the ob/ob genotype in mice (Zhang *et al.*, 1994). However, it is unlikely that most human obesity results from simple Mendelian determinism. Research suggests that genes confer a wide range of 'obesigenic' vulnerabilities, including differences in food preferences, resting metabolic rate, weight gain in response to overfeeding and body distribution of excess adipose tissue.

Genes, however, are not the cause of the obesity epidemic. Even the highest heritability estimates (in the range of 40%) leave the majority of population variance in weight to be explained by non-genetic factors. In addition, genes cannot explain why people from less obese countries gain weight when moving to more obese countries or why the prevalence of obesity in many countries has increased year by year. The most parsimonious explanation for the recent upsurge in obesity is the modern environment. Strong environmental forces converge to make unhealthy food choices almost inevitable. Unhealthy foods taste good and connect with biological preferences for sugar and fat, but are also convenient, highly accessible, promoted heavily and inexpensive; exactly the factors that should apply to healthy foods but do not. The confluence of these characteristics is so troubling that one of us (KB) has labelled modern conditions a 'toxic environment' (Brownell, 1994).

Human preferences for energy-dense foods (such as those high in sugar and fat) are either inborn or learned very early in life (Birch, 1999). The palatability of highly caloric foods may have bestowed an evolutionary advantage on our hunter-gatherer ancestors, who needed to consume as much as possible when food was plentiful to avoid starvation. In addition to being appetizing, calorie-dense foods are available as never before, not only in convenience stores, vending machines and fast food restaurants, but also in locations previously unrelated to food retailing, such as schools, pharmacies, hospitals and petrol (gas) stations. Even small changes in accessibility can alter consumption volume: in one experiment, secretaries given candy jars to keep on their desks ate nearly three times as many candies as secretaries who had the jars placed on another desk just two meters away (Painter *et al.*, 2002).

The promotion of unhealthy foods is stunning. In 1998 alone, soft drinks companies spent \$115.5 million on advertising, and fast food giant McDonald's spent more than \$1 billion. These figures tower over the mere \$1 million spent by the National Cancer Institute to promote the '5 a day' fruit and vegetable campaign (Nestle & Jacobson, 2000). The average American child views

10 000 food advertisements annually on television alone; nearly all are for foods such as sugared cereals, soft drinks, fast foods heavily processed snacks and sweets/candy. Joining this traditional marketing are high levels of 'guerrilla marketing' (e.g. product placements in movies and video games, virtual placements of products in reruns of television shows and infiltration of schools).

The economics of food also conspire to create unhealthy eating. Heavy and selective subsidies of the agriculture industry (especially the corn industry) have many effects, including artificial support of a meat-based diet and low costs for sweetening foods with high fructose corn syrup. The low cost of unhealthy foods compared with better alternatives creates an inverse relationship between energy density and cost and a positive and unfortunate relationship between nutrient density and cost, making it difficult for poor individuals to buy healthy foods. Price disparities are so great that some experts have equated dietary recommendations aimed at low income families to 'economic elitism' (Drewnowski & Barratt-Fornell, 2004).

It is probably no coincidence that meals and waistlines are being 'supersized' in parallel; an increase in portion size has coincided with the increase in obesity. Current marketplace portions of ready-to-eat foods such as bagels, hamburgers, muffins and soft drinks exceed US Food and Drug Administration serving size recommendations by two- to eight-fold (Young & Nestle, 2003). The original Hershey's chocolate bar weighed 0.6 oz.; current versions range from 1.6 to 8 oz. Studies show that consumption increases with increasing portion size. Individuals presented with increasingly large servings of potato chips on succeeding days ate more chips when served larger portions and did not compensate by altering their caloric intake at dinnertime three hours later (Rolls *et al.*, 2004). This phenomenon has been demonstrated in both children and adults and applies to many foods eaten under many circumstances. There is some evidence that people compensate less well at subsequent meals when between meal snacks come in liquid rather than solid foods (Almiron-Roig *et al.*, 2003), making soft drinks a logical target for change.

In addition to the convergence of factors encouraging a high calorie diet, the tacit promotion of sedentary behaviour is yet another manifestation of the toxic environment. Despite experts' exercise recommendations of 30 minutes per day, 28% of US adults do not engage in any physical activity and another 28% are not regularly active (Mokdad *et al.*, 2001). For much of history, individuals survived by being physically active (acquiring food was necessary and demanding). People were then paid to be active because work required physical labour. Today, energy-saving devices ranging from tractors to computers mean that individuals must expend leisure time and financial resources to join health clubs or purchase exercise equipment in order to be active. Additionally, unsafe, busy streets and suburban sprawl discourage pedestrian traffic. Although 25% of all trips are shorter than one mile, three-quarters of these are made by automobile (Koplan & Dietz, 1999).

In sum, genetic factors may predispose individuals to weight gain, but aggregate environmental pressures promoting an increasingly energy-dense diet and sedentary lifestyle bring that vulnerability

to fruition. Put more succinctly, 'genes load the gun, the environment pulls the trigger' (Bray, 1998).

Overcoming obesity: the tension between treatment and prevention

Given the negative health impact of excess weight, it is imperative that individuals who are already obese receive adequate care. Research supports a stepped approach in which treatment intensity and expense is proportional to degree of overweight (NIH/NHLB, 1998). Obese individuals are encouraged to reduce weight by increasing physical activity and consuming an appropriate diet, but those at higher BMIs may require increasingly structured interventions to that end. For example, individuals with a BMI < 27 may benefit from self-directed diet and exercise efforts or brief weight-management counselling from a primary care physician. Those somewhat heavier could consider embarking on a self-help or behavioural weight loss programme. At BMI \geq 30, individuals may benefit from pharmacotherapy or a very low-calorie diet, and, at BMI \geq 40, bariatric surgery becomes an option. Utilizing this treatment-matching algorithm, it is hoped that maximum health benefits can be achieved at minimum risk to the patient. It must be noted, however, that longitudinal studies comparing treatments across BMI categories are necessary to validate this approach.

Within the stepped care paradigm, behavioural treatments are among the most conservative and produce modest but perhaps the most sustainable weight losses. Well replicated findings suggest that a 20-week course of group behavioural treatment induces a 9% reduction in initial body weight; without further treatment, individuals typically regain one-third of their lost weight in the ensuing year (Wadden & Foster, 2000). Very low calorie diets (400–800 calories/day) result in double the weight loss of the 1200–1500 calories/day meal plan of traditional behavioural approaches, but are associated with such rapid weight regain that there is no significant difference between the two treatments at two-year follow-up (Torgerson *et al.*, 1997). One of the more robust findings of the behavioural literature is that physical activity is the best predictor of sustained losses (Pronk & Wing, 1994) (see 'Physical activity and health' and 'Physical activity interventions').

Pharmacotherapy represents the next most intensive approach. Two primary medications are approved by the US Food and Drug Administration for weight reduction and maintenance. Combined with improved diet, both drugs produce modest weight losses. Sibutramine, which acts on receptors in the hypothalamus to increase satiety, produced a 7% reduction in initial weight at one year compared with a 2% reduction in patients assigned to placebo (Lean, 1997). Orlistat, which partially blocks the absorption of dietary fat, produced a 10% loss in contrast to 6% with placebo (Davidson *et al.*, 1999). Neither medication alone has been shown to be superior to behavioural interventions, although it is possible that the combination of behaviour therapy and pharmacotherapy may improve outcome.

For people double their ideal body weight or more, obesity surgery can be impressive. Different surgical methods have been used over the years, moving from the intestine initially to the stomach at

the present time. Surgical advances have greatly reduced complications, improved weight losses and reduced costs (e.g. laparoscopic surgery has decreased hospital stays). Obesity surgery produces striking weight losses (100 pounds or more in many cases), good maintenance and clear changes in risk factors.

Initial treatments set the goal of helping patients achieve ideal weight (Foster, 1995), but large weight losses are rare and difficult to maintain. In addition, it is now clear that even small reductions of 5–15% of initial body weight may help reduce (but certainly not eliminate) the health complications of obesity such as hypertension and Type II diabetes (Blackburn, 1995). Unfortunately, such small improvements are seldom satisfying to patients and often lead to unhappiness and abandonment of the diet and exercise regimen. Thus, given that current treatments are either not very effective (e.g. behaviour therapy, pharmacotherapy) or too expensive to implement broadly (e.g. surgery), they should be conceptualized as needed care for the afflicted but not sufficient to reduce prevalence. Prevention must become the priority and environmental change the means to that end.

Public policy approaches

Public policy has a profound impact on diet and activity patterns of the population. There are countless examples, including the following: (1) agriculture subsidies that affect the prices of healthy and unhealthy foods; (2) trade policy that affects the availability and price of particular foods in different countries; (3) a failure to regulate food advertising, thus offering food companies unfettered access to children; (4) education policy that fails to connect healthy eating and physical activity with academic performance; and (5) community planning policies in which neighbourhoods are constructed in ways that discourage physical activity.

The environment conspires to damage eating, inhibit movement and overwhelm personal responsibility. Policy change is a powerful means for improving the environment, but only recently has this concept been considered in the realm of obesity prevention. Relatively little research has evaluated the impact of policy change, hence it is difficult to establish priorities. Based on what is known about the determinants of obesity, combined with experience in areas such as tobacco control, it is possible to propose certain approaches as a beginning.

Policy interventions span a wide range of possibilities affecting issues as broad as economic policy to local issues such as selling soft drinks in schools. These have been discussed in detail elsewhere (Brownell, 1986; Brownell & Horgen, 2004; Nestle, 2002; Nestle & Jacobson, 2000; Schmitz & Jeffery, 2000). Examples will be given here.

The first two examples pertain to creating a healthier food environment for children. One is to restrict children's food advertising. The high exposure, combined with research showing that such advertising has a negative impact on eating, suggests that reduction would be helpful (Brownell & Horgen, 2004; Horgen *et al.*, 2001; Story & French, 2004). Young children do not have the cognitive ability to distinguish between advertising and regular programming, placing them at particular risk.

Banning soft drinks from schools would be another potential public policy solution to protect children. A single 20 oz bottle of a typical cola drink contains 15 teaspoons of sugar. Soft drink consumption is associated with weight gain, displacement of milk consumption and dental cavities (American Academy of Pediatrics, 2004). Unfortunately, many school districts turn to 'pouring rights' contracts with soft drink companies to raise money for academic needs and extra-curricular activities. Unhealthy eating is then both promoted and modelled in the school environment. Replacing soft drinks with healthier beverages might help reverse this troubling trend.

A third potential public policy approach would be to tax unhealthy foods. Given the inverse relationship between energy density and cost, current pricing schemes encourage the consumption of high-calorie, processed foods to the exclusion of fresh fruits and vegetables. A tax on poor foods could work not only to decrease consumption of these foods but also to raise funds for public health programmes. One comprehensive review suggested that even small levies, such as one penny per can of soda drink, could raise substantial revenues (Jacobson & Brownell, 2000).

A final public policy solution would be to invest in community improvements that would promote the integration of physical activity into everyday life. For example, municipal funds could be directed towards building parks and sidewalks. New urban developments could eliminate homogenizing zoning requirements which discourage walking. Indeed, even simple, inexpensive interventions such as posting signs encouraging the use of stairs rather than escalators have demonstrated some effectiveness (Brownell *et al.*, 1980) (see also 'Health promotion').

Conclusion

By any standard, obesity is a global crisis. The death, disability and personal suffering attributed to poor diet, physical inactivity, and weight gain are startling. Extrapolating ahead from the condition of today's children, the picture becomes even more grim.

Society's response, particularly in individualist cultures like that of the United States, has been to blame obesity on the individual, ascribe negative personal characteristics as the cause, and resist changing conditions which make it so difficult for people to eat better and increase activity. The resistance to change is profound because of the political influence of massive food and agriculture businesses.

Treatments for obesity may help those in need but show no promise as a public health intervention. Lack of effectiveness and high cost limit the impact and number of people who can be treated, thus making prevention a priority. The default approach, to count on education in the hope that people will be persuaded to change, has thus far demonstrated limited impact. Public policy change, beginning with the concept of protecting children from a toxic environment, is likely to have the largest and most rapid influence. Courageous action, based in science and buffered from special interests, will be necessary to reverse the troubling deterioration in diet, physical activity and weight seen around the world.

Oral care and hygiene

Gerry Humphris

University of St Andrews

Oral diseases and prevention

Virtually without parallel, individual action can successfully prevent the onset of two major oral diseases; dental caries and periodontal disease. Dental caries is a localized progressive decay of the tooth, marked by the demineralization of the enamel by organic acids. These acids develop owing to the fermentation of carbohydrates in the diet by plaque bacteria. A cavity is produced by the continued destruction of the tooth mineral and protein, resulting eventually in the tooth pulp and the surrounding tissues becoming infected. Periodontal disease is an inflammatory condition of the connective tissues which support the tooth and gums (gingivae). It is the result of toxins produced from bacterial plaque which initiates an inflammatory reaction. The tissue breakdown which ensues is due to the inflammatory response being left unchecked. The bone supporting the tooth atrophies leading to high tooth mobility and eventual tooth loss. Although the two diseases are not ordinarily life-threatening, they do influence the quality of life (Locker, 2004; McGrath & Bedi, 2004) and the economic efficiency of nations through the loss of millions of working hours each year, costs associated with treating the diseases and debilitating pain from the diseases themselves (Miller *et al.*, 1975).

Caries and periodontal disease are ubiquitous. The World Health Organization report on oral health presents a comprehensive picture of the extent of both diseases, especially in industrialized countries. (Petersen, 2003). Approximately 60–90% of school children have been affected and almost all adults (above 95%). Most children worldwide show evidence of early signs of periodontal disease. Severe periodontitis is found in about 5–15% of the global population. This condition is often responsible for premature tooth loss. It is clear that lifestyle has a major impact on the incidence of both these diseases, especially, frequent intake of sugary foods and drinks, tobacco and alcohol consumption. A good example is smoking behaviour and its link with periodontal diseases (see, for example, 'Cancer: head and neck'). Over half of the incidence of this disease in adults is attributable to smoking. (Tomar & Asma, 2000) From an international perspective, models are being developed which include behavioural risk factors to understand caries levels across varied communities. (Pine *et al.*, 2004)

There are a number of other conditions which are typically seen in oral medicine units such as lichen planus, burning mouth syndrome, candida and oral cancer. Malfunctioning saliva glands can produce dry mouth (Sjogren's syndrome). Craniofacial conditions require psychological issues to be explored such as temporomandibular dysfunction and body dysmorphic disorder. A review of the psychological factors implicated in nine oral health disorders

encourages psychologists and other social scientists to collaborate with oral health specialists (Albino, 2002). The major emphasis of a great deal of this work has been to develop and evaluate a variety of methods of changing individual preventive health behaviours. These behaviours can be divided into two main groups. First, those that improve oral hygiene and include tooth brushing, flossing (and other mechanical aids to remove plaque) and dieting to reduce sugar intake and, secondly, those behaviours that are seeking professional advice, such as attendance to oral screening programmes and dental check-ups. Two sections below summarize some of the important psychological findings associated with each of the two groups of preventive health behaviours. A short section will follow noting some of the changes in oral health and how psychologists are responding.

Psychological approaches to oral hygiene

The encouragement of new preventive health behaviours such as the use of fluoride mouth rinses, has demonstrated the limited positive effect of informative campaigns with young people (Kegeles & Lund, 1982). The success of these approaches may be limited as many of these behaviours have a strong habitual element to them, therefore previous behaviour may help to explain current behaviour (Humphris & Weinman, 1990). Theory of Planned Behaviour constructs (Tedesco *et al.*, 1993) have successfully predicted flossing and tooth brushing behaviour (see 'Theory of planned behaviour'). Interventions which have introduced modelling and reinforcement procedures rather than concentrating solely on attitude change paradigms (for a review, see Blount *et al.* (1989)) have shown substantial impact. These behavioural approaches have clearly demonstrated the benefit of analyzing the consequences of the behaviour to the individual (see 'Behaviour therapy'). However, the problems of maintenance and generalization outside the limits of the programme intervention still have to be overcome, as well as resource implications.

Psychological approaches in oral care

There are many examples of applying psychology in the dental office or surgery. They can be categorized into differentiating the psychological profiles of people who enter the care system and the psychological factors responsible for adherence to advice. Oral health disorders are typically chronic and therefore require continued care over extensive periods. These areas will be briefly discussed under the next three subsections.

Entrance into the care system

Numerous studies, consisting of national and regional cross-sectional surveys have investigated the variables believed to be responsible for the public's utilization of dental services. Three factors, other than the system variables associated with geographical location and the supply of dental personnel includes cost, perception of need for treatment and anxiety or fear. A large literature now exists on understanding the aetiology, maintenance and treatment of dental anxiety (Kvale *et al.*, 2004). The great advantage of studying this psychological construct in the dental context is that it is common (Kent, 1997) and most people are not embarrassed to discuss their worries unless their fears are very severe (Moore *et al.*, 2004). Attempts to reduce dental anxiety by the use of explanatory and advisory leaflets, modelling films and introductory preparatory sessions have shown proven benefits in increased attendance especially for moderately dentally anxious people (Gatchel, 1986). Even the completion of a brief formal dental anxiety assessment instrument has been found to confer benefit in certain circumstances (Dailey *et al.*, 2002)

Acceptance of treatment

Avoidance of certain dental procedures such as the local anaesthetic injection and the use of the high-speed drill is a common psychological phenomena, which causes considerable distress to the patient and concern for the dentist. Technological advances in dental technology are changing traditional treatment approaches however. These include the use of laser hand pieces removing the dread of the high-speed drill's whine. Minimal invasive approaches, which are also of low cost, have been developed, especially for less developed countries (Frencken & Holmgren, 2004). One such procedure (atraumatic restorative treatment) consists of the decayed tooth material being literally scooped out from the tooth cavity and an anti-bacterial lining introduced, followed by an airtight filling material which caps the tooth. Dental clinicians may help their patients by attending carefully to their patients' concerns through listening; providing patients the opportunity to control aspects of the timing of their treatment (e.g. stop signals); and giving advice on pain management. Other procedures found to be effective include relaxation and distraction. (Humphris & Ling, 2000) (see 'Relaxation training' and 'Pain management').

Maintenance of care

To encourage care over longer periods, the psychological issues discussed above for oral hygiene practices are important. The outcomes for dental visitors from utilizing screening and treatment services have been found to be important determinants for repeated

appointments. Patient satisfaction scales have shown the importance of dental personnel attending not only to the technical quality of their service but also to the personal aspects of dealing with individuals, each with unique concerns and wishes. Clinicians may improve the strong associations that patients make to a particular practice by attending closely to appropriate communication skills designed to set the patient at ease, to make the dental environment predictable and introduce a relaxed and friendly personal style (Sondell *et al.*, 2004). It is widely recognized that dentists are prone to occupational stress and burnout (see 'Burnout in health professionals'). These unpleasant psychological states are known to influence quality of care and appear to be linked to significant changes in the design of health service organizations. Research continues to identify those individuals most at risk at the start of their careers (Humphris *et al.*, 2002) and ways to prevent staff developing severe burnout (Brake *et al.*, 2001).

The future

The trend of caries reduction, some improvements in periodontal health and increased personal longevity bring the possibility of major changes in the oral health of western industrialized populations, so that the problems experienced in the future may focus on the attrition of tooth enamel and its repair. Individuals' responses to a chronic reduction in the effectiveness and aesthetics of worn teeth will become an important area for the future. A related topic is the increasing technology of prosthetics and provision of implants to replace teeth lost through infection, traumatic accident or malignancy. The employment of psychological models of disability and distress have contributed to the careful evaluation of some of these procedures (Lindsay *et al.*, 2000). What is not often appreciated by the public that these new advanced prostheses, possible because of dramatic improvements in bio-materials will require life long maintenance including annual inspections to ensure the implant's viability. Oral-facial cancer appears to be increasing in some populations especially in countries where tobacco consumption has shown a rapid increase (e.g. China and Eastern Europe). Interest is growing in attempting to prevent this particularly aggressive cancer. The field of food selection and its importance in modifying preferences to a non-carcogenic diet, the beliefs of individuals about fluoride additives in water supplies and the public's views towards water quality, are areas to which psychologists are making increasing contributions. The common risk factor approach will become an important consideration in the implementation of future oral health promotion programmes. The benefits of reducing sugar intake will impact not only on the incidence of caries but also on body mass index and obesity concentrating coordinated efforts to improve a spectrum of health improvements.

Osteoarthritis

Isidro Villanueva and Alex Zautra

Arizona State University

Osteoarthritis (OA) is the most common rheumatic disease and most prevalent form of arthritis (Centers for Disease Control and Prevention, 1990). OA is described as a degenerative non-inflammatory type of arthritis that mainly affects the joint cartilage; however, in a proportion of subjects, some mild inflammation can occur. OA is characterized by softening and disintegration of articular cartilage, with reactive phenomena such as vascular congestion and osteoblastic activity in the subarticular bone, new growth of cartilage and bone (i.e. osteophytes) at the joint margins and capsular fibrosis.

Epidemiology of osteoarthritis

Moderate-to-severe OA affects more than 12% of the adults between the ages of 25 and 74 years (CDC, 1990). Estimates of the prevalence of OA based on radiographic evidence range from 30–90%, depending on age group (Lawrence *et al.*, 1998). In women, for

example, OA is currently the most prevalent chronic condition and the rate of self-reported cases is projected to increase in the next decades. A population-based study showed incident rates of 2/1000 per year for knee OA (Wilson *et al.*, 1990). Advancing age, female gender and obesity constitute some of the identified risk factors for OA (see 'Obesity'). Symptomatic OA affects roughly 6% of the adult population, 10% of persons over 65 years of age (Felson *et al.*, 1987). Among those individuals between the ages of 55–64, the rate is estimated at 7.5% for women and 4.3% for men (Davis *et al.*, 1991).

Estimated medical care costs for individuals with arthritis in the US were \$15 billion and total costs were \$65 billion in 1992 (Yelin & Callahan, 1995). It has also been estimated that OA is responsible for 75–80% of the total cost of arthritis (Felts & Yelin, 1989). The management of the risks of gastrointestinal complications of non-steroidal anti-inflammatory drugs (NSAIDs) may add a substantial amount to the cost of treatment (Straus, 2001).

Clinical features of osteoarthritis

The principal clinical features of OA are pain, stiffness, decreased function, joint instability, muscle weakness and fatigue. Pain worsens with use of the affected joint and is alleviated with rest. Morning stiffness lasting less than 30 minutes is common. In advanced stages of arthritis most patients show profound structural articular changes, including the impairment of muscles and other peri-articular tissues. These structural changes, accompanied by co-morbidities and age-related regression in physical conditioning, determines further impairment and disability at advanced ages (Manek, 2000).

Impact of arthritis on physical function

Arthritis, in general, is a principal cause of disability, as compared to several other chronic health conditions and after adjustment for age, gender and co-morbidity (Guccione *et al.*, 1994). Functional tasks, such as ascending stairs, walking, transfer from seated to standing position and daily activities, are reported to be severely impaired in arthritis patients. There are multiple interrelated biomechanical and psychological factors which have been reported to influence the pathways that lead to physical disability in people with arthritis (O'Reilly *et al.*, 1998; Salaffi *et al.*, 1991; van Baar *et al.*, 1998a). Quadriceps weakness has often been found to be the greatest single predictor of lower limb functional limitation (Slemenda *et al.*, 1997). Neurological deficits, impaired proprioception, laxity, restricted range of motion and aerobic deconditioning have all been correlated with worse scores on physical function tests (Sharma *et al.*, 1999; Van Baar *et al.*, 1998). Psychological factors such as self-efficacy, coping, depression and anxiety have also been shown to be independent predictors of disability among individuals with knee OA (Lorig & Holman, 1993; Rejeski *et al.*, 1998; Summers *et al.*, 1988) (see 'Self-efficacy and health' and 'Coping with chronic illness').

Management of arthritis

The development of new drugs for OA is hampered by, among other factors, the lack of surrogate markers of disease activity. New information on the role of inflammation in OA has increased our awareness of the disease process and suggested potentially valuable new treatment targets; however, a great deal of clinical research remains until effective new treatments for OA are available. Analgesics and NSAIDs are the most commonly used medications, yet they provide only partial relief. The use of analgesics and, especially, NSAIDs results in high incidence of side effects, with increased risk of major gastrointestinal complications (i.e. ulcers, bleeding, perforation). The prevalence of NSAID-induced ulcers is 10–30% and 15–35% of all peptic ulcer complications are caused by NSAIDs (Tenenbaum, 1999).

The goals for managing arthritis are reduction of pain, prevention or reduction of disability and improvement of quality of life. For many arthritis patients, pain, disability and reduced quality of life persist in spite of treatment (see 'Quality of life'). There is clearly a

need to develop new approaches to enhance the effectiveness of therapeutic strategies.

Health interventions in arthritis

Many guidelines recommend patient education and exercise as complements to medication (Hochberg *et al.*, 1995; Lane & Thompson, 1997). Results with these interventions vary across individuals, regardless of disease activity or medication use.

Exercise therapy

Regular physical activity is associated with better health for people of all ages (Pate *et al.*, 1995) (see 'Physical activity and health'). Current recommendations for the accumulation of 30 minutes of moderate physical activity on most days of the week provide a feasible and effective treatment for persons with arthritis (Department of Health and Human Services, 1996). Many of the factors that lead to disability in arthritis can be improved with exercise (i.e. muscle strength, proprioception, range of motion, cardiovascular fitness and co-morbidities associated with arthritis, such as diabetes, hypertension and obesity) (Baker & McAlindon, 2000; O'Grady *et al.*, 2000).

Muscle dysfunction may be implicated in the pathogenesis and progression of knee OA (Sharma, 2001). Strong quadriceps can decrease impulse loading on the lower limb, which has been identified as a potential factor contributing to onset and progression of knee OA (Radin *et al.*, 1991). Rehabilitation programs have shown a decrease in joint pain and disability without exacerbation of arthritis pain (Schilke *et al.*, 1996; Slemenda *et al.*, 1997).

Regular exercise can also have an impact on psychological status. Affect, effective coping and perception of self-efficacy, have been reported to improve (Bell *et al.*, 1998; Hurley *et al.*, 2003; Keefe *et al.*, 1996). Rejeski *et al.* (1998) found that aerobic and resistance exercise increased self-efficacy, which in turn mediated the effect that such programmes had on disability (see 'Physical activity interventions'). Studies in arthritis have shown beneficial effects of exercise therapy on outcomes (Bautch *et al.*, 1997; Borjesson *et al.*, 1996; King *et al.*, 1991; Kovar *et al.*, 1992); however, psychological characteristics, which are shown to be potential mediators, have rarely been measured.

Psycho-educational interventions

Patient education, defined as any set of planned educational activities designed to improve patients' health behaviours and/or health status (Lorig *et al.*, 1993), is thought to be beneficial in helping patients to cope and co-operate with their disease and its management. Although improvements in pain, functional ability, psychological wellbeing and health status have been shown (Goepfinger & Lorig, 1997; Lorig *et al.*, 1993; Mazzuca *et al.*, 1999), analytic reviews are ambiguous about the effect on these outcomes in arthritis patients (Hawley, 1995; Hirano *et al.*, 1994; Superio-Cabuslay *et al.*, 1996). A recent review found moderate effect sizes for pain and low for functional ability (Hawley, 1995).

The Arthritis Self-Help Course (ASHC) has proven to be effective for patients with arthritis on aspects such as behaviour changes,

self-efficacy and health status (Lorig *et al.*, 1993). It focuses on increasing the participant's perception of being able to cope with pain and other symptoms. The intervention has shown to have a positive effect on the frequency of exercise and relaxation behaviours while reducing pain (Lorig *et al.*, 1985). It has been reported that changes in outcomes obtained with this intervention are not related to changes in behaviours (Lorig *et al.*, 1989), but to changes in self-efficacy (Lorig & Gonzalez, 1992). The ASHC has been shown to be effective in the long-term with improvements in pain and self-efficacy maintained after four years while reducing physicians' visits (Lorig *et al.*, 1993). The reported data do not, however, support the existence of a strong link between changes in self-efficacy and improvement in health outcomes. Thus, it is important to investigate additional psychological dimensions as potential predictors or mediators of this effect.

Emotion-regulation interventions

On the horizon are psychosocial interventions with a new emphasis on emotional regulation (Zautra, 2003, pp. 117–31; Zautra *et al.*, in press). These approaches focus directly on the quality of the emotional life of the patient, and introduce methods through which the patient is better able to regulate their emotional state. Mindfulness meditation, for example, has been used with increasing frequency in pain management (Kabat-Zinn, 1990). In this approach the emphasis is placed not on cognitive-behavioural approaches of pain reduction, but rather on acceptance and 'letting-go' of suffering associated with pain and other stressors. These approaches do not target negative affective states exclusively. More sophisticated emotion-regulation models address the preservation and enhancement of positive states, and the value of emotion complexity rather than simply dampening negative emotions (Davis *et al.*, in press). Once we recognize pain as an emotional process (Craig, 2003) which is influenced by central mechanisms, there can be little doubt but that integrative approaches such as these will be valuable additions to the clinician and his/her osteoarthritis patient (Hamilton *et al.*, in press; van Puymbreck *et al.*, 2004) (see also 'Pain' and 'Pain management').

Traditional physiopathological vs. biopsychosocial model

The vast majority of treatment decisions in rheumatology are driven by the traditional physiopathological model (Hurley *et al.*,

2003). According to this model OA is the consequence of a lifetime of mechanical (ab)use that causes joint damage, physiological disfunction and impairment. Clearly, this model is too simplistic to explain the complexities of a chronic condition such as arthritis. For example, the biomedical model cannot explain why people with advanced joint damage frequently report less pain than people with minimal structural damage, whereas others with low levels of damage often report severe pain (Creamer *et al.*, 1999). Nor can it explain why some people receive considerable benefit from a particular intervention, whereas other people with similar disease activity obtain little or no benefit (Hurley *et al.*, 2003).

Alternatively, the assumptions of the biopsychosocial model for arthritis suggest that there is a biological cause of nociception that is perceived as painful, but the model takes a broader view of pain and disability stating that people's 'pain behaviour' is a product of their beliefs, understandings, experiences and emotions, which may be modulated by their social environment (Turk, 1996). This model emphasizes the role people's beliefs and use of specific coping strategies play in adjustment to living with arthritis. Consequently, this model views arthritis as the result of complex interactions between joint damage, muscle dysfunction, obesity, pain, disability, psychological profile, social support and economic resources (Hurley *et al.*, 2003).

The identified psychological dimensions, however, still explain only a small percentage of the variance of different outcomes in studies with arthritis patients (Persson *et al.*, 1999). Identifying further predictive or mediating factors in emotion regulation may increase understanding of the dynamics of treatment response in the context of different health interventions. Targeting these characteristics in the design of better psychosocial interventions could result in better health outcomes for patients with arthritis or other chronic diseases. Also, the ability to predict outcomes based on psychological profiles may potentially be used for the identification of subjects that could most benefit from psychosocial and complementary health interventions. To date, most studies investigating these issues have been cross-sectional and have studied differences between patients instead of changes over time in the same individuals. A longitudinal design would permit a more thorough examination of potential causal relationships between psychological dimensions and health status change.

Osteoporosis

Myra S. Hunter

King's College London

Osteoporosis is an age-related condition characterized by decreased bone mass and increased susceptibility to fractures. It does affect men but is more common in women after the menopause, predisposing older women particularly to fractures of the wrist, spine and hip (see 'Menopause and postmenopause'). Osteoporosis is considered a major health problem and is increasing in prevalence due to changes in lifestyle, increasing longevity and the greater proportion of older people in the population. The prevalence of osteoporosis in women in the UK was 8.1% in 2002. Therefore, approximately 2.6 million women in England and Wales would have osteoporosis (NICE, 2004) and in the United States this figure would reach at least 20 million women (Turner *et al.*, 2003).

Osteoporosis is usually defined, somewhat arbitrarily, by bone density measures (BDM) of bone mass lower than age-matched norms (typically BDM below -2.5 SD). However, fractures may not develop until the seventieth decade. Peak bone mass occurs at the age of 35, after which time bone repair becomes gradually less efficient. After the menopause, bone is lost more rapidly for about 3 to 5 years, and then slows down again. In women over 50 the risk of osteoporosis is estimated to be about one in three and approximately one in six for hip fracture. Risk factors for osteoporosis include low body mass index, current smoking, early menopause, family history of maternal hip fracture and long term systemic corticosteroid use and conditions affecting bone metabolism.

'Primary prevention' aims to increase bone mass during years of bone maturation in the general population by promoting adequate calcium intake (800–1000 mg per day), regular weight-bearing exercise (e.g. brisk walks) and reduction in tobacco, alcohol and caffeine use. There is evidence from large scale cross-sectional general population surveys that knowledge about osteoporosis is limited and that women are not taking adequate preventative measures (Silver Wallace, 2002; Terrio & Auld, 2002). Primary prevention programmes, targeting women of all ages, have produced rather mixed results. For example, Sedlack *et al.* (2000) evaluated three osteoporosis educational programmes of varying levels of intensity and found that while all programmes increased knowledge there were no corresponding changes in beliefs or behaviours. Similarly, Blalock *et al.* (2000) compared an information pack (information

about osteoporosis) with an action pack (how to increase exercise and calcium intake). Those having the information pack increased knowledge but in neither group were there effects upon behaviours. Increasing knowledge amongst young people and producing lifestyle changes for a condition that may, or may not, develop in the future is a problem for primary prevention. Klohn and Rogers (1991) examined young women's intentions to prevent osteoporosis by increasing calcium intake and exercise. They manipulated descriptions of osteoporosis along dimensions of visibility, time of onset and rate of onset. Their results indicated that informing young women that osteoporosis can result in visible or disfiguring consequences increased the appraisal of severity of the condition and also increased intentions to comply with a regimen of increased calcium and exercise. Further prospective research is needed to examine the relationships between intentions and behavioural change in younger women.

'Secondary prevention' refers to efforts to minimize bone loss due to ageing and postmenopausal changes and includes assessment of risk and advice, mainly about diet, exercise and hormone use, for middle-aged and older women. The main focus of medical research has been on the use of oestrogen, or hormone replacement therapy (HRT), which can reduce the risk of spine, hip and other osteoporotic fractures (Lees & Stevenson, 2001). However, recent epidemiological evidence suggests that, for HRT to be an effective method of preventing fractures, continuous and lifelong use is required, which is problematic since only a small proportion of women are prepared to take HRT long term (see 'Hormone replacement therapy').

Although there are conflicting reports, it is generally considered that increasing calcium alone has minimal impact upon reducing bone loss, unless levels are unduly low initially. However, adequate calcium is essential for benefits to be gained from exercise (Smith, 1990). Exercise, and physical activity, has been associated with a positive influence on bone mass in a range of cross-sectional studies, but the effects of exercise interventions have been less consistent. Exercise regimes have been variable between studies, as has the duration of the intervention (Smith & Gilligan, 1991). In a randomized trial of weight-bearing exercise among women treated with HRT after a surgical menopause, the addition of exercise was

associated with a highly significant 8% increase in spinal bone density in one year, compared with HRT alone (Notelovitz *et al.*, 1991). In addition to strengthening bones, physical activity may reduce the risk of fractures by improving muscle strength and balance, which may act to prevent falls, especially in the elderly (see 'Physical activity interventions').

Community studies focusing on middle-aged and older women appear to be more promising than those targeting younger women. In a UK study two 2-hour health promotion workshops were offered to 45-year-old women, which increased knowledge about the menopause and lifestyle changes (Liao & Hunter, 1994). Five years later the women, then aged 50, were reassessed in order to examine the long-term impact of the intervention (Hunter & O'Dea, 1999). The intervention group had retained their higher levels of knowledge compared with the controls. Smoking prevalence reduced in both groups by 7% across the five years; while exercise levels increased in the intervention group from 44% to 56% but remained the same at 39% for the controls. Turner *et al.* (2003) developed an osteoporosis prevention programme, which produced changes in behaviours, particularly weight-bearing physical activity, dairy product intake and decreases in caffeine. Whereas a similar community based

programme was less successful (Blalock *et al.*, 2002). Further research is needed to examine the optimum methods of producing behaviour change.

'Treatment' refers to efforts to maintain and prevent fractures and further bone loss, as well as orthopaedic interventions and rehabilitation, in those suffering from osteoporosis. Drug therapies include HRT, bisphosphonates, selective oestrogen receptor modulators, parathyroid hormone, calcium and vitamin D. The choice of interventions is influenced by factors such as BMD, stage of disease, nature and site of fracture, age, co-morbidities and side effects. Another approach that warrants attention in the prevention of osteoporotic fractures, particularly hip fractures, is the avoidance of falls. Strategies to reduce the incidence of falls in the elderly might include the elimination of environmental hazards, increasing muscle strength, use of hip protectors and avoidance of drugs which impair balance. For example, a 30-minute educational programme provided for women aged 60 plus in several community settings increased intentions to take calcium and to use strategies to reduce falls (Curry *et al.*, 2002). For those who develop fractures that cause pain and reduce mobility, research is needed to explore ways of improving quality of life (Cook *et al.*, 1993).

Parkinson's disease

Marjan Jahanshahi

Institute of Neurology, University College London

This progressive neurological disorder is named after James Parkinson who first described it in 1817 under the label of 'shaking palsy'. The major symptoms are resting tremor, slowness of movement initiation and execution, muscular rigidity and postural abnormality. About 1 in 1000 of the population suffer from it. It is a disorder of old age, with the average age of onset in the sixties, although in hospital-based series 10 to 20% of cases started before the age of 40. The disorder is related to degeneration of dopamine-producing cells in the substantia nigra pars compacta resulting in depletion of striatal dopamine. Parkinson's disease provides a model of basal ganglia dysfunction, through which the contribution of the striatum to movement, cognition, affect and motivation can be studied. Dopamine replacement therapy is the main medical treatment, which initially controls the motor symptoms but after prolonged use is associated with side effects such as dyskinesias and on-off fluctuations. Since the mid 1990s, surgical techniques such as pallidotomy and high frequency deep brain stimulation of the internal segment of the globus pallidus or the subthalamic nucleus have been increasingly used and shown to be effective treatments of chronic Parkinson's disease.

Psychological features

Cognitive impairment

Dementia, that is a loss of intellectual abilities and memory impairment of sufficient severity to interfere with social or occupational functioning, when present develops late in the course of the illness (see also 'Dementias'). The rate of dementia in Parkinson's disease has been estimated to be 15–20% (Brown & Marsden, 1984). It has been suggested that the nature of dementia in Parkinson's disease and other subcortical disorders such as Huntington's disease and Progressive Supranuclear Palsy may be different from the cortical dementia of Alzheimer's disease (Albert *et al.*, 1974). Instead of the amnesic, aphasic, apraxic and agnosic features of cortical dementia, subcortical dementia is characterized by forgetfulness, slowing of thought processes, alterations in personality and mood and a reduced ability to manipulate acquired knowledge. However, the validity of the distinction between cortical and subcortical dementia has been questioned on the basis of the neuropathological and neuropsychological evidence (Whitehouse, 1986; Brown & Marsden, 1988).

Cognitive impairment in non-demented patients with Parkinson's disease is more prevalent, affecting about 40% of patients (Cummings, 1988). Impairment on cognitive tasks requiring effortful processing, internal control of attention, self-directed planning, sequencing and temporal ordering have been described in these

patients. The basal ganglia are intimately linked with the prefrontal cortex and since the general picture of cognitive dysfunction in non-demented patients with Parkinson's disease has similarities to that shown by patients with damage to the prefrontal cortex, many refer to the 'frontal deficit' in Parkinson's disease (see Brown & Jahanshahi, 1991). The striatum is also considered to be a substrate for certain types of procedural learning (Soliveri *et al.*, 1992). Consistent with this, implicit learning on tasks such as the serial reaction time task and the weather prediction task is impaired in Parkinson's disease.

Psychiatric problems and psychosocial functioning

The rate of depression in Parkinson's disease is estimated to be between 30 to 50% (Cummings, 1992). Depression in Parkinson's disease may be a result of the alteration of brain monoamines that are implicated in the aetiology of both Parkinson's disease and depression. Alternatively, depression may be a reaction to the onset and experience of living with the progressive illness which entails disability in daily activities, alteration of social and occupational roles, financial concern and dependence on others (see 'Coping with chronic illness' and 'Disability'). Although physical disability is a major contributor to depression, psychological factors such as low self-esteem and use of maladaptive coping strategies are also important determinants of depression in Parkinson's disease. Certain subgroups of Parkinson's disease patients may be more vulnerable to depression: patients in the earliest as well as those in the most advanced stages of illness, those with an early age of onset and those with rapid progression (see Brown & Jahanshahi, 1994).

The unpredictability of function associated with on-off fluctuations, the impairment of balance and risk of falls when walking are among the symptoms likely to contribute to development of anxiety and particularly 'fear of falling' which are quite common and can lead to avoidance of leaving the house and eventually social isolation. Hallucinations and delusions are other psychiatric symptoms experienced in Parkinson's disease which are typically drug-induced. Apathy characterized by reduced motivation and lack of affect, and fatigue described as an overwhelming sense of tiredness and lack of energy, are common in the mid to late stages of the illness and can result in patients remaining inactive most of the day. Sexual problems are relatively common but often overlooked in Parkinson's disease because of the advanced age of most sufferers (see 'Sexual dysfunction'). Sleep disturbance and pain are common complaints, both with multiple causes, but often secondary to the motor symptoms such as rigidity that can make turning in bed difficult or result in aching of the neck and back (see 'Sleep and health').

Management

The course of this progressive disorder varies across patients, with some showing little disability, cognitive impairment or depression after many years, while others becoming severely disabled, demented or depressed. The approach to management should, therefore, be tailored to the needs of the individual patient.

Neuropsychological assessment may aid in differential diagnosis of idiopathic Parkinson's disease from other akineto-rigid Parkinsonian syndromes. In patients who become demented, behavioural techniques can be used to manage the behavioural problems associated with dementia and the carer/family's need for support should not be ignored (see 'Behaviour therapy').

It has been recommended that in chronic neurological disorders such as Parkinson's disease, the focus of medical management should be on ensuring the best 'quality of life' for the patient and their family (see 'Quality of life'). As result, in recent years quality of life has become an important outcome measure in evaluating medical or surgical interventions for the illness. Depression, disability, postural instability and cognitive impairment have been found to be predictors of quality of life in Parkinson's disease, accounting for 72% of variance of quality of life scores in one study (Schrag *et al.*, 2000). Therefore, to enhance the quality of life of the patients, depression and disability could be targets for management efforts of the multidisciplinary team.

The natural history of depression in Parkinson's disease is not linear or parallel to the progression of the physical illness. Therefore, it can not be assumed that symptomatic improvement of Parkinson's disease would result in a parallel improvement of

depression. Depression in Parkinson's disease needs to be treated directly. Evidence suggests that depression in Parkinson's disease is undertreated (Cummings, 1992). One reason for this may be a failure to detect depression because of the similarity of some of the symptoms of the two disorders (e.g. psychomotor retardation, lack of facial expression). Another reason for a failure to detect and treat depression in Parkinson's disease may relate to the fact that adaptation to chronic illness is a dynamic process which shows many variations across time and individuals. Thus, the peak time of psychological distress and depression may differ across sufferers: for some it may be early on in relation to accepting the diagnosis, for others it may be later in the course of illness as it becomes more disabling or when dopaminergic medication lose some of their efficacy and medication-related complications such as on-off fluctuations, end-of-dose akinesia, and dyskinesias develop. Individually tailored therapeutic programmes should be on offer throughout the course of the disease from the point of diagnosis to allow the patient and the family to adjust to the changing demands of the disease. Cognitive-behavioural techniques are useful in the management of these patients (Ellgring *et al.*, 1990). Antidepressant medication is effective in the treatment of depression in Parkinson's disease (Cummings, 1992).

Similarly, given their multifactorial nature, it cannot be assumed that anxiety, sexual problems, sleep disturbances or pain in Parkinson's disease can be 'cured' simply by treating the motor symptoms. Direct treatment of anxiety, sleep problems and pain may be necessary. Sex therapy, taking account of the added stresses of chronic illness and the interfering effect of the motor symptoms and medication, may be appropriate.

Pelvic pain

Robert R. Edwards and Jennifer A. Haythornthwaite

Johns Hopkins University School of Medicine

Introduction

Because of the dearth of research examining the involvement of psychosocial factors in acute pelvic pain, this chapter focuses on chronic pain in the pelvic region, excluding abdominal pain. Although remarkably common in the female population, chronic pelvic pain (CPP) constitutes a broad and poorly-defined diagnostic category. Indeed, a recent survey of published studies noted that over 90% of investigators did not specify anatomical locations of pain beyond noting that it was 'in the pelvic region', and approximately three-quarters of published CPP studies included no information on whether physical pathology was present (Williams *et al.*, 2004).

The most commonly utilized definition of CPP; 'recurrent or constant pain in the lower abdominal region that has lasted for at least 6 months', ignores aetiology (Zondervan & Barlow, 2000). The International Association for the Study of Pain (IASP) has also promulgated a definition for CPP without obvious pathology, but such terms have been criticized for drawing an artificial distinction between organic and non-organic pain (Grace, 2000). Current conceptualizations of pain generally utilize the IASP's definition of pain as 'an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage' (International Association for the Study of Pain, 1979). This inclusion of affect in the definition of pain has largely abolished old distinctions between 'organic' and 'functional' pain. It is now widely accepted that psychological factors such as affect and cognitions are intimately tied to the experience of pain these factors influence the perception and report of pain and are in turn modulated by the experience of pain (Turk & Okifuji, 2002) (see 'Pain' and 'Pain Management'). This biopsychosocial model of the experience of pain (Nielsen & Weir, 2001) has spurred much investigation into the psychosocial underpinnings and consequences of chronic pain, including CPP.

CPP is predominantly a women's health problem, affecting approximately one in seven US women (Mathias *et al.*, 1996), though estimated rates vary widely depending on the setting studied. Although epidemiological studies estimate a community prevalence of 15% in women aged 18–50 (Mathias *et al.*, 1996), surveys in gynaecologists' offices/consulting rooms yield estimates of 39% among women aged 18–45 who reported CPP, with even greater prevalence noted in younger women and African-Americans (Jamieson & Steege, 1996). In primary care settings, rates are comparable to asthma and back pain, and the lifetime prevalence is estimated to be around 33% (Zondervan *et al.*, 1998). In the mid-1990s, total annual direct costs of CPP in the USA were estimated at \$3 billion (Mathias *et al.*, 1996).

In approximately two-thirds of cases, the cause of CPP is unknown (Mathias *et al.*, 1996). Because of the frequent lack of physical findings, women with CPP are often suspected of having a psychological aetiology to their illness, contributing to feelings of demoralization and frustration (Grace, 2000). Compared with their pain-free counterparts, women with CPP use three times more medications, have four times more non-gynaecologic operations and are five times more likely to have a hysterectomy (Williams *et al.*, 2004). Patients diagnosed with CPP have a higher prevalence of first-degree relatives also diagnosed with CPP than in the general population, and CPP is often co-morbid with inflammatory bowel disease, irritable bowel syndrome and fibromyalgia (Marshall, 2003). Moreover, women diagnosed with CPP are at greater risk for dysmenorrhea and dyspareunia, both of which are associated with diminished quality of life (see 'Quality of Life').

Risk factors

The aetiology of CPP is quite variable and can include gynaecological, urinary, musculoskeletal, neuropathic, immunological and gastrointestinal factors. For example, a woman with endometriosis and a woman with post-herpetic neuralgia (i.e. shingles) affecting the pelvic region would both be diagnosed with CPP and could be included together in a CPP research study (Williams *et al.*, 2004). In spite of this aetiological variability, a number of factors have been shown to be associated with an elevated risk of CPP. Medically, the presence of another chronically painful condition such as irritable bowel syndrome or fibromyalgia appears to confer increased risk (see 'Irritable bowel syndrome'). The presence of endometriosis is a reliable predictor of the development of CPP (2004). A history of abdominal or pelvic surgery, or of a Caesarean delivery, are also risk factors for the future development of CPP (2004).

Non-medical risk factors for CPP include being female or African-American (Kjerulff *et al.*, 1996; Jamieson *et al.*, 1996). The majority of women with CPP are of reproductive age, suggesting that postmenopausal and premenarchal women may be at lower risk (2004). A recent investigation also noted that lower educational achievement increased the likelihood of CPP (Roth *et al.*, 2001). Additionally, several cross-sectional findings indicate that women with CPP are more likely than pain-free controls to be separated or divorced (2004). Multiple studies have identified the number of past sexual partners as a risk factor (Reed *et al.*, 2000). Perhaps the most widely-recognized risk factor, aside from female sex, is a history of physical or sexual abuse, described in detail below.

Sexual and physical abuse

Many have hypothesized that a history of abuse may be a primary aetiological factor in women's complaints of CPP (Ehlert, Heim & Hellhammer, 1999). However, methodological limitations in existing studies, including retrospective cross-sectional designs and non-standardized screening questions, necessitate caution in drawing firm conclusions. In spite of these limitations, the existing literature does suggest that patients with CPP show elevated rates of sexual and physical abuse history. In controlled studies, the prevalence of childhood sexual victimization of CPP patients has been rated at around 50–60%, compared to 20–30% for gynaecological controls (Fry *et al.*, 1997; Reed *et al.*, 2000). CPP patients have also demonstrated higher lifetime rates of sexual abuse compared to patients with low back pain (Lampe *et al.*, 2000) or chronic headaches (Walling *et al.*, 1994). This latter study also found increased risk when major sexual abuse was reported in both childhood and adulthood (Walling *et al.*, 1994), a finding replicated in a much larger sample of non-pregnant women surveyed in a primary care setting (Jamieson & Steege, 1997). A recent study revealed that while childhood physical abuse was predictive of the later development of chronic pain generally, childhood sexual abuse was specifically related to the development of CPP (Lampe *et al.*, 2003). However, we should also note that a recent prospective study of abuse in chronic pain found that while retrospective self-report of childhood abuse was greater in chronic pain patients relative to controls, objectively documented physical or sexual abuse was not associated with the later development of any type of chronic pain, suggesting that abuse–pain relationships are complex (Raphael *et al.*, 2001).

Psychological and psychiatric sequelae of CPP

Failure to identify clear organic precipitants to CPP has spurred many investigators to consider the influence of psychological factors (Grace, 2000). Clear differences emerge when women with and without CPP are compared, although the cross-sectional methodologies make causal interpretations impossible. For example, the lifetime prevalence of major depression in women with CPP has been reported at 64%, compared to 17% of pain-free control women presenting to a gynaecological clinic (Harrop-Griffiths *et al.*, 1988). Women with CPP, both with and without identified organic pathology, have been shown to have greater scores on the Beck Depression Inventory than gynaecological patients without CPP (Fry *et al.*, 1997). Interestingly, there is some evidence that the aetiology of CPP does not impact on women's psychological status; a recent meta-analysis found that CPP groups with and without identified organic pathology did not differ from one another on measures of depression, anxiety, or psychopathology (Mcgowan *et al.*, 1998), though both groups differed consistently from healthy controls. Since psychological and psychiatric co-morbidity are common across many chronic pain conditions (Turk *et al.*, 2002), the most informative studies compare CPP with other pain groups. Pelvic pain may produce more negative sequelae than pain in other locations, independent of pain severity (Wesselmann *et al.*, 1997). The pelvic region has important personal significance, and, in an analogue study, subjects asked to imagine genital pain appraised themselves as being more ill, more worried, more irritable, more

depressed and more likely to be experiencing an emergency than when asked to imagine pain in other locations (Klonoff *et al.*, 1993).

As in many chronic pain conditions, women with CPP have been shown to demonstrate diminished quality of life, with greater pain severity being associated with reduced functioning (Rannestad *et al.*, 2000) (see 'Quality of Life'). Women with endometriosis and CPP describe poorer health, greater interference in activities and greater pain during intercourse compared to women with no diagnosis or other non-gynaecological pains (Mathias *et al.*, 1996). Although women with CPP describe much of the pain-related interference common to most chronic pain conditions (e.g. reduced social activities, impaired work performance), pain during intercourse and the resulting sexual interference appears to be a particularly significant problem. Eighty-eight percent of CPP respondents describe having pain during or after intercourse at least some of the time in the past month (Mathias *et al.*, 1996). Women with CPP report sexual interference that is similar to those with vulvodynia, which is significantly greater than pain-free controls (Reed *et al.*, 2000) and women presenting for infertility treatment. However, studies have yet to fully examine the impact of this sexual interference on interpersonal relationships; moreover, little research has examined the possibility that sex therapy reduces pain during or after intercourse (see also 'Sexual Dysfunction').

Alterations in pain processing

Several laboratory studies have examined pain sensitivity in women with pain in the pelvic region. Women with dysmenorrhea reported higher levels of anxiety and higher ratings of pain in response to calibrated noxious stimuli presented in the laboratory (Granot *et al.*, 2001). The authors concluded that enhanced pain sensitivity might partially contribute to the symptoms of dysmenorrhea. Similar findings were demonstrated in women with vulvar vestibulitis, who also showed higher increases in blood pressure during painful stimulation (Granot *et al.*, 2002). Women with vulvar vestibulitis who were most sensitive to laboratory pain stimulation also obtained the least benefit from surgical and non-surgical treatments (Granot *et al.*, 2004). These findings suggest the possibility that central nervous system processing of pain may be abnormal in patients with CPP, as has been found in fibromyalgia patients (Gracely *et al.*, 2003). Whether this sensitization precedes or is consequent to the development of CPP is not known; however, the fact that greater laboratory pain sensitivity was associated with reduced treatment benefit highlights the importance of considering dysregulation of central pain processing in treating CPP.

Treatments

Research on the efficacy of treatments for CPP is still in its infancy (Stones *et al.*, 2000); while many treatment approaches have been recommended, the majority have not been rigorously tested. The following treatments have been recommended for CPP patients solely on the basis of their effectiveness in alleviating pain in patients with other chronic conditions: non-steroidal anti-inflammatory medications, oral contraceptives, exercise and physical therapy (2004) (see also 'Contraception' and 'Physical activity interventions'). For certain conditions such as interstitial cystitis,

additional pharmacological treatments also include antibiotics and antihistamines. Surgical approaches may also be recommended, depending on the presumed cause of the pain. There are some encouraging data for hysterectomy: women with CPP who underwent hysterectomy experienced greater pain relief than women treated medically, with approximately 75% of surgically-treated women obtaining some pain relief at 1-year follow-up (see 'Hysterectomy'). Clinical trials of acupuncture and acupressure demonstrate superiority over placebo treatments in the reduction of pain (ACOG, 2004), and these treatments may represent a viable, less invasive intervention before proceeding with surgery (see 'Complementary medicine').

Psychological and psychiatric treatments

Although psychological assessment and treatment are frequently recommended for CPP, very few studies have examined the efficacy of psychological or psychiatric interventions in comparison to a control group. Tricyclic antidepressants (TCAs) have been repeatedly shown in other pain disorders to improve pain, sleep and mood (Salerno *et al.*, 2002). Open-label trials (Walker *et al.*, 1991) and clinical reviews (Reiter, 1998) suggest that the use of TCAs may be helpful for women with CPP, although systematic clinical trials have yet to be completed. One small, randomized, double-blind crossover trial of sertraline revealed no improvement in pain or disability compared to placebo (Engel, Jr. *et al.*, 1998). Larger, clinical trials examining the efficacy of antidepressants in this population are clearly needed. Biofeedback has shown impressive results for women with vulvodynia, with a substantial reduction in pain intensity, improved sexual functioning, and improvements in psychological adjustment (Bergeron *et al.*, 2001) (see 'Biofeedback'). Supportive therapy, encompassing patient education and promotion of effective

self-care strategies, is mildly effective in CPP; stress and anxiety reduction have been found to be beneficial to some extent in most patients (see 'Cognitive behaviour therapy'). The multidisciplinary care that has been consistently successful in treating other chronic pain conditions (Flor *et al.*, 1992) has been adapted for the treatment of CPP (see 'Pain management'). Significantly more women randomized to receive an integrated approach of combined medical evaluation, psychological treatment and physical therapy improved on measures of pain and disability compared to those receiving standard care (Peters *et al.*, 1991). In other studies of multi-modal treatment, outcomes are generally improved using a multi-disciplinary approach. For example, disabled patients treated multi-modally are almost twice as likely to return to work (Dinoff *et al.*, 2003). Surprisingly however, randomized clinical trials have not continued to examine psychological interventions for CPP or its combination with other treatment modalities.

Summary

CPP is a highly prevalent and costly condition, with a variable aetiology and uncertain treatment course. CPP has long been associated clinically with psychiatric comorbidity, a history of sexual abuse and severe psychological sequelae. Since longitudinal studies are rare, we have little information on whether psychological disturbance precedes CPP, or is consequent to the development of pain. Although preliminary work and several randomized, controlled, studies of psychological interventions are promising, future work examining the efficacy of multidisciplinary care, empirically-validated psychological treatments such as cognitive-behavioural therapy and biofeedback is necessary to develop optimal intervention strategies.

Post-traumatic stress disorder

Donna Posluszny¹, Stacie Spencer² and Andrew Baum¹

¹University of Pittsburgh Medical Center

²University of Pittsburgh

The history of medicine, occupational health and psychiatry has been punctuated by recurring themes related to what is now called post-traumatic stress disorder (PTSD). For several centuries, aversions to, and maladies from, extremely stressful events have been described, but clues to their causes have only recently been discovered. Previously called 'railway spine', 'battle fatigue' and 'shellshock', post-traumatic stress syndromes have been a topic for speculation and diagnosis when no other label will suffice.

Over the past 30 years, investigation of traumatic stress has exploded and a substantial mass of research evidence has been gathered. Initially, this was primarily due to an interest in the uniquely pervasive symptoms of Vietnam veterans. However, tragedy is not limited to war and the development of PTSD is not limited to soldiers. The recent proliferation of PTSD research in diverse populations has added to the understanding of PTSD as a mental health disorder, to our understanding of human reactions to stress,

and to knowledge about possible links between mental and physical health.

PTSD first appeared in the third version of the Diagnostic and Statistical Manual of the American Psychiatric Association (APA, 1980) and was clarified in DSM-III-R (APA, 1987). Prior to this time, it was believed that prolonged reaction to a traumatic event was due to pre-existing personal weakness (McFarlane, 1990; Tomb, 1994). However, with the accumulation of data indicating a consistency in reactions to combat and non-combat traumatic events, it became apparent that the nature of the traumatic event plays an important role in the reaction to that event. Thus, the severity of the event was one of the criteria for a diagnosis of PTSD and was defined as that which would be 'markedly distressing to almost anyone'. This tautological definition was challenging to operationalize. In DSM-IV, the focus shifted from the severity of the event to exposure and reaction to the event.

PTSD is best described as an anxiety disorder that often follows exposure to an extreme stressor that causes injury, threatens life, or threatens physical integrity (APA, 1994). Characteristics of PTSD include persistent re-experiencing of the traumatic event or situation through intrusive distressing thoughts and dreams, acting or feeling like the event is recurring and intense psychological and physiological reactions to cues that are associated with the event. Also characteristic of PTSD are the avoidance of thoughts, feelings, people, places and activities related to the event, difficulty remembering important aspects of the event, restricted range of affect, feeling detached, and a sense of a shortened life-expectancy. The signs and symptoms of PTSD can be either acute, lasting for less than three months or more chronic, lasting for several years. In some cases, the onset of symptoms is delayed for six months or more.

Incidence of PTSD

Family and relationship abuse, criminal assault, rape, motor vehicle accidents, airplane crashes, natural disasters (e.g. floods, earthquakes and hurricanes), human-caused disasters (e.g. the Buffalo Creek Dam collapse), exposure to noxious agents (e.g. Three Mile Island) or pathogens (e.g. HIV) have also been associated with PTSD symptoms. Though variable, approximately 10–30% of people who are exposed to an extreme stressor appear to develop PTSD and 9% of the population in the United States, overall, experiences symptoms of PTSD in their lifetime (Breslau *et al.*, 1991; Tomb, 1994). Incidence rates vary with the event: incidence of PTSD following rape is estimated at 80%, after tragic death at 30%, after motor vehicle accidents with injury at 23%, long after childhood molestation (23%) and after serious accidents at 13% (Breslau *et al.*, 1991; Green, 1994). PTSD rates in firefighters following a serious bushfire were as high as 36% (McFarlane, 1992), and PTSD rates for male and female Vietnam veterans are as high as 31% and 27%, respectively (Fairbanks *et al.*, as cited in Green, 1994; Kulka *et al.*, 1990). These rates reflect lifetime rates for PTSD and are considerably larger than current rates at any given time. Dissecting incidence in Vietnam veterans, for example, shows that of the 31% or 27% with lifetime PTSD, only approximately 15% and 9% showed current PTSD from 1990–1994 (Fairbanks *et al.*, as cited in Green, 1994; Kulka *et al.*, 1990).

PTSD following specific events

As suggested above, a number of highly stressful events have been identified that can cause people to experience symptoms of PTSD. Typically, these events involve life threat or otherwise compromise victims' sense of safety and control. We briefly consider a few major areas of investigation focused on well-established causes of the disorder.

Criminal assault and rape

Rates of PTSD are high immediately following domestic violence or rape (e.g. Rothbaum *et al.*, 1992; Jones *et al.*, 2001). In about half of these cases, symptoms gradually improve in a few months. Specific crime features have been associated with the onset of PTSD symptoms in rape victims. If rape was by a stranger, involved use of weapons, was perceived as life-threatening, or resulted in actual injury or completed rape, victims appear to be more likely to develop symptoms of PTSD (Bownes *et al.*, 1991; Resnick *et al.*, 1992).

Perceptions of control are important in the development of PTSD following criminal assault, and general perception of control over aversive events predict PTSD symptom severity (Kushner *et al.*, 1993) (see 'Perceived control'). Intrusive thoughts also play a significant role in maintaining PTSD symptoms following rape. Victims with PTSD symptoms take longer to process or respond to high-threat words than do rape victims without PTSD and no-rape controls (Cassidy *et al.*, 1992; Foa *et al.*, 1991). Interference on this task has been correlated with intrusive thoughts (Cassidy *et al.*, 1992).

Disasters

Research on disaster-related PTSD covers a wide range of events including earthquakes (Yang *et al.*, 2003) tornadoes (North *et al.*, 1989), volcanic eruptions (Adams & Adams, 1984), floods (Green *et al.*, 1990a; North *et al.*, 2004), airplane crashes (Perlberg, 1979; Smith *et al.*, 1989) and nuclear accidents (Baum *et al.*, 1983; Wert, 1979). It is difficult to summarize findings regarding PTSD across these disasters because of methodological differences in research and differences in stressors or context (Smith & North, 1993). This variability across studies may help explain why symptom rates reported in disaster studies range from 2–100% and why there is no apparent pattern of symptoms by disaster event (Smith & North, 1993).

There are specific features of disasters which are related to PTSD. One distinguishing characteristic is whether the disaster is 'natural' or 'technological'. Results suggest that natural disasters are associated with more chronic stress (e.g. Baum *et al.*, 1983). For example, symptoms of PTSD persisted for as long as 6 years following the radioactive gas leak at Three Mile Island and for as long as 14 years following the Buffalo Creek Dam collapse (Baum *et al.*, 1993; Green *et al.*, 1990b). Symptoms of stress appear to be more prevalent and to last longer following technological disasters, although exposure to both kinds of disasters is often brief (Smith *et al.*, 1989). Perceptions of control also reflect important differences between natural and technological disasters (Baum *et al.*, 1993; Davidson *et al.*, 1982). Both are uncontrollable, but technological disasters reflect a loss of control. Natural disasters are distressing,

but human-made disasters threaten peoples' assumptions about order and control. For example, one study compared flood victims and a no-disaster control group with a group of neighbours of a leaking hazardous waste dump and found that the latter were more alienated, physiologically aroused and performed less well on challenging tasks nine months after finding out about the leak (Baum *et al.*, 1992).

Combat veterans

As noted above, PTSD was not uncommon among Vietnam veterans, and research from other conflicts has been consistent with these studies. Up to 38% of survivors of the siege of Sarajevo in Bosnia Herzegovina had measurable PTSD three years later and up to half of Gulf War veterans seeking care for unexplained medical problems had PTSD (Hikmet *et al.*, 2004; Natelson *et al.*, 2001; Rosner *et al.*, 2003). More recent studies of PTSD in more proximal conflicts are important in filling in gaps in the existing literature and expanding on some of these key differences. War-related PTSD is not unique in Vietnam veterans. There is evidence of PTSD among World War II and Korean War veterans, but more cases have been reported from the Vietnam War. The most obvious reason for the difference in reported rates may simply be that researchers were alerted to, and looking for, PTSD in Vietnam veterans. At the same time, there appear to have been characteristics of the Vietnam conflict that may have contributed to unexpectedly high rates of distress. There is also evidence of PTSD among both male and female veterans (e.g. McTeague *et al.*, 2004; Monnier *et al.*, 2004; Pereira, 2002). The persistence of PTSD symptoms is associated with intrusive memories of combat events (Davidson & Baum, 1993). Vietnam combat veterans also exhibit interference for combat-trauma related stimuli but not for neutral, positive, or other threat stimuli (McNally *et al.*, 1993).

Terrorism

Recent studies have targeted terrorism as a potential cause of psychological trauma. Research on this topic has been limited by logistic factors and the nature and frequency of these stressors. There is evidence that people exposed to the bombing of the Murrah Federal Building that was bombed in Oklahoma City experienced significant trauma and PTSD (Tucker *et al.*, 1999). Susceptibility to terrorism is affected by proximity (i.e. whether an individual was there and directly affected; Fullerton *et al.*, 2004) but people far from the epicentre of the attack can experience important psychological syndromes (Schuster, M.A., Stein, B.D., Jaycox, L.H., Collins, R.L., Marshall, G.N. *et al.*, 2001). Media exposure may play a significant role in this phenomenon, contributing to distress experienced far from the point of attack (e.g. Dougall *et al.*, 2005). Other susceptibility factors for response to terrorism remain to be studied but appear to include history of PTSD (e.g. Qin *et al.*, 2003).

PTSD and physical health

Interest in PTSD is 'bidirectional' if you will, with investigators of the effects of PTSD on mental and physical health and on medical procedures and illnesses on PTSD. A recent text (Schnurr &

Green, 2004) summarizes a good deal of work on the former and research is increasingly addressing the latter (Tedstone & Tarrier, 2003). Serious medical illnesses, such as cancer and heart disease, are stressful and expose people to a broad range of threats, burdens and potential losses. They often pose sudden and intense life threat, introducing the possibility of psychological trauma and many aspects of their treatment are stressful as well. They also challenge one's fundamental outlook on life and may evoke existential anxiety and fear.

Symptoms of PTSD have been documented in a variety of medical illnesses, although the general incidence of PTSD tends to be lower than that associated with more traditional types of traumatic events. Cancer has been a main area of focus, as the life-threatening nature of the illness, suddenness of diagnosis and severe impact on life brought on by treatment requirements lend themselves to possible traumatic reactions (for review, see Kangas *et al.*, 2002). Most of this work has targeted breast cancer patients with early stage disease, and finds that 3–12% of the sample meet PTSD criteria, although many more report symptoms of PTSD (e.g. Alter *et al.*, 1996; Cordova *et al.*, 1995; Green *et al.*, 1998; Tjemland *et al.*, 1998). PTSD has also been documented in lymphoma survivors (Lella & Tross, 1986), gynaecologic cancer patients (Posluszny *et al.*, 2003), lung cancer patients (Dougall *et al.*, 2004) prostate cancer patients and cancer patients undergoing bone marrow transplants (Jacobsen *et al.*, 1998; Mundy *et al.*, 2000). Studies of other disease populations suggest similar evidence patterns (e.g. 8–20% of heart attack survivors report clinically significant PTSD symptoms; Doerfler *et al.*, 1994; Ginzburg *et al.*, 2003; Shemesh *et al.*, 2001) (see 'Coronary heart disease: impact'). PTSD symptoms have also been documented in patients undergoing trauma surgery or seeking treatment for a traumatic injury (Glynn *et al.*, 2003; Zatzick *et al.*, 2003), as well as patients experiencing severe burn injuries (Patterson *et al.*, 1990; Perry *et al.*, 1992; Roca *et al.*, 1992) (see 'Burns').

Predictors of PTSD

Not all of those exposed to traumatic stressors develop PTSD afterwards. In fact, most do not. Other variables, including childhood trauma, early separation from parents, abnormal adolescent development, pre-existing personality disorders (e.g. depression and anxiety disorders), or family history of anxiety may make some people more susceptible to developing PTSD (Astin *et al.*, 1995; Brady *et al.*, 1994; Green *et al.*, 1990a). Factors that precede exposure to traumatic factors and interactions among past, present and anticipated events appear to be important as well (Breslau *et al.*, 1991; Hendin *et al.*, 1983; Holloway & Ursano, 1984). However, evidence does not support the notion that premorbid factors alone determine development of the disorder (e.g. Boman, 1986; Foy *et al.*, 1984; Green *et al.*, 1990a; Green & Berlin, 1987; Ursano *et al.*, 1981) (see 'Stress and health').

It is possible that the more powerful, sensual and evocative the event, the more likely the survivor will be to develop PTSD. This is consistent with data that indicate that higher rates of PTSD are observed following severe, horrific and grotesque events (e.g. Green, 1990; Green *et al.*, 1990a). While evidence from WWII prisoners of war suggests that the severity of the trauma (e.g. amount of weight lost, amount of torture) can predict PTSD

(Speed *et al.*, 1989), for most traumatic events PTSD is predicted by the individual's appraisal of the event as severe rather than the objective severity of the stressor (Perry *et al.*, 1992). In fact, intrusive thoughts about combat in Vietnam was a better predictor of current distress than was severity of combat exposure (Davidson & Baum, 1993). A longitudinal study of burn survivors, measured PTSD symptoms at 2, 6 and 12 months following the traumatic event (Perry *et al.*, 1992). Rates of PTSD at 2 months were predicted by lower perceptions of social support. At 6 months, PTSD was predicted by negative affect and intrusive thoughts experienced at 2 months and at 12 months PTSD was predicted by negative affect and avoidant thoughts experienced at 6 months.

Biobehavioural factors

While the extent to which PTSD and more common forms of distress share common pathways and origins is not clear, some have argued that PTSD can be considered an extreme consequence of stress (e.g. Davidson & Baum, 1986). As such, several biological substrates for the disorder have been proposed. Some have investigated 'trauma centres' in the brain, focusing on noradrenergic activity (e.g. Krystal, 1990). Noradrenergic activity has been implicated as a key component of stress responding, and inhibition of central noradrenergic activity with drugs decreases the stress response

(Redmond & Krystal, 1984). Manipulation of norepinephrine and other catecholamines also affects fear-enhanced startle responses, and enhanced startle reactions are symptomatic of PTSD (Davis, 1980; Orr, 1990). Alternatively, some have argued that helplessness is an important aspect of PTSD and the biological effects of inescapable shock in animals have been used as the basis for a model of the profound changes associated with PTSD (e.g. van der Kolk *et al.*, 1985).

Some investigators have found that post-traumatic stress syndromes reflect decreases in some hormones while increasing others; in one study mean urinary cortisol in male inpatients with PTSD were comparable to those of paranoid schizophrenics but lower than those exhibited by other schizophrenics or patients with bipolar or major depressive disorders (Kosten *et al.*, 1987). At the same time, PTSD patients showed norepinephrine levels that were greater than those of the other patient groups and more epinephrine than all but bipolar (manic) patients. These findings have been replicated and extended and the norepinephrine/cortisol ratios have been used as a diagnostic tool for PTSD (Mason *et al.*, 1988). Irregularities in the cortisol-producing hypothalamic-pituitary-adrenal cortical axis have been investigated in more detail and appear to be a likely factor in the development and/or maintenance of PTSD (e.g. Yehuda *et al.*, 1990; Yehuda, 2002) (see also 'Psychoneuroimmunology').

Postnatal depression

Sandra A. Elliott

St. Thomas' Hospital

'Postnatal depression' is the term applied to depression in the postnatal year (Elliott, 2000). Prevalence studies suggest that up to 30% of postnatal women have symptoms of depression and between 10% and 15% fulfil diagnostic criteria for depressive disorder (O'Hara & Swain, 1996). These figures do not include the 'blues' (emotional lability for a day or two around days 3 to 5) or puerperal psychosis (severe, but rare, disorders with onset typically within 14 days and usually requiring hospitalization). There is no space to address postnatal depression in men (Matthey *et al.*, 2000). The text also relates only to English-speaking women in cultures similar to the indigenous population of the UK. Whilst there have been a few studies in other cultures (e.g. Clifford *et al.*, 1999) and countries (e.g. Cooper *et al.*, 2002), the transcultural approach to the study of perinatal mental health is still in the early stages (Marks *et al.*, 2004).

Experience and consequences

Controlled studies have demonstrated marked differences in prevalence between postnatal women and appropriate controls for both blues and puerperal psychoses but not for postnatal depression. However, postnatal women do report higher levels of depressive symptoms and social maladjustment, particularly marital adjustment (O'Hara *et al.*, 1990). Research is therefore consistent with clinical experience that postnatal depression has a greater psychosocial impact than depression at other times. Many women are very distressed about the depression itself when it occurs at this critical time in their life and relationships. Postnatal depression can place considerable extra strain on partners and close family members, affecting social and leisure activities and causing financial problems within the family (Boath *et al.*, 1998).

Infants of mothers who experienced postnatal depression are more likely to be insecurely attached to their mothers, to have behavioural problems and deficits in cognitive functioning and these problems may still be present at school age (Hay *et al.*, 2003; Murray *et al.*, 2003). Detailed ratings of videotaped mother–infant

interactions have revealed differences between depressed and non-depressed women, suggesting that this may be one mechanism by which postnatal depression influences subsequent infant development. The characteristics of interaction which are typical of parent–child communication, and which attract infant attention, are the very characteristics most disrupted by depression. Murray *et al.* (2003) postulated four processes by which postnatal depression could be connected with later difficulties in the child. Firstly, the lack of contingency in the parent's response could affect the child's learning about its own agency. Secondly, insensitive or unresponsive parental behaviour may fail to develop the infant's ability to sustain attention. Thirdly, any hostility or markedly intrusive behaviour may cause infant distress, creating problems with cognition and memory. Finally, self/other distinctions may not be learnt if the parent has a reduced level of imitation of the infant's expressions. However, it is also possible that the association between postnatal depression and developmental difficulties in the child is a result of a third factor not yet accounted for.

Vulnerability factors and precipitants

Almost every conceivable factor has been postulated as a cause for postnatal depression. Few have proved consistently associated (O'Hara & Swain, 1996). The biggest surprise is the lack of evidence for an association with progesterone or other hormones. However, there are significant methodological problems with trying to map peripheral measures of fluctuating hormones with mood, so it is not possible to state with confidence that hormonal dysfunction plays no part in the aetiology of postnatal depression. Hormones may play a significant part in a minority of depressed women (Gregoire *et al.*, 1996; Harris, 1996; Lee, 2000).

Research is broadly consistent with psychosocial models, which view childbirth as a significant life event at a time of increased physical and emotional vulnerability, with the same potential for precipitating depression as other major events (see 'Life events

and health'). Though many academic disputes continue about whether childbirth has specific effects which distinguishes postnatal depression from depression at other times (e.g. Elliott, 1990, 2000; Nicolson, 1998; Whiffen & Gotlib, 1993) most researchers agree that postnatal depression is related to similar predisposing factors as is depression at other times, i.e. a previous psychiatric history; previous consultation with a doctor for depression, anxiety or 'nerves'; depression or anxiety during pregnancy; a poor marital relationship; and inadequate social support (O'Hara & Swain, 1996).

Life events, both independent such as the death of a parent before the arrival of the baby, and related such as premature birth and admission to a Neonatal Intensive Care Unit, may precipitate depression in the postnatal period. Most psychological models of depression propose diathesis–stress aetiology (see 'Stress and health'), which acknowledges the role of pre-existing vulnerability and stressful events in the aetiology of depression. Research findings are broadly consistent with such models (O'Hara *et al.*, 1991). However, there have been surprisingly few papers specifically addressing psychological models for postnatal depression (Hipwell *et al.*, 2004; Moorhead *et al.*, 2003; Warner *et al.*, 1997), which may be because evidence suggests that aetiologically it is the same as depression at other times. It is the context and consequences that differ, so the task would be to adapt psychological models developed for depression in general. Grazioli and Terry (2000) found some evidence of support for the diathesis-stress component of Beck's cognitive theory (see 'Cognitive behaviour therapy'), since dysfunctional attitudes about performance evaluation had a greater impact on postnatal depressive symptoms at high levels of parental stress. They propose that future studies specific to the postnatal period should develop measures specific to that context.

Leverton devised questions to assess vulnerability factors in pregnancy, which were predictive of psychiatric status in the first three months postpartum (Elliott *et al.*, 2000). However, no one has yet been able to produce an antenatal measure with sufficient predictive power to identify 'high risk' individuals (Austin & Lumley, 2003). Such instruments are valuable for research purposes, but ethical and practical difficulties seriously limit their use in clinical practice (Henshaw & Elliott, 2005).

Detection

Women may be reluctant to report depressive symptoms for fear of stigma through illness labelling and/or because they believe (incorrectly) that postnatal depression per se can lead to the removal of their baby by health or social workers. Many undiagnosed depressions improve with time and the help of family or friends. However, some do not, and untreated can last past the baby's first birthday. Cox and colleagues therefore developed a screening questionnaire for use at the 6-week postnatal check and at specified intervals thereafter (Cox & Holden, 2003). Given that dysphoria lies on a continuum (Green, 1998), the positive predictive value of this questionnaire, known as the Edinburgh Postnatal Depression Scale (EPDS), is surprisingly high, though it varies with the population under test and the type of criterion psychiatric interview. All validations have been in research contexts rather than routine clinical practice

(Murray *et al.*, 2004). Postnatal screening questionnaires share the ethical dilemmas of invasion of privacy, labelling and practical problems for large-scale administration with antenatal vulnerability questionnaires (Henshaw & Elliott, in press). Many using the questionnaire may not be aware that the EPDS will also produce raised scores with anxiety (Ross, 2003) or other disorders which include depressed mood or anxiety (Czarnocka and Slade, 2000; Leverton and Elliott, 2000). However, when used by properly trained health professionals they can form part of early intervention programmes (Elliott *et al.*, 2001).

Prevention and treatment

In accordance with the research on aetiology, prevention programmes focus on psychological vulnerability and psychosocial stress rather than the biological changes after delivery (Elliott *et al.*, 2000; Zlotnick *et al.*, 2001). A common theme to these programmes is demystifying the experience of depression (Elliott, 1990). Unhappy feelings are expected, accepted and understood. Previously 'invisible' stresses in women's lives become visible, enabling women to come to terms with or change the aspects of their lives that depress them. Pregnant women are also discouraged from having 'superwoman' expectations or perfectionist beliefs about their performance in the motherhood role (Grazioli & Terry, 2000). The idea is that expecting some adjustment difficulties and negative moods as the norm will mean that these are not catastrophized to produce 'depression about depression' (Teasdale, 1985).

Unfortunately, there is inconsistent evidence about the efficacy of prevention programmes. Debates continue about whether certain programmes are ineffective or whether positive results in other trials are a statistical artefact or of insufficient clinical significance to be cost effective (Stuart *et al.*, 2003).

In contrast, various treatments appear to be effective, including primary care interventions based on non-directive counselling (Holden *et al.*, 1989, Wickberg & Hwang, 1996) as well as specialist psychological therapies such as cognitive behaviour therapy and psychodynamic approaches (Cooper *et al.*, 2003) and interpersonal psychotherapy (O'Hara *et al.*, 2000) (see 'Cognitive behaviour therapy' and 'Psychodynamic psychotherapy'). Three pilot trials suggest group treatments may also be beneficial (Honey *et al.*, 2002; Meager & Milgrom, 1996 and Fleming *et al.*, 1992). There has been only one controlled trial of antidepressants for postnatal depression (Appleby *et al.*, 1997), which showed no added benefit over counselling and high rates of women declining to take part in the trial because of concerns about antidepressants. The lack of evidence on the effects of antidepressants on breastfeeding infants makes psychological interventions the first-line treatment for many postnatal women (Stuart *et al.*, 2003).

Healthcare systems

Multilevel, multidisciplinary systems are required to make the most effective use of the high levels of health professional contact (Elliott *et al.*, 2003; Henshaw and Elliott, 2005). The first requirement is for midwives to make sensitive enquiries about previous and current mental health problems. It is particularly important

that those with previous bipolar disorder or puerperal psychosis are referred to a psychiatrist to develop a care plan because of their greatly increased risk of a rapid relapse after the birth (Oates, 2005).

Even though antenatal groups are unlikely in themselves to prevent postnatal depression, they can provide a context for preparing primiparae for their new lives and to learn about resources available if they experience psychological difficulties postnatally. Early detection may ensure that a few non-directive counselling based visits by a primary care professional will be sufficient to halt and reverse the

spiral. Such visits may reveal complex issues such as abuse in childhood, neglect or difficult relationship with mother, previous pregnancy loss or cot death, bereavement or marital problems. Alternatively, visits may identify other mental health problems such as obsessions and compulsions or post traumatic stress symptoms following a difficult birth experience (Czarnocka & Slade, 2000) (see 'Post-traumatic stress disorder'). Referral on to cognitive or psychodynamic psychotherapy from a psychologist or other psychological therapist should then be suggested to the mother.

Pregnancy and childbirth

Lyn Quine¹ and Liz Steadman²

¹University of Kent

²Canterbury Christ Church University

Over six hundred thousand children will be born in England and Wales in 2005. While the huge majority of these will be healthy, some 6000 will die before their first birthday and some 45000 will be of low birthweight, placing them at risk. Still others will be disabled as a result of complications during the pregnancy or birth. For some mothers the quality of the birth experience will be poor and their satisfaction with antenatal services low. In this review we examine the principal social and psychological variables that may affect these outcomes and consider the contribution that psychological theory has made to our understanding of the epidemiological factors of pregnancy and childbirth.

In the following brief overview, we argue that risk factors are not distributed randomly in society and independent of living and

working conditions, but are disproportionately prevalent among lower socioeconomic groups. We suggest some of the pathways by which risk factors may mediate social inputs and outcomes.

Early childhood mortality

Infant mortality in England and Wales has fallen from 9.4 per 1000 live births in 1984 to 5.6 per 1000 in 2000. Improvements in absolute social conditions played a major role in reducing mortality in the last century, along with increased medical knowledge and improved services, but marked effects of relative social and economic disadvantage are still present. For example, there are noticeable regional differences across the country, and large differences

between district authorities within the same region, associated with their prevailing social and economic conditions (see 'Socioeconomic status and health').

The significance of social class is extremely marked: mortality rates during the first year are strongly class related even when age and parity are controlled. In the United Kingdom, the Office for National Statistics publishes data based on the father's occupation, and for each of the indices there is a steady gradient from low mortality in Social Class I to high mortality in Social Class V. For 1998–2000, mortality in Social Class V was twice that of Social Class I, and in fact showed a very slight widening, by 0.5%, between the three-yearly figures for 1997–1999 and 1998–2000. However, for births registered by mother only, many of whom will be teenage mothers, the infant mortality rate in 1998–2000 was 7.6 per 1000 births, which is approximately a third higher than the overall national rate. The steepest gradient in infant mortality occurs for the postneonatal period: 2.7:1 for postneonatal mortality against 1.6:1 for neonatal mortality. Postneonatal mortality is of particular importance because the child who dies after the first month of life will normally have been discharged from hospital and therefore domestic, social and environmental factors are more likely to be implicated than quality of neonatal medical care.

Low birthweight

Another index of pregnancy outcome is low birthweight, now normally defined as 2500 g or less. As with early childhood mortality, there is a sharp difference between the top and bottom of the social scale in England and Wales. For babies born into Social Class V, the infant mortality rate is 68% higher than those born into Social Class I, and when children up to age of four are included, the mortality rate in Class V is double that of Class I (Schuman, 1998). However, there has been a sharp decline in both perinatal and infant mortality among low birthweight children over the years. Despite this, low birthweight children who survive have high rates of medical and developmental problems (e.g. Barker, 2004) though whether these too are class related is not known.

Complications of pregnancy

National Health Service (NHS) Maternity Statistics provide the most important measure of complications in pregnancy in England, as they estimate total maternity discharges (of delivered women only) by complications. This includes a very wide range of complications.

The figures indicate a slight trend towards fewer reported complications. In 1994–1995, for example, hypertension was a complication for 7% of women, and fetal problems reported in 25% of deliveries, whereas in 2002–2003 the figures had dropped to 6% and 20% respectively. In 2002–2003 the principal recorded complications were prolonged second stage labour and prolonged pregnancy (Department of Health, 2004). Although the figures are not broken down by social class, the literature indicates that there is evidence for an association between pre-term delivery and socioeconomic factors, including social class (e.g. Peacock *et al.*, 1995) (see 'Premature babies').

Social and psychological factors affecting pregnancy and childbirth

The preceding review of epidemiological data has shown that one of the most important social inputs affecting pregnancy outcome is social class. There is a downward trend towards adverse pregnancy outcomes through the social classes, a pattern that has been reported many times throughout the health literature on children and adults alike. Our next concern is to examine whether social and psychological risk factors are disproportionately prevalent among lower socioeconomic groups and whether such factors might act as mediators between social class and outcome, thus providing a psychological explanation for some of the statistics.

Psychosocial factors: life events and social support

Studies have found that a high frequency of life events during pregnancy is associated with pre-term delivery and other adverse pregnancy outcomes. For example, Newton and Hunt (1984) found that both pre-term delivery and other adverse pregnancy outcomes were associated with life events and that life events were more common among working class women (see also 'Life events and health'). An even better predictor of low birthweight was smoking during pregnancy, which the authors suggested was a mediator of stress. Many other studies have reported similar findings (e.g. Peacock *et al.*, 1995).

The literature also suggests that a woman can be protected or buffered from the effects of severe life events if she has good support networks, and again it has been suggested that working class women are less likely to have good social support networks (Oakley & Rajan, 1991) (see *Social support and health*).

However, the problems in disentangling the effects of social support and life events are well documented. Many life events, such as bereavement, also include loss of social support. In addition, there are problems in disentangling the effects of personality variables such as neuroticism and self-esteem (see 'Personality and health'). Intervention studies that have manipulated social support are therefore instructive. Social support throughout the pregnancy has been shown in some studies to reduce the incidence of low birthweight and pregnancy complications, hospital admissions in pregnancy and use of neonatal intensive care. Furthermore, the effects of social support can be maintained well after the birth has taken place. In a longitudinal intervention study in England, Oakley *et al.* (1996) found that factors such as the child's and mother's health, and the child's development were not only enhanced during and after the birth, but that these advantages were still evident at 1-year and 7-year follow-ups.

Simply having another woman present at the birth has been shown to reduce women's use of analgesia, pain during labour and assessments of how well they coped during labour (Hofmeyr *et al.*, 1991). Support can also have a positive effect on fetal heart rate and birthweight: fetuses of women in labour with poor social support can show a higher incidence of abnormal heart rate, as well as lower birth weight (Lidderdale & Walsh, 1998) (see 'Social support interventions').

Emotional factors: maternal distress, anxiety and depression

A number of authors have found a significant relationship between emotional factors and a variety of pregnancy outcomes from complications of pregnancy and satisfaction with the birth experience to fetal and neonate behaviour (e.g. Van den Bergh, 1990). Other literature has focused on the role of psychological rather than physiological processes. A classic longitudinal study on pregnancy and mothering in the East End of London carried out by Wolkind and Zajicek (1981), for example, found that the average weight of children born to mothers with a diagnosed psychiatric condition was significantly lower than for children with psychiatrically healthy mothers. The disturbed mothers were on average younger, attended antenatal classes less frequently and smoked more; and it was smoking that predicted low birthweight best of all. The evidence thus begins to suggest a complex pattern of relationships between social class and outcome, with psychosocial risk factors acting as mediators.

Other studies have explored a variety of related concepts, including trait and state anxiety, psychodynamic defences, maternal distress and emotional state (e.g. Mulder *et al.*, 2002). Some writers argue that psychological and life stress variables do not function independently but work in synergy.

Cognitive factors: knowledge, beliefs and attitudes to pregnancy

Much of the work on the role of knowledge has been by the use of intervention studies. The main interest has been to test whether increasing knowledge, for example through antenatal classes, leads to more appropriate behaviours and more positive outcomes. The effects of antenatal classes and outcome as a form of social support on behaviour have been studied by Dragonas and Christodoulou (1998), while Renkert and Nutbeam (2001) examine what women really learn through antenatal education. The evidence is not entirely consistent in either area, but the overall trend is towards positive relationships.

According to Becker's Health Belief Model (Janz & Becker, 1984), whether a woman takes action to avoid complications in pregnancy, by making full use of antenatal services, smoking less and changing her diet, for example, is predicted by three main variables: how vulnerable she perceives herself to be to the complications; how severe or important she believes them to be; and her evaluation of the benefits and costs of taking action (see 'Health belief model').

It has been suggested by Becker that, in order for health beliefs to be translated into action, a trigger is necessary to reinforce their personal relevance. In a study by Reading *et al.* (1982), this idea was applied to the role of ultrasound scanning. Of two groups of women who were scanned at their first antenatal visit, one group were given high feedback, in which they were shown the size and shape of the fetus and its movements were pointed out, and the other group were given no picture and no specific verbal description or comments. Both groups were given advice about smoking and drinking. At follow-up, adherence with this advice was significantly higher in the women who had been given feedback than in those who had not.

Other studies of beliefs during pregnancy have used Ajzen's model, the Theory of Planned Behaviour (Ajzen, 1991) (see 'Theory of Planned Behaviour'). For example, this model has been used successfully to predict breastfeeding intention and duration (Duckett *et al.*, 1998), and smoking cessation during pregnancy (Bennett & Clatworthy, 1999). In each case, the model showed that beliefs played an important role.

Findings concerning the relationship between women's beliefs and attitudes towards pregnancy and pregnancy outcome suggest that beliefs do have an impact on subsequent behaviour. For example, Owen and Penn (1999) report that 80% of women who quit smoking during pregnancy believed that smoking was very dangerous to their baby, compared to only 30% of those who continued to smoke. It has been argued that attitudes may influence a woman's behaviour during pregnancy through posture, diet, smoking, drinking, how early she visits a doctor for antenatal care, how well she takes care of herself and so on, all of which, in turn, may affect the outcome of the pregnancy.

Coping resources and strategies

It is in the way that women cope with their pregnancy that many of the psychosocial mediators are drawn together. Coping has been defined as the problem-solving efforts made by an individual when the demands of a given situation tax adaptive resources (Lazarus *et al.*, 1974) (see 'Stress and health'). The central process is cognitive appraisal, which is a mental process by which people assess whether a demand threatens their wellbeing (primary appraisal), appraise their resources for meeting the demand, formulate solutions and select strategies (secondary appraisal). For a number of women, lack of material resources may reduce their choice of coping strategies: lack of physical resources may mean that pre-existing physical or psychological ill-health will impede the process of coping; lack of social resources may mean that fewer people can be called upon to help; lack of psychological and intellectual resources may produce cognitive problems including an inability to respond to difficulties in optimistic, persistent and flexible ways, an explanatory style that focuses on the internal, stable and global factors of negative events (see 'Attributions and health') and low self-efficacy (see 'Self-efficacy and health'). Pregnancy care will be seen as the responsibility of outside professionals, and internal locus of control will be weak. This may lead, in turn, to the selection and use of ineffectual coping strategies and the likely result will be an increased willingness to take dangerous behavioural risks, whether failing to carry out positive measures, such as taking up antenatal services, or continuing to pursue negative behaviours, such as smoking and drinking in pregnancy. The central issue is whether such women can be identified and classified, and the answer appears to be that many are from lower socioeconomic groups where maternal deprivation is prevalent (e.g. Quine *et al.*, 1993).

Behavioural factors: smoking

As an example of behavioural factors associated with pregnancy outcome we select just one, that of smoking. A summary of research on smoking and pregnancy outcome, also covering the effects of 'passive smoking', can be found in Cornelius and Day

(2001). Smoking during pregnancy has been shown many times to be associated with fetal and neonatal mortality, low birthweight and developmental retardation and indeed the first evidence appeared as early as 1957. More recently, the St George's Hospital birth weight study has investigated prospectively the association between pregnancy outcome and a large number of socioeconomic, psychological and behavioural variables, including smoking. Results so far from the St George's data show that smoking is related to foetal growth and that for women who smoke there is a twofold increase in the risk of preterm delivery (e.g. Peacock *et al.*, 1995). All the reported effects increase with the number of cigarettes smoked but, if the mother changes her behaviour before the end of the fourth month of pregnancy, the risk to the baby is determined by the new pattern of behaviour and not the original one. Although these studies provide evidence that the association is causal and serious, some researchers (e.g. Oakley, 1989) argue that smoking in pregnancy is linked to various aspects of women's material and social position. Working class women experience poorer material conditions and lower social support, which makes negative life events and chronic long term difficulties more likely. These, in turn, lead to stress. Smoking is a coping strategy used in response both to stress and to impoverished material and social conditions.

However, an important point to emerge from the research is that the effects of smoking during pregnancy appear to operate independently of potentially confounding factors, such as social class, parity, the mother's age and height and the sex of the child, though there are, of course, marked differences in the incidence of smoking by social group. For example, 31% of women from the manual classes smoke as against 21% in the non-manual classes, and data from the 2000 Infant Feeding Survey conducted by the Department of Health indicate that 4% of pregnant women in Class I continued to smoke during pregnancy against 26% in Class V. The implication is that many women who smoke continue to do so during pregnancy: pregnancy does not stop them and, again, the problem is more prevalent in the lower socioeconomic groups (see 'Tobacco use').

Finally, what has been established is that maternal smoking during pregnancy is not only associated with an increased

risk during gestation and delivery, but also for the offspring to later develop childhood or adult behavioural or medical conditions, such as early onset adult diabetes (Montgomery & Ekblom, 2002) and tobacco dependence (Buka *et al.*, 2003).

Pregnancy outcome: a summary

In this review we have seen that social class has marked effects on pregnancy outcome. We have examined the psychosocial and behavioural risk factors for poor outcome and concluded that they, also, are distributed disproportionately among the lower socioeconomic groups. The most important aspect of lower social class appears to be impoverished material and social conditions and resources, which lead, we argue, to two principal effects. On the one hand, they produce an increase in negative life events and chronic long-term difficulties, often with an absence of social support. On the other, they lead to a reduction in the level of access to information, in part through lack of education. Life events and lack of support may lead in turn to emotional problems, including lowered self-esteem, stress, anxiety and depression, while poor education and lack of access to information produce a corresponding range of cognitive problems, including a lack of knowledge and a set of beliefs and attitudes that lead the woman to see herself as vulnerable to illness and complications but helpless to prevent them. The emotional and cognitive effects combine to produce a set of coping styles and strategies that are characterized by hopelessness and a willingness to take potentially serious risks. From there, it is a short step to inappropriate behaviours, poor uptake of maternity services and attendance at antenatal care, smoking, drinking, poor diet and self-care and thence to negative outcomes. The brief review presented here is essentially a framework for integrating past findings and guiding future research. However it suggests that further examination of psychosocial and behavioural factors offers promise for understanding the underlying processes linking deprivation to pregnancy outcome.

Premature babies

Heather Mohay

Queensland University of Technology

Definition of prematurity

The World Health Organization (1993) classifies infants on the basis of gestational age with those born at <37 weeks gestation classed as preterm, those born at <32 weeks as very preterm and those at <28 weeks as extremely preterm. Birthweight is also frequently used to classify infants. Those with birthweights of <2500 g are classed as low birthweight (LBW), those <1500 g as very low birthweight (VLBW) and those <1000 g as extremely low birthweight (ELBW). The latter are generally born at <28 weeks gestation and have the highest mortality and morbidity rates (Draper *et al.*, 1999). Lubchenco (1976) argued that both birthweight and gestational age need to be considered when classifying infants. She classified infants with a birthweight <10th percentile for their gestational age, i.e. those exhibiting intrauterine growth retardation, as small for gestational age (SGA). These infants may be born at term or earlier in pregnancy and as they require somewhat different medical management and are at greater risk for perinatal death or adverse developmental outcomes

than appropriately grown infants of the same gestational age (Lubchenco, 1976) it is important for them to be accurately identified.

Preterm birth occurs in approximately 7% of confinements with infants with birthweights of <1000 g accounting for less than 1% of all deliveries (Australian Institute of Health and Welfare National Perinatal Statistics Unit, 2003).

Survival rates

Nowadays, providing they are cared for in a neonatal intensive care unit (NICU), over 95% of preterm and very preterm infants survive as do more than half of those born as early as 24 weeks gestation and weighing around 500 g. Advances in neonatal care have particularly affected the survival of ELBW infants however the medical interventions necessary to keep these infants alive may cause complications which are associated with adverse developmental outcomes

(Hack & Fanaroff, 1999). Survival alone is not therefore an adequate measure of success. The health, development and quality of life of survivors along with the impact of their survival on their families and on health and education services must also be considered.

Developmental outcomes for preterm infants

Many of the follow-up studies of preterm infant have been marred by poor research design. In addition wide variations exist in the selection of study populations, the age of follow-up, the outcome measures used and the definition of disability adopted (Aylward, 2002; Bhutta *et al.*, 2002) (see 'Disability assessment'). These shortcomings make it difficult to compare studies, but preterm infants are clearly at increased risk of adverse developmental outcomes.

Developmental disabilities

Variations in the criteria used to define severity of disability and to select the conditions and level of disability to be reported, have resulted in wide disparities in the disability rates reported by different studies. However, the consensus is that preterm infants are at higher risk for disabilities than term infants and that ELBW infants are at greater risk than their larger preterm counterparts. In the general population approximately 4% of children have major childhood disabilities. In VLBW infants this rises to about 14% and in ELBW infants it is at least 25%. Most of these disabilities are mild to moderate rather than severe with intellectual impairment and cerebral palsy being the most common disabilities reported. (Vohr *et al.*, 2000).

Correcting for prematurity when assessing growth and development

A correction is normally applied to the age of preterm infants to allow for their shorter gestation. This involves subtracting the number of weeks they were born preterm from their chronological age. Conventionally this correction has been made until children reach two years of age but there is some evidence of continued catch-up, suggesting that correction for gestational age should continue into school years (Ment *et al.*, 2003; Rickards *et al.*, 1989). When age is corrected for prematurity the development of preterm and full-term infants is comparable although preterm infants are, on average, somewhat behind in all domains of development, with the smaller more preterm infants faring worse than their larger preterm age-mates.

Growth

Children born preterm are more likely than those born at term to have growth parameters <10th percentile in the first two years of life (O'Callaghan *et al.*, 1995) Some catch-up growth occurs during childhood (Hack *et al.*, 1996) but they tend to remain shorter and lighter than their full-term counterparts even in adolescence (Saigal *et al.*, 2001) (see *Growth retardation*).

Health

In the NICU preterm infants may have many medical problems and they continue to experience more illness and hospital admissions than full-term infants during the first two years of life (Hack & Fanaroff, 1999). However, as they get older they become more robust and suffer no more health problems than other children (Saigal *et al.*, 2001; Stjernqvist & Svenningsen, 1999).

Movement and motor development

Cerebral palsy is diagnosed in approximately 14% of preterm infants with those having a birthweight of <1000 g being at higher risk than the larger preterm infants. In addition a significant number of preterm infants have other neurological abnormalities or minor movement problems which may interfere with educational progress (Burns *et al.*, 1999; Powls *et al.*, 1995). Nonetheless most premature infants reach the major motor milestones at very similar (corrected) ages to full-term infants.

Cognitive development

Intellectual impairment occurs in at least four times more children born preterm than those born at term with smaller preterm infants at greater risk than those born closer to term. However, when children who have a disability are excluded, the mean developmental quotient of preterm infants in the first two years of life and their subsequent IQ, have generally been found to be within the average range, although below those of term infants (Bhutta *et al.*, 2002). Despite these relatively optimistic finding with regards to IQ, more detailed studies have identified problems in specific abilities such as perceptual organization, even in neurologically intact preterm infants. Furthermore over 40% of VLBW infants and 50% of ELBW infants have learning problems at school and more than 20% have attention deficits (Anderson *et al.*, 2003; Saigal *et al.*, 2003; Stjernqvist & Svenningsen, 1999) (see *Hyperactivity*). Indeed these have been identified as the two most common problems affecting children born preterm.

Infant assessments provide only global measures of development and do not identify more subtle cognitive deficits. Executive dysfunction has been shown to be associated with learning problems and attention disorders in school-aged children (Jarvis & Gathercole, 2003) and there is some evidence that children who were born preterm display deficits in executive function even before they enter school (Harvey *et al.*, 1999). Measures of executive function may therefore provide a means of early identification of children who will later experience learning or attention difficulties. Differences in the brain structure of preterm infants shown in Magnetic Resonance Imagery may also be linked to these subtle abnormalities in cognition and attention (Peterson *et al.*, 2000).

Language development

Approximately 3% of preterm infants have a sensorineural hearing loss requiring the use of hearing aids and many others have intermittent conductive hearing loss due to recurrent middle ear infections (Vohr *et al.*, 2000) (see 'Deafness and hearing loss'). Hearing impairment is associated with delayed language development but if

these children are excluded, preterm infants show little delay in their early language acquisition (McAllister *et al.*, 1993) although subtle problems, particularly in expressive language, may become apparent at school age (Jennische, 1999).

Social/emotional development

Parents frequently report that preterm infants are irritable and fussy and have irregular feeding and sleeping patterns, but their scores on temperament measures differ very little from those of full-term infants (Oberklaid *et al.*, 1986). Furthermore, apart from attention deficits and overactivity, they do not have more behaviour problems, delinquency or psychiatric disorders than their peers during childhood and adolescence (Hille *et al.*, 2001). Nor do they have poorer global self-esteem despite being smaller, more poorly co-ordinated and having lower school achievements (Saigal *et al.*, 2002) but they do appear to have some difficulties with peer relationships (Wolke, 1998).

Influence of preterm birth on parents

The development of preterm infants is not only influenced by the adverse circumstances surrounding their birth and early weeks of life but also by the long-term environment in which they live. A supportive and stimulating home environment may offset the problems associated with early medical complications. Unfortunately a disproportionate number of preterm infants live in socially disadvantaged families where parents have limited resources. Hence the children's development may be compromised by both medical and psychosocial adversity (see 'Socioeconomic status and health' and 'Pregnancy and childbirth').

Preterm birth and the ensuing anxiety about their infant's well-being in the NICU are stressful for parents. Postnatal depression, anxiety about the infant's survival and development, guilt that they may have caused the early birth and helplessness in the face of complex technology and staff expertise, are common emotions experienced by mothers of preterm infants (Davis *et al.*, 2003) (see 'Postnatal depression').

The transition from hospital to home can also be anxiety provoking as parents question their ability to care for the infant. A situation in which the infant is immature, behaviourally disorganized and medically vulnerable and the parents feel anxious, incompetent and financially stressed, is ripe for the establishment of inappropriate interaction patterns and poor attachment which can have long-term detrimental effects on the parent-child relationship and the child's development.

Conclusions

The survival rate for preterm infants has increased dramatically and many of these children show normal patterns of development. Nevertheless the risk of disability is increased and their development in all domains is likely to be inferior to that of full-term infants. This becomes particularly apparent at school age when children born preterm are at high risk for learning difficulties, attention disorders and overactivity.

The risk for disability and poor developmental outcome is inversely related to birthweight and gestational age.

Both medical complications associated with prematurity, and psychosocial disadvantage contribute to adverse developmental outcomes for preterm infants. The medical care and subsequent education of these children places a substantial burden on health and education services as well as an emotional and financial strain on the family.

To reduce the frequency of negative sequelae and the costs associated with them it is necessary to:

1. improve medical management to avoid the complications associated with poor developmental outcomes
2. establish reliable methods for the early identification of infants who have behavioural or cognitive deficits which will interfere with their educational progress and develop intervention programmes to reduce these problems
3. support parents in the NICU and at home to enable them to provide optimal environments to promote their infants' development.

Premenstrual syndrome

Jane M. Ussher

University of Western Sydney

Premenstrual distress is now widely recognized to be a major social and health problem, with epidemiological surveys estimating that 95% of women experience physical and psychological changes premenstrually. Up to 40% experience moderate distress, categorized by clinicians and researchers as Premenstrual Syndrome (PMS) and 11–13% experience severe distress and disruption to their lives, categorized as Premenstrual Dysphoric Disorder (PMDD) (Steiner & Born, 2000). However, ever since discussions of premenstrual distress first appeared contemporaneously in the medical and psychoanalytic literature in 1931, this has been a research field dogged by controversy and disagreement.

Initially described as 'premenstrual tension', and attributed to either hormonal imbalances (Frank, 1931), or to intrapsychic conflict exacerbated by women's social role (Horney, 1931), it was renamed 'Premenstrual Syndrome' in 1953, 'Late Luteal Phase Dysphoric disorder' in the DSM III-R and 'Premenstrual Dysphoric

Disorder' in the DSM-IV. Regardless of the diagnostic classification adopted, the divide between biomedical and psychological explanations continues to this day, with a range of competing theories associating PMS with a single causal factor. Biological theories of PMS can be divided into six categories: gonadal steroids and gonadotrophins; neurovegetative signs (sleep, appetite changes); neuroendocrine factors; serotonin and other neurotransmitters; β -endorphin; and other potential substrates (including prostaglandins, vitamins, electrolytes and CO₂) (Parry, 1994, p.47). The psychosocial theories include: personality; cognitions associated with femininity and menstruation; the influence of stress and life events; and propensity for psychological illness (Walker, 1997). Following controlled clinical trials, the mostly widely advocated theories at the current time are serotonin imbalance, leading to the prescription of selective serotonin reuptake inhibitors (SSRIs) (Mortola *et al.*, 2002); or cognitive schemas, linked to life stress, leading to the adoption of

cognitive-behaviour therapy (CBT) (Blake *et al.*, 1998; Hunter *et al.*, 2002a) (see 'Cognitive behaviour therapy').

One limitation of existing research is that aetiological assumptions are erroneously made on the basis of statistically significant relationships between reporting of symptoms and the particular dependant variable of interest, or on the basis of treatment efficacy. Aspirin is an effective cure for headache, and inhalation of CO₂ an effective treatment for panic attacks, yet we would not propose that either aspirin or CO₂ are implicated in the aetiology of either disorder. The very premise of a causal relationship is also flawed, as the discovery of a correlation between premenstrual distress and a particular hormone does not mean that the hormone caused the distress. Each may be related to a third variable, such as stress, or not related at all (Gannon, 1988).

Equally, conducted within a positivist epistemological framework (Ussher, 1996), existing research reifies PMS as a disorder, implicitly conceptualizing it as a static or fixed entity, with the occurrence (or non-occurrence) of symptoms as the end-point of analysis (Ussher, 2002a). The cultural construction of 'PMS' or 'PMDD', women's ongoing appraisal and negotiation of changes in emotion, behaviour, or bodily sensations, the meaning of PMS in their lives and the role of relationships in the development of premenstrual symptoms are issues that are marginalized or negated.

Women's negotiation of PMS in a cultural and relational context

The bodily functions we understand as a sign of 'illness' vary across culture and across time (Sedgewick, 1987). Women's interpretation of psychological and bodily changes as being 'symptoms' of PMS cannot be understood outside of the social and historical context in which they live, influenced by the meaning ascribed to these changes in a particular cultural context. In cultures where PMS does not circulate as a discursive category, women do not take up the position of PMS sufferer, and do not blame PMS, or the premenstrual body, for psychological distress (Chandra & Chaturvedi, 1992). This has led feminist critics to argue that PMS and PMDD are merely the latest in a line of diagnostic categories which act to pathologise the reproductive body (Parlee, 1991; Nash & Chrisler, 1997). However, we also need to acknowledge the vulnerability experienced by women premenstrually, the role of the body or social stressors in premenstrual experiences and women's subjective evaluation and negotiation of psychological and bodily changes (see also 'Cultural and ethnic factors in health').

Recent research has demonstrated that the development of premenstrual symptoms, and the construction of these symptoms as 'PMS', is a shifting process of negotiation and coping, which occurs in a relational context. For example, in research conducted in the UK and Australia, three inter-related processes of appraisal and coping were found to be central to the experience and construction of PMS. These were, awareness of premenstrual changes in emotion, ability to cope, or reactivity to others; expectations and perceptions of these changes; and mode of response or coping (Ussher, 2002a). At each stage in this process, women could resist, or take up, the position of 'PMS sufferer': the construction of premenstrual change as PMS was not inevitable. Relational issues were a major predictor of self-diagnosis and coping. Feeling out of control and unable to

tolerate negative emotional or bodily change, particularly in situations where there were overwhelming demands from partner or children, was the most common description of PMS given by women in narrative interviews (Ussher, 2003a). The most problematic 'symptoms' were anger or depression in the context of family relationships, leading to the desire to be alone and to eschew responsibility, followed by shame or guilt (Ussher, 2003b). Women, and their families, attributed these 'symptoms' to PMS, even when alternative explanations could be found and thus through a process of splitting, disassociated negative emotions or behaviours from the woman. Many women also reported self-silencing and self-sacrifice in relation to their families during the non-premenstrual phase of the cycle, with grievances in relationships coming to the fore and being expressed premenstrually (Ussher, 2004b). This rupture in self-silencing appears to function to allow the expression of both day-to-day frustrations, and anger associated with more substantial relationship issues, which are repressed during the rest of the month as women attempt to be 'good' (Ussher, 2004a). This supports previous findings that women who report premenstrual symptoms also report higher levels of relationship dissatisfaction or difficulties (Ryser & Feinauer, 1992) and that constructions of femininity are tied to experiences of premenstrual distress (Cosgrove & Riddle, 2003) (see also 'Gender issues and women's health').

There is evidence from previous research that that many women do experience increased vulnerability or sensitivity to external stress during the premenstrual phase of the cycle, resulting from a combination of hormonal or endocrine changes, sensitivity to changes in autonomic arousal and differential perceptions of stress premenstrually, linked to cultural constructions of 'PMS' as negative and debilitating. Experimental research has also demonstrated that dual or multiple task performance is more difficult premenstrually, and whilst women can compensate with increased effort, this can result in increased levels of anxiety. It is thus not surprising that many women report reacting to the stresses and strains of daily life with decreased tolerance premenstrually, particularly when they carry multiple responsibilities. This is the one time in the month that they cannot live up to internalized idealized expectations of femininity, with increased vulnerability, or reduced tolerance, leading to a rupture in self-silencing.

A material-discursive-intrapsychic model of premenstrual distress

In order to understand these different aspects of women's premenstrual experience, we need to adopt a multi-factorial perspective. This can be achieved through adopting a Material-Discursive-Intrapsychic (MDI) model, which posits that an ongoing interaction of material (e.g. changes in hormones, physiological arousal, neurotransmitters, or life stresses), discursive (e.g. cultural constructions and representations of PMS, reproduction and gender) and intrapsychic factors (e.g. mode of evaluating and coping with changes, expectations of self, defence mechanisms) combine to produce emotions, bodily sensations and behaviours, which come to be diagnosed as 'PMS' or 'PMDD' by the woman herself, or by a clinician (Ussher, 1999).

Multifactorial models for PMS, within a biopsychosocial framework, have previously been put forward (Walker, 1995; Blake,

1995; Ussher, 1992; Bancroft, 1993). However, MDI does not position either psychological or biological aetiological factors as the point of origin of PMS; it develops the analysis of psychological processes involved in PMS beyond the cognitive-behavioural; and is the first to explicitly engage with constructionist and discursive accounts of PMS, through acknowledging the role of discursive representations of 'PMS' and femininity in analyses of the development and course of premenstrual symptoms. In using the MDI model as the basis of prevention and intervention for PMS, a combination of approaches would be suggested as optimum. This would include: the challenging of negative cultural constructions of the

reproductive body and of PMS; couple therapy, if relationship issues are a significant factor in women's distress; individual psychological interventions which take material, discursive and intrapsychic factors on board (e.g. Ussher *et al.*, 2002b); and if necessary, biomedical treatments (such as SSRIs) to alleviate severe symptoms. Such a multifactorial approach to PMS is common practice when clinicians are working with individual women; this approach can be justified on the basis of the research literature and now needs to appear as a legitimate focus in theoretical analyses of PMS, heralding a move away from narrow unilinear models of aetiology and treatment.

Psoriasis

Catherine J. O'Leary

Guy's Hospital

Psoriasis

Psoriasis is a chronic, non-contagious skin condition affecting between 1% and 2% of the populations of industrialized countries (Russo *et al.*, 2004). It is characterized by lesions of skin which are inflamed, itchy and scaly. Severity can range from lesions on the elbows alone to extensive body coverage. The most common form of psoriasis is chronic plaque, characterized by lesions round in shape, a few centimetres in diameter, raised and covered in a silvery scale. Any part of the skin may be affected including the scalp. Psoriasis can also result in pitting, discolouration and separation from the nail bed of both finger and toe nails. In addition, 1 in 20 psoriasis sufferers have psoriatic arthritis of the joints. Many people with psoriasis experience the Koebner phenomenon in which lesions occur in areas where there has been skin trauma or injury, such as a cut, an injection site or burn.

The severity of psoriasis is rarely static. The majority of individuals cycle between differing levels of severity throughout their lifetime, experiencing 'spontaneous' remissions and flare-ups during the course of their condition. There is no cure for psoriasis and instead treatment is aimed at reducing symptoms and improving the appearance of the skin. Medical treatments include topical ointments and creams, phototherapy and systemic treatments. These can be unpleasant to use and time-consuming, often involving frequent hospital visits.

In recent years, it has become clear that in addition to the physical problems such as pain, itching and flaky skin, psoriasis also causes a great deal of psychological disability. There is evidence to suggest that people with psoriasis experience high levels of anxiety (Fortune *et al.*, 2000) and depression (Akay *et al.*, 2002), suicidal ideation (Gupta & Gupta, 1998), reduced quality of life (Scharloo *et al.*, 1998) and sexual dysfunction (Gupta & Gupta, 1997) (see 'Quality of life' and 'Sexual dysfunction').

Interestingly, research has suggested that increased levels of emotional distress are not directly related to the severity of psoriasis (Stern *et al.*, 2004). Instead several factors appear to contribute to such distress, one of the main contributing factors being a fear of negative evaluation. Leary *et al.* (1998) found that a strong fear of negative evaluation was significantly correlated with poorer social life, family relationships, recreation and leisure and emotional wellbeing. Similarly, Fortune *et al.* (1997) found that anticipating negative reactions from others and a fear of being rejected were strongly related to psychosocial disability and a poor quality of life. Common stressors experienced by Fortune *et al.*'s (1997) sample included feeling the need to wear inconvenient or unattractive clothes in order to cover up and

strangers making insensitive or rude remarks (see also 'Facial disfigurement').

In one survey, individuals rated the stigma associated with psoriasis as being the worst aspect of the condition and reported feeling the need to hide their skin from others, avoiding many daily activities such as swimming, wearing short sleeves or going to the hairdressers (Stankler, 1981) (see 'Stigma'). In one study, 19% of the sample reported incidents where they had been asked to leave a public place such as a swimming pool because of the appearance of their skin (Ginsburg & Link, 1993).

The location of the psoriasis also appears to be a significant contributor to psychological distress and this ties in with a fear of negative evaluation. Psoriasis occurring in areas that are not so easily covered up such as the face, neck and hands, results in poorer levels of quality of life (Heydendael *et al.*, 2004). The way in which psoriasis interferes with day to day chores or one's ability to work has also been found to influence the amount of psychological distress experienced (Ginsburg & Link, 1989).

Rapp *et al.* (2001) found that the coping strategies used by many psoriasis sufferers actually impaired quality of life. More specifically, telling others about psoriasis, covering the lesions and avoiding people was associated with poorer levels of health-related quality of life. In contrast, telling people that psoriasis is not contagious was related to smaller decreases in quality of life. Scharloo *et al.* (2000) found that people who coped by expressing emotions, seeking social support and distraction were less anxious and depressed and had a better physical health at a 1-year follow-up (see 'Emotional expression and health' and 'Social support and health'). In contrast, the belief that psoriasis causes many symptoms was associated with more visits to the outpatient clinic and worse levels of quality of life and depression one year later.

Recent studies have examined illness perceptions; that is individuals' common sense understanding of their psoriasis, and how these beliefs affect quality of life and psychological wellbeing (see 'Lay beliefs about health and illness'). Scharloo *et al.* (1998) found that beliefs about the diagnosis and the symptoms associated with psoriasis were important factors in explaining the variance in quality of life. Fortune *et al.* (2000) found that if psoriasis sufferers believed that they were to blame for having psoriasis then they were more likely to experience pathological worry. Worry was associated with a stronger belief that psoriasis had an emotional cause and the belief that psoriasis would be chronic or recurring (see also *Attributions and health*).

Although it is unclear why psoriasis develops, it is often suggested that psychological stress in the individual's life may cause the

condition to flare and worsen. There have been a number of studies looking at the role stress plays in the onset and exacerbation of psoriasis (see 'Stress and health'). However, the findings have been mixed and this may be the result of numerous methodological difficulties such as small samples sizes, retrospective design and psychometric invalidity (for example Arntez *et al.*, 1985; Gaston *et al.*, 1987; Payne *et al.*, 1985). In addition, these studies have been hampered by difficulties regarding the definition of stress. Overall there is a lack of firm evidence linking stress to the onset or worsening of psoriasis (O'Leary *et al.*, 2004; Picardi & Abeni, 2001).

Much of the evidence suggesting a relationship between stress and psoriasis has arisen from self-report studies, with high proportions of individuals with psoriasis reporting stress as the major precipitating factor in the onset and exacerbation of their condition (Mazzetti *et al.*, 1994; Zachariae *et al.*, 2004). Al'Abadie *et al.* (1994) found that people with psoriasis were more likely to report a stressful experience as pre-dating the onset or exacerbation than those with other skin conditions (for example acne, alopecia, basal cell carcinoma). In a large survey of Nordic sufferers ($n > 5000$) 35% reported that the onset of their psoriasis occurred during a period of worry, whilst over 65% of the sample reported that their condition was exacerbated by stress (Zachariae *et al.*, 2004). The authors of this survey suggest that there may be a subgroup of individuals who are more psychologically reactive to their psoriasis.

It is important to note that many individuals with psoriasis have been informed by their practitioners or through self-help books (e.g. Marks, 1981) that psoriasis is related to stress. This is likely to lead to a cognitive bias in the remembering and reporting of stressful events. In a recent study examining causal beliefs in psoriasis (O'Leary *et al.*, 2004), a strong belief in stress as a causal factor was found in over 60% of the sample. This belief was significantly associated with higher levels of anxiety, depression and perceived stress. However, there was no association between perceived stress and measures of psoriasis severity. This suggests that the perception that stress as a causal factor may in fact be detrimental to emotional wellbeing.

A number of psychological interventions for people with psoriasis have been developed and these tend to be based on two basic assumptions: (i) that psychological stress is related to the exacerbation of the condition and (ii) that much of the psychological morbidity in psoriasis is related to factors such as the anticipation of others' reactions, feelings of shame or embarrassment and not the severity of psoriasis.

The efficacy of such psychological interventions has generally been reported in the form of case studies. Winchell *et al.* (1988) reviewed four case studies in which relaxation and suggestions of improvement resulted in actual improvements in severity. In one case, the intervention resulted in complete remission. Whilst case studies can be a useful source of information, controlled trials with larger samples provide more conclusive evidence.

Zacharie *et al.* (1996) have examined the efficacy of a stress-management programme using a randomized control trial design.

In this study, 51 patients were assigned to a treatment group or a control. The intervention consisted of cognitive-behavioural stress management, relaxation training and imagery training (see 'Cognitive behaviour therapy' and 'Relaxation training'). The results demonstrated small but significant improvements in psoriasis severity in the treatment group from baseline to end of treatment. There were no changes in the control group. Interestingly there was no change in perceived stress for either group throughout the trial. This suggests that an improvement in levels of daily stress cannot account for the change.

Kabat-Zinn *et al.* (1998) applied a meditation-based stress reduction programme to 37 patients with psoriasis undergoing photo(chemo)therapy (UVB or PUVA). Patients were assigned to either the treatment condition (audiotaped instructions played during photo(chemo)therapy) or a control condition (no taped instructions). The patients were not blinded but were told that the tapes would make treatment more pleasant. Nothing was said to create expectations of an improvement due to the tapes. There was a trend towards faster clearance of plaques in the treatment group, although the results did not reach statistical significance. Due to the lack of significance this study presents only tentative evidence for the efficacy of a stress-reduction approach to intervention.

Main *et al.* (2000) have developed a biopsychosocial approach to the treatment of psoriasis, The Psoriasis Symptom Management Programme (PSMP). The PSMP is a 6-week group programme, and involves cognitive-behavioural techniques aimed at modifying unhelpful thoughts and beliefs and relaxation, alongside traditional medical management. Whilst their preliminary results appear to be encouraging (Richards *et al.*, 1999), less than 10% of those offered the PSMP accepted a place questioning the requirement for such psychological therapy (Fortune *et al.*, 1998). A recent outcome study (Fortune *et al.*, 2004) has shown that at 6-month follow-up, the PSMP had been successful in modifying some illness perceptions, namely perceptions relating to the number of symptoms associated with the condition, the strength of belief in the severity of the condition and in attributions for emotional causes. However, perceptions relating to cure or control of psoriasis or beliefs about physical causes did not change. Similarly the use of coping strategies did not change.

In summary, current research suggests that psoriasis can result in psychological disturbance. Furthermore, someone with relatively mild psoriasis may be more distressed than someone with severe psoriasis if that psoriasis occurs in visible places, stops them from working or socialising or if they expect people to judge them harshly. The implications of these research findings are that clinicians cannot estimate the psychological impact of psoriasis simply by looking at the extent and severity of the condition. There is preliminary evidence to suggest that psychological treatments aimed at reducing social anxiety and modifying unhelpful beliefs (for example the belief that one is being evaluated negatively) help people to cope with this chronic skin condition.

Radiotherapy

Sara Faithfull

University of Surrey

Radiotherapy is a common treatment modality for cancer with over 50% of individuals receiving radiation at some time during the course of their disease. Despite the extent of its use and the length of time it has been available our knowledge is limited in how it affects individuals not only physically but also emotionally and socially. Radiotherapy can cause problems through side effects of treatment. These can be temporary symptoms (acute effects) that occur during or in the months following treatment, but also longer lasting effects (late effects) that can develop many months to years following radiotherapy. Much of the knowledge that exists as to how people react or cope with radiation treatment is focused on the physical effects and much less on the psychological responses. However radiation reactions can often exacerbate existing functional or emotional difficulties that can be as a result of the disease, age or a combination of therapies. This chapter explores the incidence and specific psychological problems identified as a result of radiotherapy treatment for cancer. The evidence is reviewed for psychosocial interventions for those undergoing or completing radiotherapy.

The need to include information representing patients' views of their condition has become more important as survival from cancer has gradually increased. Evaluations of treatment modalities have psychological and social consequences. Clearly, with cancer treatment, a person's physical health status contributes much to the psychological impact of a treatment modality. However, factors that should also be considered are the emotional impact and the effect cancer treatment has on social and personal relationships.

Incidence of psychosocial problems

Assessing the psychological impact of cancer treatment on patients is expressed in terms of current definitions of anxiety and depression. Early studies of psychological morbidity suggest that 20 to 35% of all individuals with cancer experience anxiety and/or depression during the course of their therapy (Fallowfield, 1990) (see 'Cancer: general'). Many studies have identified the emotional and physical distress associated with radiotherapy (Forester *et al.*, 1978; Christman, 1990; King *et al.*, 1985). However, the proportion of people who experience distress or have psychological problems is unclear. Peck and Boland's (1977) much quoted work first identified that patients fear and misunderstand the use of radiation treatment and have negative attitudes to its effectiveness as cancer therapy. They interviewed people ($n=50$) undergoing radiotherapy and found most experienced mild to moderate anxiety. They determined that at the start of treatment 60% experienced anxiety. This rose to 80% after treatment was completed. However, much has changed in health care since this study was conducted, with greater openness

about cancer diagnosis and information-giving prior to treatment. Maraste *et al.* (1992) identified that 15% of women undergoing adjuvant breast irradiation experienced distress as anxiety rather than as depression or other psychological states. More recent work has identified that individuals still fear radiation and consider it negatively (Hammick *et al.*, 1998). However, Hammick *et al.*'s small study does not identify whether this attitude influences people's experiences or distress more widely. Young & Maher (1992), in an audit of a counselling service, found that 44% of those attending a British radiotherapy centre had abnormal levels of anxiety. Beyond this there has been little systematic study of the social or psychological reactions to radiation treatment and the proportion of people who experience specific problems.

Emotional distress is not limited to just the time of radiotherapy; it is recognized in several studies that it changes over the course of treatment. Physical symptoms may persist or worsen over several weeks and, therefore, the period of delivery of treatment may not represent the true time course of the impact of therapy. Holland *et al.* (1979), in a study of women with breast cancer having adjuvant radiotherapy, found that they had higher overall anxiety scores than women not having therapy. As women neared the end of their treatment, they became more depressed and were less hopeful about being cured. Forester *et al.* (1978) also found that patients reported restlessness, anxiety, apprehension, social isolation and feelings of withdrawal at the end of treatment. Ward *et al.* (1992), in a small study of women's reactions to completion of radiotherapy, acknowledge that the end of treatment does not always bring relief. Out of the 38 women interviewed, 11 (30%) found termination of treatment upsetting, and this was frequently connected to a worsening of side effects and not just the completion of the course of treatment. Women who were most anxious or depressed at the beginning of treatment were those most upset at treatment completion. This is also reflected in work by Graydon (1988) who suggests that emotional distress at the beginning of treatment is predictive of post-treatment functioning. Anderson and Tewfik (1985), in a sample of 45 women treated with external beam radiotherapy, found significant changes in anxiety between pre- and post-treatment assessments. As treatment progressed, patients with an initially high level of anxiety reported a significant reduction, those with moderate anxiety reported no change and those with low levels of anxiety reported significant increases. Several studies identify that fear at the outset of treatment is predictive of how well individuals adapt to radiotherapy. However, given the complexity of the radiotherapy treatment context, it is not surprising that a wide range of stresses can affect individuals at different times during the treatment trajectory (Lamszus & Verres, 1995).

Many of the studies discussed focus on specific populations and it is not clear how they can be generalized or whether disease specific determinants influence distress. These studies are focused within narrow parameters of distress and psychological morbidity, which may not reflect the everyday difficulties experienced with radiotherapy treatment (Fitch *et al.*, 2003). Munro *et al.*, who explored broader perceptions of distress in radiotherapy, found that men and women interviewed within the first 24 hours of starting radiotherapy had concerns that were different from their concerns at the end of treatment. Twenty people were asked to rank cards giving details of treatment related sequelae or concerns in order of severity of distress caused. It was found that concerns at the end of treatment were practical in nature, for example not being able to wash. Lower down the list were concerns that the treatment might not work. Distress was also caused by physical symptoms: fatigue ranked second both at the beginning and end of radiotherapy. However, Munro *et al.* (1989) only investigated distress at two time points, the beginning and end of treatment, which meant any distress experienced in the period following treatment remained undiscovered. Assessments that focus specifically on psychological morbidity, such as depression or anxiety, may not capture these other issues and therefore may not be particularly helpful in clinical practice, or address aspects of service delivery that result in distress. With a broader perspective, identifying what patients themselves feel as distressing, different elements may be identified that influence the impact of treatment. In the absence of a large-scale study looking prospectively at psychological problems, distress, physical symptoms and quality of life in cancer, it is impossible to draw meaningful conclusions. The emotional impact of treatment is not simple to assess and few centres routinely screen patients undergoing radiotherapy (Faithfull, 2003).

Clinical implications

Information provision and reduction of anxiety

Studies exploring strategies for the provision of information in radiotherapy have mainly been conducted in North America. The literature highlights that individuals undergoing radiotherapy have little knowledge or insight into what to expect with regard to the potential side effects of radiotherapy. Research has shown that preparatory information prior to receiving radiotherapy helps improve coping and has been shown to significantly reduce emotional distress and improve functioning following treatment (Johnson *et al.*, 1989). Rainey (1985), in an evaluation of the provision of audiovisual educational material, found that the intervention used improved knowledge of treatment but that differences between the control and intervention groups diminished as treatment progressed. Those having the intervention had less emotional distress.

Porock (1995), in a prospective study, found that those who received structured information experienced less anxiety and had higher levels of satisfaction during and after treatment (see also 'Patient satisfaction'). Dodd and Ahmed (1987) looked at differences in preference for information and found people preferred a more cognitive style of information. Studies of different types of information have shown that regardless of the style of patient education, all forms help improve the knowledge of radiation treatment for those having therapy (Israel and Mood, 1988; Johnson *et al.*, 1989).

The assumption is that by making people better informed they will feel less anxious and be able to cope more effectively throughout treatment. Although this has been demonstrated in surgical and coronary care (Mumford *et al.*, 1982), the exact mechanism and time scales may be different for radiotherapy.

There is a problem in these studies in that evaluations of the effectiveness of information provision are often based on knowledge recall. Understanding or being able to recount facts about radiotherapy is not equivalent to the benefits that such information may have in terms of outcomes. Information and patient education had greater impact at the start of radiotherapy than when therapy was completed (Rainey, 1985). This may be because those who felt less prepared for treatment were able, as treatment progressed, to improve their knowledge. It has been suggested that information improves self-care ability and the use of strategies by patients themselves (Dodd, 1984, 1988). Self-care strategies have not been shown to have significant benefits in terms of symptom control or reducing emotional distress (Johnson *et al.*, 1988, 1989). One possible reason for this is that effective self-care strategies may depend on the socio-economic status and social support mechanisms from family and friends, which may vary widely between different people (Hanucharukul, 1989). Evidence is now available in the literature that suggests that not only do different cancer groups require different levels of information, but, also, the type and timing of information are also important (Campbell-Forsyth, 1990; Frith, 1991). Few studies have identified how informational interventions have an impact on psychological distress (see, for example, 'Stressful medical procedures' and 'Surgery'). However a study by Steigelis *et al.* (2004) identified that radiotherapy information provision has a correlation between individuals feelings of control and the level of illness uncertainty and that this is especially important for high-risk patients who perceive little control and more uncertainty (see 'Perceived control'). Therefore, targeted information giving has been shown to be most effective where it is given in combination with emotional support and pre treatment visit to the radiotherapy department.

Counselling and psychotherapy interventions

Studies have identified that radiotherapy treatment results in high levels of anxiety and emotional distress (Peck & Boland, 1977; Forester *et al.*, 1978) and, therefore, researchers have tried to reduce these sequelae by offering psychotherapy or counselling services. Forester *et al.* (1985), in a randomized trial, used a psychotherapeutic approach to try to reduce distress. The intervention was not a specific type of psychotherapy but reflected the individuals' emotional needs (see 'Counselling'). Thirty minutes of psychotherapy were given weekly over 10 weeks to provide emotional support. A significant reduction was found in both emotional and physical signs of distress in the intervention group, compared with those having conventional medical follow-up. Criticisms of this study were the feasibility of offering such intensive counselling to all those undergoing radiotherapy and the potential cost. In response, a further study using group psychotherapy showed that this decrease in emotional distress was also achieved using a group approach (Forester *et al.*, 1993) (see 'Group therapy'). Interestingly, subjects who had the lowest baseline distress scores seemed unaware of their

cancer diagnosis and were found by the end of therapy to have higher distress levels. The overall conclusion was that psychotherapy was able to enhance the quality of life for those undergoing radiotherapy treatments. The degree to which individuals acknowledge their cancer was considered an important factor in their initial distress level and subsequent response to radiotherapy.

More recently there has been an increasing awareness of the psychosocial needs of those undergoing cancer treatments and this has been reflected in the provision of counselling services for radiotherapy. However, there are few constructive reviews of their effectiveness. Young and Maher (1992), in an audit of the work of a radiographer counsellor, provide insight into the dilemmas of providing such a service. Young and Maher felt that counselling had been of benefit in 50% of those who had received it. They believed counselling had reduced emotional distress, but pointed out that this was a subjective assessment at one time point that had not been evaluated in a randomized trial. They reported that the work was stressful and that the counsellor was deluged with referrals, but that overall such a service did have benefits.

Conclusion

Radiotherapy as a cancer therapy has clearly a level of psychosocial morbidity. Routinely screening for morbidity may be problematic in terms of referral ability and capacity in busy radiotherapy departments. However it is imperative to identify those undergoing

radiotherapy in need of intervention and concentrate limited resources on those who would most benefit. The research evidence identifies that existing radiotherapy assessment tools that assess morbidity may not reflect emotional concerns. There are indications that the broader spectrum of radiotherapies impact is being overlooked, and that concerns about adapting to the effects of treatment, worry about every day concerns such as travel and the bother factor of physical symptoms are underrepresented. With a broader perspective, identifying what patients themselves feel as distressing, different elements may be identified that influence the impact of radiotherapy. People often have misunderstandings as to the effects or why they are having radiotherapy, and improved informed consent and information provision has made progress in reducing some of this anxiety prior to radiotherapy. What should be remembered is that psychosocial distress changes over the course of radiotherapy and, although information is often targeted at the start of therapy, anxiety can be just as high at the completion of treatment. The provision of combination interventions such as counselling and information are beneficial to patient outcomes and have been shown to reduce anxiety. With new radiotherapy treatments emerging and more combination therapies the impact of radiotherapy is harder to entangle for the whole effect of cancer therapy. Defining what causes distress and how it changes over time are important issues for clinical practice, with implications for decisions about when care or support is required and who should receive it.

Rape and sexual assault

Irene H. Frieze¹ and Maureen C. McHugh²

¹University of Pittsburgh

²Indiana University of Pennsylvania

Rape is one of the most feared events in the lives of many women (Roze & Koss, 2001). There is no clear definition of rape (Frieze, 2005). It is seen differently by those who have experienced various types of forced sex and by therapists, other helpgivers and those in the legal fields (Kahn & Mathie, 2000). In one large US study of college women, only 46% of the women defined by the researchers as being raped thought of their own experiences as ‘rape’ (Fisher *et al.*, 2000). However, even those who do not define what happened to them as ‘rape’ may suffer psychological or physical symptoms.

Rape is defined in various ways by different legal codes, but basically involves forced sexual contact. The most common form of rape involves a male perpetrator and a female victim, but other forms also exist. The rapist may be a complete stranger, someone who casually knows the victim, or someone who is well known. Marital rape is increasingly being recognized as a crime.

Studies attempting to determine the prevalence of rape provide widely varying estimates, depending on the specific definition of ‘rape’, the sample questioned and the methodologies used. Acts that are legally defined as rape may not be perceived as such by the victim. And, many rapes are never reported to authorities. In a national random sample of adults in the United States who were surveyed about various sexual experiences, 23% of women said they had been raped (forced to have sex) at some point in their lives, while 4% of men reported being forced to have sex (Laumann *et al.*, 1994).

Younger women and adolescents and African-American women are the most common victims of reported rapes in the USA. Rates vary greatly across the world. Rape is used during wartime as an act

of aggression by one group against the women associated with the ‘enemy’.

Researchers have debated whether rape is primarily a sexual crime or an aggressive crime. It is generally believed that both can be true, and that some rapists are more motivated by sex and others by aggressive feelings. Some rapists appear to believe that their victims enjoy being forced to have sex and may even seek out the same victim again. Others clearly intend to physically injure or even kill their victims (Groth, 1979).

The large majority of the rapes found in anonymous surveys involve acquaintance rapes. Rapes involving strangers are more likely to be violent and are more often reported to authorities, but they are relatively rare, compared to forced sex involving people known to each other. Forced sex occurring in ongoing relationships is often accompanied with other forms of partner violence, but not always (see ‘Domestic violence’). When the assailant is known to the victim, and especially if the assailant is a regular partner, forced sex is often not defined as ‘rape’ by the victim. Researcher opinions differ about whether or not any form of unwanted sexual activity should be classified as ‘rape,’ especially in cases where the ‘victim’ does not classify it as rape.

Those who have been raped may show reactions to that event for many years, although many who are forced to have sex do not appear to be traumatized. Typical reactions of those who do react strongly vary over time, and a number of stage models have been proposed to describe these changing reactions (e.g. Burgess & Holmstrom, 1985). The victim of rape, similar to victims of other traumatic events, typically has an immediate emotional reaction

which may take the form of denial, disbelief, numbness, or disorientation (Frieze *et al.*, 1987). The specific reactions of rape victims have been labeled as 'Rape Trauma Syndrome' (Burgess & Holmstrom, 1985). After the initial shock, rape victims might experience any of a variety of emotions including anger, anxiety, helplessness and psychosomatic and other physical symptoms. Unlike other crime victims, rape victims often experience difficulties in sexual functioning. There may also be difficulties in relating to men in general, and to a husband or boyfriend, for the female who has been raped. These short-term reactions are followed by more long-term effects which may include nervous breakdown, attempted suicide and other effects labeled as post-traumatic stress disorder (American Psychiatric Association, 1980; Kilpatrick *et al.*, 1985) (see 'Post-traumatic stress disorder'). Not all rape victims follow this sequence, though.

The strong psychological reactions of some rape victims appear to be greater than one might expect by analyzing only the physical injury resulting from the rape (Frieze *et al.*, 1987). One reason for this is that rape and other forms of victimization lead the victim to question or reassess basic assumptions about the world. People generally believe that they are safe and are not potential rape victims. Many women fear rape, and even those women who do fear rape attempt to live their lives in ways that they feel will protect them. When someone does become a rape victim, they must cope not only with the direct consequences of whatever happened to them, but also with the violation of their belief in a safe world. The fear and anxiety so commonly found in rape victims results from a fear of what could happen again even more than from what has already happened.

A number of coping mechanisms have been identified that characterize rape victim responses. These include redefining what

happened so that it provides a sense of meaning to the victim. Reactions such as self-blame can be dysfunctional if they add to guilt feelings in the victim or cause her to withdraw from normal activities (Burt & Katz, 1987). It is not uncommon for rape victims to move their residences and to stop seeing old friends. This may be done to protect themselves from the possibility of another rape or because previous social interactions have become uncomfortable.

Rape victims may hesitate in seeking help from the medical or therapeutic communities, police, or even from friends, because they have found that other people have negative beliefs about victims generally and rape victims in particular. A set of stereotypic beliefs ('rape myths') that blame women for tempting men or being in the wrong place at the wrong time are widely held (Burt, 1980). Such feelings may be communicated to the help-seeking victim, resulting in a 'second injury' of a psychological nature (Symonds, 1976).

The first form of treatment for rape victims is often medical. The physician must look for signs of physical injury and for signs of sexually transmitted disease or pregnancy. Once these medical needs are taken care of, the rape victim may then seek psychological counselling (Allison & Wrightsman, 1993). Although this may be one-to-one therapy, treatment often occurs in self-help groups. Many clinicians and others working with women who have been raped feel that they should be labeled as 'rape survivors' rather than 'rape victims' once they have begun to cope with their trauma. Medical staff and therapists need to be careful to avoid blaming the rape victim and causing a 'second injury'.

Other forms of sexual assault tend to have similar consequences for their victims, but are generally less traumatic. These include exhibitionism, voyeurism and forced touching.

Reconstructive and cosmetic surgery

Nichola Rumsey

University of the West of England

Introduction

Reconstructive surgery to normalize congenital abnormalities or repair injuries following trauma has a long and venerable history (Harris, 1997), however, until relatively recently, elective plastic surgery for cosmetic purposes was often sought covertly (Macgregor, 1979) and was considered an option accessible only to the wealthy. Currently, cosmetic surgery is considered a boom industry, and is increasingly accepted as an additional tool in the armoury of beauty enhancement techniques in Western societies. In the USA, the rates for procedures such as breast augmentation and rhinoplasties have increased by 700% in the past decade (Sarwer, 2002) and figures for the UK also show a dramatic increase in uptake. The increased popularity is fuelled by greater levels of disposable income amongst segments of the population, ever increasing media coverage of appearance-enhancing techniques and advertisers promoting myths and dreams associated with beauty.

The jury is still out in relation to whether people derive significant long-term psychological benefits from cosmetic surgery (Sarwer & Crerand, 2004). Most seek surgery as a solution to social and psychological problems. In addition, it is widely accepted that psychological factors play a significant role in every stage of treatment, including the decision to seek surgery, coping in the postoperative phase and in longer-term adjustment to changes in appearance (Pruzinsky, 2004), yet the input of psychologists into preoperative assessment and postoperative support is very much the exception rather than the rule.

Preoperative assessment

Pruzinsky (2002) recommends that a preoperative assessment of prospective patients for both reconstructive and cosmetic surgery should include an exploration of the motivation for surgery, the expectation of outcome, the extent of current dissatisfaction with the feature in question and body image in general, the impact of patients' concerns on daily functioning and their current and past psychological functioning.

Motivation for reconstructive surgery

The problems reported by those seeking reconstructive surgery frequently involve difficulties in social situations. Feelings of self-consciousness, social anxiety, negative self-perceptions and evidence of behavioural avoidance are common (Rumsey & Harcourt, 2005). Despite the prevalence of assumptions of a relationship between the severity of the disfigurement and the degree of

preoperative distress, research has consistently shown these to be unfounded. Increasing numbers of patients are undergoing reconstructive surgery following the surgical excision of malignant tumours. In these cases, the decision of whether and when to undergo reconstructive surgery can be complicated by issues of life threat. Harcourt *et al.* (2003) have illustrated that the uptake rates for breast reconstruction following mastectomy vary considerably between treatment teams, and are influenced by information and advice given by the surgeon (see 'Cancer: breast').

Treatment decision-making

The involvement of prospective patients in treatment decision-making should be encouraged, with pressure from families and significant others to undergo surgery assessed and minimized. Surgical procedures should be carefully planned to take account relevant physical (e.g. growth) and social (e.g. transition to a new social group) factors. For children and adolescents with very visible disfigurements which are causing distress, the balance between waiting for physical growth to be completed to optimise the chances of a good long-term result and the potential psychological problems associated with a long wait for surgery, can be a precarious one. Patients' wishes should be given as much weight as possible, with treatment decisions kept under regular review (Hearst & Middleton, 1997) (see also 'Cleft lip and palate' and 'Facial disfigurement').

Undue influence exerted by prevailing surgical protocols should be avoided (for example, the expectation that surgery will take place at a particular age). Prospective patients should be able to feel free to decline treatment if they wish.

Care providers may have to curb their enthusiasm to intervene, and remind themselves that psychological reactions to disfigurements vary considerably. They should also bear in mind that the aspiration of people with disfigurements is often to look unremarkable, rather than perfect (Pruzinsky, 2004).

In the preoperative phase, the psychologist should assess whether another intervention, for example, counselling, cognitive-behavioural intervention or social skills training would be an appropriate forerunner, adjunct or alternative to surgery (see 'Cognitive behaviour therapy'). If the person is experiencing significant additional life stressors, appearance concerns may become a 'hook' on which to hang other problems. If surgery is planned on the UK National Health Service, there may be a long wait before the procedure takes place. In such cases it would also be appropriate to consider additional interventions during the wait (for example, coping strategies designed to reduce the person's avoidance of social situations).

Motivation for cosmetic surgery

Sarwer and Crerand (2004) have noted that the results of studies exploring the motivation to seek cosmetic surgery appear to have been influenced by the assessment method used, with interview studies reporting higher rates of psychopathology than studies employing psychometric measures. Research carried out in the 1960s relied heavily on interviews, and suggested that potential patients were frequently neurotic, with a substantial proportion suffering from a discernible psychiatric diagnosis (for example, disturbances of body image such as eating disorders or body dysmorphic disorder (see 'Eating disorders' and 'Facial disfigurement'). Research in the 1970s and 80s made more frequent use of standardized measures, and reported more modest levels of psychopathology. Most commentators agree that those suffering from body image disorders should be referred for psychiatric assessment and treatment, rather than accepted for surgery. An exception has been a study by Edgerton *et al.* (1991) which concluded that combined surgical-psychological rehabilitation provided relief for 83% of a sample of 67 cases, who were judged preoperatively to have moderate or severe psychological disorders.

A raft of psychological factors have been proposed to explain the motivation to seek cosmetic surgery of those in whom psychopathology is absent. These include perceptual processes (e.g. self-esteem, body image and the relationship between the two), developmental factors (e.g. maturational timing and history of appearance related teasing), cognitive processes (e.g. social comparisons; biases in the processing of information during social interactions) and sociocultural processes (e.g. the influence of media images). However, no clear psychological profile is yet apparent.

While some prospective patients seek surgery merely as a confidence booster, others are seeking solutions to more debilitating concerns. Feelings of self-consciousness and social anxiety are common, with frequent complaints that personal, social or occupational functioning is affected in a detrimental way by appearance-related distress. As in reconstructive surgery, the decision to undergo a cosmetic procedure should be a personal one and not the result of pressure from family or friends (Rumsey & Harcourt, 2005). The majority of prospective patients will have been experiencing distress for some time. It is therefore relevant to explore the timing of the decision to seek surgery as there may be a significant precipitating factor.

Expectations of outcome

In all forms of appearance enhancing surgery, care should be taken that expectations of outcome are realistic (see also 'Expectations and health'). In what ways does the prospective patient anticipate that life will be different post-surgery? There should be a realization that despite messages to the contrary in media articles and advertising, surgical intervention will not provide a 'magical' cure for problems experienced presurgery. With reconstructive surgery, it is rarely possible to restore an appearance to its pre-disfigured state (Pruzinsky, 2002) and many patients (for example, those undergoing breast reconstruction) will require a series of operations over a lengthy time period. The question of 'when to stop' in the quest for a normal appearance can be complex.

Surgeons should endeavour to make the changes the patient wants, resisting any temptation to produce a technically more attractive result (Macgregor, 1979).

Clear information should also be provided to ensure that patients are prepared for postoperative bruising and swelling and for the often distressing early postoperative appearance of surgical wounds. This is particularly important when procedures are likely to result in an unusual level of post-surgical discomfort. In orthognathic surgery for example, patients may be required to endure some degree of mechanical restraint of the jaw for a period of several weeks and may be restricted to a liquid diet. Some patients experience distress and feelings of panic resulting from the restriction. In all forms of plastic surgery, there is often a significant period before the final outcome can be assessed.

Emergency admissions

Many psychological factors are relevant in the acute and postoperative phases for plastic surgery patients admitted as emergencies. For example, Wisely and Tarrier (2001) and others have highlighted the potential of psychological interventions to relieve the difficulties experienced by burns patients, their families and by the staff treating them. In the acute phase, distress frequently relates to the experience of pain, to sleep deprivation, to anxiety associated with unplanned hospitalization and emotions relating to the cause of the injury. Patients may display post traumatic stress symptoms (Pruzinsky, 2002) (see 'Post-traumatic stress disorder'). In the reconstructive phase, intervention may be helpful in order to establish realistic expectations of the outcome of surgery (for example the relationship of the likely outcomes to a person's original appearance and function). Interventions can be provided in the form of play therapy for children, or individual treatment or support groups for adolescents, adults and families. In the later phases of treatment, liaison with schools or the workplace has been shown to be beneficial, both in terms of preparing the patients for a return to school or the workplace and also for peers or colleagues who may be uncertain of how best to behave (Frances, 2003).

The postoperative period

Pruzinsky (2002) has pointed out that in the immediate postoperative period following reconstructive surgery, patients often experience depression, anxiety and doubts concerning the eventual outcome of the surgical procedure. Reactions to changes in appearance are by no means universally positive. Buffone, for example, (1989) estimated that 30% of patients undergoing orthognathic procedures experience a reactive depression. Effective preparation for surgery may reduce post operative levels of psychological morbidity and reassurance and empathy from a psychologist or healthcare professional who has established rapport with the patient in the preoperative stage is likely to be well received.

The benefits of surgery

The benefits of plastic surgery are widely proclaimed in the media, but have yet to be established through research. Sarwer *et al.* (2002)

reported significant reductions in dissatisfaction with a specific feature in female cosmetic surgery patients, but could find no improvements to overall body image or to the importance ascribed to physical appearance in evaluations of the self. Although systematic research is lacking, there are anecdotal reports that some experience unwelcome feelings of change to their 'identity' as the result of their changed appearance (Macgregor, 1979). Some tell of difficulties in dealing with increased attention from other people to their enhanced appearance, others, particularly those whose appearance has been 'normalized' may have problems coping with the lack of attention afforded to anyone with an unremarkable appearance. In cases where disappointment is evident, psychological support and appropriate intervention have the potential to improve adjustment. A minority of patients display a seemingly insatiable desire for further surgery. In such cases, a psychiatric referral is widely

considered more appropriate than offers of further surgery (Veale, 2004).

Conclusion

More research is needed to understand fully the factors involved in the motivation of people to seek appearance enhancing surgery, and in influencing postoperative outcomes. The numbers of people undergoing cosmetic and reconstructive surgery are increasing rapidly year on year. Given that psychological factors play a significant part in all stages of both elective cosmetic and reconstructive surgery, the participation of psychologists in the evaluation, treatment and follow-up of patients has the potential to significantly improve the quality of care provision.

Renal failure, dialysis and transplantation

Keith J. Petrie

The University of Auckland

The treatment of chronic renal failure

A chronic loss of kidney function may be caused by a number of factors, these commonly include diabetes, glomerulonephritis, chronic hypertension and familial polycystic renal disease (see 'Diabetes mellitus' and 'Hypertension'). A decline in renal function causes a gradual accumulation of the body's waste products and this is indicated by increasing levels of urea and creatinine in the blood. The metabolic disturbance accompanying renal failure leads to a number of physical symptoms, most notably lethargy and drowsiness, nausea and vomiting, as well as anorexia (see 'Vomiting and nausea').

The point at which patients are offered dialysis as a treatment for renal failure can vary according to the different policies of renal units, but treatment is typically instituted when the patient's renal symptoms reach a level that interferes with their ability to carry out their work or normal daily functions. Earlier treatment is associated with better survival and a preservation of nutrition. Some patients with a particularly poor medical prognosis, or with other major health problems that interfere with successful adaptation to a life on dialysis, may be advised against treatment.

Haemodialysis and continuous ambulatory peritoneal dialysis (CAPD) are the two types of dialysis treatment used to correct the on-going effects of kidney failure. In haemodialysis, the patient's blood is passed through an artificial kidney machine that removes waste products by passing the blood across a semi-permeable membrane. Most patients on haemodialysis must dialyse three times a week for between four and six hours. Often this can be done independently by the patient in their own home or through coming in to a dedicated hospital haemodialysis unit.

CAPD works according to the same general principle as haemodialysis but the whole process is conducted inside the body. In CAPD, dialysis fluid is run into the peritoneal cavity via a surgically implanted catheter. The peritoneum is a large semi-permeable membrane that lines the cavity, and once the dialysis fluid has been run in, it is left to exchange substances with the patient's blood. The fluid is drained after about 4–6 hours and the whole cycle is repeated each day, on three or four occasions. Improved rates of survival and correction of anaemia, as well as a more liberal diet, are features of CAPD. The choice between haemodialysis and CAPD is an important one for patients with each treatment having both advantages and disadvantages that have to be set against the patient's social and occupational circumstances.

The transplantation of a kidney from a cadaver or a living relative is the other treatment option for renal failure patients. The introduction of a new generation of immunosuppressive drugs has resulted in improved rates of graft function; now, with these drugs,

90% of kidney transplants from a deceased donor are successful. Transplantation is generally recognized as the best treatment available for end-stage renal failure. Freed from the drudgery of dialysis and the symptoms of kidney failure, transplant patients report significantly higher quality of life and have lower rates of psychological problems (Gudex, 1995) (see 'Quality of life'). However, there are some disadvantages to transplantation in terms of the need to take long-term medication and increased rates of malignancy. The possibility of coping with a failed graft for patients is a significant psychological blow, and one some patients do not want to risk facing again. A failed graft is often particularly traumatic when the kidney has been donated by a relative. Unfortunately, the demand for kidneys is outstripped by their availability, which consigns a sizeable proportion of patients to long-term dialysis. The impending arrival of successful xenografts may overcome the current shortage of kidneys but will undoubtedly bring with it additional psychological adjustment problems.

Psychological problems and quality of life

The difficulties inherent in renal disease are a function of the physiological consequences of kidney failure, the restrictions imposed by a relentless dialysis regimen and the ongoing psychological adjustments required by a chronic illness. One of the most disabling effects of end-stage renal disease (ESRD) is lethargy and tiredness. This interferes not only with daily work function, but also with family relationships, as the patient often lacks the energy to engage in previously enjoyed social activities. A reduction in sexual activity is also common in ESRD (see 'Sexual dysfunction'). Patients on dialysis also complain of a variety of other physical symptoms such as itchy skin and sleep problems that interfere with their daily life (see 'Sleep disorders'). The recent development of recombinant human erythropoietin that acts to raise the oxygen-carrying capacity of the blood has had a major impact on treatment of ESRD by reducing tiredness and other symptoms due to anaemia.

The process of dialysis treatment also creates difficulties that compromise wellbeing. Most common among these are problems with the fluid and diet restrictions required, the development of needle stick fears in haemodialysis patients, and trouble with dialysis technique that can result in periodic infections. Often patients' frustrations with their condition and ongoing dialysis show themselves in compliance problems with the treatment, diet and fluid restrictions. Non-compliance is a major problem in patients on dialysis as the regimen has many of the characteristics that work to decrease compliance (see 'Adherence to treatment'). The treatment is complex, long-lasting and directly impacts on the

patient's lifestyle. Non-compliance can also lead to conflict between staff and patients. Staff may become aggravated with patients who are perceived as not doing their share in managing their condition and, conversely, patients can come to see staff as representing an enforcement rather than a therapeutic role. This can result in patients feeling unable to bring up their personal difficulties and problems with staff. There is some evidence that behavioural programmes utilizing self-monitoring and reinforcement can improve the level of adherence to fluid restrictions among haemodialysis patients (Christensen *et al.*, 2002) (see 'Behaviour therapy').

Given this combination of physiological and psychological problems it is not surprising to find higher rates of psychiatric problems and impaired wellbeing in dialysis groups when compared to renal transplant patients and general population groups (Gudex, 1995). Uncertainty about the future and a lack of energy seem to be important factors in contributing to the differences in reported quality of life between patients on dialysis and the general population. Compared with transplant patients, patients on dialysis report a poorer quality of life, more problems with activities of daily living and significantly more negative emotions such as anxiety and depression (Cameron *et al.*, 2000; Gudex, 1995; Petrie, 1989). Despite the difficulties in assessing depression in dialysis patients because of the overlap in somatic symptomatology, high levels of depression have been consistently found in dialysis patients (Kimmel, 2002; Levenson & Glocheski, 1991).

Adjustment to treatment

The adjustment to treatment for renal failure shares similar characteristics to other chronic illnesses. The first part of this process involves coping with a loss of body function and an awareness of

the need for long-term treatment. The next phase is learning the techniques associated with dialysis and dealing with the restrictions that this routine places on daily life and relationships. The final phase is an incorporation of the changes in appearance, function and lifestyle necessary with treatment into a new self-image and identity. The ability of patients to deal with each of these stages varies quite significantly depending on their own psychological resources. Difficulties in the early stages can have considerable impact on eventual adjustment to dialysis. A common emotional reaction is that of denial. This may range from a reluctance to accept that dialysis is really necessary to a casualness in using proper dialysis technique, or frequent breaking of dietary and fluid restrictions later in the treatment process (see also 'Coping with chronic illness').

A number of psychosocial factors have been shown to be associated with adherence to dialysis and dietary restrictions. These include lower levels of social support, the patient's negative perception of their illness and lower patient satisfaction with the care from their medical specialist (Kimmel *et al.*, 1998; Kovac *et al.*, 2002) (see 'Social support and health', 'Lay beliefs about health and illness' and 'Patient satisfaction'). Recent work also suggests patients' own ideas about the cause of renal failure and the effectiveness of treatment may be promising areas for future research on adherence to dietary and fluid restrictions (Krespi *et al.*, 2004).

The treatment of renal failure creates considerable difficulties for patients and their families. They must adapt to the loss of a bodily function and the accompanying energy-sapping symptoms. Given the demands and restrictions of life on dialysis as well as the psychological issues of dependency and an uncertain future, the surprising aspect is perhaps not how many patients become depressed but how resilient the majority are to the demands and restrictions of renal disease.

Repetitive strain injury

Gerard P. van Galen

Nijmegen Institute for Cognition and Information

Repetitive strain injury (RSI) is a syndrome in the upper extremities (hands, arms, shoulder and/or neck) and is characterized by sensations of pain, stiffness, fatigue, heat and cold, tingling, numbness, redness of the skin, cramps and loss of fine movement control, eventually leading to general disability. Usually pain, fatigue and stiffness, especially in the neck and shoulder region, are early symptoms, whereas functional loss and disability are mostly seen in advanced states. Initial, temporary episodes of pain and fatigue during repetitive tasks are defined as phase I severity. In phase II the pain has become more persistent and has generalized to other everyday movements. In phase III, pain and functional loss are continuous and unrelated to repetitious movements.

Since symptoms primarily develop in people whose work involves repetitious movements during long shifts, RSI is considered a typical occupational disorder with overuse of upper extremity muscles as a common denominator, although excessive computer gaming has been known to cause RSI complaints as well ('Nintendo arm'). Alternative terms are 'occupational overuse syndrome', 'work-related upper extremity disorder' (WRUED) and sometimes 'focal dystonia', although the latter term essentially refers to a different, neurological disorder.

Specific and non-specific forms of RSI

RSI complaints generally do not relate to any known biological disorder. Only in a minority of cases (<15%) does standard medical examination reveal tendomyogenic or peripheral neuro-conductive abnormalities (Kiesler & Finholt, 1988). To allow a differential diagnosis of specific or non-specific RSI a protocol has been developed with discriminating provocative tests (Sluiter *et al.*, 2001). Today, it is standard practice to distinguish the specific types of RSI from the nonspecific varieties where examination cannot uncover a biological cause. These non-specific forms of RSI include carpal and cubital tunnel syndrome, Guyon channel syndrome, trigger finger, epicondylitis, rotator cuff syndrome, thoracic outlet syndrome and tendonitis and arthrosis of the upper limbs.

Incidence

RSI complaints are widespread in the occupational population of industrialized countries. In the Netherlands, for example, 20–40% of the working population suffer from RSI, with higher incidence rates in industrial workers (e.g. agribusiness) than in office workers (National Health Council of the Netherlands, 2000). Other risk groups are hairdressers, plumbers, musicians, cleaning and laundry personnel. The impact of RSI on sick leave is high:

annually, 8% of all employees are absent for shorter or longer periods and between 5 and 10% of incapacity benefit claims are RSI-related. Other countries have similar statistics (Dembe, 1999; Levenstein, 1999).

Aetiology

Risk factors

Epidemiological, predominantly retrospective, studies have analyzed self-reports and medical files on complaints, work conditions and personal characteristics to identify correlations between complaints and risk factors. Authoritative reviews have been published by the US Department of Health and Human Services (Bernard, 1997), the USA National Research Council (2001) and Bongers *et al.* (2002). There is strong evidence that primary factors in the aetiology of RSI are excessive, repetitious and/or forceful motions accompanied by static postures. Apart from these primary workplace factors, epidemiological studies also indicate an association with negative psychosocial factors such as high workload, low appreciation and deviating self-control mechanisms.

Parallel to the epidemiological findings, comparative descriptive research, comparing patients and healthy controls, has revealed pathophysiological abnormalities such as hyper-algesia and loss of kinaesthetic sensitivity in RSI patients. Also, higher levels of muscular co-contraction and limb stiffness have been observed during motor tasks (see below). The problem with such findings, however, is that symptoms may well be the result of the syndrome and not the cause.

Poor ergonomics

From an ergonomic perspective, the design of most computer keyboards and visual display units (VDUs) elicit unsupported, pronated postures of the hands and an anterior position of head and shoulders. The VDU is often awkwardly placed (not at eye level, too far or too close). Although, thus far, there has been little well-controlled research into better designed tools, designers have tried to reduce the inherent awkward hand and wrist posture of conventional keyboards by constructing a vertically tilted or upright keyboard. Evidence suggests that this can lower muscular tension while keying (Rempel *et al.*, 1999; Tittiranonda *et al.*, 1999).

Personality

There is hardly any evidence for a typical RSI personality. Although some studies have found correlations between RSI and anxiety and

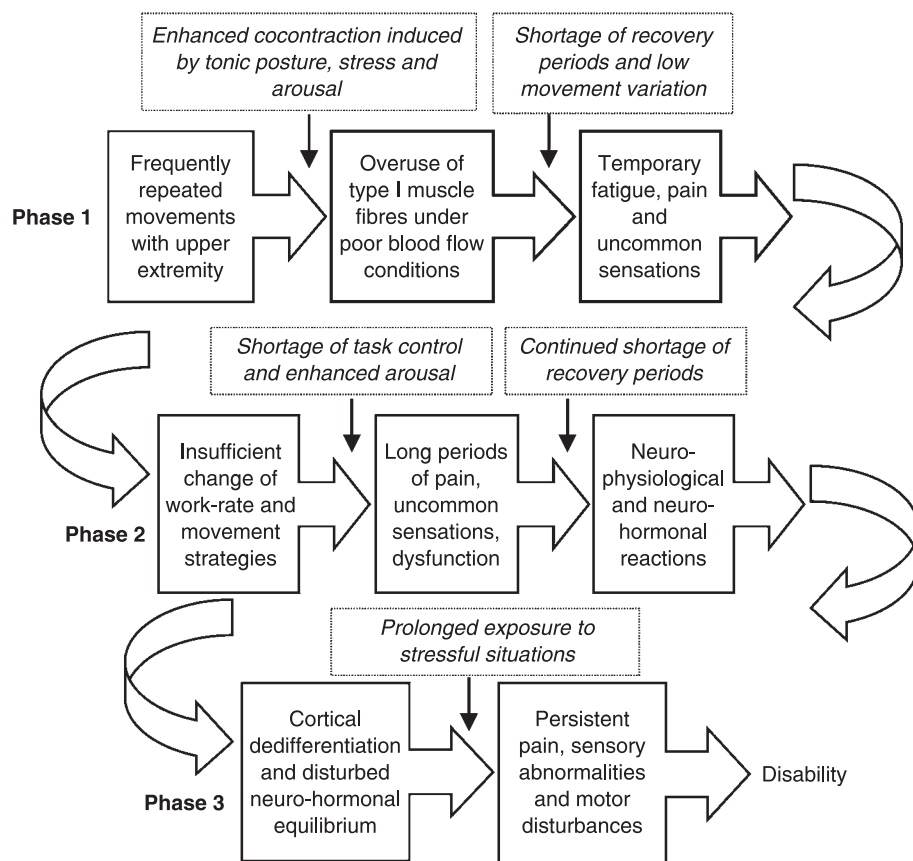

Fig 1 Model representing the three consecutive phases in the development of RSI complaints. Pathophysiological processes are positioned according to temporal evolution from phase 1 to phase 2 and 3. Environmental factors are given in italics.

depression or internal locus of control, it should be stressed that these were weak correlations and only present in advanced states of the syndrome. Moreover, these results may be due to the pain (Vlaeyen & Linton, 2000) (see 'Pain' and 'Pain management'). None of the studies has uncovered any psychiatric conditions in RSI patients when measured after the onset of RSI (Windgassen & Ludolph, 1991).

Pathophysiological accounts

Divergent pathophysiological mechanisms have been proposed for the aetiology of the syndrome. Explanations can be divided into three categories. First, there are the more peripheral theories on tissue damage caused by overuse. A second group, which is more behaviourally oriented, centres on findings of high degrees of muscle tension associated with precise, repeated movements and task-related stress. A third group focuses on neurological and neuro-hormonal changes resulting from pain and distress due to exposure to prolonged repeated movements. In recent accounts RSI is described as a multi-factorial syndrome starting with peripheral muscular dysfunction, exaggerated by stress factors, leading to a hampered blood flow, pain and dysfunction. In more advanced states this eventually causes central neurological dysfunction. Figure 1 summarizes this view in a three-phase model.

Tissue damage and the Cinderella hypothesis

Although imaging techniques have failed to detect unequivocal tissue damage in RSI patients, there is evidence from animal research that repeated movements at least have temporary negative effects on type I muscle fibres and indirectly on stapling of Ca^{++} ions in muscle tissue that may cause pain and cell damage. Pain, in turn, may lead to enhanced muscle tension, initiating a cycle of hampered blood flow, more pain and more tension. Specifically in repetitive fine movements, the smallest type I muscle fibres are continuously active and are, therefore, like Cinderella in the fairy tale, more exposed to overuse. Electromyographic studies have indeed found evidence of type I deficits (Westgaard & DeLuca, 1999; Sogaard *et al.*, 2001).

A less well-documented proposal claims that repeated movements lead to friction and temperature damage in tendons. The problem here again is that such damage has rarely been detected in human and animal models. However, from a theoretical viewpoint, it may well be possible that, especially for abnormal, non-neutral joint postures, friction and pulling strain on tendons is high.

Muscle tension and co-contraction

The second, behavioural explanation starts from the observation that RSI patients have less effective movement strategies (Bloemsaat *et al.*, 2004). Hughes and McLellan (1985) measured

the EMG of fore- and upper-arm muscles in patients and controls during tapping and handwriting tasks. The patients exhibited higher levels of muscular co-contraction, i.e. the fine-tuning in their agonist-antagonist muscle combinations was inferior to that found in the controls. Gomer *et al.* (1987) reported analogous outcomes in postal workers: the introduction of a complicated postal address coding system led to enhanced distress and hand tremors, changing the EMG spectral density function, all indicative of a disturbed muscle metabolism. A common denominator in co-contraction research is that repeated movement, high precision demands and mental load all lead to enhanced levels of muscular tension and co-contraction (Laursen *et al.*, 2002; Visser *et al.*, 2004). High muscle tension makes movements more fatiguing and finally less precise, again leading to still higher levels of contraction. Van Galen and Van Huygevoort (2000) propose a stress and human performance theory in which they postulate that all human movement is the product of noisy neuromuscular recruitment and servomechanisms. Different biomechanical degrees of freedom allow humans to control their inherently noisy movements. Amongst these are using optimal force levels (approximating 28% of the maximum force), feedback and feedforward control and applying friction and support with the work plane. A particular useful degree of freedom is limb stiffness, achieved by installing optimal levels of co-contraction between antagonist muscle pairs. Varying stiffness through co-contraction or by applying higher friction with work planes, however, has its limitations in that higher levels of stiffness make movement energetically less efficient. Several investigations have indeed provided evidence that stiffness and co-contraction is enhanced in conditions of stress and mental load and in RSI patients and the elderly extra sensitivity has been demonstrated (Bloemsaat *et al.*, 2004; Gribble *et al.*, 2003). In the proposed model (see Figure 1) it is assumed that non-neutral and inflexible postures during repetitive tasks interact with mental load and other physical stressors, such as auditory noise, poor illumination, vibration, etc. All of these have an impoverishing effect on neuromotor output signals, leading to higher tension and poor metabolic conditions for muscles, tendons and joints.

Neurological processes

Some of the research on RSI has focused on central neurological changes specifically during distal movements. In animal studies with owl monkeys, Byl *et al.* (1996) measured receptive fields in the cortex after prolonged exposure to a repetitious squeezing task. They found deterioration and dedifferentiation in cortical area 3b. This condition coincided with a loss of sensorimotor discrimination, which has also been found in patients. An alternative theory about a central neurological component in the persistence of pain in advanced states of RSI is of neuroendocrine origin. Clauw and Chrousos (1997) hypothesized that continuous coping with pain and stress in advanced states of pain may eventually lead to a lowered pain threshold following an initial increase. Their explanation focuses on the pituitary and adrenal glands, which normally work together in stress coping but may be exhausted

after long exposures to stress (see 'Stress and health' and 'Psychoneuroimmunology'). Patients thus become highly sensitive to even very common pain stimuli.

Towards an integrative model

In Figure 1 the three explanatory theories of RSI and their ingredients overuse, bad postures, task stressors, social pressures, central neurological deformation, all leading to sub-optimal stiffness regulation, pain and dysfunction, have been integrated in a comprehensive model.

Treatment and prevention

There is a profusion of preventive measures for the workplace and rehabilitation techniques for RSI patients, but only a few have been tested in methodologically sound trials (for overviews of rehabilitation studies, see Karjalainen *et al.*, 2003a,b; Konijnenberg *et al.*, 2001; Verhagen *et al.*, 2004; for studies on preventive interventions see Lincoln, 2001). Ergonomic training in situ has not yet delivered long-lasting positive results but there is some evidence that working with vertically oriented keyboards and less sideward forearm postures for mouse-handling have positive effects on muscle tension and complaints. Alleviation of complaints through software inducing controlled pauses during VDU work are very limited and reductions in sick leave non-existent (Van den Heuvel *et al.*, 2003). Behavioural programmes targeting muscular relaxation through biofeedback from surface electromyography (Nord *et al.*, 2001; Faucett *et al.*, 2002) have proved more effective (see 'Biofeedback' and 'Behaviour therapy'). Apart from ergonomic measures and direct muscle-training techniques there is a wide variety of physiotherapeutic interventions aimed at a more general enhancement of stress-coping skills. They include exercise training, fitness, massage and concurrent cognitive training and counselling (see 'Counselling' and 'Cognitive behaviour therapy'). To date, however, there is little or contradictory evidence for their efficacy.

Conclusion

Although still only partly understood, the syndrome of repetitive strain injury can be defined as complaints due to muscular overuse, non-neutral static postures, high muscle tension and task-related stress. In advanced states central neurological dysfunction is likely to play a role. A full understanding of the syndrome can only be attained if we consider both peripheral and physiological mechanisms and the more behavioural and emotional components as elements which exaggerate each other's effects in motor processes. Although further treatment and prevention research is required, it is assumed that reorganizing work schedules, improving tools and work environments and training workers to apply more relaxed movement strategies will help us to master RSI, at present one of the most prevalent occupational hazards.

Rheumatoid arthritis

Kathleen Mulligan and Stanton Newman

University College London

Rheumatoid arthritis (RA) is a chronic inflammatory disease that affects the synovial tissue surrounding the joints. This inflammation is associated with swelling and pain. As the disease progresses, joint tissue may become permanently damaged. The combined effects of inflammation and joint damage result in progressive disability. The causes of RA are, as yet, unknown but it is generally considered an autoimmune disease, although there is no clear evidence of what factors trigger this destructive response of the body's immune system. The onset of symptoms is gradual and insidious in most instances, although a small proportion of individuals (10–15%) may have a more rapid progression.

Joint pain, swelling and stiffness are the main symptoms of the disease, but individuals also report fatigue and general malaise. Individuals with RA describe their pain as throbbing and burning, but not as scalding, drilling or cutting (Wagstaff *et al.*, 1985). They describe their pain differently from individuals with osteoarthritis; in particular they are likely to refer to 'heat' (see 'Osteoarthritis'). Stiffness has always been harder to define and may be difficult for patients to distinguish from pain, but individuals with RA refer to resistance to movement, limited range and lack of movement (Helliwell & Wright, 1991). Clinically important levels of fatigue have been reported in over 40% of patients (Wolfe *et al.*, 1996). A multidimensional assessment of fatigue in RA found higher levels of general and physical fatigue as opposed to mental fatigue and different aspects of fatigue selectively explained variance in different dimensions of quality of life (Rupp *et al.*, 2004).

The impact of RA on individuals' lives is considerable. Using the SF-36, a generic measure of health-related quality of life, studies (e.g. Picavet & Hoeymans, 2004) have shown that RA is associated with impaired quality of life, especially on dimensions of physical functioning (see 'Quality of life' and 'Quality of life assessment'). A small minority of people with RA are wheelchair- or bed-bound and, for the rest, walking may be both difficult and tiring. Individuals with RA also report being concerned about falling (Jamison *et al.*, 2003), so they may further restrict their mobility. The net effect of RA on individuals' quality of life is considerable and is compounded by its impact on capacity to work and reduced income (Wolfe & Hawley, 1998). It can also reduce social and leisure activities and ability to perform domestic roles.

Studies which have compared individuals with RA to the general population have found raised levels of depression (Dickens *et al.*, 2002) which is frequently accompanied by anxiety (Van Dyke *et al.*, 2004). It is important, however, to recognize that RA does not lead to higher levels of depression than other chronic clinical conditions (DeVellis, 1993). Studies have failed to find a direct relationship between the physical markers of the extent or activity of the disease and depression. Evidence has, however, been accumulating that the

impact of RA is mediated through a number of psychological factors. Notable amongst these are self-efficacy, coping responses and illness beliefs (see 'Lay beliefs about health and illness' and 'Self-efficacy and health').

Self-efficacy refers to the self-confidence people have in their ability to perform a particular behaviour. The Arthritis Self-Efficacy Scales (Lorig *et al.*, 1989) assess people's self-efficacy to perform a number of everyday activities of daily living but also other elements of managing arthritis, such as the ability to reduce pain and deal with the psychological demands of the illness. The results of several studies indicate that self-efficacy may be an important concept for our understanding of functioning in arthritis. For example, it has been found to be related to daily ratings of pain, mood, coping and coping efficacy (Lefebvre *et al.*, 1999), to changes in health status over two years (Brekke, Hjortdahl & Kvien, 2001) and to outcomes in intervention studies (Smarr *et al.*, 1997).

The strategies people use to try to limit the impact of their arthritis are also important. Studies may be divided into those that have focused on the way people cope with specific symptoms of RA, such as pain, and those that have considered coping with RA in general. Studies on coping with pain in RA have assessed whether particular coping strategies lead to better psychological wellbeing. The general finding is that the use of active coping strategies is associated with better outcomes than more passive coping strategies (see 'Pain' and 'Pain management'). Smith *et al.* (1997) found a relationship between coping strategies and a number of measures of psychological adjustment. For example, using the active coping strategy of positive reappraisal of pain was associated with greater life satisfaction and positive affect whereas the passive coping strategy of disengagement was associated with poorer adjustment. The use of passive pain coping strategies, such as catastrophizing and praying and hoping, has been found, along with helplessness, to mediate between disability and pain and between disability and depression (Covic *et al.*, 2003). Studies that have examined how individuals cope with RA in general have also found the use of passive coping strategies to be associated with poorer outcomes, for example, poorer social functioning (Scharloo *et al.*, 1998). The strategy of wishful thinking has been associated with poorer wellbeing, while the coping strategy of cognitive restructuring (rethinking the cognitions around the illness and its implications) tends to be associated with better psychological wellbeing (Newman & Revenson, 1993). It is important to be aware, also, that the way people cope with RA may change over the course of the disease, for example, denial appears to be greater in the early stages (Treharne *et al.*, 2004).

The way people think about their RA may be another important influence on outcome. Groarke *et al.* (2004) assessed the illness

beliefs and coping strategies of women with RA and found that illness identity was associated with poorer outcomes in that people who attributed more symptoms to RA reported poorer physical function and more pain and depression (for more information on illness beliefs see 'Illness cognition assessment'). More serious perceived illness consequences were associated with poorer physical function and more pain. In this same study, patients who perceived their illness as more controllable reported less physical impairment, pain and depression, while those who thought that their RA would last a long time reported poorer physical function. The importance of coping strategies was also apparent in that depression was associated with high use of coping by denial and with less frequent use of the active coping strategies of planning, seeking instrumental social support, positive reinterpretation and growth and acceptance.

These studies have established that how one thinks about and what one does to confront RA has an impact on outcome and have spawned a number of approaches to intervention which aim to alter how individuals manage their RA in order to improve psychological wellbeing and reduce symptoms and disability.

Psychological interventions

The interventions developed and applied to individuals with RA have involved a variety of components, drawn from different theoretical approaches. One of the most widely used psychological interventions in RA and other chronic painful disorders is cognitive-behaviour therapy (CBT) (see 'Cognitive behaviour therapy'). CBT includes a number of components such as relaxation training, cognitive coping strategies, goal-setting with self-reinforcement, communications training, assertiveness training and problem-solving. One of the

objectives of CBT is to enable individuals to perceive themselves to have more personal control over symptoms such as pain (Keefe & Caldwell, 1997) and over the course of their disease (see also 'Perceived control'). Because increased perceptions of control have been found to have a positive effect on mood and other aspects of wellbeing (Rhee *et al.*, 2000), CBT can also help to address any accompanying depression. The concept of self-efficacy has also been an important influence on the development of interventions in RA. The widely used Arthritis Self-Management Programme (Lorig, 1986), for example, aims to enhance participants' self-efficacy to manage pain and other aspects of their arthritis by teaching skills such as problem-solving, cognitive symptom management and communication with healthcare professionals.

There can be considerable overlap between interventions in the components (or combination of components) that they include, making evaluating the efficacy of individual components difficult. Studies also measure several different outcomes such as psychological wellbeing and reductions in pain and disability. Consequently, it has proved difficult to ascertain which component has the most effect on the outcome variables under study (Newman *et al.*, 2001). A Cochrane review grouped studies according to their main approach and found that those which focused mainly on strategies to facilitate behaviour change appeared to produce more favourable outcomes than those which used primarily information provision or counselling (Riemsma *et al.*, 2002). The number of studies in each category was small suggesting that further research is necessary to investigate the comparable efficacy of different approaches. It is important to note that a particular approach may be more beneficial for some outcomes than others; for example, self-management interventions seem to be particularly successful in changing behavioural outcomes (Newman *et al.*, 2004) (see 'Self-management').

University of Reading

Although the term accident is in general use it has some important drawbacks. In the English language the term implies that the event was unintended and that it was random with no apparent cause. No great issue will be taken with the unintended part of the definition (though driver suicides do play a small part, Hernetkoski & Keskinen, 1998). The reader should, however, not operate with the assumption that these events are random with no apparent cause. Although the disadvantage of the term accident is commonly voiced, one advantage of the term is rarely considered. Unlike alternative terms such as 'crash' the term 'accident' offers the opportunity (not taken up on this occasion) to examine behaviour across a wide variety of domains including occupational settings, home environment, aviation and maritime environments. While the term crash does not have much credence in domains such as occupational settings, the term accident can readily be applied and may offer the possibility that similar processes (such as inexperience, fatigue and violations) may operate across domains. Despite the clear flaws in the term it will, on balance, be retained for the present purposes.

An interesting feature of the study of traffic accidents is that they are relatively rarely considered in the context of health. This is most unfortunate.

The magnitude of the problem

Across the world the major cause of death among 1 to 40 year-olds is road accidents (World Health Organization, 2004). For high income countries the casualty trends are decreasing, but, for low to middle income countries, the casualties are increasing. Overall, between the years 2000 and 2020, the forecast is that worldwide traffic deaths will

increase by 66% (Kopits & Cropper, 2003). In terms of hospital use in low and middle income countries, road traffic casualties are the most frequent users of operating theatres and intensive care units (Odero *et al.*, 1997). Even in high income countries with relatively good safety records the casualties are considerable. For example, Evans (1991) calculated that in the USA there were more traffic deaths in the years 1977–1988 than in all US battle deaths in all wars from the revolutionary war through to the Vietnam war. Road accidents are, therefore, a major public health issue for most countries in the world.

Demographics

Across the world the fatality rate for age and gender presents a consistent pattern. Younger drivers have a higher fatality risk than older drivers and men have a higher fatality risk than women (Peden *et al.*, 2002). Even when the relative numbers of drivers and their mileage is taken into account the same conclusion is reached (Evans, 1991).

Violations

Parker *et al.* (1995) note that the term human error has been used rather imprecisely to describe very different ways in which behaviour can contribute to accidents. In a factor analysis of self-reports, three distinct factors emerge (Reason *et al.*, 1990). These factors have been labelled errors, lapses and violations. Errors have been defined as deviations from planned actions; lapses as failures of

attention; and violations as deliberate infringements of safe practices. Although it is often argued that it is only violations that are related to accident involvement (e.g. Lawton *et al.*, 1997) there is evidence for a role for both errors and lapses.

The relationship between violations and accident involvement is well established. Gerbers and Peck (2003) found that those drivers who have violated have a subsequent accident rate that is more than three times higher than those with no violations. Violations that have been shown to be important are speed choice, close following and drunk driving. The link between speed choice and accident involvement has been shown by work demonstrating that casualties track speed limit changes (Rock, 1995); those observed to drive faster have more accidents (Wasielewski, 1984) and those who choose faster speeds on a video test have more speed-related accidents (Horswill & McKenna, 1999). Close following is implicated by the work of Evans and Wasielewski (1983) who found that observed following distance was associated with accident involvement. The relationship between drunk driving and accident involvement has been known for some time. A recent challenge for most societies is to determine the maximum level of alcohol that is permitted for drivers. Mann (2002) has noted that different societies might consider different criteria. For example, if research is considered that examines the decrement produced by alcohol on skilled performance then a level of 20 mg% would be justified. However, if research on elevated collision risk is considered then a level of 50 mg% would be justified.

Driving skill/experience

One obvious thought is that those who are more skilled have fewer accidents. Williams and O'Neill (1974) found that, contrary to prediction, those who were more skilled (race drivers) had more accidents on normal roads. Logically, some basic skill is required otherwise the vehicle would frequently be out of control. In learning to drive the relationship between driving test errors and accident involvement can be examined. Here the pattern is not entirely clear. Maycock (1995) reports that the one consistent finding across gender was that a higher order skill, awareness and anticipation was related to accident involvement. Although Baughan and Sexton (2002) found that awareness was implicated, they also found that general test errors were a better predictor of accident involvement, but, critically, these relationships were dependent on taking other factors into account. High-fault drivers drive less often and less in the dark, to the extent that they do not actually have more accidents. It is only when driving experience and driving at night are taken into account that there is a statistical relationship.

Maycock *et al.* (1991) examined the effects of age versus driving experience and found that experience dominated. In the first year of driving there was a 30% reduction in accident liability irrespective of age. In moving from age 17 to 18, drivers could expect a 6% reduction in accident liability. More particularly, McCartt *et al.* (2003) have shown that the accident rate is very high in the first few

months or 1000 miles of driving and then decreases. Clearly, drivers are learning, but what? One candidate is hazard perception, which refers to the ability of drivers to detect potential threats. It has been shown that new drivers are slow to detect hazards, but with experience and/or training hazard perception improves (McKenna & Horswill, 1999).

Fatigue

Horne and Reyner (1999) have argued that not only are sleep-related accidents more common than generally realized, but, also, they are more liable to be serious. The increased severity is a function of the fact that little avoidance action takes place in the form of steering or braking. Fatigue-related accidents are difficult to quantify and, in part, determining that an accident is fatigue-related relies on a process of elimination. To label an accident as fatigue-related, the general approach is to eliminate such factors as alcohol, medical disorder, suicide, and vehicle defects and then to determine whether avoidance behaviour (such as steering and braking) is absent. On this basis it has been estimated that sleep-related factors account for between 9 and 16% of all accidents and between 15 and 20% on motorways (Horne & Reyner, 1995; Maycock, 1996). Clearly, some proportion of these accidents may be due to sleep disorders. While it has been found that those with a sleep disorder, such as sleep apnoea (see 'Sleep apnoea') are more than six times more likely to have had a traffic accident (Teran-Santos *et al.*, 1999), it might be thought that the prevalence in the general population would be low. However, epidemiological investigation of the prevalence of sleep apnoea indicates that this may occur, often unrecognized, in 1 in 20 adults and in a milder, normally unrecognized form in 1 in 5 adults (Young *et al.*, 2002).

Maycock (1996) reported that 29% of drivers indicated that they had come close to falling asleep at the wheel at least once. In my own work I have found that, in a survey of over 10 000 drivers who were attending a speed awareness course, 16% indicated that they had fallen asleep at the wheel in the last two years. Acute sleep loss would appear to play a part in causing road accidents. Both Hartley (2004) and Stutts *et al.* (2003) report that having less than six hours of sleep the night before is a risk factor. It has also been found that those on night shift are at higher risk of a sleep-related accident (Stutts *et al.*, 2003). It would appear, therefore, that any factor that delays or disrupts sleep may be a risk factor (see 'Shiftwork and health' and 'Sleep and health').

Conclusion

Road traffic accidents are a major public health problem that is increasing. Tackling this problem will include finding methods to deliver new drivers with safe learning experiences, reducing driving violations and reducing the number of sleepy drivers.

Screening: antenatal

Elizabeth Dormandy

King's College London

Antenatal screening is an important part of antenatal care as practised across the world (see 'Antenatal care'). Pregnant women and their partners are routinely offered a range of screening tests to identify those who are at increased risk of a fetal anomaly including chromosomal abnormalities, structural abnormalities or haemoglobin disorders. Recently there has been a policy shift regarding the aim of antenatal screening, from reducing the incidence of conditions to facilitating informed choices for those offered screening (National Screening Committee, 2000) (see also 'Screening: general

issues'). This chapter describes the choices available for pregnant women and considers the extent to which informed choice is realized.

Screening Choices

Women are offered screening tests which differ according to the condition screened for, the time in pregnancy, the detection rates

and the safety of associated diagnostic tests. This section describes the choices available to women about antenatal screening.

Screening for chromosomal abnormalities

Down's syndrome (Trisomy 21) is the most common chromosomal abnormality screened for and affects about 1 in 700 live births in the UK. A variety of screening tests using different markers have been introduced during the last twenty years. These include ultrasound measurement of nuchal translucency and measurements in maternal serum of alpha-fetoprotein, pregnancy associated plasma protein, human chorionic gonadotrophin, oestriol or inhibin. Screening tests use different combinations of markers, with the name reflecting characteristics of the test such as the number of markers assessed (Double or Triple), the type of marker assessed (nuchal translucency), where it was developed (Bart's or Leeds) or the way the risk assessment was performed (Integrated). As markers alter during gestation, reliable screening requires ultrasound dating of pregnancy and tests to be taken at specific times in gestation. The reported detection rates for antenatal screening tests for Down's syndrome vary between about 50 and 95% with a 5% false positive rate. The most cost effective screening test at the moment is reported to have a 95% detection rate with a 5% false positive rate (Gilbert *et al.*, 2001) (see 'Fetal well being').

Screening results are usually reported as the risk of having a baby affected by the condition. Women are identified as being at increased risk in comparison either to a specified cut-off or other risk, such as age-related risk. Health professionals and women find communicating and understanding risk results difficult (see 'Risk perception' and 'Communicating risk'). Women at increased risk are offered diagnostic tests such as amniocentesis or chorionic villus sampling (CVS). These identify with virtual certainty if a fetus is affected, but are associated with a risk of miscarriage, which is greater for CVS than for amniocentesis.

If Down's syndrome is diagnosed in the fetus, women are offered the choice of continuing or terminating the pregnancy. This is a complex and tough area for women and their partners to deal with. Most women with a diagnosis of Down's syndrome terminate the pregnancy (Mansfield *et al.*, 1999) (see 'Abortion'), but little empirical work has been done to explore how best to inform and support women and their partners making decisions following a diagnosis of chromosomal abnormality.

There has been much discussion between health professionals about which test characteristics are most valued by women. A recent study has shown that pregnant women and health professionals both valued safe tests, conducted early in pregnancy with higher detection rates, but that health professionals placed greater emphasis on earlier tests than did women (Bishop *et al.*, 2004).

Screening for structural abnormalities

Women are offered ultrasound scans to screen for structural anomalies and UK guidelines recommend an ultrasound scan between 18 and 20 weeks gestation. A recent systematic review reported that ultrasound screening detected about half of the structural abnormalities and that detection rates varied according to the organ or system studied, with higher detection rates for central nervous

system abnormalities than for skeletal or cardiac abnormalities (Bricker *et al.*, 2000). Some structural anomalies may also indicate an increased risk of chromosomal abnormality. Ultrasound screening can also identify markers of uncertain significance, so called 'soft-markers', that often resolve within a short period of time. Diagnostic tests following ultrasound screening are usually more detailed ultrasound scans.

Women place a high value on ultrasound scans and perceive ultrasound scans as a social occasion to 'see' their baby, rather than as an opportunity to screen for fetal anomalies (Bricker *et al.*, 2000). These differences in the perceived aims of ultrasound scan between pregnant women and healthcare professionals can leave women and their partners shocked if anomalies are suspected or identified (Baillie *et al.*, 2000).

Screening for sickle cell or thalassaemia

Sickle cell disorders and thalassaemia are inherited disorders that affect haemoglobin and are most common among people of African and Caribbean descent and among people of Mediterranean and South Asian descent respectively (see 'Sickle cell disease'). Although screening for these conditions has been available in the UK for 30 years, evidence suggests that women have not made informed choices about these tests. Some women are not offered tests in a timely manner to allow a reproductive choice (Modell *et al.*, 2000). Screening is offered inappropriately, for example on the basis of family name or skin colour (Atkin & Ahmad, 1998) and women are poorly informed about the screening test (Ahmed *et al.*, 2002). The poor quality of the screening service offered to women at risk for sickle cell and thalassaemia may be associated with the ethnicity of the at risk groups (see 'Cultural and ethnic factors in health').

Choices about diagnostic tests

Samples for diagnostic testing are taken by CVS between about 10 and 14 weeks or by amniocentesis after 14 weeks. Samples can be analysed either by karyotyping or by molecular methods such as FISH (fluorescent in situ hybridization) or PCR (polymerase chain reaction). Karyotyping and molecular methods differ in the number of chromosomes examined and the time taken for analysis. Karyotyping requires the cells to be cultured and examines all 23 pairs of chromosomes present in a cell, whereas molecular tests examine specific chromosomes. Reporting time takes up to three weeks for karyotyping, and two to three days for molecular tests.

The choice between CVS and amniocentesis is usually determined by the time the screening test result is known, with CVS offered earlier in pregnancy. In the UK the predominant method of analysis is karyotyping, but the method of analysis and the selection of those to whom it is made available varies across the country (Grimshaw *et al.*, 2003). A recent survey has shown that about two-thirds of pregnant women, about half of their partners and just over half of healthcare professionals prefer molecular to karyotypic analysis (Grimshaw *et al.*, 2003).

Informed choice

Research on the factors associated with making informed choices has tended to assess one dimension only, usually knowledge about a procedure. It is now widely acknowledged that informed choice is more complex than this and involves several dimensions. A consensus is emerging that an informed choice has two core characteristics: first, it reflects an individual's values, and second, it is made in the context of good knowledge (Bekker *et al.*, 1999). An informed choice has been defined as: 'a decision based on relevant knowledge, consistent with the decision-maker's values and behaviourally implemented' (Marteau *et al.*, 2001). A recent study reported that about half the women offered antenatal Down syndrome screening made an informed choice (Dormandy *et al.*, 2002) (see also 'Informed consent').

Women's experience of screening

Women place great value on information about antenatal screening tests, and there is some evidence to suggest that women prefer to discuss screening with a health professional rather than receiving written information (Stapleton *et al.*, 2002). Women's level of knowledge about screening tests is low and interventions to increase knowledge about antenatal screening tests have not been effective.

Women who receive increased risk results from screening are anxious, with anxiety levels returning to normal following a normal diagnostic test result, but for some women anxiety remains after a normal diagnostic test result (Green *et al.*, 2004). Concerns have been raised that providing information will result in increased anxiety but evidence suggests this is not the case (Green *et al.*, 2004), and there is some evidence that information may reduce anxiety (Rowe *et al.*, 2002).

The influence of healthcare professionals

There is limited and conflicting evidence about the extent to which healthcare professionals may influence individuals' choices about antenatal screening tests. It is known that health professionals present information differently in different contexts. For example, health professionals provide more negative information about a condition in the context of antenatal screening than in the context of a baby born with a condition (Loeben *et al.*, 1998). There is some evidence that health professionals' attitudes may be associated with the uptake of screening tests. A descriptive study of antenatal HIV testing indicated an association between health professionals' attitudes towards HIV testing and uptake in women who consulted them, but this was not found in a study in the context of antenatal Down's syndrome screening (Simpson *et al.*, 1999; Dormandy & Marteau, 2004). One small study has examined the association between health

professionals' attitudes and women's decisions about termination in the context of fetal sex chromosome abnormality. Health professionals reported providing more negative information about the condition to a group of parents who subsequently terminated the pregnancy than did health professionals to a group of parents who decided to continue with the pregnancy (Hall *et al.*, 2003) (see 'Attitudes of health professionals').

The social context of informed choice

Concern has been expressed that offering antenatal screening for fetal anomalies represents a eugenic policy, and may undermine the role of disabled people in society (Alderson, 2001). Facilitating informed choice has been seen as a way of separating antenatal screening programmes from eugenic aims (Kerr *et al.*, 1998): that is it enables women to act in line with their own values and attitudes rather than the values of others. An alternative interpretation is that informed choice is an ideology rather than reality because of the difficulties health professionals experience when providing non-directive counselling (Williams *et al.*, 2002): that is women are likely to act in line with society's values rather than their own.

Screening programmes

The low levels of women's knowledge is perhaps not surprising given the poor written information available and the low levels of health professionals' knowledge about screening tests (Murray *et al.*, 2001; Sadler, 1997). Screening is often poorly implemented with a lack of guidelines or awareness of guidelines and tests offered inappropriately or tests not offered. In the UK, national programmes for Down's syndrome screening, ultrasound screening and haemoglobinopathy screening have been implemented, in part to address these problems. The success of these programmes at improving women's experiences and rates of informed choice has yet to be evaluated.

(See also 'Antenatal care', 'Fetal wellbeing' and other chapters on Screening.)

Conclusion

Screening for fetal anomalies is widely offered to pregnant women and their partners but the evidence suggests that rates of informed choice are low. For screening programmes to achieve their aim of offering informed choices to all women, three objectives need to be met. First, empirical evidence on how to facilitate informed choice is required. Second, evidence-based standards for facilitating informed choice need to be set. Third, rates of informed choice need to be monitored.

Screening: cancer

Kevin D. McCaul and Amber R. Koblitz

North Dakota State University

Secondary prevention, or the early discovery of cancer through screening, is based on the idea that identifying a disease before symptoms develop will enable early treatment and extended survival. Screening tests to detect cancer have increased in number over the last decade, and technological advances are certain to produce many more such tests in the decade ahead. In fact, the development of technologies useful for cancer detection has outpaced research demonstrating the value of those new

technologies. As a consequence, different screening tests are associated with different levels of uncertainty about whether they can accurately detect cancer and reduce deaths from cancer.

Reducing cancer deaths is an important goal. Cancer is the second leading cause of death in industrialized countries (ACS, 2004a), cancer treatment often creates significant psychological and physical suffering, and survivors continue to show poorer health outcomes compared to people who have not experienced cancer

for years after treatment (Yabroff *et al.*, 2004) (see 'Cancer: general'). Given the potential importance of cancer screening in reducing mortality, we raise four questions: (a) What effective cancer screening tests are available? (b) How can we encourage people to adopt cancer screening behaviours? (c) What are the psychological consequences of cancer screening? and (d) What are the important directions for future psychological research concerning cancer screening?

Cancer screening technologies

An ideal cancer screening technique is reliable and accurate, carries little or no risk, allows for early detection which can lead to cancer prevention, and is inexpensive. Not surprisingly, no such test exists, and all screening technologies differ in the extent to which they meet these different criteria. Given imperfect screening tests, it is worth considering the value of screenings most commonly performed to detect the following (most frequently diagnosed) cancers: breast; prostate; colon; and cervical (see Curry *et al.*, 2003).

Three common screening modalities are available to identify breast cancer in patients; clinical breast examination (CBE), mammography and breast self-examinations (BSE). We will not deal with BSE in any detail here, because of a more complete discussion in the present volume (see 'Self-examination'); suffice it to say, however, that many researchers are unconvinced that BSE is a worthwhile screening technique. CBEs are typically performed in a health care setting by a health professional who simply searches the breast tissue for abnormalities, and (similar to BSE), it is also unclear whether CBEs have a mortality benefit, although they are easy to perform and inexpensive. Mammograms are a more intrusive screening in which the breast is scanned by low-dose X-rays. Mammography is the best (albeit imperfect) screening test currently available, showing a significant effect in reducing mortality for older women (see also 'Cancer: breast').

Two controversial screenings are available for prostate cancer; digital rectal examination (DRE) and prostate-specific antigen (PSA) detection. DREs are inexpensive, involving only a brief exam by a health professional, but the exam may have little value in terms of contributing to reduced mortality. PSAs are also relatively inexpensive, involving only tests for PSA concentrations in blood. PSA detection is much more sensitive (more likely to detect cancer) than DRE, but its specificity (degree to which it also does not identify men without cancer as having cancer; that is, false positives) differs for men of different ages. More problematic, though, are lingering doubts about the necessity of treating all prostate cancers and potentially serious treatment complications (e.g. impotence). Thus, much uncertainty surrounds the value of PSA, sparking researchers to study how best to provide information to men so they can make an informed decision about the test (see Myers, 2005) (see also 'Cancer: prostate').

Health professionals can use several tests to detect colorectal cancer; faecal occult blood test (FOBT), flexible sigmoidoscopy, double contrast barium enema and colonoscopy. The FOBT test faecal specimens for the presence of occult blood. Flexible sigmoidoscopy relies on a small digital camera to identify polyps and cancer in the descending colon. Double contrast barium enema is

a radiological exam that looks for polyps or cancer in the rectum and colon. Colonoscopy, a more expensive test, is nevertheless the 'gold' standard test used to identify colorectal cancer, allowing the physician to examine the entire colon and to remove polyps to actually prevent cancer from occurring (Mandel *et al.*, 1993). Recent studies have revealed a relationship between screening and decreased incidence of colorectal cancer, although identification of the best screening test remains a contentious issue (Curry *et al.*, 2003) (see also 'Cancer: digestive tract').

The Pap smear is the screening test of choice for cervical cancer, even though the test lacks sensitivity and has considerable inter-observer disparities. If a Pap smear detects the presence of abnormal cells, cervical cancer can often be prevented, making this screening test a high priority (see also 'Cancer: gynaecological').

Encouraging people to screen

Screening levels

Adoption of different screening techniques differs widely by cancer type and screening methodology (ACS, 2004b). Most women in the USA, for example, are adherent to recommended screening for cervical (82%) and breast cancer (70%). Rates are meaningfully lower for colon cancer (39% of people older than 50 in the last year) and prostate cancer (54% of men having a PSA test in the previous year). Because of the uncertainty surrounding screening for prostate cancer and because colon cancer can be prevented, colon screening rates should be higher than for prostate cancer (Sirovich *et al.*, 2003). Moreover, the overall screening rates obscure an important fact: Screening levels are significantly lower for people of lower socioeconomic status, and the disparity has increased in the USA since 1987 (Swan *et al.*, 2003). Socioeconomic disparities are also observed in countries with national screening programmes, such as the United Kingdom (McCaffery *et al.*, 2002).

Most of the screening data concern whether people have 'ever' or recently been screened, and we know much less about repeated screening. The latter question is especially important because the determinants of repeated screening may be distinct from those of initial screening. Rothman (2000) theorizes that beliefs about the costs and benefits of screening determine initial testing, but one's experience with screening itself (e.g. was it painful?; Elwood *et al.*, 1998) determine whether people will return. Answering the question about repeated screening will take longitudinal designs (see Rakowski *et al.*, 2004) and, as far as we are aware, the Rothman hypothesis has not been tested in the cancer screening context.

Understanding screening

Researchers interested in the determinants of screening have often correlated a long list of variables with screening behaviour, often using multiple regression. Although such research may be valuable initially for uncovering relationships, it is an atheoretical approach – a better strategy is to test variables based on an overall model of the process; best of all is to compare different models (Weinstein, 1993). The latter strategy says that some theoretically driven variables will predict screening better than others and these variables might differ

across screening types. Too little of this sort of comparative research has been conducted.

Most theoretical models used to understand screening behaviour have been based on some version of subjective utility theory. This theoretical approach (see Kahneman & Tversky, 2000) suggests that in considering whether to act, people consider the likely costs and benefits, weight those outcomes by how personally important they are, and implicitly perform an algebraic computation to arrive at an overall decision. Of course, people rarely make decisions in precisely this way (Simon, 1955), but, nevertheless, costs and benefits predict whether or not people will get screened (Zapka & Lemon, 2004). Costs and benefits (barriers) are at the heart of the Health Belief Model (HBM; Strecher *et al.*, 1997), and variables drawn from this model have routinely been shown to correlate, though modestly, with screening (Yarbrough & Braden, 2001) (see 'Health belief model').

More recently developed theoretical approaches add several features to the rational sorts of 'belief' models. Leventhal's Illness Representations Model, for example, introduces illness beliefs not typically represented in the HBM (for example, 'when does colon cancer start to appear?'; 'what causes colon cancer?'; 'Can I control whether or not I get colon cancer?'). Leventhal *et al.* (2001) also point out that emotional responses to cancer, such as fear, can motivate screening adoption or avoidance (see 'Lay beliefs about health and illness').

A second type of theoretical model suggests that people go through discrete decision-making stages before engaging in screening (Rakowski *et al.*, 1992). Weinstein's (1988) Precaution Adoption Model, for example, emphasizes perceptions of personal vulnerability to cancer, and risk judgments have been shown to predict screening (e.g. Katapodi *et al.*, 2004; McCaul *et al.*, 1996).

Finally, Miller *et al.* (1996) developed a model emphasizing the potential importance of individual differences as screening determinants. The Cognitive-Social Health Information Processing Model (C-SHIP) provides a framework that emphasizes the beliefs, expectations, feelings, and goals that a person brings to the situation. The model suggests that people differ in how they process information and that these differences will interact with situations. The C-SHIP model nicely accounts for a number of findings related to BSE and mammography screening for breast cancer, and this model deserves additional research.

Most models of health-protective behaviour at least acknowledge situational determinants, although they differ in their emphasis on such variables. However, contextual variables are likely to have large effects on screening. Indeed, physician recommendation is well known as the best predictor of breast cancer screening in the USA. Women who have been screened are much more likely to report that their doctor 'suggested' they have a mammogram (Fox & Stein, 1991), for example, and physician advice predicts both first-time and repeated mammograms (Lerman *et al.*, 1990). A second important contextual variable is whether or not screening is centralized. In the UK, for example, the national healthcare system pays for screening after defining who is eligible. In the USA, payment for screening is highly dependent on individual insurance providers. In the latter case, individual beliefs and feelings may predict more variance in screening behaviours, whereas contextual factors are likely to play a much larger role in national healthcare systems (see 'Screening: general issues').

Increasing screening

Many researchers have taken the variables predicting screening and incorporated them into screening interventions. And many different strategies have shown some success. Decreasing barriers by lowering costs is important, for example, especially for under-served populations (e.g. Legler *et al.*, 2002; Skaer *et al.*, 1996). Similar system changes have been made within the medical environment, to ensure appropriate recommendations are made and reminders integrated within surgery/office systems (Costanza *et al.*, 2000). At the individual level, researchers have focused on tailoring interventions to the particular attributes of each individual. So, for example, one message might be used for a man who fears the colonoscopy procedure; a completely different message would be used for a woman who says she is not at all at risk for colon cancer. Although tailored messages attract more attention than those which are not tailored (Skinner *et al.*, 1999), we do not know if the impact in terms of increased screening is worth the extra costs of tailoring (e.g. Clark *et al.*, 2002).

The consequences of screening

Given that we are recommending screening, it is important to remember that screening is not cost-free. Cancer screening can be stressful: for example, Pap smears are uncomfortable; so, too is preparation for a colonoscopy. More importantly, screening results are sometimes in error, and an important problem is a false-positive result. The jury is still out on the overall effects of false positives, but two tentative conclusions seem warranted. First, false-positive results are upsetting and create increases in anxiety (Aro *et al.*, 2000; Cunningham *et al.*, 1998). However, it is also important to note that (a) distress is relatively short-lived (Wardle *et al.*, 1993) and (b) false positive results do not generally inhibit people from obtaining a follow-up screening or from continuing to engage in screenings; indeed, some data suggest that false-positive screenings produce *better* subsequent adherence (Burman *et al.*, 1999; Lerman *et al.*, 1991 but also see Ford *et al.*, 2003).

Conclusions and questions to ask

We have learned much from research to date; indeed, a recent special issue of the journal *Cancer* includes many empirically tested 'lessons learned' (Meissner *et al.*, 2004). However, here are things we still need to know with much more precision than at present:

- How do we best communicate the uncertainty often surrounding imperfect screening tools so that people are 'fully informed' (Rimer *et al.*, 2004)?
- Why do persons identified as of 'lower socioeconomic status' show lower rates of screening and how can we change this important disparity?
- How do theories compare in their power to predict screening? (Weinstein, 1993).
- What determines repeat as opposed to initial screening?

- Are the consequences of imperfect screening tools minimal that result in false positives small enough that they are easily offset by the benefits? (See also 'Screening in healthcare', 'Screening: antenatal', 'Screening: cardiac', 'Screening: genetic' and 'Self-examination: breasts, testicles'.)

Screening: cardiac

Alethea F. Cooper

St. Thomas' Hospital

Cardiac risk factors

Cardiac screening is a focus of attention because cardiovascular diseases are responsible for the deaths of 16.7 million people worldwide each year (World Health Organization, 2003), but 50% of deaths and disability from cardiovascular disease (CVD) can be reduced through reduction of major coronary risk factors (World Health Organization, 2002). Population-based studies, such as the well known Framingham Heart Study, demonstrated several major risk factors to be independent predictors of coronary heart disease (CHD) although the studies were based on a mainly White population in Massachusetts, USA. Major risk factors include cigarette smoking, hypertension, high serum low-density lipoprotein cholesterol, low levels of high-density lipoprotein cholesterol, diabetes mellitus and advancing age. Data from the Framingham Heart Study form the basis of internationally used coronary prediction algorithms (Wilson *et al.*, 1998), two dimensional risk charts (Wood *et al.*, 1998) and a Cardiac Risk Assessor computer programme (The Framingham Risk Equation; Anderson *et al.*, 1991) for calculating risk in patients without known existing CHD. Psychological factors are absent from risk calculation instruments, although recent reviews have detailed the role of psychological factors in manifestation of CHD (Rozanski *et al.*, 2005).

Cardiac screening is generally based on a 'high risk' approach in which individuals in the general population at particularly high risk are identified for provision of advice, further diagnostic investigation, or treatment in order to reduce their risk of manifestation of CHD or CVD. A reduction of risk factors is important because people with multiple risk factors for heart disease are three to five times more likely to die, suffer a heart attack, or other major cardiovascular event than people without such conditions or risk factors (DoH, NSF, 2000). Modifiable behavioural risk factors include smoking, diet, physical inactivity and overweight/obesity. The Nurses Health Study (Stampfer *et al.*, 2000) demonstrated that women in whom these risk factors are low carry 84% less risk for heart disease

and stroke. Risk factors such as hypertension, hypercholesterolaemia and diabetes are usually modified through pharmacological management if behavioural interventions (increasing exercise, dietary changes) have proved to be ineffective.

Although not addressed specifically within this chapter, it should be remembered that there are inequalities in cardiac risk that are manifest between countries, social classes and ethnic groups.

Psychological reaction to screening

An adverse reaction to a screening programme was first described by Haynes (Haynes *et al.*, 1978) in steelworkers, whose levels of absenteeism rose on receiving a diagnosis of hypertension. The most direct adverse psychological response to health screening is increased anxiety, which may occur not only in patients who receive positive results but also on invitation to attend for screening and also on receiving a negative result. Studies investigating the results of screening in relation to these possible outcomes are described in detail below.

Response to information about increased risk

A systematic review examining the psychological impact of risk assessment for various illnesses identified 21 studies investigating the impact of informing individuals about CVD risk (Shaw *et al.*, 1999). Sixteen of these studies examined the impact of screening for hypertension, two looked at the effect of screening for total cholesterol, one compared receiving a label of low risk vs. high risk and two investigated the impact of screening vs. no screening (one study involved screening plus an intervention). Outcome measures in the CVD studies were emotional (anxiety, depression, distress), cognitive (health perceptions) and behavioural (absenteeism from work), and were evaluated according to short-term (within one month of risk assessment) and/or long-term (greater than one

month after risk assessment) impact. The results of the studies specific to CVD risk are consistent with the overall results of the review, which are based on a total of 54 studies.

Quantitative analysis of a small selection of the 54 studies, including one or two investigating CVD risk, indicated that receiving a positive adverse test result was associated in the short-term with increased anxiety (Irvine *et al.*, 1989), but not in the long-term for anxiety or for depression (Ambrosio *et al.*, 1984; Rudd *et al.*, 1986). Quantitative evaluation of risk assessment on short-term depression was not conducted.

A descriptive analysis was undertaken for all studies. Eight CVD studies investigated absenteeism which increased in just two. A negative impact on perceptions of health was revealed in three out of five studies (one short-term impact, one long-term, one not specified). It should be noted that the quality of these cross-sectional studies received a low grade by the review authors. In two more highly graded prospective studies, no long term effect was found in one and in the other perceptions of current health improved.

A recently published randomized controlled trial confirms the results of the review. Christensen *et al.* (2004) investigated psychological distress, in relation to receiving a low, moderate, elevated, or high risk label, in 1507 people aged 30–49 in Denmark. Four elements of psychological distress: anxiety/insomnia; depression; social impairment/hyochondria; and social dysfunction were measured before screening, then again one and five years later, using the GHQ-12 (Goldberg, 1978). Participants were randomized to a control group (no screening) or one of two intervention groups involving health screening and written feedback but with either an optional or planned follow-up visit with the primary care physician. No differences were found in GHQ-12 scores during the follow-up period according to group randomization or according to self-report baseline risk (current smoker or overweight). This result confirmed results of an earlier, smaller study by Christensen (1995) in 273 men aged 40–49 where there were no changes in GHQ scores at six months following identification of increased/high risk for CHD on screening.

In a non-randomized study, Connelly *et al.* (1998) examined the impact of receiving a high, moderate, or low risk score in 5000 middle-aged (45–69 years) men. The 28-item GHQ (Goldberg & William, 1988) was completed prior to initial screening, immediately following risk factor labelling, and three months later. Receiving a label of 'above average risk' of heart disease did not appear to lead to increased psychological symptoms, although men receiving a 'moderate risk' label were at immediate increased risk.

Response to information about minimal risk

Few studies have examined the impact of receiving a 'low risk' screen result in a between-group design where the control group underwent no screening. However, when examining within-group data in studies where a 'low risk' label is compared with 'high risk', there is little evidence of a short or long-term effect (Connelly *et al.*, 1998; Shaw *et al.*, 1999). A separate issue related to receiving 'minimal risk' feedback is that of false reassurance. In a study of 428 men between 30 and 33 years of age it has been suggested that men who

screened negative for CVD risk may have used the result to justify their health behaviour; importantly, these men did not exhibit healthier behaviour with regard to smoking, diet, or physical inactivity when compared to those who screened positive for CVD risk (Tymstra & Bieleman, 1987).

The response to receiving a negative result has been more extensively investigated in relation to patients undergoing diagnostic coronary angiography for symptoms of chest pain, although this test is not strictly a screening procedure. Between 34 and 56% of patients undergoing coronary angiography have either normal coronary arteries (NCA) or mild non-obstructive atherosclerosis (Beitman *et al.*, 1989; Carter *et al.*, 1994). However, a substantial body of evidence suggests that such individuals may continue to report symptoms and are compromised with regard to emotional, social and physical functioning. In one prospective study 46 patients undergoing coronary angiography on the basis of symptoms were told they had insignificant lesions and should not limit activities. However, at one year, 29 patients continued to consult a doctor for cardiac-related symptoms (Bass *et al.*, 1983). After one decade up to three-quarters of patients continued to report chest pain, had undergone further hospital treatment and were using cardiac medication. One-third were unable to work for medical reasons (Potts & Bass, 1993).

Patients with non-cardiac chest pain have a good outcome in relation to cardiac mortality, but it is recommended that in order to prevent such morbidity, an 'early and confident diagnosis of non-cardiac chest pain should be made' with an emphasis on the psychological aspects of medical management (Bass & Mayou, 2002). Bass and Mayou (2002) suggest that following a diagnosis of NCA, symptoms of depression and association of the chest pain with anxiety or panic attacks should be sought, as should the presence of possible precipitating stressful life events; patients' beliefs about their chest pain should also be elicited. Effective, consistent communication between healthcare professionals and the patient as well as between healthcare professionals in primary and secondary care should help to minimize the concerns of the patient and reassurance, education and information may be sufficient in 30–40% of patients. However, in the 60–70% of patients with continuing symptoms and limitation of physical activity, specialist management and treatment is recommended and may necessitate pharmacological treatment for oesophageal disorders or antidepressants, psychological support and intervention (e.g. cognitive behavioural therapy and/or further medical investigation such as referral to a gastroenterologist (Bass & Mayou, 2002).

The association between psychosocial factors and chest pain associated with NCA was investigated in a case-control study by Cheng *et al.* (2003). Compared with patients with rheumatism or healthy individuals, individuals with NCA were less likely to receive social support in times of stress, more likely to show a monitoring perceptual style, and to demonstrate inflexible problem-focused coping with poor management of stress-related emotions. The authors point out both are potentially anxiety-provoking mechanisms which could increase tension in the thoracic muscles and worsen breathing patterns, thus provoking chest pain and reinforcing perceptions of cardiac pain. The role for psychological intervention and management posited by Bass and Mayou (2002) is thus reinforced.

Approaches to cardiac screening

The possible psychological consequences of screening for CHD should not be considered in isolation from the impact of interventions to reduce high risk in cases where this is identified. A recent review showed little impact of primary prevention population-based interventions (Ebrahim & Davey Smith, 2001). Marteau and Kinmouth (2002) suggest the current strategy of population based targeting of individuals rather than recruitment through an informed choice paradigm may influence the success of interventions. The authors argue for debate regarding shifting towards an informed choice approach to cardiac screening and summarise succinctly the argument for conducting cardiovascular screening within an informed choice paradigm (Marteau & Kinmouth, 2002). Informed choice involves the provision of high quality, personally relevant information and, as such, the ultimate choice of the individual reflects his or her values. Although informed choice is imperative in circumstances such as antenatal screening it is suggested that this approach may be more cost effective than a traditional public health approach to cardiac screening because it may result in participants who are more motivated to take action to reduce their risks. The authors acknowledge that such an approach may result in an increase in health inequalities and stress that written material be comprehensible and should also be of a nature that does not induce high levels of fear.

The role of risk perception and consequences of interventions

Illness perceptions have been shown to be of paramount importance in relation to management and coping with CHD, as well as response to acute symptoms. Perceptions of risk of heart disease have also been assessed along with the importance attached to individual risk factors prior to screening and intervention in the British Family Heart Study in 3725 patients by Marteau *et al.* (1995). Although there were strong associations between perceived risk and levels of individual risk factors, as well as overall risk score calculated using epidemiologically derived data, a third of people held views of heart disease risk that were different to the overall risk score. Study participants ascribed less importance to blood pressure and cholesterol and more to smoking and parental death from heart disease. Patients were categorized as 'optimists', 'realists' or 'pessimists' according to the relationship between their perceived risk of CHD and actual risk score: the reported presence of personal and family related risk factors accounted for significant differences between the three groups. The study authors suggest that possible differences between an individual's perceived risk and a calculated risk score should be considered by health professionals prior to intervention to address cardiovascular risk, in order to improve communication and, thus, optimize likelihood of engagement in lifestyle behaviour change.

This raises another important issue. Although it would appear that cardiac screening and/or participation in an intervention does not

result in long-term psychological distress, an unexpected finding in the British Heart Study suggests that intervention participants, when successfully achieving modest risk reduction specifically with regard to weight loss and smoking cessation, may be likely to perceive a diminution in their ability to further lessen their cardiac risk (Marteau *et al.*, 1996). Such 'false reassurance' could be harmful for such individuals in the presence of continued raised risk.

Result of interventions to reduce adverse effect of screening

There is evidence that interventions that aim to reduce the adverse psychological consequences of receiving a positive test result following screening are effective (Shaw *et al.*, 1999). Such interventions have included information provision (vs. no information) reassurance (vs. typical counselling), and cognitive behavioural stress management (vs. no intervention; see 'Stress management' and 'Cognitive behavioural therapy'). Required elements of an effective screening intervention include information regarding the condition, and the likelihood, meaning and implications of possible test results.

Summary and avenues for future work

Whilst a result indicating increased risk following cardiac screening may be associated with an immediate increase in psychological distress, it appears this is unlikely to remain the case at follow-up as little as one month later. This is probably dependent on the manner in which risk information is provided because interventions to negate adverse outcome have been shown to be effective. The result of screening and receiving a 'minimal risk' label has received little investigation although the concept of false reassurance should be considered.

More recently, it has been suggested that other psychological sequelae may occur as a result of screening and intervention programmes, such as reduced perception of ability to make changes following intervention participation. It is suggested this may be a result of disempowerment in those who have been unable to achieve change or false reassurance in those who have implemented small changes, particularly in visible risk factors such as weight loss and smoking cessation; but this needs to be understood more fully.

The use of an informed choice paradigm for cardiac screening may be subject to future debate and the amount of information provided before and following screening and how it is communicated are issues that warrant careful consideration with further evaluation.

Screening: genetic

Shoshana Shiloh

Tel Aviv University

Screening tests are medical tests carried out on presumably healthy people to identify an existing illness or pre-disease condition. They comprise a sub-category of health protective behaviours, sometimes labelled detection behaviour or secondary prevention. Screening is advocated as a cost-effective means of identifying individuals at a very early, pre-symptomatic stage of a disease when treatment is more effective and less costly. Identifying people at risk for disease enables health services to target those most likely to benefit from early intervention (see 'Screening in healthcare').

Psychologically, screening is different from other health behaviours. In contrast to 'true' preventive behaviours (e.g. exercising) that reduce the likelihood of future disease and provide a sense of safety, screening behaviours detect the presence of a serious illness and can be frightening. For this reason, conclusions gained from studying the former might not apply to screening behaviours. Despite these observations, there is still no specific theoretical framework for screening behaviour.

Four dimensions of screening have meaningful psychological implications:

1. *Screening for disease versus risk factors.* Detecting a risk factor for an illness (e.g. high cholesterol levels) is likely to be less fear-provoking than disease detection, since a positive test indicates only an increased chance of future harm. However, the recent completion of the sequencing of the human genome has brought predictive genetic testing to learn about one's risk to develop many common medical conditions (cancers, diabetes) later in life, for which there is little, or no prevention. Screening for such risk factors raises concerns about possible adverse social and psychological impacts of knowing one's risks, and is one of the major challenges facing health psychology in the twenty-first century.
2. *Screening individuals at-risk versus population screening.* Most people undergoing population-based screening programmes are certain their health is fine. For them, the very act of screening may introduce doubts about their health, and a positive result shifts them from certainty into an upsetting state of uncertainty. On the other hand, testing for those already identified as being at increased risk for a disease, regardless of the outcome, provides some certainty. Given that uncertainty about one's health is an aversive state, the psychological implications of screening for at-risk and the general population may be considerably different.
3. *Prenatal versus pre-symptomatic screening.* Many screening tests can be performed prenatally by procedures such as amniocentesis and ultrasound (see 'Screening: antenatal' and 'Fetal well-being'). Unlike pre-symptomatic testing, many prenatal tests have become routine and are afforded less deliberation and intentional action. However, procedures like amniocentesis carry a small risk to the fetus and thus, involve stress both from the procedure and the test result. Moreover, prenatal diagnosis implicates an option of abortion, which provides a complete relief from the health threat but elicits ethical dilemmas and additional distress.
4. *Genetic versus somatic testing.* Unlike somatic pre-symptomatic testing, genetic information has implications not only for the tested individuals but also for their families and future generations. Guilt, shame, stigma and intricate family dynamics are involved. Carriers of genetic predisposing mutations for hereditary cancer experience difficulty divulging the result to family members, and receive both supportive and unsupportive responses from extended family members related to their carrier status. Thus, the genetic revolution in medicine that makes available many new screening tests is expected to affect the lives of large populations and require more involvement of psychologists.

Some of these dimensions may partly overlap, like genetic testing and screening for risk factors. But, some genetic testing

identifies an existing condition (e.g. Down's syndrome), and some somatic testing identifies risk factors (e.g. HIV antibody testing). Thus, the four-dimensional representation of screening results in $2 \times 2 \times 2 \times 2 = 16$ combinations of screening tests that will have different psychological implications for the same medical condition being tested. For example, a screening test for breast cancer may be experienced differently if it is somatic (mammography) or genetic (testing for mutations carrying an increased risk for developing the disease in the future). These tests may be experienced differently by women of the general population compared to women at high risk because of family history of the disease. The same genetic screening test can (potentially) be performed pre-natally, among at-risk families and the general population, and raise completely different ethical, social and psychological concerns.

Psychological research on screening behaviour has addressed two main questions. First, What motivates healthy individuals to be tested? Second, What are the psychological impacts of being tested? Most studies were conducted on one screening test and one population. In view of the multidimensionality of screening behaviours, over-generalization from any single study to other screening situations with different dimensional features should be avoided. Following is an overview of some of the pertinent findings.

Motivations for genetic screening

The bulk of the research has identified four categories of factors: cognitions; information/communication; emotions and individual differences.

Cognitions

Many studies of screening were theoretically based on health behaviour models like the Health Belief Model (HBM) (Maiman & Becker, 1974), and the Theory of Planned Behavior (Ajzen, 1998) (see 'Health belief model' and 'Theory of planned behaviour'). These models outline several general belief categories associated with health behaviour: beliefs about the disease threat, about benefits and costs of the specific behaviour, control beliefs and beliefs about social norms. Findings from numerous studies on a variety of populations and screening tests have supported the idea that beliefs explain screening intentions and behaviour.

The Health Belief Model was used as a framework for understanding differences between tested and untested persons among populations at-risk for severe hereditary conditions (Evers-Kiebooms & Decryuenaere, 1998). Perceived benefits of testing predicted most of the variance in parents' intentions to use prenatal diagnosis (Sagi *et al.*, 1992), attitudes and subjective norms were the best predictors of intentions to participate in genetic testing for hereditary cancers (Braithwaite *et al.*, 2002), and perceived risk was found related to greater readiness to undergo genetic testing for breast cancer susceptibility (Jacobsen *et al.*, 1997).

Perceived preventability of the disease was found especially important for predictive genetic testing (Shiloh *et al.*, 1999). The distinction between unpreventable diseases like Huntington's disease (HD) (see 'Huntington's disease'), and diseases for which

there are strategies that can reduce risk, like breast cancer, can explain the differences between uptake of predictive genetic testing for those two diseases among at-risk populations: 15% for HD (Bloch *et al.*, 1989) and 43–80% for breast cancer mutation (Loader *et al.*, 1998).

Information/communication factors

Cognitions are largely formed by information, hence a separate but related body of research focused on communication and doctor–patient issues. Media coverage of genetic testing has been extensive in recent years, but this coverage is often not useful and may even be misleading for individuals at risk for genetic disease (Stockdale, 1999). Healthcare providers play a major role in genetic screening tests: their recommendation or referral of patients to cancer genetic susceptibility testing was found related to their beliefs about factors that affect cancer risk, and the practice environment (Sifri *et al.*, 2003).

The guidelines of the UK General Medical Council (1999) state that information provided prior to consent for a screening test should include the purpose of screening, the likelihood of positive and negative findings, the possibility of false positive and false negative findings, the uncertainties and risks attached to the screening process, any significant medical, social or financial implications of screening and follow-up plans. These guidelines emphasize the risks and benefits of both the procedure and the results.

The information given before screening is important in producing responses to test results. Despite this, screening tests, especially in pregnancy care, are sometimes presented as routine procedures with little attendant explanation of the purpose of the test, the likelihood of being recalled, the meaning of positive or negative results, or probable action following a positive result. More knowledge about genetic testing does not simply lead to unambiguous acceptance. While those with a low level of knowledge had difficulty taking a stance on testing, those with the highest level of knowledge were both more enthusiastic and more sceptical about testing (Jallinoja & Aro, 2000).

How the information is framed and presented is also important. The same information communicated in positive terms would be less motivating than a negative frame. For example, women receiving a negatively framed prenatal risk-factor test result were more likely to opt for amniocentesis than women receiving a positively framed test result (Shiloh *et al.*, 2001). Michie *et al.* (2004a) found that even small changes within an information leaflet can change attitudes towards genetic testing. For example, attitudes towards testing were more positive when the information leaflet was glossy and in colour vs. black and white. These authors raised the concern that form and method of presentation may unintentionally change attitudes, and eventually behaviour, and they emphasized the need for evaluation studies about genetic information leaflets before they are used clinically.

Emotions

Emotional motivations exist as well. In contrast to policymakers, for whom the primary goal of screening programmes is to reduce disease prevalence, many participants perceive these programmes as a way to regulate emotions, to be reassured.

Reassurance-seeking can explain uptake of predictive genetic testing for conditions for which no preventive treatment is available, like HD, and seeking prenatal diagnosis with no intention to abort an affected fetus. Women's opinions about genetic testing for breast cancer risk also showed a greater attention to the emotional and social consequences of positive test results than to physical outcomes (Vuckovic *et al.*, 2003).

Worry and anxiety are clearly related to screening behaviour, but the strength and direction of the relationship are uncertain. Cancer worry (but not perceived risk) predicted greater interest and more favourable beliefs about the benefits of genetic testing for breast cancer risk (Cameron & Diefenbach, 2001) (see 'Screening: cancer'). But, women with extremely high levels of cancer anxiety were also reported to reject genetic testing (Shiloh *et al.*, 1998). These contradictory findings can be explained by a curvilinear relationship, with increasing levels of worry predicting higher screening levels up to a point, and trailing off when worry gets too great.

In addition to emotions experienced when a screening decision is made, a range of affects have been addressed lately, like regret, guilt, anger, surprise and disappointment, anticipated by individuals as a result of different choices and test results. Intentions to pursue genetic testing were significantly affected by anticipated emotions and concerns about the ability to handle them (Hadley *et al.*, 2003).

Emotional factors may also explain the 'intention-attendance gap' observed in many screening programmes. Most individuals express very favourable attitudes toward a wide range of screening tests, but this does not translate into similarly high rates of utilization. A goal conflict may exist between utility considerations and fear of obtaining positive test results, and between a desire to reduce uncertainty and hopes to receive good news. This corresponds with the possible conflict delineated in the self-regulatory model (Leventhal, 1971) between two parallel action plans elicited in reaction to health threats: to reduce the danger and to reduce the fear experienced (see 'Lay beliefs about health and illness').

Demographic and individual differences

There is evidence that beyond process level factors, cultural and individual differences are also associated with genetic screening behaviour. For example, African American and Latino women undergo prenatal diagnostic testing less often than White and Asian women, possibly because the potential acceptance of a child with Down's syndrome was found highest among African-Americans and Latinos, who were also more likely than Asians and Whites to state that their faith/religion would influence the prenatal testing decision (Learman *et al.*, 2003) (see also 'Cultural and ethnic factors in health').

Individual differences were also found positively related to screening intentions for genetic risk factors for breast cancer among women of the general population. Women who were more interested in being tested were characterized by higher levels of desire for control, more external (powerful others) health locus of control, less preference for self-treatment, more preference for medical information and stronger need for closure (Shiloh *et al.*, 1998) (see 'Perceived control'). Among relatives of carriers of breast cancer genes, those who chose to undergo genetic testing following an

educational counselling programme were more likely to be older, to have lower levels of optimism and to report higher levels of cohesiveness in their families (Biesecker *et al.*, 2000).

Summary

Cognitive, communicational, emotional, cultural and personal factors combined additively and interactively explain much of the variance in screening behaviours. Empirical evidence supports combinations of predictors. Such combinations are consistent with self-regulatory theories of health behaviour like the Cognitive-Social Health Information Processing theory (C-SHIP), which maintains that interpretations and expectancies, beliefs, affects, goals and values activated together during cognitive affective processing determine individuals' reactions to health threats (Miller *et al.*, 1996).

Outcomes of genetic screening

Apart from medical outcomes, reactions to screening after receiving positive and negative test results were studied extensively. Most studies focused on cognitive, emotional and behavioural outcomes.

Cognitive outcomes

Laboratory studies using the TAA paradigm¹ showed that screening test results were interpreted within a cognitive frame of beliefs about illnesses, initiated biased information-processing and stimulated self-protective cognitive processes such as minimization (Ditto & Croyle, 1995). The results provided clear support for denial reactions to unfavourable medical test results, especially when individuals perceived no possibility of a preventive action to reduce the threat. Despite this, individuals were ultimately responsive to risk factor information, but the evidential requirements they demanded for accepting an unfavourable result were stricter than for accepting a favourable diagnosis. A false consensus bias in risk factor appraisals was also revealed: subjects told that they have TAA deficiency estimated its prevalence in the general population to be higher than did subjects told they do not. Appraisals of test results were also found to involve social comparisons and to be sensitive to social influences.

Similar cognitive processes were reported among women undergoing genetic screening tests for carrying the fragile X mutation. After receiving test results, non-carriers perceived fragile X syndrome to be more serious than before testing than carriers. Coping strategies activated by participants were minimization, acceptance of the possibility of being a carrier, a sense of being able to deal with the outcomes, positive comparison, problem solving and positive interpretation (McConkie-Rosell *et al.*, 2001).

Experimental studies showed that the availability of genetic testing also activates hindsight bias and responsibility attributions. After reading a scenario in which a woman declined to take a genetic screening test and had an affected baby, retrospective judgments

of the likelihood that the child would have had a genetic disorder were higher. Moreover, the more likely a negative outcome was perceived to be, the more responsible the mother was held for not taking the genetic screening test (Menec & Weiner, 2000) (see 'Attributions and health').

Emotional outcomes

Prenatal genetic screening tests influence the emotional experience of pregnancy. The genetic test itself induces considerable stress independent of the invasiveness of the testing procedure. Significant reductions in stress from pre-screening to post-screening were found among women and their partners upon receiving a normal test result (Kowalcek *et al.*, 2002). However, receiving an abnormal prenatal diagnosis, or experiencing pregnancy loss as a result of the diagnostic testing was extremely distressing and required extensive psychological counselling and support (Bourguignon *et al.*, 1999) (see 'Screening: antenatal' and 'Abortion'). Gender differences were also observed. Following screening for carriers of cystic fibrosis, women responded more positively than men to a negative test result and less positively than men to a positive test result. These differences were attributed to women's greater appraisals of threats to reproduction compared to men's, and men's greater use of a minimization coping strategy with threat (Marteau *et al.*, 1997).

Pre-implantation genetic diagnosis (PGD) is a new and exciting technology, that may alleviate much of the emotional burden involved in prenatal diagnosis and termination of affected pregnancies by using in vitro fertilization and genetically screened healthy embryos to establish a pregnancy. The psychological effects of these new procedures are still unknown.

Both negative and positive emotional consequences of screening for disease risk were also found. Unaffected individuals in cancer-predisposition testing programmes were generally accurate in anticipating emotional reactions to test results. However, cancer patients participating in genetic testing experienced higher levels of anger and worry than they had anticipated, and underestimation of subsequent distress emotions related to increase in general psychological distress after six months (Dorval *et al.*, 2000). Some buffers may attenuate adverse emotional effects of a positive test result. For example, increased levels of distress during the waiting period between testing and disclosure of results for breast cancer genetic risk were found associated with an unoptimistic personality and a tendency to suppress emotions (Lodder *et al.*, 1999).

A systematic review of the literature about screening for individuals' genetic risk of disease (Shaw *et al.*, 1999) showed that receiving a positive test result was likely to cause anxiety, depression, poorer perceptions of health and psychological distress in the first four weeks after testing. But, there was no evidence of severe or persistent adverse psychological effects in the long term. Feared extreme reactions like suicide were not found even among people informed with certainty that they will develop an untreatable fatal disease like HD.

Surprisingly, there were even reports of decreased distress following positive results in testing for HD (Wiggins *et al.*, 1992).

¹ A research procedure in which study participants are 'tested' for the presence of a fictitious risk factor they believe is real, are randomly assigned to receive either a positive or a negative test result, and complete questionnaires about the fictitious condition, the test and their actual health.

These findings were explained by various factors, including providing certainty to high-risk populations in a state of uncertainty prior to testing, pre-selection of those who undergo the test, pre-test expectations, minimization coping strategies and the effects of pre-testing counselling (Marteau & Croyle, 1998).

Behavioural outcomes

Being detected in screening as a carrier of a genetic mutation is expected to result in behavioural changes. Most pregnant women detected in screening tests as carriers of the cystic fibrosis mutation came for counselling, had their partner tested, and, if he was also a carrier, had prenatal diagnosis (Levenkron *et al.*, 1997). Moreover, in screening programmes carried out in high schools for detecting recessive gene carriers of various genetic diseases, test results were recalled and resulted in testing of partners and requests for prenatal diagnosis even 20 years after screening (Mitchell *et al.*, 1996).

The evidence with regard to genetic screening for personal disease risk is more complex. A literature review (Marteau, 1995) concluded that people seem to make few, if any, changes in behaviour following screening from which they learn about their health risks. In studies that found behavioural changes following screening, the direction of change was inconsistent. For example, informing smokers about their genetic susceptibility for cancer made them more depressed and fearful, but did not enhance their attempts to quit smoking (Lerman *et al.*, 1997). In one study, positive test results even led to increased smoking when combined with fatalistic views (McNeil *et al.*, 1988).

On the other hand, among individuals at hereditary risk for colon cancer, mutation-negative individuals decreased and mutation-positives increased their use of colonoscopy (Hadley *et al.*, 2004). Genetic testing and identification of women at increased risk for breast and ovarian cancers increased surveillance and risk-reducing operations among mutation carriers, including oophorectomy (Schwartz *et al.*, 2003), which may ultimately impact ovarian cancer mortality. However, in another study, decline in screening for breast cancer was attributed to a false sense of over-reassurance following a favourable result in testing for hereditary cancer (Meiser *et al.*, 2001).

How and what health professionals communicate with patients about genetic testing may explain variance in behaviours following testing. For example, worries and the desire for inappropriate screening following negative genetic testing results for genetic colon cancer risk can be avoided by emphasizing high accuracy and low residual risk in communicating test results (Michie *et al.*, 2004b).

Clinical implications

Beyond the theoretical interest, much of the research in the field deals with practical public health questions, such as how to promote screening behaviour and how to prevent adverse effects of testing. Concern about the psychological effects of notification of positive screening results for severe conditions prompted the call that all such screening programmes be accompanied by informed consent and counselling services.

Optimal decision making about genetic screening requires a personal, reasoned evaluation of positive and negative consequences of testing. Simple educational and counselling strategies can be successful in reducing distress and improving adherence in screening programmes. Studies assessing the effectiveness of interventions designed to prevent adverse psychological reactions to screening tests reported favourable results. Interacting with a genetic counsellor was found preferred for its personal, individualized nature, but computer educational programmes were also found accepted or preferred for being self-paced, private and informative (Green *et al.*, 2001). Interventions guided by research findings and theory were suggested with the goal of preparing the individual for predictive genetic testing by cognitively and emotionally activating potential reactions to test results, facilitating accurate appraisal of cognitive and emotional reactions and enabling successful processing of those reactions (Shoda *et al.*, 1998). Caution was raised, however, against interventions reducing anxiety too much, below the appropriate dose necessary for adequate continuing protective behaviour (Shaw *et al.*, 1999).

Self-examination: breasts, testicles

R. Glynn Owens

The University of Auckland

Technological advances have provided the means whereby several cancers can be screened by a range of devices. These include the use of automated cytology scanning for abnormal cells in cervical smears, mammographic techniques for the early detection of breast tumours, and the use of genetic screening methods to detect various cancers which are to a greater or lesser degree genetically determined (e.g. some breast and colonic cancers) (see 'Screening: cancer'). Such developments notwithstanding, there remains a potential role for self-examination procedures since (a) there remain many cancers for which technological procedures are not available (b) some procedures involve elements of risk, for example, the use of ionizing radiation in mammography, which limit the frequency with which they can be applied and (c) practical constraints may limit the applicability of the procedures to only a subset of those at risk.

For example, in the UK some 1 in 12 women will have breast cancer at some point in their lives, but for a number of reasons, (including logistical reasons and variation in the characteristics of the disease in women of different ages), screening by invitation is currently available only once every three years, and only to women in the 50–64 age group (with plans for extension up to age 70 in the near future). Yet breast cancer is far from unknown in younger women, and nor is it unknown for a tumour to grow to a significant size in less than the three-year time interval between successive examinations. Even the best screening by invitation programmes have take-up rates below 100%, and of course for many cancers no routine screening programme exists. Thus testicular cancer, the most common cancer in young men in the European Union, and malignant melanoma, a cancer whose incidence is one of the fastest rising in many countries, are both seriously dependent on early detection and treatment. Despite this, no routine screening programme exists, and self-detection and reporting remains the main route to presentation.

Self-examination differs from technological approaches in a number of important ways. On the positive side, the cost of such programmes is minimal, they can be made available to the whole of the population at risk, and the inherent risk to the individuals is (arguably) minimal. Despite these advantages, however, self-examination strategies have disadvantages that have led some commentators to decry their use altogether. Chief among these disadvantages are (a) the difficulty of producing self-examination procedures that can be easily and effectively learned by those at risk (b) the difficulty of persuading individuals to perform self-examination with sufficient regularity and (c) the added problem that once a potential symptom is discovered, it remains the responsibility of the individual to present for diagnosis and treatment without significant delay.

Such problems reveal a number of respects in which a better understanding of psychological processes may increase the effectiveness of self-examination procedures, and psychologists have been active in researching many of these aspects.

Self-examination in practice

Psychological research into self-examination dates back many years. With respect to the problems outlined above, the main areas of study have concerned take-up of the procedure and delay in presentation, both of which are critical if any programme of self-examination is to be effective. As regards take-up, there are several aspects including the need to increase the number of people who undertake self-examination and the need to ensure that those who do practise self-examination do so correctly, with the appropriate frequency and throughout the period of life for which it is acknowledged to be relevant. For the most part, results of such research have not been encouraging, generally indicating that few people perform such self-examination and that of those who do, only a minority perform the procedure with appropriate regularity. Thus Duffy and Owens (1984) in a UK study found only 10% of women claiming to perform monthly breast self-examination. For testicular self-examination (TSE) figures as low as 2% have been reported (Sheley *et al.*, 1991). Given that studies of frequency of self-examination typically rely on self-report data, there is the additional possibility that even these low figures are inflated by recall biases and social desirability effects.

The role of knowledge on likelihood and effectiveness of self-examination has been assessed in a number of studies. Ivaz (2002) conducted a questionnaire survey of boys aged 14–16 in inner London, finding that although a large proportion knew about the age group most affected and that testicular cancer was curable if treated early, less than half were aware of how to perform TSE and only 8% did so regularly. Even lower rates of TSE were reported by Lechner *et al.* (2002), finding only 2% of a sample of young men (aged 15–19) in Holland reporting regular TSE. The effect of specific training in breast self-examination (BSE) was investigated by Philip *et al.* (1984), who conducted a longitudinal study of a group of women who had been taught BSE with a control group; when followed-up no significant difference in staging was found between experimental and control groups, although the tumours presented by the former were significantly smaller.

Such discouraging findings have prompted several researchers to identify psychological factors which distinguish those who perform self-examination from those who do not. Such studies have often drawn on established health psychology perspectives such as Becker's (1974) Health Belief Model or Ajzen and Fishbein's (1980)

Theory of Reasoned Action (see 'Health belief model' and 'Theory of planned behaviour'). Whilst these models have been considered with respect both to BSE and TSE (e.g. Umeh & Rogan-Gibson, 2001; Brubaker & Wickersham, 1990), results have generally been of varying consistency. Some studies which have investigated the variables directly have found significant relationships; for example Reno (1988) found that perceived benefits and perceived susceptibility (dimensions of the Health Belief Model) correlated significantly with TSE practice, and Gil *et al.* (2003) noted that rates of BSE were higher in women with a family history of breast cancer and associated higher perceived susceptibility. It is notable however that in the latter study, although those with a family history substantially overestimated their own risk as around 50%, only a third of the women performed regular BSE. Other psychological variables such as self-efficacy have also been investigated, with some evidence suggesting their relationship to self-examination practice (e.g. Luszczynska & Schwarzer, 2003). Actual knowledge of the disease has been reported as a significant predictor of both TSE (Rudolf, 1988) and BSE (Owens *et al.*, 1985).

An encouraging sign in recent research has been the wider recognition of cultural and sub-cultural factors in determining self-examination and similar behaviours, with Sadler *et al.* (2003) and Petro-Nustus and Mikhail (2002) investigating self-examination practices among Japanese-American women and Jordanian women respectively, while Fish and Wilkinson (2003) looked at lesbians' accounts of why they do not perform BSE. Such recognition of varying perceptions amongst different societal groups seems likely to enhance understanding of variation in take-up and continued practice (see also 'Cultural and ethnic factors in health').

It must be remembered, of course, that self-examination, unlike screening by health professionals, leaves an additional responsibility with the individual; once a suspected symptom has been found, this needs to be presented without delay for diagnosis and (if necessary) treatment. Whilst a simplistic 'commonsense' perspective might expect that if someone takes the trouble to self-examine, they will therefore take appropriate action on discovery of a symptom, research suggests that this is not necessarily the case, with Duffy and Owens (1984) for example, finding no correlation between BSE practice and promptness of reporting. As with self-examination practice, there is also the possibility that reporting of delay is subject to recall and social desirability bias, although a study using a guided-recall procedure concluded that there was little evidence of such bias in reports of delay (Owens & Heron, 1990).

Conclusions

Given the practical limitations of technological screening, or screening by health professionals, effective self-examination procedures remain highly desirable. As yet, however, evaluations of such procedures have failed to provide encouraging evidence of their efficacy, although this may result at least in part from the failure of researchers to recognize the additional role of delay of presentation when symptoms are discovered through self-examination. There remains a need for effective psychological strategies that will enhance take-up of effective self-examination and prompt reporting of detected symptoms.

Sexual dysfunction

Patricia J. Morokoff

University of Rhode Island

Sexual functioning in men and women encompasses behaviours, physiological responses and subjective states of awareness. These phenomena are influenced by personal and relationship histories as well as cultural expectations. A linear sexual response cycle was hypothesized by Masters and Johnson (1966), in which desire precedes initiation of sexual activity, followed by arousal, orgasm and resolution. The psychosexual diagnostic categories of the American Psychiatric Association's *Diagnostic and statistical manual of mental disorders* (DSM) (third edition and onwards) are based on this model. In general, a sexual *dysfunction* is a physiological response and/or state of awareness contrary to these expectations for normative sexual functioning. This chapter will summarize issues relating to sexual dysfunctions including prevalence, risk factors and treatments.

Sexual dysfunctions in men

Definitions and prevalence

Erectile dysfunction (ED) has been defined as 'the persistent inability to attain and maintain a penile erection adequate for sexual performance' (NIH Consensus Panel, 1993). Knowledge of the epidemiology of this condition has been facilitated by two large population/community based studies, the National Health and Social Life Survey (NHSLs) (Laumann *et al.*, 1999) and the Massachusetts Male Aging Study (MMAS) (Feldman *et al.*, 1994). In the NHSLs study, the percentage of men reporting difficulties maintaining or achieving an erection ranged from 7% for those aged 18–29 to 18% for those aged 50–59. In the MMAS baseline study, complete ED was reported by less than 10%, moderate by 25% and mild by 17%. The likelihood of complete ED tripled from 5 to 15% between the ages of 40 and 70. Over 52% of men reported some level of ED. However, in neither the NHSLs or MMAS study were men asked if their erectile functioning was a problem. It is generally agreed (see DSM-IV-TR) that a psychosexual functioning diagnosis should not be made unless the symptom is viewed as a problem. Therefore these studies cannot be said to provide data on the prevalence of the diagnosis of ED, but rather on erectile symptoms (see 'Men's health').

In addition, other symptoms of sexual dysfunction were reported in the NHSLs study, including premature ejaculation (approximately 30%), hypoactive sexual desire (approximately 15%) and difficulty achieving orgasm (less than 10%). Overall, 31% of men reported some type of sexual problem.

Risk factors for erectile dysfunction

There are numerous behavioural and lifestyle risk factors, including smoking and being overweight, that predict future ED (Feldman *et al.*, 2000), while initiation of physical activity lowers risk (Derby *et al.*, 2000). In addition being unmarried, the victim of childhood sexual abuse, or a perpetrator of abuse is associated with erectile problems as is emotional distress and declining income (Laumann *et al.*, 1999) (see 'Risk perception', 'Sexual risk behaviour', 'Tobacco use', 'Obesity', 'Rape and sexual assault', 'Domestic violence: intimate partner violence and wife battering'). Medical conditions and associated treatments create risk for ED. Diabetes mellitus; heart disease; hypertension; decreased HDL; medications for diabetes, hypertension and cardiovascular disease; and prostate cancer treatment have all been found to be associated with ED (Kubin *et al.*, 2003) (see 'Diabetes mellitus' and 'Hypertension'). Depression is associated with ED, especially among younger men (Nicolosi *et al.*, 2004). Other related psychological characteristics include low levels of dominance and increased anger (Feldman *et al.*, 1994). Finally, there is significant comorbidity among symptoms of sexual dysfunction in men (Cameron *et al.*, 2005). Men who report symptoms of ED also report lower orgasmic function, sexual desire, less mutual initiation of sex and sexual satisfaction. Men without ED reported greater relationship satisfaction, sexual self-confidence and sexual spontaneity.

Assessment and treatment

Since erectogenic medications, such as Viagra, came on the market, the number of men seeking treatment for ED and other sexual dysfunctions has increased dramatically (Skaer *et al.*, 2001). Before 1998 male sexual dysfunctions were typically treated by urologists or mental health specialists, but now primary care physicians are most likely to be consulted. This dramatic shift in provider utilization prompted publication of guidelines for optimal assessment and treatment of men's sexual problems (Lue *et al.*, 2004; The Process of Care Consensus Panel, 1999). An interview to determine sexual, medical and psychosocial history is the first step in assessment with sensitivity to cultural, religious and ethnic factors. Physical examination is necessary to corroborate aspects of the medical history as well as potentially revealing unexpected physical conditions. Further diagnostic evaluation is often recommended. The Process of Care Consensus Panel (1999) identified first, second and third line treatment options. First line options include oral erectogenic drugs (e.g. Viagra), vacuum constriction devices and psychosexual therapy. A comparative study

of treatment by random assignment to erectogenic drug only, psychotherapy only, or combined treatment showed significantly greater erectile improvement for those in treatments that included psychotherapy (Melnik & Abdo, 2005). Second line treatments included prostaglandin E₁ administered intraurethraly or through intracavernosal injection. Third line treatment involves surgical implantation of a penile prosthesis (see 'Intimate examinations', 'Cognitive behaviour therapy' and 'Psychodynamic psychotherapy').

Sexual dysfunctions in women

Definitions and prevalence

Symptoms of sexual dysfunction are more prevalent for women than men (43 vs. 31%, Laumann *et al.*, 1999). However, questions have been raised as to whether the presence of such symptoms actually constitutes dysfunction. Traditional sexual dysfunction diagnostic categories for women were critiqued and revised (Basson *et al.*, 2004; Basson, 2005). The revisions recognized empirical evidence challenging the linear model proposed by Masters and Johnson (1966). For example, there are various motives for initiating sex besides spontaneous desire (Cain *et al.*, 2003), such as expressing love for a partner or decreasing anxiety and guilt about sexual infrequency. Responsive desire may occur following adequate levels of sexual arousal and pleasure. Furthermore, women's experience of sexual arousal may not be tied to genital vasocongestion (Morokoff & Heiman, 1980) (see 'Gender issues and women's health').

Desire disorders are the most common sexual dysfunction in women: 27–32% reported lack of interest in sex in the NHLS study. The proposed diagnostic revision would most likely reduce this number by distinguishing between those who do not spontaneously experience sexual interest and those who become interested once sexually involved.

The DSM-IV-TR definition of female sexual arousal disorder is 'Persistent or recurrent inability to attain, or to maintain until completion of the sexual activity, an adequate lubrication-swelling response of sexual excitement'. Difficulty experiencing lubrication was reported by 18–27% of women in NHLS. The revised sexual arousal disorder is divided into three separate categories: subjective sexual arousal disorder, genital arousal disorder and combined sexual arousal disorder.

Orgasmic disorder (7–9% in NHLS) is described as lacking, markedly diminished, or considerably delayed, despite self-report of high sexual arousal. Vaginismus (difficulty in allowing vaginal entry of a penis, finger, etc.) and dyspareunia (8–21% in NHLS) indicating persistent or recurrent pain with attempted or complete vaginal entry, are retained as diagnostic categories.

It is significant to note, that despite the traditional separation of dysfunctions, empirical investigations have found a strong relationship among them (Dennerstein & Lebert, 2004).

Risk factors for dysfunction

Sexual responsiveness and interest, followed longitudinally, demonstrate consistency across time (Dennerstein & Lebert, 2004). They are increased by the presence of a new partner, positive feelings toward a partner, and higher frequency of sex. The two most important predictors of absence of sexual distress were general emotional wellbeing and emotional relationship with the partner during sexual activity (Bancroft *et al.*, 2003).

Other factors associated with sexual problems in women include age, lower educational attainment and nonmarried status (see 'Socioeconomic status and health'). Unlike men, women with poor health were not more likely to report problems in any category except sexual pain (Laumann *et al.*, 1999). Mixed results for childhood sexual abuse have been reported: a significant relationship to arousal disorder was found in the NHLS data, but no relationship to any sexual functioning variable was reported by Dennerstein *et al.* (2004) (see 'Rape and sexual assault').

Assessment and treatment

Interviewing is the cornerstone for assessment of women's sexual functioning. Because relationship quality is an important predictor of dysfunction, it is a key area for assessment. Physical examination is recommended for particular problems. Directed sex therapy is effective for women who have never experienced orgasm (Heiman & Meston, 1997). For those who experience situational orgasm, treatment is only somewhat efficacious and may require a relationship focus including improvement in sexual communication (Kelly *et al.*, 2004). There is a paucity of research investigating psychotherapy for arousal disorders (see 'Diagnostic interviews' and 'Communication assessment').

Psychopharmacological treatments are primarily hormonal. Oestrogen therapy, either topical or systemic, is effective in increasing lubrication and other parameters of sexual functioning in postmenopausal women (Alexander *et al.*, 2004). However, risk of cardiovascular disease or cancer must be taken into account in considering such treatments. Testosterone replacement therapy increases sexual pleasure in women with oophorectomy compared to placebo (Shifren *et al.*, 2000) and is effective in increasing sexual desire in women reporting low sexual desire with normal testosterone levels (van Anders *et al.*, 2005). Long-term safety of testosterone administration is not known (see 'Hormone replacement therapy' and 'Menopause and postmenopause').

Conclusions

The study of female sexual dysfunction has lagged behind that of men. Research is needed to better understand the anatomy and mechanisms of sexual arousal in women, potentially providing the basis for development of vasoactive drugs. For men, information on the natural history of erectile function is needed. For both men and women it is imperative to examine sexual problems in the context of relationships and culture.

Sexually transmitted infections

Barbara Hedge

South Devon Healthcare NHS Foundation Trust

Introduction

Good sexual health is an integral part of quality of life. However, sexually transmitted infections (STIs) are common and rates are rising (White, 2004). Although diagnoses of STIs declined in the mid-1980s coinciding with awareness of Human Immunodeficiency Virus (HIV), since 1995 there has been a gradual, sustained overall increase of 57% with rates of syphilis increasing by 1058%, chlamydia by 196%, gonorrhoea by 139% and a first attack of herpes simplex by 15%. This can partially be explained by increased numbers presenting for STI screening and an increase in the sensitivity of diagnostic tests over this time. However, it also indicates a fall in safer sexual practices, particularly in young adults and in men who have sex with men (see 'Sexual risk behaviour').

STIs are frequently accompanied by painful, burning or itching lesions or discharge in the genital, anal and oral regions. They may also result in serious systemic disease; links have been made between genital warts and cervical carcinoma, syphilis and damage to the cardiovascular and central nervous systems and to congenital disorders, gonorrhoea with sterility and chlamydia with pelvic inflammatory disease (the leading, preventable cause of infertility).

Recognition of the enhancement of the sexual transmission of HIV in those with STIs (Schacker, 2001) and their related adverse health burden (Ebrahim *et al.*, 2005) has resulted in STI prevention becoming a global priority.

Psychological responses to STIs

Diagnosis

Research into the psychological impact of STIs is largely limited to studies of those with genital herpes (see 'Herpes'). Genital herpes can be a painful infection, particularly in the first episode and can have unpredictable recurrences. Common psychological reactions to its diagnosis are shock, anxiety, depression, anger, shame, low self-esteem, surprise and confusion (Mindel & Marks, 2005; Patrick *et al.*, 2004). Particular concerns are the risk of transmitting infection to sexual partners and the anticipation of sexual and relationship difficulties.

With the advent of drugs that reduce the probability of recurrences and the severity of attacks, psychological functioning appears to improve significantly suggesting either a reduced concern about the diagnosis or that distress reduces over time as individuals adjust. Similar negative psychological reactions have been identified in those with vaginal candidiasis (Irving *et al.*, 1998) and those infected with human papillomavirus (HPV) (Conaglen *et al.*, 2001).

People who have contracted STIs through a sexual assault, when safer sexual practices are rarely adopted, are particularly psychologically vulnerable (see 'Rape and sexual assault'). High rates of acute anxiety, post-traumatic stress disorder (PTSD), phobias and sexual dysfunction have been reported (see also 'Post-traumatic stress disorder' and 'Sexual dysfunction'). Others for whom a STI reveals sexual secrets may experience increased psychological reactions and relationship difficulties.

Stress and recurrence of infection

Retrospective studies suggest an association between recurrences of genital herpes and stress (Dalkvisk *et al.*, 1995) and that high stress might directly reactivate the virus. However, a meta-analysis by Zorilla *et al.* (1996) concluded that depression, rather than stress, increased the risk of a recurrence. Prospective studies (e.g. Rand *et al.*, 1990), find no evidence that an increase in daily stress precedes a recurrence, and no association between anxiety and depression and the number of recurrences. It is possible (Dalkvist *et al.*, 1995) that the low mood or high stress identified to precede a recurrence could be a reaction to latent symptoms related to the virus. Alternatively, the stress response might be the consequence of frequent recurrences. Reviews of the literature do not provide conclusive support for either argument (Shah & Button, 1998). Manne and Sandler (1984) using Lazarus and Folkman's (1984) stress appraisal model found that individuals who experience more frequent recurrences report poor adaptive coping skills and are less able to plan how to deal with a recurrence, cope with the resultant distress or take an active role in minimising its impact (see also 'Stress and health').

As social support is frequently reported to buffer the effects of stress (see 'Social support and health') it might be expected that high levels of social support would enable individuals to cope more effectively and experience less recurrences. There is some support for this; Silver *et al.* (1986) found those with high levels of social support to show less psychopathology but to experience the same number of recurrences as those with lower levels. However, Longo and Clum (1989) found no association between social support and recurrences.

Methodological problems make causal interpretations difficult. Studies usually investigate individuals with frequent or severe recurrences and so findings are unlikely to represent the majority who have infrequent or mild recurrences. Measures of stress also vary considerably. Nor is there a clear immunological model of linkage between psychological factors and infections that could inform this measure (see 'Psychoneuroimmunology').

Psychological interventions

Coping with infection

Few studies have investigated the effectiveness of cognitive behaviour therapy in the management of the psychological sequelae of STIs. McLarnon and Kaloupek (1988) found a cognitive therapy group to be superior to a discussion group in decreasing recurrences of genital herpes, but to be no better in reducing distress. Relaxation training also appears beneficial particularly when the intervention also includes information about HSV, stress management and imagery techniques (Longo *et al.*, 1998) (see 'Cognitive behaviour therapy' and 'Relaxation training').

Sexual difficulties are frequently reported by individuals with STIs. These may be associated with pain on sexual contact or fear of infecting a sexual partner. When the sexual problem is not transient and does not resolve once an STI is cured, then to raise mood and improve quality of life, psychological intervention is merited (Rosen, 1998).

Reduce the probability of further infections

The spread of STIs can be limited by sexual abstinence or safer sex. Many health promotion studies have found that information provision alone is insufficient to encourage health behaviour change. Although giving information regarding STI transmission and its prevention is necessary, Shepherd *et al.* (2004) report that decreasing sexual risk behaviours is dependent on information being provided in conjunction with negotiation skills training and motivation building. Wingood and DiClemente (1996) note that successful interventions are those based on sociopsychological models of behaviour that address gender issues in the negotiation of safer sex, employ peer educators and use multiple intervention sessions. Whether such interventions can produce long term change is uncertain.

Informing a sexual partner of the need either to abstain from sex or to use condoms might require the disclosure of infection. However, disclosure can lead to stigma (Newton & McCabe, 2005) (see 'Stigma'). Green *et al.* (2003) found that many did not disclose

until their secret might be discovered e.g. before co-habiting. Disclosure was influenced more by the probability of rejection, of never having another sexual relationship and with anticipated shame should their infection become widely known, than by the risk of infecting a partner.

Prevention of STIs is of particular significance given the increased susceptibility of individuals to acquiring HIV when having an STI. Thus, assisting individuals with communication, social and assertiveness skills through strategies that provide ongoing reinforcement of the safer sex message is required (Niccolai *et al.*, 2005) (see also 'HIV and AIDS').

Clinical implications

The impact of STIs both at diagnosis and when living with non-curable infections suggests the need for psychological support. Cognitive behaviour therapy groups and relaxation training, which have been demonstrated to be useful, are simple, time-limited and relatively inexpensive.

GUM clinics are frequently perceived as threatening (Scoular *et al.*, 2001) and psychosocial factors such as shame and embarrassment still mediate individuals' willingness to attend. Thus, interventions to prevent further spread of infection require clinic services to manage feelings of stigma and shame as well as being sensitive to emotions and preserving confidentiality.

Conclusion

A range of psychological symptoms are associated with STIs. Provision of psychological support can reduce the distress associated with symptoms and the stigma of STIs and contribute to the control of STI infection and the spread of HIV. Offering these in a sexual health centre setting that offers maximum confidentiality would seem beneficial.

Sickle cell disease

James Elander

University of Derby

Sickle cell disease (SCD) is a group of blood disorders caused by genetically determined amino acid substitutions in the beta polypeptide chains of the haemoglobin molecule. The abnormality causes haemoglobin to polymerize, or gel, when oxygen tension is lowered, making the red cells stiffen and elongate into a characteristic sickle or crescent shape, causing episodic vaso-occlusion and tissue infarction. It is a lifelong chronic condition and although survival rates have improved significantly over the last 50 years, those affected continue to suffer from chronic anaemia, susceptibility to infections, a shortened life expectancy and recurrent episodes of severe pain. In the UK, the condition affects over 10 000 people, with over 140 babies with SCD born every year (Hickman *et al.*, 1999). In the USA, one in every 400 African-American new births are babies with SCD (Consensus Conference, 1987), and many more are affected in Africa, the Caribbean and parts of Asia. Worldwide, as many as 300 000 babies are born every year with sickle cell disorders (Angastiniotis & Modell, 1998).

Genetic testing and screening, coping and adjustment and pain management are all important psychological issues in SCD, and sickling episodes in the brain have potential neuropsychological consequences (Kral *et al.*, 2001; Prenalger *et al.*, 2002). It was often said that psychological aspects of SCD were under-researched, but this is now less true than in the past. The growing research literature means that the condition is much better understood than previously, but the extent to which that has been translated into

improved services and better quality of life for sufferers is very variable.

Genetic testing and screening

Abnormal forms of the beta polypeptide chain gene on chromosome 11 are responsible for SCD. Inheritance is autosomal recessive, so that for SCD to occur, abnormal forms of the gene must be inherited from both parents. Individuals who inherit an abnormal form of the gene from one parent and a normal form from the other are asymptomatic trait carriers. The SCD trait increases carriers’ resistance to malaria, and the groups of people primarily affected by SCD are those who live in, or are descended from those who lived in, parts of the world where malaria has been endemic. About one in 10 people of Afro-Caribbean descent and one in four of West African descent, are carriers of the SCD trait (Department of Health, 1993; Marteau & Anionwu, 1996). Those affected by the condition in Europe and North America are therefore predominantly members of ethnic minority groups, but a simplistic association with ethnicity has a number of undesirable implications (Dyson, 1998) (see ‘Cultural and ethnic factors in health’).

Antenatal screening aims to identify carriers, who can then be offered genetic counselling, prenatal diagnosis and selective abortion. Neonatal screening aims to identify babies with SCD so that

comprehensive care and prophylactic measures against infection and other complications can begin as early as possible. In Europe and North America, the relative cost effectiveness of selective and universal screening depends on the prevalence of SCD and the size of the ethnic minority communities selected for screening (Davies *et al.*, 2000; Zeuner *et al.*, 1999). Genetic screening for SCD also raises ethical, social and political issues (Atkin & Ahmad, 1998). One qualitative study showed that many of the negative experiences reported by users of a UK screening and counselling service were associated with service providers' perceptions of SCD as an ethnic minority condition (Atkin *et al.*, 1998) (see also 'Screening: antenatal' and 'Screening: genetic').

The psychology of testing and screening centres on the reproductive decisions faced by those identified as carriers or as parents of unborn affected children. This often takes place in the context of a tension between the explicit aim of screening, which is to enable affected individuals to make informed choices and the widely held, but frequently challenged, implicit aim, which is the eventual elimination of the condition. Studies in the UK (Petrou *et al.*, 1992) and in the Caribbean (Alexandre *et al.*, 1997) showed that couples at risk of having a child with SCD were more likely to take up prenatal diagnosis and selective termination if the choice was offered early in pregnancy, if a more severe type of SCD was involved, and if there was already a child with SCD in the family. In one study in Africa, parents were less likely to choose to terminate affected pregnancies if they were themselves SCD sufferers rather than carriers (Durosinmi *et al.*, 1995) (see also 'Abortion'). A study of women identified as carriers by a US screening programme found that, consistent to some extent with the health belief model, intentions to have partners tested were predicted by greater knowledge of the condition, lower perceived burden of intervention and greater perceived seriousness of the condition. Factors predicting acceptance of prenatal diagnosis included being older, wanting to have more children, and prior awareness of the risk of having a child with SCD (Rowley *et al.*, 1991).

The increase in demand for screening and genetic counselling services has also raised the issue of how to train non-specialist staff so that those services can be offered in primary care as well as specialist centres. Trials of interventions to promote SCD screening in primary care have produced encouraging results (e.g. Modell *et al.*, 1998), but high quality genetic counselling may be more difficult to provide in primary settings. In one study, women who received SCD genetic counselling in primary settings were less likely to have their partner tested than those counselled in specialist tertiary centres (Rowley *et al.*, 1995) (see also 'Screening in healthcare').

Coping and adjustment

Findings on coping and adjustment processes in SCD have been consistent with those from research in a wide range of other chronic illnesses, although SCD sufferers may be more likely to be affected by risk factors for poor coping and adjustment. One review concluded that adults with SCD experience high levels of depression and maladjustment compared with other illnesses, and that social support and life stress were better predictors of adjustment than illness variables (Midence & Elander, 1996).

In one study, for example, a stress and coping model accounted for nearly half of the variance in psychological adjustment (Thompson *et al.*, 1992) (see 'Stress and health' and 'Coping with chronic illness').

Cognitive and behavioural strategies for coping with pain are an especially important aspect of positive coping in SCD. Research in the US showed that pain coping strategies were not related to pain frequency or duration, but appeared to mediate psychological adjustment and the consequences of pain. Strategies that involved negative emotional responses to pain were associated with more severe painful episodes, more frequent hospitalizations, higher levels of distress and lower levels of activity during painful episodes (Gil *et al.*, 1989, 1992). In the UK, negative emotional responses to pain were associated with impaired quality of life (Anie *et al.*, 2002) (see 'Pain' and 'Quality of life').

Findings like those have led to the development and evaluation of interventions to improve pain coping in SCD. In the USA, coping skills training for children led to more active pain coping compared with standard care and diary data showed fewer healthcare contacts, fewer school absences and less interference with household activities on pain days when children practised pain coping strategies (Gil *et al.*, 2001). Similar benefits were reported for a coping skills training intervention for adults (Gil *et al.*, 2000). In the UK, community-based cognitive behavioural therapy for pain management led to reductions in psychological distress and affective pain and increases in use of positive pain coping strategies, compared with standard care and participant-led discussion groups (Thomas *et al.*, 1999).

Hospital pain management

Episodic vaso-occlusive pain is the most frequent reason for hospital treatment among patients with SCD, yet pain management remains one of the most controversial and problematic aspects of SCD care. Painful episodes are treated with injections or infusions of pethidine (meperidine), morphine or diamorphine, though a range of analgesic methods have been evaluated, including adjunctive medications and patient-controlled analgesia (Elander & Midence, 1996). Patients often report that their pain is poorly managed, and hospital pain management sometimes results in disputes with staff and other problematic outcomes. One qualitative study identified mistrust, stigmatization, excessive control and neglect as themes in patients' experiences of hospital care and proposed an explanatory model in which experiences of mistrust and control undermine patients' self-reliance and coping skills (Maxwell *et al.*, 1999).

Problems with hospital pain management may be caused in part by mistaken staff perceptions of analgesic addiction, which are probably more likely in SCD than other painful conditions for which opiate analgesics are required. Sickle cell disease causes episodic acute pain rather than chronic pain and sufferers often recover to full health after a painful episode but attend hospital again with severe pain several weeks or months later. People with SCD often develop well-established pain coping styles and strategies and, outside hospital, are used to playing an active role in managing their own pain. Those factors, as well as the fact that, in Europe and North America, people with SCD are almost always members of minority

ethnic groups, would be expected to make people with SCD more vulnerable to misperceptions of addiction than patients with other painful conditions. Dissatisfaction with hospital care is often associated with reports of patients being stigmatized as drug addicts (e.g. Maxwell *et al.*, 1999), and hospital staff often grossly over-estimate the prevalence of analgesic addiction among SCD patients (e.g. Shapiro *et al.*, 1997). Staff training interventions that aimed to reduce staff concerns about drug dependence and increase responsiveness to patients reports of pain have been shown to increase the effectiveness of pain management in SCD (Brookoff & Polomano, 1992).

Detailed analyses of pain behaviours and analgesic use support the view that misperceptions of analgesic addiction may contribute to problematic pain management. One study looked at the extent to which SCD sufferers' analgesic use met authentic criteria for substance dependence, and the extent to which their attempts to manage pain made them vulnerable to misperceptions of addiction. Only 2% of the sample met authentic criteria for substance dependence, but nearly one-third reported attempts to cope with pain that would be perceived as substance dependence by an observer who did not take account of the pattern of their pain (Elander *et al.*, 2003). Genuine symptoms of substance dependence were correlated with known risk factors for addiction in pain patients, whereas pain coping that could be misperceived as addiction was correlated with known risk factors for pseudoaddiction, a condition where

under-treated pain causes behaviours resembling addiction (Lusher *et al.*, 2006). Behaviours that could be misperceived as addiction were associated with problematic outcomes of hospital pain management, supporting the view that the spurious perception of addiction may adversely influence staff-patient interactions and the delivery of hospital pain management in SCD (Elander *et al.*, 2004). More research is needed on the factors that affect medical staff perceptions of patients with SCD, in order to develop and evaluate interventions to counter the misperception of analgesic addiction and improve interpersonal aspects of hospital pain management (see 'Attitudes of health professionals' and 'Pain management').

Conclusions

Sickle cell disease is a condition with several features that have significant psychological implications. For some aspects of SCD, such as the factors influencing coping, adjustment and quality of life, research has shown that the condition has a great deal in common with other chronic illnesses. For others, such as hospital pain management, certain unique features of the condition need to be considered. Research into the psychological consequences of SCD is likely to continue, but research has also begun to focus on developing and evaluating supportive interventions to improve the quality of life of those affected.

Skin disorders

Ulrich Stangier

Friedrich-Schiller-Universität Jena

Overview of the general area

There is a long tradition of the view that emotional stress might act as a precipitating factor in the onset or exacerbation of skin disorders. The close relationship of the skin with psychological functions is reflected in a variety of expressions such as ‘to be red with rage’ or ‘to jump out of one’s skin’. In addition, psychoimmunological and psychoendocrinological research has demonstrated that psychological factors significantly affect the course of a variety of medical conditions including dermatological disorders. However, there is no evidence that dermatological disorders are related to specific psychological traits. Rather, that the impact of skin disorders on quality of life indicates that the impairment of appearance associated with visible and sometimes disfiguring dermatological conditions creates significant psychosocial stress.

The relationship between psychological factors and skin disorders is further complicated by the fact that manipulations such as self-injurious skin picking may cause artificial dermatological lesions. Finally, a high proportion of patients report symptoms that are not adequately explained by a dermatological disease or a known pathophysiological mechanism, such as body dysmorphic disorders.

The focus of the present paper is on psychological factors related to skin disorders. With respect to somatoform and artificial disorders, the interested reader is referred to other sources (e.g. Stangier & Ehlers, 2000).

Research Evidence

Vulnerability to stress

There is evidence from a large number of studies that stressful life events, daily hassles and chronic stressors can significantly affect the manifestation and course of skin disorders (see also ‘Life events and health’ and ‘Stress and health’). However, only a few studies meet generally accepted methodological standards of life events research. Most of the studies are based on retrospective self-report and did not control for confounding factors such as discontinuation of medical treatment and seasonal effects. In a comprehensive and carefully conducted review of data from available studies, Picardi and Abeni (2001) concluded that there was evidence for the impact of stressful events on the course of atopic dermatitis, psoriasis, alopecia areata and urticaria. In contrast, insufficient data

exist for the role of life events in most other skin disorders, such as acne and vitiligo. Some of the psychoimmunological mechanisms involved in the exacerbation of dermatological symptoms have been well studied in atopic dermatitis. This research suggests that, in response to psychosocial stress, a reduced responsiveness of the hypothalamus–pituitary–adrenal axis might trigger the activation of cutaneous inflammation (Buske-Kirschbaum *et al.*, 1997). In addition, psychological stress induces the activation of circulating helper T-lymphocytes and of cutaneous membrane molecules resulting in an increased ability of T-lymphocytes to migrate to the skin (Schmid-Ott *et al.*, 2001a,b). To sum up, systemic and cutaneous abnormalities in the immunological response to stress factors indicate that patients with atopic dermatitis show an increased psychobiological sensitivity to stress. Further studies are needed to clarify whether these findings can also explain the role of stress in the exacerbation of other inflammatory skin disorders, such as psoriasis or urticaria (see also ‘Psychoneuroimmunology’).

Physical responses to stress are not the only pathway between stress and increased skin pathology. Behavioural factors such as scratching, exposure to noxious stimulation and use of alcohol or smoking, are also intensified under stress and thus mediate the effect of stress on the skin.

Psychological factors increasing the vulnerability to stress include factors such as anxiety, depression and dysfunctional coping behaviours, such as avoidance. However, there is not much evidence that the manifestation of specific skin disorders is related to these factors. A large number of studies indicate that increased levels of anxiety and depression can be found in people with psoriasis, urticaria, alopecia areata, vitiligo and scleroderma, and in severe cases of acne and genital herpes (for review of literature see Stangier & Ehlers, 2000). In addition, several studies consistently demonstrated significantly increased trait anxiety in atopic dermatitis. However, the interpretation of the findings is complicated by the cross-sectional design of the studies, which does not provide evidence of a causal relationship. Furthermore, most studies included patients who sought out treatment because their skin disorder had become worse. Thus, it is probable that self-report of psychological symptoms, such as anxiety and depression, reflects the distress caused by exacerbation of the skin condition rather than being a precipitating factor. Prospective studies, which compare psychological symptoms during acute exacerbations and symptom-free intervals, are a more appropriate approach.

Coping with the distress of illness

Although dermatological conditions are rarely life-threatening, the somatic, social and emotional effects of skin disorders can lead to significant emotional distress and psychosocial impairment. Several studies indicate that about 30% of dermatological outpatients suffer from impaired mental health and psychiatric symptoms (Hughes *et al.*, 1983; Wessley & Lewis, 1989; Aktan *et al.*, 1998; Picardi *et al.*, 2000). Rapp *et al.* (1999) found that the health-related quality of life of psoriasis patients was comparable to patients with other severe chronic health conditions, including cancer, arthritis, hypertension, heart disease, diabetes and depression (see ‘Quality of life’).

Within the framework of coping theory, skin diseases can be regarded as causing physical, interpersonal, or psychological threat that can lead to problems in adjustment.

1. *Physical threat.* Itching, as a core symptom of many dermatological diseases, can cause severe impairment of physical well-being that is comparable to pain. Many dermatological patients experience intense itching sensations as intolerable and very disabling (Bernard, 1994). Furthermore, itching usually provokes scratching. Scratching temporarily inhibits the itching sensation but, in the long-term, causes inflammation and increased itching, which leads to a vicious circle. Many patients with atopic dermatitis and other pruritic skin disorders perceive the vicious circle of itching and scratching as a loss of control, accompanied by feelings of helplessness, embarrassment and guilt (Stangier *et al.*, 2003).
2. *Interpersonal threat.* Patients with visible skin lesions, e.g. in psoriasis, often experience negative social reactions ranging from excessive expression of compassion to open rejection and discrimination (Leary *et al.*, 1998). This stigmatization is often based on irrational fear of infection or disgust at the red inflamed, thickened or weeping skin morphology. Visibility of skin lesions and negative social reactions are important factors reducing quality of life in patients with psoriasis (Kent & Keohane, 2001). In turn, some patients tend to anticipate negative evaluation and avoid social situations, entering a fear-avoidance circle of increased fear of rejection leading to social retreat (Thompson & Kent, 2001) (see also ‘Facial disfigurement’).
3. *Psychological threat.* Visible and disfiguring skin lesions are associated with feelings of reduced physical attractiveness and negative body image. Since most skin diseases follow a chronic relapsing course, patients might be sensitized by the up and down of rashes and remissions, developing a hypochondriacal self-monitoring and rumination about the threatening emotional and social consequences. This preoccupation often results in the conviction of being ‘disfigured’, negative self-esteem and depression (Richards *et al.*, 2001).

Clinical implications

The results of several controlled studies suggest that cognitive behaviour therapy may be effective in the clinical management of dermatological conditions (see ‘Cognitive behaviour therapy’). However, most of the essential components of the treatments are not specifically related to skin disorders, including relaxation training, cognitive restructuring and social skills training (see ‘Relaxation training’). Specific interventions include biofeedback training, self-control techniques to reduce scratching and social skills training to cope with stigmatizing reactions (see ‘Biofeedback’). It should be noted, that a careful assessment of factors affecting the skin disorder, using exploration, questionnaires and diaries, and an accurate psychological diagnosis in individual patients is necessary to derive effective interventions (Stangier & Ehlers, 2000).

Relaxation training and guided imagery

Several relaxation techniques have proven successful in the behavioural treatment of skin disorders. Progressive muscle relaxation (PMR) is especially useful in pruritic skin diseases such as atopic dermatitis and chronic urticaria, other inflammatory diseases including psoriasis and infections such as genital herpes.

This method has been shown to be useful as a competing response for scratching as part of the habit-reversal-technique (see below). In addition, guided imagery as a particularly valuable addition to relaxation in the treatment of skin disorders. Patients are generally guided through imagining or visualizing the healing process (Zacchariae *et al.*, 1996). Autogenic training is a form of relaxation training involving self-suggestions. Ehlers *et al.* (1995) demonstrated that autogenic training was significantly superior to dermatological education in reducing symptoms of atopic dermatitis.

Biofeedback training

Biofeedback training aiming at the reduction of skin temperature, skin conductance or EMG levels have extensively been studied during the 1980s in a series of controlled case studies with dermatological patients. Despite the positive results obtained with biofeedback training, the mechanisms for its effects remain unexplained (Sarti, 1998). Since it may be that patients basically learn to reduce their general sympathetic arousal rather than to influence a specific physiological function, this effect may be achieved with less effort through relaxation techniques. A specific advantage of biofeedback training might be, however, that the patients improve their perception of specific cutaneous physiological processes. In addition, patients expecting traditional medical treatment may accept this technical treatment better than pure relaxation training.

Self-control of scratching and itching

Several controlled studies have shown that habit reversal training, alone and in combination with progressive relaxation, reduced scratching behaviour and led to long-term improvements in the symptoms of atopic dermatitis (Ehlers *et al.*, 1995). The habit reversal technique includes training the patients' abilities to become aware of situational triggers, to interrupt automatic scratching and to use a competing response procedure to block the itching sensation.

The efficacy of this self-control technique might be increased by imagery interventions to inhibit itching sensations:

- guided imagery of cool sensations on the skin or of sensations associated with healing influences on the affected skin
- direct suggestions to modify the awareness and perception of itching
- positive self-instruction to replace catastrophic cognitions about itching by coping-related cognitions

- distraction techniques to focus concentration on manual or mental activities, pleasant sensations or other more intensive stimuli.

Standardized group treatment packages

There is increased evidence that for patients with chronic dermatological disorders structured group programmes represent the most effective treatment approach (see 'Group therapy'). In randomized trials, such treatment packages have been shown to significantly reduce symptoms and improve psychological functioning in atopic dermatitis (Ehlers *et al.*, 1995), psoriasis (Fortune *et al.*, 2002) and malignant melanoma (Trask *et al.*, 2003). Typically, the treatments combine the following components:

- modification of stress vulnerability by relaxation training, cognitive restructuring and social skills training
- social skills training and cognitive restructuring to improve coping with disease-related social problems
- patient education and providing information on factors affecting the skin condition and treatment approaches.

Furthermore, specific programmes for children with atopic dermatitis and their parents have been developed. Usually, interventions for children are tailored to the specific age and include information about disease, skin care and treatment, habit reversal training, progressive muscle relaxation, problem-solving training and positive self-instructions to improve disease management and coping with common stressors (Hampel *et al.*, 2001). Parental education programmes cover medical, nutritional and psychological issues including stress management, dealing with itching and scratching, and sleep disturbances (Staab *et al.*, 2002).

To sum up the current status of research, substantial progress has been made in developing and evaluating psychological treatments of dermatological disorders in which psychological factors play an important role. However, there are still a number of areas that need to be addressed in future research. For instance, the acceptability of psychological treatments for dermatological patients is still a problem. In addition, patients usually present with a complex interaction of dermatological symptoms with psychological and social factors. The process of identifying psychological problems, motivating the patient for treatment and finally referring him to a psychologist or psychiatrist can be a time-consuming process. Therefore, an important implication is the need for a close collaboration of dermatologists, psychologists and/or psychiatrists.

Sleep apnoea

Jane Harrington

Royal Free and University College Medical School

Introduction

Obstructive sleep apnoea is usually referred to as Obstructive Sleep Apnoea/Hypopnoea Syndrome (OSAHS) as it provides a more accurate description of the condition. OSAHS is caused by blockage of the airway, typically when the soft tissue at the back of the throat collapses during sleep due to lack of muscle tone, predominantly during rapid eye movement (REM) sleep. OSAHS is common and is one extreme of a continuum of sleep-disordered breathing (SDB) (Young *et al.*, 1993) that ranges from normality with few obstructive events, to a life-threatening condition, which may present with cardiovascular, respiratory, or sleep related symptoms

(Shneerson, 2000). OSAHS differs from central sleep apnoea, which is caused by problems with brain mechanisms that control breathing and can be found in patients with cardiac failure or neurological disease, particularly stroke (Douglas, 2002) (see 'Stroke').

The currently accepted definition of OSAHS is the co-existence of at least five obstructive breathing events per hour of sleep with unexplained excessive daytime sleepiness or at least two other major symptoms (American Sleep Disorders Association, 1999). Apnoeas are characterized by repeated nocturnal episodes of cessation of airflow and hypopnoeas as a 50% reduction in airflow, with both lasting for at least ten seconds (Shneerson, 2000). These obstructed breathing events are terminated by arousals from sleep

and are sometimes associated with temporary dips in oxygen saturation (Engleman & Joffe, 1999). It has been estimated that 2% of women and 4% of men in the middle-aged workforce meet the diagnostic criteria for OSAHS (Young *et al.*, 1993).

Risk factors

One of the principal risk factors associated with OSAHS is obesity (Vgontzas *et al.*, 1994; Young *et al.*, 1993). About half of all patients with OSAHS are clinically obese, with body mass indexes (BMI) exceeding 30 (Douglas, 2002). Obesity in conjunction with craniofacial abnormalities is also associated with OSAHS (Ferguson *et al.*, 1995; Lofaso *et al.*, 2000). Craniofacial abnormalities include small upper airway, large tongue, large uvula, recessed chin, enlarged tonsils and/or soft palate. Individuals who are habitual snorers generally have a higher prevalence of apnoeas/hypopnoeas (Young *et al.*, 1993). There is a tendency for OSAHS to run in families and there is data suggesting that the pathophysiology of SDB including OSAHS may have a genetic basis, which could explain the familial aggregation (Gaultier & Guilleminault, 2001). Lifestyle factors can also have an effect on OSAHS. In a sample of men with mild to moderate OSAHS even a relatively small consumption of alcohol significantly increased apnoea frequency (Scanlan *et al.*, 2000) (see also 'Obesity').

Assessment of OSAHS

A diagnosis of OSAHS can be easily missed unless patients present with sleepiness plus snoring as the primary complaint. Patients with possible OSAHS are generally investigated by performing overnight sleep studies (polysomnography) to assess breathing activities during sleep (Douglas, 2002). The main components of polysomnography are the electro-encephalograph (EEG), which determines whether the patient is awake or asleep. Electro-oculograph (EOG), electro-myograph (EMG) and electro-cardiogram (ECG) determine sleep stage, arousals and cardiac function. Airflow obstruction can be determined by plethysmography, which measures rib cage and abdominal movement or by thermistor assessment of oronasal airflow. Arterial oxygen saturation is often monitored using pulse oximetry (Shneerson, 2000).

Daytime sleepiness can be assessed using objective and subjective measures of sleepiness. Objective measures include the Maintenance of Wakefulness Test (MWT) (Mitler *et al.*, 1982). This involves patients lying in a quiet darkened room where they are instructed to stay awake. Sleep onset latencies are calculated from the time the room is darkened until the appearance of the first 30-second epoch of any stage of sleep measured by a polysomnograph. There is also a behavioural modification of the MWT known as the Oxford Sleep Resistance Test (OSLER) (Bennett *et al.*, 1997), where the patients press a button in response to a small light when it flashes. The test terminates when a patient fails to respond to the light seven times consecutively (indicating sleep onset) or after 40 minutes. One of the most frequently used self-report measures is the Epworth Sleepiness Scale (ESS), which asks patients to rate the likelihood of themselves dozing off in a variety of situations (Johns, 1993) (see also 'Sleep and health').

Treatment

Initially treatments are aimed at relieving the patients' symptoms. Recommendations may include weight loss, reducing alcohol consumption, avoiding benzodiazepines and other hypnotic drugs, avoiding sleep deprivation, positional treatment (sleeping on the side rather than in a supine position), improving the nasal airway with inhaled steroids or nasal dilators and smoking cessation (Schneerson, 2000). Secondary treatments are reserved for patients who have more frequent and severe OSAHS that does not respond to initial treatments, either because they are ineffective or due to poor adherence (Schneerson, 2000). Patients with mild OSAHS may be treated with REM sleep suppressants such as antidepressants, which can be effective if OSAHS is mostly confined to REM sleep. Patients with moderate to severe sleep apnoea may be offered continuous positive airway pressure (CPAP), mechanical devices or surgery (Schneerson, 2000).

CPAP therapy is the treatment of choice for most patients (Douglas & Engleman, 1998). This involves patients wearing a face mask at night, while air is pumped in and maintained at a fixed level. CPAP acts by raising the pressure within the upper airway to a sufficient level to prevent occlusion (Douglas, 2002). Evidence suggests that CPAP is an effective treatment for OSAHS (Ballester *et al.*, 1999; Engleman *et al.*, 1994; Engleman *et al.*, 1998; Jenkinson *et al.*, 1999). Mandibular repositioning splints are designed to keep the lower jaw protruded during sleep, thus preventing the tongue falling back and narrowing the throat. Currently mandibular repositioning splints are used for patients with mild to moderate sleep apnoea who do not tolerate CPAP (Douglas, 2002). There are numerous surgical treatments for OSAHS designed to cure rather than control the problem. The most commonly performed surgical procedure is uvulopalatopharyngoplasty but there remains a need for carefully conducted research to establish the efficacy of this procedure (Douglas, 2002).

Nocturnal features of OSAHS

The most common clinical feature of OSAHS is loud snoring that can exceed 65 dB (Guilleminault, 1994), similar to that of pneumatic drills or motorbikes (Douglas, 2002). Most OSAHS patients report that they wake unrefreshed yet believe that they sleep fairly soundly and are unaware of the recurring arousals from sleep, which are too transitory to be recalled (Douglas, 2002). Patients may also report restlessness during the night, which is reflected by increased tossing and turning with a proportion displaying more agitated behaviour with gross movements of the arms and legs (Guilleminault, 1994). Some patients also awaken with a feeling of choking or gagging and report being unable to breathe for several seconds resulting in panic before being able to breathe again (Douglas, 2002). Nocturia is a frequently reported problem, with as many as four to seven nightly trips to the bathroom being reported by 28% of OSAHS patients (Guilleminault, 1994).

Daytime consequences of nocturnal events

The diagnosis and therapy for OSAHS focus on the nocturnal features of the condition, but it is the daytime consequences of these

nocturnal events that result in the principal presenting complaint. Patients with OSAHS experience psychological problems falling broadly into four areas, daytime sleepiness, impaired psychosocial wellbeing, cognitive deficits and reduced driving ability (Engleman & Joffe, 1999).

Excessive daytime sleepiness (EDS) is most prevalent of these problems with over 90% of patients affected by it (Douglas, 2002). Although excessive daytime sleepiness is the most frequently measured symptom in OSAHS patients also report problems of fatigue and lack of energy over sleepiness. When required to select the one most significant symptom, more patients chose lack of energy (approximately 40%) than any other problem, including sleepiness (approximately 22%) (Chervin, 2000).

Depression and anxiety are commonly associated with OSAHS (Barnes *et al.*, 2002; Engleman & Joffe, 1999) and patients with severe OSAHS have significantly higher depression scores (Akashiba *et al.*, 2002). Compared with patients with non-apnoeic snoring, those with OSAHS have more intense depressive symptoms and somatic concerns (Aikens & Mendelson, 1999). In patients evaluated for SDB, higher depression scores have been related to both objective and subjective measures of sleepiness (Sforza *et al.*, 2002). However, other researchers have found that the links between mood and sleep in individuals with OSAHS disappear after controlling for covariates such as age, BMI and hypertension (Bardwell *et al.*, 1999).

A systematic review of quality of life in OSAHS found that patients have impaired health-related quality of life (QOL) compared with healthy age- and gender-matched controls (Moyer *et al.*, 2001), particularly when the condition is severe (Akashiba *et al.*, 2002) (see also 'Quality of life'). In one study, newly diagnosed patients were asked to select the most important items to them from a large pool of items potentially related to QOL. Items having the greatest impact on QOL grouped into five domains: (1) daytime sleepiness; (2) nocturnal symptoms; (3) limitations of activities; (4) emotions; and (5) interpersonal relations (Lacasse *et al.*, 2002). Patients with mild and moderately severe OSAHS scored significantly lower than patients without OSAHS on physical functioning using a generic measure of health-related QOL. Moderate to severe OSAHS patients also had significantly lower scores on vitality (Yang *et al.*, 2000).

Research has demonstrated that people diagnosed with sleep apnoea frequently exhibit some degree of cognitive impairment (Findley *et al.*, 1986; Naëgelé *et al.*, 1995). The areas of cognitive functioning that appear to be affected the most are general intellectual functioning, attention, memory and executive and motor functioning (Décarý *et al.*, 2000). Some researchers have argued that sleep fragmentation, which contributes to patients with OSAHS experiencing EDS, is the main cause of the observed neuropsychological deficits; while others suggest that the harmful effect of nocturnal hypoxemia (diminished oxygen in arterial blood) is the main contributing factor (Décarý *et al.*, 2000). Patients with hypoxemia demonstrate more cognitive impairment than those without

(Findley *et al.*, 1986). Research has shown that hypoxemia is most predictive of deficits in executive function and psychomotor skills, whereas EDS predicts deficits in measures of attention (Bédard *et al.*, 1993; Décarý *et al.*, 2000; Naëgelé *et al.*, 1995).

EDS and lack of concentration may contribute to road traffic accidents, as they are associated with greater risk of falling asleep at the wheel (Ohayon *et al.*, 1997). There is evidence that patients with OSAHS have a greater probability of having a road traffic accident than the normal population (Terán-Santos *et al.*, 1999). One study using a driving simulator compared a group of patients with OSAHS with a group of normal individuals tested on two occasions, once sober and again after drinking alcohol. The results demonstrated that patients with OSAHS are not only much worse than controls when matched for age, gender and driving experience but drove less well than the group of normal individuals given alcohol (George *et al.*, 1996). Research comparing the effects of sleep deprivation, alcohol and OSAHS on simulated driving (steering) performance found that patients with untreated OSAHS lay between that of alcohol intoxication and sleep deprivation. Alcohol impaired steering error occurred equally throughout the whole drive, whilst sleep deprivation caused progressive deterioration through the drive (Hack *et al.*, 2001) (see 'Road traffic accidents').

There is some evidence to suggest that EDS and snoring also leads to increased risk of occupational accidents (Lindberg *et al.*, 2001). Furthermore, self-reported sleep disturbance in a large sample of 47 860 individuals over a 20-year period was predictive of fatal accidents in the workplace (Åkerstedt *et al.*, 2002).

Impact of OSAHS on the family

OSAHS has an impact on both sufferers and their families, especially partners. Almost all partners will report loud snoring that occurs every night and in severe cases happens in all sleeping positions. Patients have been referred for assessment 'because of pressure from family members unable to escape the noise anywhere in the house, from neighbours and from passers-by on the street!' (Douglas, 2002, p. 50). Most partners will have witnessed apnoeas and for many these are the major concern, but partners will also complain about the patients' restlessness in bed at night. This results in sleeplessness for the partner and occasionally in physical injury (Douglas, 2002). Partners report very poor sleep quality and poorer self-reported health status compared with matched population (McArdle *et al.*, 2001). They also report increases in the patients' irritability which may damage family life (Douglas, 2002).

In conclusion, OSAHS can be a debilitating condition that has an impact on the individual and their families. Many of the adverse effects of OSAHS are reversible with CPAP being the treatment of choice.

Sleep disorders

Jason Ellis

University of Surrey

Introduction

Even though sleep disorders are a major public health concern and have been shown to cause and exacerbate various psychiatric and medical problems, their assessment, diagnosis and treatment in research and clinical practice remains largely inconsistent. The aim of this chapter is to introduce the various types of sleep disorder that exist and provide a background to the complex relationship between diagnostic criteria and the conception of sleep disorders by the clinician, the researcher and the individual. Moreover, through an examination of the most commonly reported sleep disorder, insomnia, the effect of differing diagnostic criteria on epidemiological estimates are exemplified.

What is a sleep disorder?

It is common for people to experience the odd sleepless night or feelings of fatigue and sleepiness during the day. However, when these problems persist, cause significant distress, and result in modifications in behaviour, it is broadly termed a sleep disorder. Sleep disorders are generally defined under two main categories, parasomnias and dyssomnias, with parasomnias being an abnormality during sleep and dyssomnias being a disruption in the quality, quantity and timing of sleep episodes.

Parasomnias

Whereas parasomnias were traditionally assumed to be a product of an underlying psychological or psychiatric disorder, or physical manifestation of a dream state, more recently they have been attributed to an intrusion of one sleep stage on another or disruption in the transition between sleep stages or between sleep and wakefulness. The most common parasomnias are characterized by a brief arousal before, during, or after the incident, and can occur during NREM sleep (e.g. sleep-walking) or REM sleep (e.g. REM behaviour disorder in which normal sleep paralysis falters during REM and the individual acts out violent or aggressive dreams). The treatment for most parasomnias is pharmacological but requires a thorough sleep assessment (i.e. Polysomnography; PSG). However, as parasomnias are usually precipitated and perpetuated by stress and anxiety, psychological interventions are also efficacious in reducing the frequency of occurrence.

Dyssomnias

Dyssomnias cover a range of conditions, from narcolepsy (sleep attacks during the day) and hypersomnia (excessive sleep need) to Restless Legs Syndrome (RLS) and Periodic Limb Movement Disorder (PLMD; sleep prevention or awakening due to aches, twitches or cramps in the lower legs) and any form of breathing related disorder (see 'Sleep apnoea'). However, the most commonly reported dyssomnia is insomnia.

Insomnia

Insomnia, broadly defined, is a complaint in initiating, maintaining or acquiring sufficiently restful sleep and is the second most reported health complaint after chronic pain (Gallup, 1995). The consequences of insomnia can be seen on both micro- and macro-levels. Not only is insomnia significantly related to the onset, progression and chronicity of various psychological and physiological conditions (i.e. Type II diabetes, depression, coronary heart disease, cancer), the negative consequences of insomnia can be seen in terms of decreased social and occupational functioning, absenteeism from work, alcohol and drug dependency and road traffic accidents (see 'Road traffic accidents').

Epidemiology and diagnostic criteria

Prevalence estimates for insomnia range between 0.4% and 67.5%, depending upon the method of data collection and the population under study (see Lichstein *et al.*, 2004 for a review). Another reason for such divergent prevalence rates is the choice of diagnostic criteria used and overall operationalization of insomnia.

Currently there are three diagnostic systems used to define insomnia: The International Classification of Diseases (ICD-10; World Health Organization, 1992), the Diagnostic and Statistical Manual of Mental Disorders – 4th edn. (DSM-IV; American Psychiatric Association, 1994) and the International Classification of Sleep Disorders (ICSD-2; American Sleep Disorders Association, 2005). All three diagnostic manuals use a categorical axial system; however, they cite different criteria to define and sub-type insomnia. For example, the ICD-10 makes no distinction between 'primary insomnia' (where insomnia is the only or main presenting problem) and 'secondary insomnia' (where the insomnia is comorbid with a physical or mental disorder), unlike the DSM-IV and ICSD-2. Moreover, where the ICD-10's diagnostic criteria for 'non-organic insomnia' suggests a frequency of three disrupted nights per week

and the ICSD-2's 'chronic psychophysiological insomnia' suggests the disruption should be 'nightly', the DSM-IV has no frequency criteria.

The ICSD-2 appears to be the most comprehensive, with over 40 sub-classifications which are outlined in terms of diagnostic features, minimal criteria, severity and duration. However, Edinger and colleagues found that sub-typing insomniacs using cluster analysis resulted in 14 sub-groups which were incomparable with most of the ICSD-2's sub-classifications (Edinger *et al.*, 1996).

The ICSD-2 also requires objective verification for a diagnosis of insomnia using PSG, even though subjective insomniacs (self-defined insomniacs without objectively poor sleep) report similar levels of interference to daytime and night-time functioning and PSG findings do not account for individual differences in sleep requirements (Sateia *et al.*, 2000). Moreover, the temporal stability of PSG can only be validated after three weeks when examining sleep maintenance insomnia and two weeks for sleep onset insomnia (Wohlegemuth *et al.*, 1999). Most studies however have not undertaken PSG for such extensive periods as this practice would have ethical and practical implications. Additionally, it is common for insomniacs to demonstrate night-to-night variability in the quantity and quality of their sleep.

In the light of these definitional problems, the American Academy of Sleep Medicine proposes '... to define insomnia as a complaint on the part of the patient of poor or unsatisfactory sleep.' (Sateia *et al.*, 2000, p. 244.)

The progression of insomnia

Spielman *et al.*'s (1987) cumulative model provides a good conceptual framework from which to examine the course of insomnia. Based around the premise that insomnia is a hyperarousal disorder (cognitive, affective, biological and cortical in nature) Spielman *et al.*'s model suggests existing predisposing factors make some more vulnerable to insomnia than others. These predisposing factors are compounded by precipitating events, resulting in acute insomnia, which, in turn, is maintained by perpetuating cognitions and sleep disrupting behaviours after the severity of the precipitating stressor has lessened, resulting in a cycle of chronic insomnia. However, Spielman also contends that certain conditions (specifically illnesses which affect the central nervous system, chronic pain, depression and neurological disorders) would circumvent or limit the applicability of any psycho-behavioural aspects of the model.

Predisposing factors

Personality characteristics have been the most commonly examined in relation to predisposing factors. Characteristics such as a vulnerability to worry or depression, ambitiousness, neuroticism and maladaptive perfectionism have been identified. However, other researchers have found no specific personality traits pertinent to insomnia (Salin-Pascual *et al.*, 1992).

One possible explanation for this disparity may be the population under study, either general population or clinical. Considering up to 70% of people with chronic insomnia do not seek treatment (Gallup, 1995), significantly higher scores on neuroticism, depression and hostility scales have been found for those who seek treatment

compared with those that do not (Stepanski *et al.*, 1989) (see 'Symptom perception' and 'Personality and health').

Bonnet and Arand (1996) addressed the nature of the relationship between personality and insomnia by inducing insomnia sleep parameters on non-insomniacs. They found mimicking insomniacs' sleep patterns did not lead to similar personality profiles associated with reporting insomnia. Similarly, restricting the sleep of insomniacs even further than 'normal' did not lead to higher scores on traits such as neuroticism (Bonnet & Arand, 1998). They conclude that specific 'trait-like' personality characteristics (e.g. neuroticism) can predispose an individual to chronic insomnia.

Precipitating factors

A stressful life event, either positive or negative, has been the most implicated precipitating factor in insomnia research. However, many insomniacs cannot define a particular stressful life event pre-dating the onset of their insomnia, and stress perceptions have been shown to be poorly related to levels of sleep disruption. More recent research has explored the possibility that it is the style of coping that may relate to insomnia as opposed to the stressor *per se*. To that end, links between the onset of insomnia and maladaptive cognitive coping styles have been advanced (Ellis & Cropley, 2002) (see 'Stress and health').

Perpetuating factors

The cumulative model states that sleep-incompatible cognitions, behaviours and environmental conditions (i.e. sleep hygiene) can perpetuate the course of insomnia and are generally outlined in most self-help books and initial consultations with a healthcare provider. Sleep hygiene includes the moderation of nicotine, caffeine and alcohol; keeping a structured sleep/wake routine; creating a sleep-conducive environment (cool, dark and quiet); a relaxing pre-bed routine; regular exercise; and only using the bedroom for sleep-compatible behaviours (i.e. sleep and sex). Where changes in bedtime routine and environment have been shown to relieve insomnia in some cases, sleep hygiene has shown little efficacy when used as a singular intervention strategy (Chesson *et al.*, 1999). Additionally, differences in sleep hygiene practices between insomniacs and normal sleepers have not been found (Ellis *et al.*, 2002; Harvey, 2000). However, as studies have generally examined differences between insomniacs and normal sleepers, the possibility remains that a pre-existing vulnerability to sleep-incompatible behaviours may exist.

One perpetuating factor has, however, been consistently highlighted in relation to chronic insomnia: disproportionate or dysfunctional sleep-related cognitions (Roehrs *et al.*, 2000). This area of research has produced several cognitive models of insomnia, although the main cognitive factors that relate to insomnia are reporting dysfunctional beliefs about sleep and utilizing negative cognitive coping strategies.

Treatment

Although the most common treatment for insomnia, since their introduction in the 1970s, has been the use of benzodiazepines

(BZS), there is considerable controversy about their use (see 'Drugs: benzodiazepines'). Guidelines from the Committee on Safety in Medicines (1988) suggest the use of BZS for short-term transient insomnia for a maximum of four weeks. However, in 2002 the Department of Health in the UK reported 12.7 million prescriptions for BZS, 30% of which were for more than 56 tablets (indicating long-term use). The prolonged use of BZS has been associated with a host of problems including tolerance, rebound insomnia, addiction and falls in older adults. Consequentially, new benzodiazepine receptor agonists (i.e. Zaleplon and Zolpidem) have shown comparative efficacy to BZS with less tolerance and rebound.

More recently, previous non-pharmacological treatments such as sleep restriction therapy (reducing actual time in bed to what is biologically required) and stimulus control (re-associating the bedroom with a rapid sleep onset) have been forged into multicomponent cognitive behavioural interventions which also address dysfunctional beliefs about sleep and maladaptive coping strategies (see 'Behaviour therapy' and 'Cognitive behaviour therapy'). This therapy appears to be highly efficacious and robust over time as it addresses the myriad problems associated with many different insomnia sub-types (Morgan *et al.*, 2004).

Spina bifida

Ineke M. Pit-ten Cate and Jim Stevenson

University of Southampton

Spina bifida is a congenital neural tube defect, characterized by a fault in the spinal column in which one or more vertebrae fail to form properly leaving a gap or split. Spina bifida occulta is a common condition in which the bones may be incomplete but the defect is covered by skin and the spinal cord usually is unaffected,

hence most people do not have any symptoms or clinical problems. Spina bifida aperta refers to an open defect of the spine in which the spinal cord does not form properly and is exposed. There are two forms; meningocele and myelomeningocele. In meningocele, the visible cyst on the back contains cerebrospinal fluid (CSF) and the

meninges but no nerve tissue. In the more common and serious myelomeningocele, the cyst contains both the nerve tissue and its coverings, hence there is always some degree of paralyses and loss of sensation below the affected vertebrae. Spina bifida is often associated with malformations of the brain stem and cerebellum (Arnold Chiari malformations) and hydrocephalus (Shonkoff & Marshall, 1990). Hydrocephalus occurs when there is an abnormal accumulation of CSF within the ventricles and or subarachnoid space of the brain.

The incidence of spina bifida varies from country to country, for example, the incidence in Ireland is 8 per 1000 live births whilst in South East Asia the condition is rare (Chauvel, 1991). In 2002 the reported rates in England and Wales for Spina bifida were 1.0 per 100 000 births (Office for National Statistics, 2004); however reporting into the National Congenital Anomaly System is voluntary and therefore these figures may be conservative.

Associated problems

The extent to which children with spina bifida experience associated problems partially depends on the level of lesion and the nerve damage involved. Such problems can include lower extremity motor impairment, sensory loss and bowel and bladder dysfunction. Children with spina bifida and hydrocephalus typically have additional brain abnormalities, further affecting neuropsychological functioning (Wills, 1993). The prognosis is poorer if the level of lesion is higher, there is associated hydrocephalus and/or kyphosis/scoliosis and when there is associated perinatal trauma or congenital organ system anomalies (Chauvel, 1991).

In general, children with spina bifida function within the low average range of intelligence, with better performances on verbal tasks than non-verbal tasks (Brookshire *et al.*, 1995). Data from a longitudinal study (Brookshire *et al.*, 1995), suggested that these differences do not reflect the motor demands of the non-verbal tasks, but may be attributable to neuropsychological deficits associated with white matter abnormalities (Donders *et al.*, 1991). This notion is supported by the findings of Dise and Lohr (1998) who reported that subjects with spina bifida aged 10–23 years experienced problems in at least one domain of executive function, regardless of their lesion level or IQ. Children with spina bifida often display academic problems, including arithmetic, spelling and reading comprehension (see Wills, 1993 for a review).

There may be social disadvantages such as decreased opportunity for peer relationships, prolonged dependency on parents and decreased community acceptance (Castree & Walker, 1981). Repeated findings of psychopathology and low self-esteem have been reported for children and adolescents with spina bifida, (e.g. Ammerman *et al.*, 1998). Results of a study by Dorner (1975) suggested that impaired mobility is associated with both social isolation and feelings of depression of the adolescent with spina bifida (see also 'Disability'). However, in more recent studies elevated levels of behaviour and social competence problems were not associated with disability parameters such as level of lesion, ambulatory status, or bladder function (Ammerman *et al.*, 1998). Not all aspects of self-esteem may be affected. For example, Appleton *et al.* (1994) reported that although children with spina bifida scored significantly lower on athletic and scholastic competence and peer

acceptance, their ratings of physical appearance, behavioural conduct and global self-worth were similar to scores of able-bodied peers.

The quality of life (QOL) of children with spina bifida may be adversely affected by the functional and psychosocial limitations associated with the condition (see also 'Quality of life'). The child health related QOL of children with spina bifida and/or hydrocephalus has been found to be significantly lower than for children with other chronic physical disorders (Pit-ten Cate *et al.*, 2002). Child health-related QOL scores were affected by severity of condition but also by the availability of resources to families.

Impact on the family

Families of children with spina bifida experience higher levels of parenting stress than families of non-disabled children (Holmbeck *et al.*, 1997). Major predictors of the impact of spina bifida on the family include the number of activities of daily living affected, and parents' perceptions of child health (Havermans & Eiser, 1991). Other important factors include maternal education, family income, number of adults in the family, number of visits to the doctor and parent employment (McCormick *et al.*, 1986). Dorner (1975) reported high rates of depression in mothers of adolescents with spina bifida, irrespective of the adolescents' physical impairment. Holmbeck and Faier-Routman (1995) reported that differences in family functioning were associated with lesion level but not shunt status. Mothers of children with higher lesion levels reported a greater willingness to grant autonomy and less parent-adolescent conflict and were more attached to their children. Kronenberger and Thompson (1992) reported that the psychological symptoms of mothers of children with spina bifida were not associated with medical indices of severity. However, significant associations were found between maternal psychological symptoms and mothers' appraised stress pertaining to the child's condition, mothers' emotional reaction to the child's condition and to other life crises. Social relationships may also play an important role in maternal adjustment (see 'Social support and health'). For example, Barakat and Linney (1992) reported that social support was related to better maternal and child adjustment in both families of children with and without spina bifida.

It is important to acknowledge that families of children with spina bifida may not be adversely affected and that for some the experience may hold some positive benefits. In a study involving mothers of children with a chronic illness, maternal reports reflected a broad capacity to give positive meaning to the impact of the child's condition on the family. More specifically, almost 90% of the mothers reported feeling better about themselves by learning to manage their child's condition, 80% reported their family had benefited from the experience in some way and 70% reported increased family strength (Chernoff *et al.*, 2001). In a study involving 20 parents of children with spina bifida and/or hydrocephalus, parents were able to identify positive as well as negative experiences in raising their child with a disability. These experiences were associated with strong emotions and affected family life in both the short and long term (Pit-ten Cate, 2001).

Long-term outcome

Few studies have been concerned with the long-term outcome of spina bifida. An exception is a prospective study set up in 1963 to study the affect of non-selective treatment of spina bifida aperta. Over the last 35 years the cohort ($N = 117$) was contacted to review survival, disability, health and lifestyles (Oakeshott & Hunt, 2003). In 2002, 54% ($N = 63$) of the original sample had died of a variety of reasons, including cardiorespiratory or renal failure, hydrocephalus and central nervous system infection. For the 54 survivors (mean age 35 years) the outcome ranged from apparent normality to severe disability, with extensive paralysis, severe learning disability and blindness (see also 'Blindness and visual disability'). Most had shunts inserted and less than a third of the sample was continent ($N = 11$) or mobile without aids ($N = 16$). About 40% of the survivors ($N = 22$) led independent lives, i.e. managing their own transport, continence care and medical needs and about one-third lived in

sheltered accommodation. Twenty (all severely disabled) survivors needed daily help mainly provided by parents. Thirteen survivors, five of whom were wheelchair-dependent, worked in open employment. Seven women and two men had a total of thirteen children, none of them with spina bifida (Hunt & Oakeshott, 2003).

Conclusion

Spina bifida may have a long-term impact on the life of people affected and their families. The affect of the condition is determined by functional and psychosocial limitations. Outcomes range from relative normality, with people leading independent lives, to severe disability, including learning disability and sensory impairments. In considering the affect of disability it is important to acknowledge potential detrimental affects as well as positive benefits.

Spinal cord injury

Paul Kennedy

University of Oxford

Aetiology, incidence and prevalence

The successful rehabilitation and community reintegration of people with spinal cord injury (SCI) has only occurred in the past 60 years. Until rehabilitation was pioneered by Guttmann at Stoke Mandeville in 1944, 90% of persons with a spinal cord injury died within the first year. Now, most industrialized economies provide comprehensive treatment and rehabilitation care for people with traumatic and non-traumatic injuries. Almost half (47%) of traumatic spinal cord injuries are caused by road traffic accidents (see 'Road traffic accidents'). Domestic and industrial falls are the cause of 27%, and between 15 and 20% are from sporting injuries. In the UK, 5% are caused by self-harm and 0.5% from acts of violence. In the USA, 15% of injuries are caused by criminal assault (Duff & Kennedy, 2003; Go *et al.*, 1995). Causes of non-traumatic injuries include infective diseases, ischaemic insults, neoplastic disorders and multiple sclerosis (see also 'Multiple sclerosis' and 'Stroke').

There are four males for every one female spinal cord injury. The mean age is 28 and the mode is 19. The annual incidence of spinal cord injury in the UK, like most other European countries, is between 10 and 15 per million; in the USA it is thought to be between 30 and 40 and in Japan, 27 per million. There are an estimated 40 000 people in the UK and 200 000 in the USA with spinal cord injury. Life expectancy estimates vary: for a young, person with an incomplete injury the relative (to normal population) survival is 96%, but for complete tetraplegics over 50, it is estimated to be 33%. A reasonably good life expectancy is probable for most people. Primary causes of early mortality include pneumonia, septicaemia, heart disease and pulmonary emboli.

The physical impact

An injury to the spinal cord occurs when sufficient force causes the cord to be compressed, lacerated, or stretched and may be associated with a fracture or fracture-dislocation of the vertebral column and displacement of the inter-vertebral discs. These hyper-extension injuries are often the consequence of sudden impact as with car accidents and falls. The neurological losses will depend upon completeness of the injury. Cervical (neck) injury may result in tetraplegia (quadriplegia). Injuries to the thoracic, lumbar and sacral levels (upper, middle and lower back) may result in paraplegia. Of injuries, 53% are neck injuries and 47% are back injuries. A complete injury is one in which all motor and sensory functions are lost below the level of the injury, as well as the loss of control of visceral functions, such as bladder, bowel and sexual

function. In paraplegia, lower trunk muscles are impaired whilst cervical injuries result in loss of function in the hands, arms, shoulder and diaphragm, as well as the lower thorax. Complete injuries above the seventh cervical segment may preclude the possibility of independent living. Sensory losses are similar to the areas of motor loss, and include loss of touch, pressure, temperature regulation and position. The loss of sexual sensation and responsiveness, control of bladder and bowel function are common to all complete lesions above the sacral roots. Incomplete injuries may result in partial damage of the cord. Complications post-discharge include pressure sores, urinary tract infections, muscular spasm and chronic pain.

Rehabilitation

Most people are transferred to a specialist spinal cord injury treatment and rehabilitation centre shortly after the onset of the disorder. Once any fracture is stabilized, generally through internal fixation, or, more rarely, external fixation or postural reduction, the person begins a period of rehabilitation which can last between three and six months, depending on the level of the injury and social circumstances. Rehabilitation enables the person to acquire new skills to address their needs and adjust physically, socially and psychologically to their physical disability (see 'Disability'). This includes learning to manage bladder and bowel functions, wheelchair use and the maintenance and development of functional independence skills. Exploring adaptations to accommodation, financial independence and personal assistance needs may also be necessary. People also require information about their new needs and emotional support in maintaining general psychosocial wellbeing.

Psychological reactions

A spinal cord injury requires major adjustments to physical, psychological and social domains. The extent to which people manage the consequences of the disability will depend on internal psychological factors, such as self-efficacy, beliefs about disability and coping strategies and external factors, such as prevailing social attitudes and social support (see 'Self-efficacy and health', 'Social support and health' and 'Lay beliefs about health and illness'). The cultural beliefs that underpin social policy are important, given that it is not the specific disability that causes most of the difficulties, but existing within physical, psychological and socially disabling environments.

The immediate psychological impact of the injury may be compounded by severe pain and disturbed consciousness because of brain injury, medication or sensory deprivation. Trieschmann (1988) points out that, in the acute phase, psychological disturbances may result from sensory responses to injury, the hospital environment and procedures utilized in the survival of the person, rather than consideration of the spinal cord injury itself.

Psychological impact

Many studies have explored both the psychological impact and psychological adjustment factors. Early researchers explored psychological adjustment to spinal cord injury in the form of a variety of stages. Whilst these models may have had some utility in recognizing and normalizing emotional reactions, there is little empirical evidence that stages exist and have been seriously challenged in the past two decades, (Galvin & Godfrey, 2001). The contemporary view emphasizes rehabilitation as a multi-factorial process, which recognizes the important contribution that coping and appraisal strategies make to adjustment (see 'Neuropsychological rehabilitation').

The emotional impact is typified by increased levels of depression, anxiety (and associated avoidance behaviours), indirect self-destructive behaviour, increased suicidal ideation, communication problems and social isolation. However, negative emotional responses are not universal. Estimates of the prevalence of depression, using clinical interview and standardized measures, indicate that 20–34% of people during the acute rehabilitation phase are depressed (Kennedy *et al.*, 2000; Elliott & Frank, 1996). Despite psychological function improving with time since injury, Krause and Crewe (1991) found that significant levels of psychological distress do persist in some individuals. Kennedy and Rogers (2000) found that case levels of depression were between a quarter and a third during the two years after discharge. Other research shows that suicide is the second leading cause of death for individuals with paraplegia (De Vivo & Stover, 1995) with a standard mortality ratio of 4.9 (De Vivo *et al.*, 1991). Suicidal ideation is more common and 34% of spinal injured persons engage potentially harmful forms of self-neglect (see also 'Suicide').

Spinal cord injury also has an impact on family members and the social context. Recent studies suggest that there are fewer marriages and more divorces than in the able-bodied population, although people who marry after injury are generally happier, more independent and sexually active than those who were married before their injury (Crewe *et al.*, 1979). Divorce rates have been reported to be anywhere from 8% to 48%. It appears that divorce rates tend to decline to the normal rate for the general population after the initial high-risk period. Some studies have shown that marital status is a powerful predictor of independent living outcome variables (Kreuter, 2000). Crewe and Krause (1992) found that individuals in post-injury marriages were a select group and that the experience of marriage further strengthened their satisfaction with life and with their own adjustment.

In people with complete spinal cord injury, sexual function is usually impaired. Males and females lose their ability to experience orgasm and general neurophysiological sexual responsiveness.

However, some males retain the capacity for reflex erections and some people report 'phantom' orgasms. Despite these losses, many people engage in sexual activity and 57% rated post-injury sexual relations as satisfying, or at least as satisfying as pre-injury (Siosteen *et al.*, 1990) (see also 'Sexual dysfunction').

Psychological adjustment and quality of life

Factors that influence adjustment, such as personality characteristics, level of injury and social supports have been investigated. There is no evidence (Trieschmann, 1988) that any personality pattern is associated with having a spinal cord injury. Frank and Elliott (1989) found that spinal cord injured people with more fatalistic beliefs about their health post-discharge tended to be more depressed. Morris (1992) reviewed studies of attributional style and found that acceptance of disability was unrelated to any attributional tendency (see 'Attributions and health'). Whilst counter-intuitive, there is a general consensus that the severity of injury does not predict positive adjustment (Kennedy *et al.*, 2000; Trieschmann, 1988). Krause and Crewe (1990) followed a cohort from 1974 until 1984 and their results confirm research findings that quality of life improves with time. Positive levels of satisfaction and psychological status were maintained with increases in marriage rates and hours spent working. Social support is beneficial to long-term adjustment, even at six weeks post injury. Kennedy *et al.* (2000) found that social support was negatively correlated with depression, anxiety and intrusive thoughts (see 'Social support and health').

Coping

The stress appraisal and coping model developed by Lazarus and Folkman (1984) has provided the theoretical underpinning for most research in this area (see 'Stress and health'). Reidy *et al.* (1991) explored coping strategies among 54 individuals with recently acquired traumatic spinal cord injury and report that patients rely most strongly on the strategies of social support, positive re-appraisal and planful problem-solving. In a two-year follow-up, they noted a decrease in seeking social support. Depression was found to have a strong correlation with the use of the escape/avoidance strategies. They conclude that proactive problem-focused coping strategies are associated with positive mood and little psychological distress. Bombardier (1992), using a multiple-assessment longitudinal design, found that emotion-focused coping styles are associated with poorer outcomes following spinal cord injury. Findings from the largest, standardized longitudinal study to date, used a multiple wave panel longitudinal design to follow a cohort of 87 people with spinal cord injury from onset until two years post-discharge (Kennedy *et al.*, 2000) indicated that the coping strategies of 'behavioural disengagement', 'mental disengagement', 'denial' and 'alcohol/drug use ideation' are associated with poor psychological adjustment. A lack of psychological difficulties was associated with 'acceptance of the injury'. Overall, coping strategies were more predictive of levels of depression and anxiety than organic moderating factors such as functional independence, sex, age, income and class (Kennedy *et al.*, 2000).

Psychological interventions

The main aims of psychological intervention with spinal cord injured people are to foster coping and adaptation, preserve social value and maximise the rehabilitation potential. This is achieved by individual and group psychotherapy, working with relationships and underpinning rehabilitation programmes with behavioural principles (see 'Behaviour therapy'). Counselling helps people express their concerns, consider coping strategies and accept the consequences of the illness or injury (see 'Counselling'). During rehabilitation, many people are confronted with change and experience a sense of loss. Whilst depression may emerge as part of a normal response, it can precipitate distorted modes of thinking, which generate negative beliefs about disability. Tirsch and Radnitz (2000) suggest six categories of cognitive distortions following spinal cord injury: (1) an overly negative view of the self and others; (2) negative appraisals of self following injury; (3) expectation of rejection; (4) expectation of failure; (5) development of excessive personal entitlement; and (6) an over-developed sense of vulnerability. Cognitive behaviour therapy is used to identify and challenge such negative beliefs using techniques such as self-observation, problem-solving and graded exposure (Kennedy, 1991; Crewe & Krause, 1987) (see 'Cognitive behaviour therapy'). In the early stages, many people over-estimate the negative aspects of the injury and under-estimate their skills, resources and competence levels.

Elliott and Kennedy (2004) in an evidence-based review of treatment studies found nine that met their inclusion criteria. Most of the psychological studies used a group intervention format. Craig *et al.* (1998) used a cognitive-behavioural intervention to effectively reduce depression compared to controls. Kennedy *et al.* (2003) and King and Kennedy (1999) adapted and developed a coping effectiveness training programme for people with spinal cord injuries. Results revealed that participants in the intervention group showed a significant reduction in depression and anxiety compared to matched controls, although there was no change in the pattern of

coping. However, Elliott and Kennedy (2004) conclude in their review that there is a need for more randomized controlled clinical trials of psychological interventions.

Individuals and couples also require access to sexual counsellors. The P-LI-SS-IT model developed by Annon (1974) is one of the most useful. This approach allows counsellors to structure an intervention according to the counsellor's level of competence. It begins with 'Permission giving', which refers to a general responsiveness to the discussion of sexual concerns. This is followed by the provision of 'Limited Information' such as through teaching sessions, education materials and videos. 'Specific Suggestions' may then be offered to individuals or couples which highlight changes in sexual function and techniques for maintaining activity. This may be followed by 'Intensive Therapy' whereby techniques such as Masters and Johnsons' sensate focus may be required (see also 'Sexual dysfunction').

The focus of rehabilitation is on changing behaviour, Trieschmann (1988) describes rehabilitation in terms of behaviour, and as a lifelong process, Norris-Baker *et al.* (1981) proposed that long-term adjustment could be predicted by engagement and rehabilitation. Developing this theme and linking it to Treatment Theory (Keith & Lipsey, 1993), Kennedy and his colleagues have developed a behavioural intervention framework known as goal planning. Kennedy and Pearce (1993) used goal planning successfully to identify individual needs and increase engagement in rehabilitation. This involved the development of a Needs Assessment Checklist of basic behavioural indicators (Berry & Kennedy, 2003), the training of key workers and regular progress review meetings (Duff *et al.*, 2004). The key strategies include involvement of clients, emphasising strengths and needs, setting specific detail about the who, what, where and when and utilizing a multidisciplinary approach. Goal planning provides a forum for the provision of regular positive feedback on mastery of specific issues, thereby minimising helplessness and fostering self-efficacy.

Sterilization and vasectomy

Robert J. Edelman

Roehampton University

Sterilization, either in the form of tubal ligation for women or vasectomy for men is a widely used method of contraception. Indeed, figures indicate that during the 1990s tubal ligation was the world's most popular contraceptive method used by some 138 million women of reproductive age worldwide (Chi & Jones, 1994). Amongst couples who use some form of contraception, approximately half opt for sterilization, with female sterilization just exceeding the rate of male sterilization (Forest & Fordyce, 1988). Interestingly, during the 1990s the United Kingdom witnessed a decline in the popularity of tubal ligation so that the UK is now one of the very few countries in which sterilization incidence in men is greater than that in women (Rowlands & Hannaford, 2003). There are many possible explanations for this including variability

across countries in the availability of both counselling and alternative contraceptive methods.

Even though it is possible to reverse both tubal sterilization and vasectomy with microsurgical techniques the chances of an attempted reversal actually resulting in a subsequent pregnancy are so uncertain that it is generally treated as an irreversible course of action.

Numerous studies from many countries have examined the social and psychological correlates of voluntary sterilization. However, it is worth noting that many are descriptive and lacking in methodological rigour. It is only within the last two decades that more rigorous research studies have enabled more substantive conclusions to be drawn. Two broad sets of psychosocial issues have been explored

in relation to sterilization: (i) factors influencing the couple's decision about contraceptive method and (ii) the outcome from sterilization in relation to (a) the couple's marital and sexual relationship, (b) the incidence of psychological/psychiatric problems and (c) post-sterilization regret and the consequent wish for reversal of sterilization.

Factors influencing the couple's decision about contraceptive method

Although the evidence is equivocal, research findings tend to suggest that women who are sterilized are slightly more disadvantaged socially than those who opt for other methods of contraception. They also tend to have more children and are more likely to have given birth before the age of 20 years. On the other hand, men on higher incomes and with a higher level of education seem to be well represented amongst those choosing vasectomy as a method of contraception, at least in the United States (Barone *et al.*, 2004). However, the most important factor determining use of sterilization rather than an alternative method of contraception is a decision by the couple that their family is complete (Hunt & Annandale, 1990).

Relatively few studies have been conducted to examine psychosocial factors predictive of choice of sterilization method. However, there is some evidence to suggest that, while vasectomy is chosen because it is perceived as easier and tubal sterilization because of its convenience (frequently being conducted at the time of delivery), it is the spouse who most wants to stop childbearing who is most influential in the decision about which method of sterilization to use (Miller *et al.*, 1991a).

Outcome after sterilization

The couple's marital and sexual relationship

In the most recently published review evaluating the effect of both male and female sterilization on sexual desire, sexual functioning and the couple's marital and sexual relations, Philiber and Philiber (1985) note that, in the majority of studies worldwide, 'no change' is the most frequently endorsed response to such questions. This result is irrespective of the sterilization method used. A similar conclusion was by reached by both Thonneau and D'Isle (1990) and Rogstad (1996) reviewing research focusing purely on the effects of vasectomy on the male's sexual relationship. However, in both the earlier reviews the authors noted that the lack of good studies meant that a cautious interpretation of results was required.

However, carefully designed longitudinal studies published since those reviews provide confirmatory evidence that neither tubal ligation nor vasectomy effect marital and sexual functioning. In one such study published after the two earlier reviews cited above, Shain *et al.* (1991) concluded that neither tubal sterilization nor vasectomy had any detrimental effects on female sexuality and, indeed, both procedures seemed to offer some short-term benefits. In a more recent study, Hofmeyr and Greef (2002), who administered measures to men prior to and five months after undergoing a vasectomy, found no post-vasectomy change in

sexual satisfaction, marital satisfaction, communication or frequency of sexual intercourse.

The incidence of psychological/psychiatric problems

There is a large and conflicting literature on the incidence of psychological problems and/or psychiatric disorder subsequent to sterilization. In the case of tubal sterilization, estimates of psychiatric morbidity after surgery have varied widely, from a high of 60% to a low of 8.8% (Philiber & Philiber, 1985). Figures have tended to be lower in more recent research, which no doubt partly reflects the increased use of standardized and more accurate methods of psychiatric assessment. Garth and Cooper (1983) concluded from their own findings that 'the operation seldom leads to psychiatric disorder' (p. 235). Psychological or psychiatric problems which do occur tend to be associated with preoperative psychological or psychiatric disturbance (Cooper *et al.*, 1985).

Such conclusions seem to be sound and generally accepted and more recent studies have not addressed this topic. In short, it seems reasonable to conclude that, for a small minority of women, sterilization will act as a precipitating factor for psychiatric disturbance while, for the majority, there seem to be no ill effects.

The most recent review of research on the somatic and psychological consequences of vasectomy also suggests that there is no evidence that the procedure is associated with either physical or mental health problems (Thonneau & D'Isle, 1990).

Post-sterilization regret

There is evidence that post-sterilization regret, particularly in the case of women, may be a problem of considerable magnitude. In Europe and North America reported rates of regret for women range from less than 10% to as high as 43%, with reported rates of regret amongst men tending to be less than 5% (Philiber & Philiber, 1985). A longitudinal study conducted over a 5-year period during the late 1980s indicated that the major pre-sterilization predictors of regret for women included being relatively young, being ambivalent about future childbearing, holding negative attitudes towards sterilization and the woman's husband being dominant in the decision-making process during which time she was in conflict with her husband (Miller *et al.*, 1991b). The most recently published review of post-sterilization regret amongst women reinforces these conclusions (Chi & Jones, 1994). These authors found that young age at sterilization together with the death of an infant or child were universally strong risk factors for regret.

The most recently published review of regret for both males and females who have undergone sterilization suggests a comparable picture for both genders. In each case the major predictors of post-sterilization regret were preoperative motivation for further childbearing, poor couple communication, high levels of conflict during decision making and dominance of decision making by one spouse (Rogstad, 1996).

Miller *et al.* (1991b) have argued that post-sterilization regret is not a simple psychological state but a complex process which begins with a renewed interest in having a baby, proceeds to the development of negative feelings about the set of decisions which

led to sterilization (i.e. the decision to terminate childbearing, to use sterilization as opposed to other contraceptive methods and which member of the couple was to be sterilized) and concludes with a desire to reverse the surgery.

Those requesting reversal are, however, far fewer than those who voice regret (Philiber & Philiber, 1985). The most frequently cited reason for reversal of both tubal sterilization and vasectomy is a change in marital status, that is, a desire to have a child with a new partner.

A number of authors (e.g. Miller *et al.*, 1991b) have argued that the best prevention of regret lies in adequate pre-sterilization counselling and information provision. Interestingly, when counselling is

offered, many women fail to attend and do not proceed to sterilization. In addition, of those who do attend for counselling many then also opt to choose other reversible forms of contraception (Mattinson & Mansour, 2003). Evidence suggests that many women are still unaware of highly effective, long-term reversible contraception, opting instead for what they perceive to be the 'straightforward, permanent choice'. Clearly, accurate information and informed counselling is important to allow discussion both of sterilization as well as the full range of alternative contraceptive methods. An informed choice is likely to reduce the likelihood of subsequent regret.

(See also 'Contraception'.)

Stroke

John Pimm

Vale of Aylesbury Primary Care Trust

Definitions, epidemiology and impact

The word 'stroke' is used to refer to a clinical syndrome, of presumed vascular origin, typified by rapidly developing signs of focal or global disturbance of cerebral functions lasting more than 24 hours or leading to death (World Health Organization, 1978).

It affects between 174 and 216 people per 100 000 population in the UK each year, and accounts for 11% of all deaths in England and Wales (Intercollegiate Stroke Working Party, ISWP, 2004). Of the 100 000 people having a first stroke each year in England and Wales half are over 75 years, 10 000 are under retirement age and about 250 are children (UK Division of Clinical Psychology, DCP, 2002).

Ischaemic cerebral infarction accounts for 69% of strokes, primary intracerebral haemorrhage 13%, subarachnoid haemorrhage 6% and 12% are of uncertain type (ISWP, 2004).

Stroke has a major impact on people's lives. It is the leading cause of severe disability in older adults and the third most common cause of death in the UK and other developed countries. Within 1 month of stroke 30% die, 35% are still significantly disabled after 1 year and 5% need long-term residential care (Department of Health, 2001). A substantial proportion of health and social care resources are devoted to the immediate and continuing care of people who have had a stroke including 20% of acute hospital beds, 25% of longer term beds and 4% of UK National Health Service expenditure (Department of Health, 2001).

Specialist stroke care reduces mortality and can improve functional outcomes (ISWP, 2004). Integration of a psychological perspective in multi-professional treatment and care of stroke survivors facilitates assessment, rehabilitation and longer-term adjustment (DCP, 2002).

Psychological sequelae of stroke

Cognitive impairments

During the first few days most stroke survivors are confused, typically this resolves leaving more focal cognitive deficits (Wade, 1994). These include difficulty with memory, language, perception, attention, spatial awareness (neglect/inattention), controlling action (apraxia) and executive tasks (reasoning, planning, insight, initiation and monitoring of behaviour). The neurobehavioural sequelae are dependent in large part on the specific blood vessels compromised by the stroke (Lishman, 1998). Cognitive impairments tend to improve over the first 6 months but residual difficulties are common. At least 35% of stroke survivors have significant cognitive impairments (Tatemichi *et al.*, 1994).

Cognitive impairment can lead to uninhibited or disorganized behaviour, or difficulty moderating emotional expression or impulses. These difficulties are often viewed as 'personality change', and are particularly distressing to carers (DCP, 2002).

Emotional consequences

The changes in an individual's life and relationships after stroke usually follow a normal process of adjustment. However, a significant number of individuals experience difficulties in adjustment. Intense and pervasive emotional and behavioural disturbances, such as depression, anxiety, emotionalism and apathy are common. These may reflect brain damage, emotional disorders, adjustment processes or a complex interplay of these.

Depression

Some argue that symptoms of depression after stroke are indistinguishable from those with depression without brain injury (Aben *et al.*, 2001). However, disturbances of interest and concentration are common, guilt is less evident and variability of mood is characteristic (Fleminger & Oliver, 2003).

Prevalence estimates for post stroke depression (PSD) vary enormously between 10–64% probably due to differences in methodology and sample composition (Aben *et al.*, 2001). Depressive

symptoms occur frequently and often have a chronic course. Berg *et al.* (2003) followed up 100 people for 18 months after stroke. They found that, 54% reported at least mild symptoms of depression on the Beck Depression Inventory and 26% were diagnosed as having major depression at some time during the follow-up. Of those who were depressed during the first 2 months 46% were also depressed at 12 and/or 18 months. Only 12% were depressed for the first time at 12 or 18 months.

Several, but not all, studies have shown an increase in the prevalence of depression over the first year after stroke (Fleminger & Oliver, 2003). Overall 20–40% of people are affected at any point in time during the first year after stroke and about 50% experience depression at some stage (Fleminger & Oliver, 2003).

With regard to predictors of PSD, early suggestions of an association between left hemisphere or anterior lesions and depression were not supported by a systematic review (Carson *et al.*, 2000). The most consistent finding is that stroke severity and functional disability are strongly associated with PSD in the post-acute phase, when the person is likely to have increased awareness of the limitations resulting from the stroke (Berg *et al.*, 2003; Dennis *et al.*, 2000). The role of factors such as pre-stroke depression, cognitive function, illness cognitions, coping behaviours and treatment deserve further study (Dennis *et al.*, 2000) (see, for example, 'Lay beliefs about health and illness' and 'Coping with chronic illness').

Anxiety

Anxiety after stroke may be specific, such as a fear of falling, fear of meeting people, intrusive distressing memories or flashbacks to the stroke, or a generalized anxiety disorder not linked to any specific provocation (Bishop & Pet, 1995).

Generalized anxiety disorder (GAD) is common and often persists. Astrom (1996), studying patients with stroke or transient ischaemic attacks, found that 28% in the acute stage, 31% at 3 months and 24% at 1 year had GAD.

Schultz *et al.* (1997) found that from 3 months to 2 years post-stroke anxiety was associated with greater severity of depression and in the early stages with greater impairment of function. However, Dennis *et al.* (2000) found that at 6 months the relationship between disability and anxiety was less strong than for depression.

Emotionalism

The term 'emotionalism' is used to describe post-stroke disorders of emotionality such as pathological laughing and crying and emotional lability. Emotionalism is associated with an increase in depressive symptoms but many sufferers do not have depression (House *et al.*, 2004). Emotionalism affects about 20–25% of stroke survivors in the first 6 months. It tends to decline in frequency and severity over the first year, but even at 12 months about 10–15% remain affected (House *et al.*, 2004).

Families and carers

Many stroke survivors will return home with the bulk of care being provided by their families. Over time, the burden of physical, psychological, social and financial stress, coupled with erosion of precious family and leisure time and lack of external support, can contribute to anxiety, depression and a decline in the quality of life of the caregiver (Hankey, 2004). Carers of stroke survivors

frequently experience high levels of psychological morbidity (Low *et al.*, 1999). Some, but not all, studies have found that the stroke survivor's physical disability is associated with carer's emotional state (Low *et al.*, 1999). Cognitive, behavioural and mood disturbance in stroke survivors correlate with burden and emotional state in carers (Low *et al.*, 1999). Carers' illness perceptions, coping behaviours and self-efficacy are associated with emotional wellbeing in stroke carers (McClenahan & Weinman, 1998).

Psychological factors in stroke recovery

There is extensive evidence that psychosocial factors are important determinants of outcomes after stroke. Cognitive impairment following stroke has a negative impact on outcome (Diller, 2000). They adversely affect a person's ability to participate in rehabilitation, perform activities of daily living and live independently. Furthermore they are confusing and distressing for patients and carers (ISWP, 2004).

Emotional states, especially depression, have major negative effects on functional recovery (Chemerinski *et al.*, 2001). Abnormal mood impedes rehabilitation and, as a consequence, prolongs the adjustment process and increases the costs of rehabilitation (DCP, 2002). Social factors, such as the level of family involvement are also associated with success in rehabilitation (Evans *et al.*, 1991).

The potential contribution of social cognition variables to stroke recovery has been receiving increased attention (Rees, 2002). For example, stroke survivors' perceptions of control contributed significantly to the explanation of functional recovery three years after stroke (Johnston *et al.*, 2004).

Clinical implications and intervention

Cognitive rehabilitation

Clinical guidelines recommend that all people should be screened for the presence of cognitive impairments as soon as is practicable after stroke (see 'Neuropsychological assessment: general principles'). The nature of the impairment should be determined, and its impact on activity and participation should be explained to patients, carers and staff. Those with difficulty on screening, and anyone not progressing as expected in rehabilitation, should have a detailed cognitive assessment (ISWP, 2004). Cognitive screening instruments for use with stroke patients have been reviewed by Rees (2002).

Neuropsychological assessment provides a description of cognitive strengths and weaknesses, which assists in the development of a cognitive rehabilitation programme. It can also aid diagnosis, establish a baseline for monitoring recovery or deterioration, assist evaluation of capacity/competence to manage legal and financial affairs, and help with planning for return to independent living and work. There are a variety of approaches to cognitive rehabilitation, for example retraining of cognitive function, developing strategies to compensate for cognitive deficits, and neuropsychotherapeutic programmes. Cognitive rehabilitation has been demonstrated to have positive effects on difficulties such as

anosognosia and denial (Youngjohn & Altman, 1989); executive dysfunction (Honda, 1999); memory impairment (Majid *et al.*, 2004); disorders of attention (Lincoln *et al.*, 2004) and unilateral spatial neglect (Bowen *et al.*, 2004) (see 'Neuropsychological rehabilitation').

Intervention for emotional difficulties

Clinical guidelines recommend that people should be given information, advice and the opportunity to talk about the impact of stroke upon their lives. Psychosocial needs should be assessed; including screening for depression and anxiety within the first month after stroke, and following this mood should be kept under review (ISWP, 2004). Assessment of emotional difficulties is complex; for some people a standardized questionnaire can be used for screening, but for many this will not be appropriate. For those identified as having emotional difficulties, multi-modal assessment, involving clinical interview, standardized rating scales and interviews with staff/relatives, by an appropriately trained health professional are essential. Specific psychological expertise is needed for the identification and discrimination of adjustment disorders, emotionalism and depression (Kneebone & Dunmore, 2000).

Effective and efficient treatment of emotional difficulties following stroke will usually require a combination of approaches, for example rehabilitation counselling, patient-centred goal setting, motivational interviewing, pharmacotherapy, cognitive behaviour therapy and family therapy (see also 'Counselling', 'Motivational interviewing' and 'Cognitive behaviour therapy'). Selection of a particular intervention will depend on the nature of the emotional difficulty, cognitive function, insight, personal goals and the stage the person is in the process of recovery.

A systematic review of pharmacotherapy and psychological therapy for the treatment of PSD found evidence of an improvement in scores on depression rating scales, and the evidence suggests that psychological therapies may be at least as effective as antidepressant medication (Hackett *et al.*, 2004). A systematic review of interventions for the prevention of depression identified a small but significant effect of psychological therapy, but not pharmacotherapy, on improving mood (Anderson *et al.*, 2004).

Goal setting has been used with anxious patients to good effect (McGrath & Adams, 1999). House *et al.* (2004) concluded, from a systematic review of treatment for post-stroke emotionalism, that antidepressants can reduce the frequency and severity of crying or laughing episodes.

Working with families and carers

There is increased awareness of the need to take account of the views of patients and carers in the planning and organization of stroke services (Kelson *et al.*, 1998). If patients and carers are involved in decision-making about care, they can more actively participate in rehabilitation and prevention measures. Clinical guidelines recommend that the needs of carers be considered throughout the process of rehabilitation and long-term support (ISWP, 2004). Carers will usually need information, practical,

emotional, social and financial support and stroke services should facilitate access to these.

Several studies have evaluated strategies to reduce the burden of informal care giving for dependent stroke survivors. These include the provision of information and educational groups and access to services such as nursing, psychological counselling, emotional support, family support workers and social workers (Dennis *et al.*, 1997; Forster *et al.*, 2004; Mant *et al.*, 2000). These studies have shown modest benefits in emotional, psychological and social outcomes (Hankey, 2004). A recent randomized controlled trial has found that training caregivers in nursing care and facilitating activities of daily living during stroke patients' rehabilitation reduced health and social care costs and caregiver burden, while improving psychosocial outcomes in caregivers and stroke survivors at one year (Kalra *et al.*, 2004).

Conclusions

Stroke is a common disabling condition. It frequently leads to severe psychological consequences for stroke survivors and their families in the areas of cognition, emotion, behaviour and relationships. Research is beginning to examine the factors determining the psychological sequelae of stroke. There is considerable evidence that neuropsychological and emotional factors influence functional recovery from stroke and some evidence that social cognition variables may make a significant contribution. Evidence is beginning to accumulate on the efficacy of interventions for psychosocial difficulties. There are many areas where further research is needed (see DCP, 2002 for suggestions). Recent clinical guidelines recognize the need for stroke services to address psychological issues to improve outcomes for stroke survivors and their families.

Stuttering

Peggy Dalton¹ and Frances Cook²

¹PCP Association

²Michael Palin Centre for Stammering Children

Stuttering (often termed ‘stammering’ in the UK) is a disorder of speech rhythm or fluency. Speakers are prevented from saying what they want to say by involuntary repetition, prolongation or cessation of speech sound or syllable. In its more severe forms, breathing irregularities, facial contortions and bodily movements may accompany the act of speaking. Individuals who stutter are usually aware of their stuttering and it can be a cause of great anxiety and anguish to them and their families.

Diagnosing stuttering

In the past, diagnosis of stuttering was based on making a distinction between the dysfluency patterns described above and normal non-fluencies such as the repetition of whole words and phrases and the use of interjections where there is no sign of struggle or abnormal tension. More recent research has indicated that there are a number of overlaps between these two categories of speech and therefore parents and professionals expressing concern about a child’s fluency are likely to be reacting to real problems in the child’s speech (Yairi & Lewis, 1984).

It is generally agreed that stuttering may occur at any time during childhood but it usually starts for the majority of children by the age of 4 years (see Yairi & Ambrose, 1999; Mansson, 2000). Approximately 75% of young children who start to stutter will spontaneously recover. The aim is to determine which children are likely to regain fluency and which are more likely to persist in stuttering. The latest research suggests that girls are more likely to overcome the problem than boys. Recovery is more likely in

children where there is no family history of stuttering or there are relatives who have stuttered but have recovered. While stuttering may resolve many years after onset, the longer a child has been stuttering the less likely they are to recover (see Yairi & Ambrose, 2005).

There is a considerable body of research showing inheritance to be a major factor in many cases (Ambrose *et al.*, 1997) although the severity and type of stuttering does not seem to be governed genetically. Thus, a child does not inherit a stutter as such, more a tendency for speech to be disrupted. Stuttering can sometimes be caused by brain disturbances in children and adults and there is increasing prevalence associated with a number of neurological conditions (Sommer *et al.*, 2002). Contrary to popular belief, tests of neurological functioning have shown there to be no differences between those who stutter and those who do not, in terms of laterality as measured by handedness, dichotic word tests or the intracarotid sodium amylal test. People who stutter however, do perform less well on tests of central auditory function, auditory and visual voice reaction times and in auditory–motor tracking tasks (see Bloodstein, 1995). The search for constitutional differences, in particular in hemispheric functioning continues. It is unlikely that any one factor will be found to be common to all cases of stuttering.

The development of stuttering

The development of stuttering is related not only to the constitutional factors referred to but also to precipitating and

perpetuating factors to be found within the environment and within the speakers themselves. Conture (2001) describes stuttering as a 'complex interaction between the environment of the person who stutters and the skills and abilities the person who stutters brings to that environment.' Many clinicians support the notion that the child's family and social environment can play a key role in facilitating fluency and therefore some environmental modifications for young children who stutter can be beneficial.

Although the origins of stuttering can rarely be shown to be emotional, there is no doubt that, where stuttering continues, psychological factors play their part in perpetuating the disorder and can have damaging effects on the person's sense of self. Individuals who stutter are usually concerned about their stuttering and may be sensitive to other people's reactions to it. Teasing or bullying by others and the experience of anxiety in an increasing range of speaking situations can lead to loss of confidence and general feelings of inadequacy. At worst, communication will be avoided as far as possible, relationships with others will no longer be sought and the person's life may become severely restricted.

The treatment of stuttering

The literature frequently cites the sharp division between those clinicians who seek to eliminate stuttering by the use of speech techniques i.e. 'speak more fluently' approaches (e.g. Ryan, 2001) and those who help the person to 'stutter-more-fluently', in other words, to reduce stuttering by easing tension and struggle and reducing the anxiety of speech situations (e.g. Van Riper, 1973). However more recently clinicians are integrating these approaches to help clients learn skills to speak more fluently and to modify their moments of stuttering (e.g. Guitar, 1998) (see 'Voice disorders' and 'Communication assessment').

Therapy approaches for young children who stutter can also appear to be quite divergent in their theoretical rationale. They may be either indirect, direct or a combination of the two. Indirect therapy approaches focus on working with parents and are typically aimed at helping them to identify family interaction and management styles, which promote their child's natural fluency. Alternatively, some clinicians work directly on the speech as a primary intervention with young children who stutter. For example, the Lidcombe Programme (see Onslow *et al.*, 2003) is based on principles of operant conditioning and is a highly structured programme, carried out by the parents with the therapist's guidance. It involves the systematic reinforcement of fluent speech, along with, in some cases, a child being asked to self-correct their stuttering. A combined approach, for example, the Parent-Child Interaction Therapy Programme (Rustin *et al.*, 1996) will start with the family interaction and management styles and then, where necessary introduce direct speech strategies (see Self-management interventions).

Although, with older children, responsibility for working on their speech is gradually passed to them, parents and the rest of the family continue to play an important part. They can encourage the young people to undertake situations which they have

hitherto left to others: answering the telephone, introducing themselves, initiating conversation with visitors. It is not easy for them to tell people what the problem is and the therapist or other members of the family can help them to explain where this is necessary.

Many young teenagers work better in groups than in individual therapy. Here the focus is on developing confidence through the use of speech management strategies and social communication skills training initially in the clinic and then in real life situations. These could include going into shops, buying train tickets, telephoning, all of which can be a source of great anxiety to many of them. Tackling their fears in company with their peers does seem to help to overcome them. Standing up and speaking in front of a group may be unthinkable to begin with in a classroom situation, but experimenting with the experience in this group context can enable them to transfer the skill to school (see 'Group therapy').

There are a number of centres in Britain, where stuttering is the focus of speech and language therapy, most notably, the Michael Palin Centre for Stammering Children in London which provides specialist assessment and therapy for children who stutter.¹ The therapy offered includes both individual and group therapy, which essentially involves parents in the work. The City Lit, another specialist centre, also in London, offers a range of courses catering for the varying needs of adults who stutter.² The programme includes a range of speech therapy approaches but all pay attention to the psychological aspects of stuttering as well as teaching speech modification techniques. Courses are offered intensively or on an evening class basis and all therapy is group-based. Short workshops focus on specific topics such as phones or interview skills.

Psychological approaches

Whatever approach is taken to the treatment of stuttering some degree of attention is almost always paid to the psychological aspects (of stuttering), especially with adolescents and adults. Sometimes it takes the form of discussing the person's fears, helping them to find strategies to overcome them, perhaps enlisting the help of friends or family. Increasingly, however, established counselling approaches are used. Therapies such as cognitive-behaviour (Butcher *et al.*, 1993) and Adlerian (Clifford & Watson, 1987) have also been developed in this area. A widely used psychotherapeutic approach to stuttering in the UK is, however, George Kelly's personal construct psychology (1955, 1991), introduced by Fransella (1972). The aim here is first to explore with the client the personal meaning of stuttering, in order to discover the degree of preoccupation the person experiences, how it governs expectations of him or herself and others. For some, it is as if they are 'stutterers' and nothing but stutterers. The therapist attempts to help the person to elaborate other roles than that of a dysfluent speaker. What else is he or she? Mother, father, sports person, artist, civil servant and so on. At the same time, situations are construed in terms of their purpose, rather than possible failures in speech. This can bring about striking change in the person's life experience. A good deal has been written about this approach in the last fifteen years: for example, Heyhow and Levy (1989),

Dalton (1994), Stewart & Birdsall (2001) (see also 'Cognitive behaviour therapy').

It will be clear that no one approach will be appropriate for all those who stutter, just as there is no one causal factor common to them all. A therapist working with stuttering will need to have a wide range of knowledge and skill in selecting what will suit the particular person, always allowing the client to experiment and make the final choice (see 'Communication assessment').

Perhaps the most striking development in the last twenty years has been that of the British Stammering Association.³ Beginning as an association to encourage self-help groups it has developed, highly professionally, into a powerful source of information which

now has an international reputation. Projects related to public attitudes, the experiences of the speakers themselves, bullying at school, difficulties at work and many others have been carried out.

Suicide

David Lester

Center for the Study of Suicide

Suicide refers to a range of self-destructive behaviours ranging from non-fatal acts which have been called suicidal gestures, attempted suicide, parasuicide self-injury, or if poisoning is used, self-poisoning, and more recently deliberate self-harm, to fatal acts in which the person dies, commonly called completed suicide.

The epidemiology of suicide

Rates of completed suicide range from 0.8 per 100 000 people per year in Azerbaijan and 1.6 in Kuwait (in 2000), according to the latest World Health Organization figures (now online at www.who.int), to 44.1 in Lithuania and 39.4 in Belarus (in 2000). The rate in the USA was 10.4 (in 2000) and in the UK 7.2 (in 2000). It is estimated that perhaps there are ten suicidal attempts for every completed suicide, indicating that rates of attempted suicide may reach as high as 440 per 100 000 per year.

Official rates of completed suicide have been criticized for their inaccuracy, especially because of the reluctance of some coroners, medical examiners and police officers to certify deaths as suicide. Studies by researchers in the UK (e.g. Cooper & Milroy, 1995) have found that up to 40% of apparent suicides are not recorded as suicides by the coroners. However, although official rates of completed suicide may be lower than the actual incidence, studies have shown that completed suicide rates among immigrant groups to nations (where their deaths are certified by the same coroners) are in roughly the same rank order as the rates in their home nations, indicating some degree of validity (Sainsbury, 1973).

In almost every nation, completed suicide is more common in men whereas attempted suicide is more common in women, although this gender difference is smaller in Asian nations than elsewhere. Recently, mainland China has reported suicide rates based on 145 National Disease Surveillance Points which indicate that female suicide rates are 30% higher than male suicide rates (Phillips *et al.*, 2002). The reasons for this reversal are unclear at the present time (see 'Gender issues and women's health').

In developed nations, completed suicide rates rise with age, sometimes peaking in middle age (especially for women) and sometimes in old age (Lester & Yang, 1998). In less developed nations and among aboriginals, completed suicide rates are often higher in young adults. The last few decades have also witnessed rising youth suicide rates in many, but not all, nations, primarily in young males. Islamic nations appear to have low rates of completed suicide (Lester, 1996).

At the societal level, the classic theory of Emile Durkheim, first published in 1897, remains the major explanatory theory. Durkheim (1897) proposed that social integration (the degree to which the members of the society are bound together in social networks)

and social regulation (the extent to which the society governs the desires and the behaviour of its members) determine the suicide rate. In modern societies, too little social integration results in *egoistic* suicide while too little social regulation results in *anomic* suicide. This theory explains, for example, the strong association between divorce and suicide rates both across nations and, within any nation, over time. Suicide resulting from very high levels of social integration and social regulation are called *altruistic* and *fatalistic* suicide, respectively.

The neurophysiology of suicide

There is no evidence that the tendency to suicide per se is inherited. However, suicide is more common in those who have a psychiatric disorder, and there is strong evidence that psychiatric disorder has a genetic component. Thus, suicide may run in families and be more common in monozygotic twins than in dizygotic twins because of the mediating effect of psychiatric disorder (Maris *et al.*, 2000).

Studies of the biochemistry of suicide have failed to reveal unique characteristics of suicidal individuals. Since the majority of suicides are depressed, and many have a depressive disorder, biochemical studies of the blood, cerebral spinal fluid and brain typically find features characteristic of depressed individuals, such as abnormalities in the serotonergic pathways. However, the disturbances in the serotonergic pathways appear to be more severe in completed suicides than in depressed non-suicidal individuals (Maris *et al.*, 2000).

Psychiatric disorder

Suicide is found to be more common among patients diagnosed with mood disorders (both major depressive disorders and bipolar disorders), schizophrenia and substance abuse. Recently there has been interest in the high rate of non-fatal suicidal behaviour in those diagnosed with a borderline personality disorder (Maris *et al.*, 2000).

However, retrospective diagnoses (using psychological autopsies) reveal that some suicides show no signs of psychiatric disorder. Estimates of the proportion of psychiatrically disturbed individuals among samples of completed suicide range from 33 to 99%. Increasingly, suicide in those with terminal illness and with other extreme trauma is viewed as rational, and the Netherlands and the state of Oregon in the USA have set up regulations to govern physician-assisted suicide. Associations such as the Hemlock Society and Compassion in Dying have websites and publications to assist individuals who wish to commit suicide, and Lester (2003) has provided a guide to making the decision to commit suicide.

The single most powerful predictor of past, present and future suicidality is depression as measured by a standardized scale. Many of these scales cover a variety of symptoms, and Aaron Beck has found that hopelessness, a cognitive component of depression, is the most useful symptom for predicting suicidality (Beck, 1986).

Other personality traits associated with suicidal behaviour include low self-esteem, anger (and aggression), deficient problem-solving skills, perfectionism and rigid and dichotomous thinking (Yufit & Lester, 2005).

Life experiences of suicidal individuals

A number of early experiences are associated with subsequent suicidal behaviour, including loss of parents (through death or divorce), physical and sexual abuse, suicidal behaviour in relatives and friends and dysfunctional families (Maris *et al.*, 2000). Suicidal individuals have typically experienced high levels of stressors in the year prior to their suicidal behaviour, and they differ from depressed non-suicidal people in experiencing a further increase in stressors in the weeks prior to the suicidal act. Media publicity of suicides by celebrities seems to provoke suicides in the following week (Stack, 1987) (see 'Coping with bereavement', 'Rape and sexual assault' and 'Intimate partner violence', 'wife battering and domestic violence').

Younger suicidal individuals appear to be more motivated in their suicidal behaviour by interpersonal problems, while older suicidal individual are more motivated by intrapsychic problems (such as depression and physical illness) (see also 'Personality and health').

Preventing suicide

The identification and appropriate treatment of depressed individuals is useful for the successful prevention of suicide. In Sweden, the physicians in one region were given educational programmes for this purpose, and the suicide rate dropped in that region compared to the rest of Sweden (Rutz, 2001). A replication study of this programme is presently underway in the UK. Recent declines in the suicide rates of some nations (such as Sweden and the USA) have been attributed to the increased prescribing of antidepressants for depressed individuals.

However, the medications used to treat depressed patients can also be used for suicide. Several authorities have calculated rates of death (per 1000 prescriptions) for various antidepressants, and some (especially the selective serotonin reuptake inhibitors) do appear to be safer than others, although the reasons for this are

not clear. Recently, there has been concern over the possibility that these antidepressants may increase the suicidality of a small proportion of adolescents. Careful monitoring of the medications given depressed patients is important (Lester, 2001).

Suicide prevention centres exist in many nations, and some nations have comprehensive coverage so that almost everyone can call a suicide prevention or crisis intervention service. In the UK and many other nations of the world, these centres are organized and certified by Befrienders International (www.befrienders.org) and in the USA by the American Association of Suicidology (www.suicidology.org). Recent meta-analyses of the effectiveness of these centres have shown that they do have a small, but statistically significant, beneficial impact on the suicide rate. They also provide excellent crisis counselling and serve as effective referral agencies for the communities they serve (Lester, 2002).

In recent years, a public health policy for suicide prevention has been promoted, namely restricting access to lethal methods of suicide. Some of this has occurred incidentally, such as the switch from very toxic coal gas to less toxic natural gas for domestic use (for economic reasons) and the removal of carbon monoxide from car exhaust (as a means of pollution control). However, additional measures aiming at suicide prevention have been proposed, including fencing in places from which people jump to their death (such as bridges and tall buildings), mixing emetics in medications, or prescribing medications in smaller amounts and passing stricter gun control laws. Available evidence suggests that the majority of people denied access to their preferred method for suicide will not switch to alternative methods. The detoxification of domestic gas in the UK, for example, was followed by a reduction in the total suicide rate (Clarke & Lester, 1989).

School education programmes have been designed in which pupils are provided information about suicide, especially the cues that a fellow student may be contemplating suicide, given some simple crisis intervention skills and informed of the resources available. The effectiveness of these programmes in preventing suicide has not been adequately explored as yet (Leenaars *et al.*, 2005).

Finally, the trauma experienced by those surviving the suicide of a loved one has spurred the growth of groups to help 'survivors' cope with their loss. Since having a loved one complete suicide is a factor which increases the risk of subsequent suicide, these groups may be useful for preventing suicide although no adequate evaluation study of their effectiveness in this regard has yet appeared (Jobes *et al.*, 2000) (see 'Group therapy'). Many of these survivors have become active in efforts to prevent suicide, helping to raise government and public awareness of the problem and to obtain funds for research and prevention programmes.

Tinnitus

Gerhard Andersson

Linköping University

Introduction

Tinnitus is an auditory perceptual phenomenon that is defined as the conscious perception of internal noises without any outer auditory stimulation. The sounds may be very loud and bizarre and the most common ones are heard like a high-pitched musical tone, or a rushing sound like escaping steam, or air. Other descriptions can be more complicated such as metallic sounds, multiple tones of varying frequencies and mixtures between buzzing and ringing (see 'Deafness and hearing loss').

Tinnitus is in most cases a temporary sensation, which many people have experienced at least sometime in their life. However, it may develop into a chronic condition, and prevalence figures show that at least 10–15% of the general population have tinnitus (Davis & Rafaia, 2000). However, most cases of tinnitus are not severe. Only about 1–3% of the adult population has severe tinnitus, in the sense that it causes marked disruption of everyday activities, mood changes, reduced quality of life and disrupted sleep patterns. Tinnitus has been reported in children, but in its severe form, it is more common in adults and in particular in the elderly (see also 'Ageing and health' and 'Noise: effects on health').

Tinnitus is known to occur in association with almost all the dysfunctions which involve the human auditory system (Lockwood *et al.*, 2002). This includes damage to the middle ear, the cochlea, the audiovestibular cranial nerve and pathways in the brain from cochlear nucleus to primary auditory cortex. A common distinction is often made between so-called objective (somatosounds, which can actually be heard from the outside) and subjective tinnitus (sounds that are heard only by the afflicted person). Objective tinnitus represents a minority of cases. Subjective tinnitus has been linked to sensorineural hearing loss, caused by various deficits such as age-related hearing loss and noise exposure (Andersson *et al.*, 2005b). Links to other conditions, such as temporomandibular joint dysfunction, have also been found. Tinnitus has been

explained as the result of increased neural activity in the form of increased burst firing, or as a result from pathological synchronization of neural activity. Other suggested mechanisms are hypersensitivity and cortical reorganization (Cacace, 2003). Recently, with the advent of modern imaging techniques, it has been observed that tinnitus involves certain areas of the brain, particularly those which are related to hearing and processing of sounds. Some involvement of the brain's attentional and emotional systems has also been seen (Andersson *et al.*, 2005b) (see 'Brain imaging and function').

Explaining the severity

What distinguishes mild from severe tinnitus is not easily established, apart from variations in subjective ratings of intrusiveness and loudness. In particular, in attempts to determine the handicap caused by tinnitus, it has not been possible to make the determination using the characteristics of the tinnitus itself (e.g. loudness, pitch etc.). However, psychological factors are of major importance in determining the severity of tinnitus (Andersson, 2002), and this has been observed in both clinical and epidemiological studies.

The problems experienced by tinnitus patients can be divided into four categories: hearing difficulties including noise sensitivity; emotional consequences; concentration problems; and insomnia. In addition, there may be interpersonal consequences and occupational difficulties (e.g. for a musician admitting tinnitus can be regarded as a sign of weakness).

Hearing loss is the most common symptom that goes together with tinnitus, and that can in itself be a great problem (see Andersson, *et al.*, 2005b). Another common problem is noise sensitivity, which in its severe form can develop into hyperacusis, which is sensitivity to everyday sounds not regarded as loud by most people (Baguley, 2003) (see also 'Noise: effects on health').

In its severe form, tinnitus is strongly associated with lowered mood and depression. Suicide caused by tinnitus is, however, rare.

Most cases reported have had co-morbid psychiatric disturbances (Jacobson & McCaslin, 2001). Anxiety, and in particular anxious preoccupation with somatic sensations, is an aggravating factor, and stress is often mentioned as a negative factor for tinnitus, and in particular in association with major adverse life events, but the evidence for this notion is weak. Personality factors have been investigated, and associations have been reported between degree of optimism and tinnitus distress (Andersson, 1996), and between perfectionism and tinnitus distress (Andersson *et al.*, 2005a) (see 'Suicide' and 'Stress and health' and 'Personality and health').

Tinnitus patients often report difficulties with concentration, for example with reading. Often this is perceived as auditory intrusions whilst trying to hold concentration on a task. Until recently, there have been few attempts to measure tinnitus patients' performance on tests of cognitive functioning, but recent research implies a role of the working memory system (Hallam *et al.*, 2004). Another line of research has focused on the role of selective information processing, with results indicating autobiographical memory bias (Andersson *et al.*, 2003), but not a selective attention bias on the emotional Stroop task (Andersson *et al.*, 2000).

Recently, family factors have been investigated showing evidence to support a role for adult attachment patterns and spouse reactions (Granqvist *et al.*, 2001). Finally, sleep problems represent a significant element in tinnitus patients' complaints (McKenna, 2000), and is often a driving reason for seeking help (see 'Sleep disorders' and 'Social support and health').

Among the most influential psychological theories on why tinnitus becomes annoying is Hallam *et al.*'s (1984) habituation model of tinnitus, which presents the notion that tinnitus annoyance is caused by lack of habituation and the neurophysiological model by Jastreboff and co-workers (Jastreboff, 1990), which is a classical conditioning model where the tinnitus signal is conditioned to aversive reactions such as anxiety and fear. The latter model puts less emphasis on conscious mechanisms involved in tinnitus perception. Other researchers have endorsed a cognitive-behavioural conceptualization of tinnitus, suggesting a major role for thoughts and beliefs regarding the phenomenon (McKenna, 2004) (see 'Cognitive behaviour therapy').

Management of tinnitus

In clinical settings, management of tinnitus involves taking history of its characteristics such as onset, loudness, character, fluctuations and severity. Audiological and neuro-otological measurements such as pure-tone audiometry, otoscopy and brain stem audiometry are also included in routine assessment to exclude treatable conditions

(Andersson *et al.*, 2005b) (see 'Neurological assessment: general principles').

There is a long history of attempts to cure tinnitus, but surgical and pharmacological interventions have been largely without any success (Dobie, 1999). When the aim is to reduce the suffering, treatment outcome is more promising, and psychologically informed treatments have been found to be helpful in randomized trials (Andersson & Lyttkens, 1999).

Among the psychosocial treatments, cognitive-behavioural therapy (CBT) is the most researched alternative (Andersson *et al.*, 2005). As for other medical conditions such as chronic pain, CBT for tinnitus distress is directed at identifying and modifying maladaptive behaviours and cognitions by means of behaviour change and cognitive restructuring. The focus is on applying techniques such as applied relaxation in real-life settings. There is now evidence from randomized trials that CBT can be effective for alleviating the distress caused by tinnitus in adults (e.g. Henry & Wilson, 1998), including a trial on the use of CBT with older adults (Andersson *et al.*, 2005c), and also that it works in a self-help format presented via the Internet (Andersson *et al.*, 2002). However, while the effects are promising, there is room for more improvement and tinnitus is a typical example of an area where multidisciplinary input is necessary (see 'Cognitive behaviour therapy').

Conclusion

Tinnitus is a poorly understood phenomenon, and, while the role of psychological factors is widely acknowledged, there is as yet little research on basic mechanisms such as information processing bias, the role of psychopathology and the influence of the tinnitus sound on working memory capacity. While there are a few cases of tinnitus for which surgical and medical interventions might help, in most cases there is no cure in the sense that the tinnitus sound will not disappear. However, longitudinal fluctuations of both loudness and severity of tinnitus have been observed, and health psychologists could benefit in the pursuit of an explanation why it is that tinnitus becomes bothersome only for a proportions of individuals. When it comes to methods to lessen the distress and to cope with the adverse consequences, such as lowered mood and sleep difficulties, CBT is a promising approach. However, the dissemination of CBT into audiological hospital settings has been slow and there are very few clinical psychologists working with tinnitus. Self-help methods are promising and could at least partly solve that problem, and there is also much to be done regarding preventive work as noise-induced hearing loss is the cause of tinnitus in one-third of cases with recent onset of tinnitus.

Tobacco use

Robert West¹ and Ainsley Hardy²

¹University College London

²Loughborough University

Tobacco use is endemic throughout the world. Tobacco can be smoked (as cigarettes, pipes or cigars), chewed (as compressed moist tobacco ‘plug’ or ‘twist’), snuffed (ground into fine powder and sniffed into the nose) or ‘dipped’ (as moist shredded or ground tobacco placed into the space between the gums and cheek)¹ (West & Shiffman, 2004). Cigarette smoking is by far the most dangerous form of use, killing some 4.9 million people each year worldwide, more than 250 000 each year in the USA and more than 100 000 each year in the UK (World Health Organization, 2002). Many factors are involved in the instigation and maintenance of tobacco use but there is a consensus that its ability to deliver nicotine to the brain lies at the heart of the problem (US Department of Health and Human Services, 1988; Royal College of Physicians, 2000).

Health effects of tobacco use

Cigarette smoking in western countries leads to a 15-fold increase in risk of death from lung cancer and chronic obstructive pulmonary

disease (COPD) and a 3-fold increase in risk from death from cardiovascular disease (see ‘Cancer: lung’, ‘Chronic obstructive pulmonary disease’ and ‘Coronary heart disease’). It also increases risks of a range of other cancers such as cancer of the bladder, larynx and oral cavity (see ‘Cancer: head and neck’). Smoking increases risk of age-related deafness and blindness, back pain, early menopause, impotence and infertility, gum disease leading to tooth loss, Type II diabetes and visual appearance of early ageing (see Hausteine, 2002).

Smoking during pregnancy increases the risk of miscarriage and perinatal death. If the baby is born alive it suffers increased risk of Sudden Infant Death Syndrome (SIDS) and respiratory problems as a baby and learning difficulties and antisocial behaviour as a child and adult (West, 2002) (see ‘Pregnancy and childbirth’).

In western countries, smokers who fail to stop die an average of some 10 years early, but half of these die 20 years early (Doll *et al.*, 2004). Smokers do not escape ‘old age’ by smoking – they spend at least as much time with diseases of old age as do non-smokers – they just do it at a much younger physical age (Stovring *et al.*, 2004).

¹ Confusingly, this type of tobacco is also often called snuff.

Cigar and pipe smoking carries a similar risk to cigarettes if the smoker inhales the smoke into the lungs. If smoke is not inhaled the risk is reduced. Smokeless tobacco use (chewing, snuffing or dipping) is much less harmful than smoking. Some products carry a significant risk of head and neck cancers but some, such as Swedish 'snus' (ground dipping tobacco contained in small permeable sachets) are prepared in a manner that results in very low levels of carcinogens and appear to carry minimal risk (Kozlowski, 2002).

The damaging health effects of smoking are due to the many hundreds of toxic components in the tar droplets together with the carbon monoxide that is inhaled. The former include known carcinogens while the latter appears to have atherosclerotic effects. Nicotine is not carcinogenic and appears to produce little or no physical harm in the doses that smokers receive it, except possibly during pregnancy or in rare cases of susceptibility to particular vascular diseases.

Health benefits of stopping

Stopping smoking improves health and reduces future disease risk at any age. The greatest benefit is obtained by stopping before the age of 35 years (Doll *et al.*, 2004). Smokers who stop at this age have a near normal life expectancy. The risk of lung cancer stabilizes at the point when cessation occurs; it does not reduce. This is why it is imperative for smokers to stop as early as possible. Similarly, stopping smoking normalizes the age-related decline in lung function, but there is little by way of recovery of function which has been lost up to that point. Many middle-aged smokers have already lost significant lung capacity through COPD without having received a formal diagnosis. Their perception is just that they have a 'smoker's cough' and are somewhat more breathless on exertion than they used to be, and they attribute this to ageing. It is imperative that these smokers stop without delay as they are on an accelerating curve of decline which will lead to severe disability and often death. In contrast to the damage to the lungs, the circulatory system does show recovery on cessation. The excess risk of heart attack reduces by 50% in the first year after cessation (US Department of Health and Human Services, 1990).

Although many smokers and health professionals regard 'cutting down' on the number of cigarettes smoked or switching to 'low tar' cigarettes as a means of reducing the risk, there is little evidence to support this. Smokers appear to have a preferred level of nicotine intake and adjust the way they smoke their cigarettes to achieve this. This may involve blocking ventilation holes in the filter which are designed to dilute the smoke, puffing more frequently or inhaling the smoke more deeply and holding it for longer.

Although many texts report that stopping smoking results in lower blood pressure, it does not. In fact, in a small number of cases, smokers develop hypertension when they stop (McEwen & West, 2002) (see 'Hypertension').

Passive smoking

'Passive smoking', i.e. exposure to smoke from other people's cigarettes, carries a significant health risk as well as being unpleasant and uncomfortable. Children whose parents smoke have an increased risk of childhood cancers and respiratory diseases. Spouses of

smokers have increased risk of lung cancer and heart disease (see 'Cancer: lung' and 'Coronary heart disease'). Working in a smoky environment also carries an increased risk which is related to the intensity and duration of exposure. These increased risks are small compared with the risks from active smoking but, given that they are completely involuntary, are unacceptable in modern society. Estimates of the numbers of deaths currently attributable to passive smoking range from 1000 to 3000 per year in the UK and more than double that in the USA (Scientific Committee on Tobacco and Health, 2004).

Acute effects of nicotine

If tobacco did not deliver nicotine people would not use it (see West & Shiffman, 2004). Nicotine is an alkaloid which somewhat resembles the naturally occurring neurotransmitter, acetylcholine (ACh). When present in the extracellular space it attaches to ACh receptors at the neuromuscular junction and in the autonomic and central nervous systems. Nicotine is lethal at doses of around 60 mg but most smokers absorb between 1 mg and 2 mg per cigarette and it is rapidly metabolized with a plasma half-life of approximately 90 minutes. In novice users, an acute dose of 1 mg of nicotine will typically cause nausea together with tremor, sweating and other symptoms of activation of the sympathetic nervous system. It also causes dizziness and what is for some people a mildly pleasant 'buzz'. After a few weeks of use, tolerance develops to the nausea. There is little evidence of chronic tolerance to the positive subjective experience of smoking. That is, a smoker of many years' standing typically needs the same dose to obtain sought-after effects as a novice smoker. However, there is acute tolerance (tachyphylaxis) to the positive effects, which means that these are typically only experienced after the smoker has gone for a period of at least a few hours without smoking.

Why people use tobacco

People usually first try smoking in adolescence (for more information on material in this section see West & Shiffman, 2004 and chapter on 'Adolescent lifestyle'). Curiosity, desire to enact or convey a particular identity, beliefs about positive effects of smoking on mood and weight control can all play some role.

Progression to regular smoking follows very varied patterns. At one extreme some young people move rapidly to daily smoking, while others may not smoke again for several years.

Many smokers report that they enjoy smoking and that it helps them cope with stress. They also believe that it helps with weight control and as an aid to concentration. So far, experimental studies have not yielded convincing evidence that nicotine reduces stress in humans. Neither is it clear that it confers benefits in terms of intellectual functioning, though its sympathetic stimulant action may help to maintain alertness in some cases. Nicotine taken acutely does reduce appetite but this does not make it an effective weight management tool. Studies with teenagers and young adults show that taking up smoking is not associated with lower levels of obesity and overweight. In later adulthood, smokers typically have a lower body mass index (BMI) than non-smokers and ex-smokers have a higher BMI than never-smokers. The weight gain on stopping

smoking averages 6–8 kg and is usually permanent. This suggests that a period of smoking may permanently disrupt the body's natural weight control mechanisms leading to higher levels of obesity in ex-smokers (see also 'Obesity').

The role of nicotine in maintaining smoking behaviour appears to relate partly to the fact that it creates an 'acquired drive' (a kind of nicotine hunger) which it then goes on to satisfy and partly to the fact that it attaches rewarding value to the activity of smoking and the sensations (such as the feeling of smoke entering the upper airways) associated with it. These processes operate at a mid-brain level and are not subject to conscious control or decision-making. They can be very powerful and very often undermine and overcome the decision not to smoke. The strength of these non-conscious motivational forces is so great that fewer than 5% of unaided quit attempts succeed for more than a few months. They also result in many smokers experiencing powerful urges or compulsions to smoke when the opportunity arises. It is generally agreed that most smokers are addicted to cigarettes in the sense that their behaviour has become out of control and it is clear that nicotine lies at the heart of the problem.

One part of the brain that appears to be pivotal to nicotine's addictive potential has cell bodies in the ventral tegmental area (VTA) in the mid-brain and projects forward to the nucleus accumbens (NAcc). A particular subtype of ACh receptor (made up of alpha-4 and beta-2 subunits) in the VTA appears to be critical to this process. When nicotine attaches to this receptor it stimulates firing of the nerve cells in which they are located which in turn leads to increased release of the neurotransmitter, dopamine, in the NAcc. This dopamine release is central to the rewarding actions of nicotine. Pathological changes to this pathway, or ones that feed into it, resulting from chronic nicotine use appear to underpin the acquired 'drive' to smoke.

The rate at which nicotine is absorbed plays an important role in the development of addiction. Nicotine from cigarettes is absorbed over the large surface area of the lungs and so a pulse is generated from each puff. This allows 'fingertip control' over the dose received. It is generally regarded that cigarettes are the most addictive form of tobacco use. Nasal snuff produces quite rapid intake via absorption through the nasal mucosa and is probably less addictive. Nicotine from dipping and chewing tobacco is absorbed mostly through the lining of the mouth so blood levels rise more slowly. The importance of the rate of absorption is thought to lie in way that the VTA-NAcc pathway is affected by a rapid increase in ACh receptor occupation by nicotine as opposed to more gradual occupation. More rapid occupation appears to lead to burst firing in the nerves which in turn causes a particular pattern of dopamine release important for reward.

Prevalence of smoking

The prevalence of smoking varies widely across different countries and cultures (see West & Shiffman, 2004). In the UK, USA, Australia and New Zealand smoking prevalence has fallen rapidly since the 1970s to between 20 and 25% with slightly more men than women smoking. It is now declining more slowly. In other parts of the world, particularly South East Asia and former Eastern Bloc countries,

smoking prevalence is rising and tobacco companies are marketing aggressively to develop these markets.

In all Asian and many African cultures smoking among women is considered a sign of moral turpitude and this has no doubt contributed to very low smoking prevalence. However, as 'western' values permeate these cultures it is expected that smoking prevalence among women will increase.

In most industrialized countries there is a strong association between smoking prevalence and economic deprivation or socio-economic status, with higher deprivation and lower status being associated with higher prevalence (see 'Socioeconomic status and health'). This appears to be partly associated with norms for the different social groups and partly due to those from more deprived circumstances being more addicted to nicotine. Thus poorer smokers take in more nicotine overall and more nicotine per cigarette than more affluent smokers and have greater difficulty in stopping when they try. The reason for this is not known.

People with mental health problems are more likely to smoke; those who do are more nicotine dependent and they are less likely to succeed when they try to stop (see West & Shiffman, 2004). It has been claimed that many smokers are 'self-medicating' for psychological or cognitive problems, but evidence for this is equivocal. It has also been suggested that schizophrenics are particularly susceptible to nicotine dependence because there is some interaction between the effects of nicotine and the physiological underpinnings of this condition. However, the prevalence of smoking in schizophrenics is no higher than in institutionalized patients suffering from other psychiatric disorders. One simple model that accounts for the associations between smoking and mental health and with economic deprivation proposes that the modest but reliable rewards of the kind produced by nicotine have greater motivational significance in individuals who are distressed and distress also reduces motivational resources necessary to exercise self-control (West, In Press).

Stopping smoking

In the UK and USA approximately 35–45% of smokers each year attempt to stop but only about 2–3% succeed long term (see West & Shiffman, 2004). Fewer than 25% of quit attempts last more than a week. Within the first few weeks many smokers experience an intense urge to smoke, accompanied by a range of nicotine withdrawal symptoms: irritability, depressed mood, restlessness, dizziness, impaired concentration, increased appetite, sleep disturbance, mouth ulcers, constipation and increased susceptibility to upper-respiratory tract infection. Although some smokers also report other symptoms such as headache, this is just a coincidence and is not linked to stopping smoking. The only symptom that persists for more than a few weeks is increased appetite which continues for at least three months.

Urges to smoke and withdrawal symptoms can be reduced by nicotine replacement therapy (NRT: nicotine transdermal patches, gum, nasal spray, inhaler or lozenges) and bupropion (also known as amfebutamone or Zyban). These medications also approximately double smokers' chances of stopping smoking successfully. They are licenced in many countries as aids to smoking cessation and can be prescribed or obtained from pharmacists or other retail outlets.

A full course of treatment costs between £40 and £80 (US\$80 and US\$160). It has been calculated that, taking everything into account, the average cost per life year gained from a course of treatment is in the order of £1000 (US\$2000). This compares with an average of about £17 000 (US\$34 000) for other life-saving medical treatments. Recognizing that these medications are extremely cost-effective life-saving treatments and that nicotine addiction is a brain disorder that has little to do with conscious choice, 'moral fibre' or 'will power', many healthcare systems (such as the National Health Service (NHS) in the UK) pay the cost of these medications, just as they would for medications to reduce blood pressure or cholesterol.

There is currently no clear evidence that one form of NRT is better than others, nor that bupropion is better than NRT. However, it appears that using a nicotine patch together with an acute delivery product such as inhaler or gum is more effective than either alone. There is also some evidence that using NRT in the weeks leading up to the quit date may improve the chances of stopping. This is an active area of research.

The tricyclic antidepressant nortriptyline has been shown to assist with smoking cessation and has approximately the same size of effect of NRT and bupropion. At the time of writing two new drugs are undergoing trials as smoking cessation aids. Rimonabant is a CB1 (cannabinoid) antagonist that appears to help with smoking cessation and also with weight loss. Varenicline is a partial agonist at the alpha-4, beta-2 receptor and appears to increase smokers' chances of stopping successfully.

Some smokers and clinicians are concerned about smokers transferring their nicotine addiction to NRT rather than cigarettes. This occurs extremely rarely in the case of the patch, and somewhat more commonly in the case of other products. This is probably related to the rate at which the products deliver nicotine. However, given that pure nicotine has minimal health effects and most of the smokers who continue to use the products would resume smoking if they were denied them, it is generally regarded that the health gains outweigh the costs and that smokers should not be forced to terminate use prematurely.

Psychological support either in groups or in one-to-one sessions can also double smokers' chances of stopping (see 'Group therapy'). It is not known what the 'active ingredients' of this support are, but it appears that multiple sessions provided by trained and experienced personnel are important. Brief sessions of counselling provided by minimally trained midwives, nurses or others have not been found to be effective (though they are important in triggering quit attempts and motivating smokers to seek specialist help) (see 'Counselling'). The effectiveness of specialist psychological

support has been recognized by some healthcare systems such as the NHS in the UK which provide it free of charge as part of a package that also includes NRT and/or Zyban. This combination of specialist psychological support and medication is the treatment of choice for any smoker wanting help with stopping and, overall, it increases the chance of long-term success (not smoking at all for at least 12 months) from less than 5% to more than 15%. Even with the best available treatment, most quit attempts will fail but each new attempt is, in effect, another 'roll of the dice', so the accumulated chances of success over the years become high. For example, if the average smokers tries to stop once a year without help starting at the age of 25 years, by the time he or she is 45 years old there is approximately a 60% chance of eventually succeeding. If he or she uses NRT the chance increases to about 80% and if he or she uses the psychological support and medication the chance increases to 96%.

The role of health professionals

Health professionals can encourage smokers to make more frequent attempts to stop and, in health systems where there is treatment available, to aid their attempts they can encourage smokers to use that treatment. This role has been formalized in a number of national guidelines which have been endorsed by relevant professional bodies (US Department of Health and Human Services, 2000; West *et al.*, 2000). For example, doctors in primary care are encouraged to ensure that they check each year whether their patients smoke and advise smokers to make a quit attempt using the most intensive form of treatment they are willing to adopt, ideally a combination of psychological support and medication.

Even in the UK, which has had formal guidelines in place for almost a decade and whose national technology assessment body (the National Institute for Health and Clinical Excellence) has given unequivocal support for medications and psychological support to aid cessation, some primary care practitioners deny their patients this treatment (McEwen *et al.*, 2004). Arguably, this amounts to professional misconduct but this has not yet been tested in disciplinary hearings.

Health psychologists are employed in the UK and some other countries as smoking cessation specialists. There is no evidence to support any particular theoretical approach, and the general model involves provision of practical support and advice on ways of minimizing the desire to smoke and using social and other motivational forces to bolster motivation to remain abstinent.

Toxins: environmental

Gerhard Winneke

Heinrich-Heine-Universität Düsseldorf

Psychology and environmental toxicology

Environmental toxins that affect human health and wellbeing may either be airborne or foodborne. The primary target of airborne environmental toxins are the upper and lower airways, and various respiratory diseases have been shown to be related to environmental exposure to air pollution. However, if a toxin enters the deeper structures of the lung due to small molecular size, inhaled chemicals will also enter the blood stream, thus causing or contributing to damage of other organ systems, such as the cardiovascular system, the immune system, the endocrine system or the brain. If primarily foodborne, environmental toxins will be ingested rather than inhaled. The distinction between airborne and foodborne is somewhat artificial because airborne chemicals are often deposited on soil and water and may, thus, enter the food chain.

Since many organs and organ systems can be targets of environmental toxins, different scientific approaches and sharing of knowledge across disciplines are required in order to arrive at a balanced rational risk assessment. If the brain is assumed or known to be the critical organ for a particular toxin, its adverse effect at a particular level of environmental exposure is typically studied within neurotoxicology. General neurotoxicology draws upon a broad spectrum of general neuroscience methods, such as neuroanatomy, neurochemistry, neurophysiology or neuropharmacology to study adverse effects of chemicals on the structure and function of the mature or developing nervous system. Also concepts and methods developed within the behavioural sciences, particularly within experimental and clinical psychology, are often used to study adverse effects of environmental agents on the brain at a functional level. This subspecialty within neurotoxicology is often called 'Behavioural' or 'Neurobehavioural Toxicology' (Annau, 1986).

The field of Behavioural Toxicology draws on animal models developed within the tradition of 'Comparative and Physiological Psychology' and humans studies using methods and concepts of clinical and/or developmental psychology (Winneke, 2006). The term 'Neuropsychological Toxicology' is typically used to exclusively characterize the human approach (Hartmann, 1988). The present review will be restricted to a discussion of environmental neurotoxins for which evidence for psychological adversity has been presented in human epidemiology.

Methodological issues

Cross-sectional or prospective longitudinal studies are typical approaches in environmental epidemiology. In cross-sectional studies functional endpoints are measured in exposed subjects at one point in time and are typically related to concurrent exposure, either relative to unexposed but otherwise comparable subjects, or relative to one continuous exposure variable using linear or logistic regression modelling. In prospective studies, associations are established between changes in psychological functions relative to the natural exposure history. This approach offers an opportunity to identify critical periods of exposure and to clarify, if the observed effects are reversible or not.

Internal exposure to environmental toxins is often characterized by some sort of biomarker (e.g. toxin or metabolite concentration in blood, human milk, hair etc.), and associations between exposure and adverse health outcome are typically analyzed by means of linear or logistic regression modelling. An important methodological issue is proper adjustment for relevant confounders. Confounders are variables exhibiting associations with both exposure and outcome. If not considered adequately their presence may either hide

existing associations, or give rise to spurious associations between the exposure variable and the target variable. Important variables in psychodevelopmental studies are parental (mostly maternal) IQ to account for genetic background and quality of the home environment to account for differences in parental stimulation during development. The quality of the home environment is typically assessed using an interview-based measure, namely the 'Home Observation Measurement of the Environment (HOME)' developed by Bradley and Caldwell (1984) yielding a summary score to describe the quality of the mother-child interaction.

Psychological impact of neurotoxins

Much of the behavioural research dealing with neurotoxic effects of environmental pollutants on psychological constructs has emphasized the developmental perspective. For example, research has examined the effect of inorganic lead, organic mercury and polychlorinated biphenyls (PCBs) on infants and children. A unique class of airborne environmental toxins with clear-cut adverse psychological effects are malodours, which are typically studied in adults.

Inorganic lead

Lead is probably the most studied toxic element. It occurs both in organic and inorganic form. Although the organometallic lead species are highly neurotoxic in acute exposure situations, chronic low-level exposure to inorganic lead constitutes the more serious public health risk. In an environmental context children are considered a sensitive risk group for lead because, on a body weight basis, their dietary intake, absorption and total retention is markedly higher for adults. In addition the blood-brain barrier is not yet fully developed in young children, and specific behavioural characteristics, such as hand-to-mouth actions and playground activities put them at higher risk of exposure.

Much of the relevant literature has recently been reviewed with an emphasis on longitudinal cohort studies (Koller *et al.*, 2004). Lead concentrations are measured in blood (PbB) or in teeth, which serve as internal markers of current or past environmental exposure. A variety of psychological tests have been used to assess the degree of central nervous system involvement. The dependent variables used in these studies included developmental scores (e.g. the Bayley Scales) and psychometric intelligence tests, such as the Wechsler IQ-scales. Other functional domains have been added in several studies, such as perceptual-motor functions, gross or fine motor coordination, sensorimotor speed and attention, as well as aspects of educational attainment.

A rather convincing body of evidence was collected in several prospective cohort studies, which followed children from shortly after birth until school age or adolescence, looking at internal exposure and developmental outcome. This set of studies show that lead-related intellectual deficits occur consistently; that early postnatal exposure to lead appears to be more important than prenatal exposure; that no clear cut threshold of exposure for these effects was found, but that the effect size of environmental lead exposure on intelligence is much smaller than that of, for example, social, genetic and parenting factors (Koller *et al.*, 2004).

Methylmercury

Exposure to metallic mercury is relevant to occupational settings and to exposure resulting from dental amalgam. However, organic mercury complexes, particularly methylmercury compounds (MeHg), are of greater concern than metallic mercury from a neuropediatric perspective. Methylation of mercury by microorganisms occurs in the marine environment and biomagnification in the aquatic food chain may give rise to elevated MeHg-exposure in selected fish-eating populations.

Much of the current evidence on neurodevelopmental and psychological effects of MeHg is summarized in a recent monograph from the National Research Council (2000). Initial knowledge about the neurological and psychological consequences of high MeHg-exposure was primarily gained in two episodes of mass poisoning in the Minamata Bay area (Japan) in 1950 and in Iraq 20 years later.

Relatively few studies have been conducted in infants and children exposed to low-level environmental exposure to MeHg: one was performed in New Zealand, one in the Seychelles Islands and two in the Faroe Islands. All of these study populations were characterized by a high proportion of marine food in their diet. However, the results were conflicting. The New Zealand study was a cross-sectional study of a relatively small groups of cases of four- and six-year-old children matched to control children. Significant MeHg-related psychological deficit was found in both age groups. The Seychelles study was a prospective cohort approach based on 779 mother-infant pairs. Prenatal MeHg-exposure was estimated from maternal hair samples collected at birth and children were followed up at several ages up to 66 months for neuro-/psychodevelopmental adversity. At no age were significant exposure-related developmental deficits observed. The two prospective Faroe Islands cohort studies are based on 182 newborns at two weeks of age or 917 children at seven years of age, respectively. Both MeHg in maternal hair during pregnancy and in cord serum served as exposure markers. In the smaller study a significant inverse association between Hg in cord blood and neurodevelopment was observed. In the larger cohort with children at school age significant inverse associations were found between Hg in cord blood and outcome in a number of psychodiagnostic tests.

Thus, two large cohort studies on the neuro- and psychodevelopmental effects of methyl mercury in fish-eating populations have produced different results. The reasons for this are unclear. A recent risk assessment effort presenting a benchmark dose estimate was based on the Faroe Islands studies (National Research Council, 2000).

Polychlorinated biphenyls (PCBs)

PCBs are mixtures of congeners that differ in the number and position of chlorine atoms on two linked biphenyl rings. Although no longer used or produced in most countries, PCBs are still of environmental concern in the context of waste disposal and because of their persistence in environmental media. Lacking biodegradability they accumulate in the food chain and finally reach humans with elevated levels in different tissues, notably body fat and human milk.

Schantz *et al.* (2003) carried out a comprehensive review of studies from the last decade into adverse effects of PCBs, as assessed

by neurodevelopmental and neuropsychological tests. This included Dutch and German studies, a study from the Faroe Islands, two studies from the United States and one in the Inuit population from Canada. Several PCB congeners were measured in maternal or cord blood, as well as in samples of maternal milk collected shortly after birth. Developmental tests and standard intelligence tests were administered at various ages. Also almost all of the studies have considered important confounders such as maternal intelligence or the quality of the home environment.

Schantz *et al.* conclude: 'As the data from ongoing PCB studies are published, the weight of evidence for PCB effects on neurodevelopment is growing. In particular, studies... have now all reported negative associations between prenatal PCB exposure and measures of cognitive functioning in infancy and childhood.' (Schantz *et al.*, 2003, p. 374). It should be pointed out, however, that important additional questions, such as the reversibility of deficit and the possible mechanistic basis of deficit still remain to be answered.

Environmental malodours

Odorants are airborne volatile chemicals affecting the sense of smell. They may occur both indoors and outdoors, and are not known to adversely interfere with structure and function of sensory organs or the nervous system. In an environmental context they are mostly poorly or even non-defined chemical mixtures occurring at low concentrations, which typically prevents their measurement by physicochemical methods. Instead, measurement of exposure in population-based studies is usually done by means of sensory or psychophysical methods, and psychological responses in the exposed population are recorded in questionnaire-based surveys. In such studies exposure to malodours from industrial, municipal or agricultural activities has clearly been shown to be associated with signs of disturbed wellbeing, such as annoyance and avoidance responses (Cavalini *et al.*, 1991; Sucker *et al.*, 2001). Because of their clear-cut psychological adversity and their negative impact on quality of life it has been proposed to classify environmental malodours as neurobehavioural toxicants (McMillan, 1999).

Clinical implications

Relative to the contribution of social and parenting factors the amount of outcome variance explained by exposure to

environmental toxins is small. For example, Koller *et al.* (2004) found that social and parenting factors account for approximately eight times as much variance in IQ as does exposure to lead (see 'IQ assessment'). Similar figures probably also hold for MeHg and PCBs. Thus, from a clinical perspective, the degree of developmental delay or deficit induced by environmental neurotoxins is subtle and will hardly be seen in the individual child, because the effect size is within the margin of error. The argument has been raised, however, that even small degrees of developmental adversity can have substantial consequences for the extremes of a population and are, therefore, of public health significance.

Malodours are considered ambient stressors having a negative impact on the quality of life but have not clearly been shown to cause or aggravate disease. However in rare psychosomatic conditions such as the unexplained 'Multiple Chemical Sensitivity (MCS)' they can trigger fear of chemical poisoning with concomitant acute anxiety or panic responses. These require clinical attention.

Conclusions

The administration of psychological tests covering cognitive and sensorimotor functions in children has helped to document the risk for neuropsychological toxicity associated with environmental exposure to low levels of metals and polychlorinated biphenyls. In many instances such observations have been used to establish or revise biological exposure limits.

It should, however, be pointed out that some research findings are inconsistent and therefore not fully acceptable within the scientific community and/or for regulatory bodies. This is particularly true if the critical effects are small and embedded in a complex background of confounding factors. Therefore questions are still being raised as to the true cause-effect contingencies. In such controversy, neurobehavioural studies using animal models are needed and would help to corroborate field observations, contribute to elaborating the underlying neurobiological mechanisms and identify critical periods of exposure.

A class of airborne environmental chemicals with unique characteristics are malodours emitted from industrial, municipal and agricultural sources. Population-based epidemiological studies have shown exposure-dependent interference with psychological adversity and quality of life. It has, therefore, been argued that environmental chemicals with malodourous properties meet the criteria of neurobehavioural toxicants.

Transplantation

Konstadina Griva^{1,2} and Stanton Newman¹

¹University College London

²Thames Valley University

With medical advances transplantation has become a common approach to treating an increasing number of end stage organ failure disorders. Kidney, heart, liver and bone marrow transplantation are being performed in many countries at an increasing rate largely limited by the availability of organs (United Network for Organ Sharing [UNOS], 2001). In addition, significant progress has been made in transplantation procedures involving pancreas, lung, cornea, skin and islet cells. Simultaneous multiple organ transplantation is advocated as the treatment of choice for patients with multiple organ failure (Schweitzer *et al.*, 1997) (see, for example, 'Coronary heart disease: heart failure'). Transplantation of external body parts such as hands (e.g. Klapheke *et al.*, 2000) and transplants from animals (e.g. White & Nicholson, 1999) are driving transplantation research and practice into new territories.

Progress in surgical techniques, organ preservation and improved methods to decrease graft rejection, including advances in histocompatibility testing and immunosuppression have resulted in unprecedented graft and patient survival rates (Niklason & Langer, 2001). For example, today 88% of patients receiving a kidney, 77% of patients received a heart and 80% of patients receiving a liver will have a functioning graft one year after the operation (British Transplantation Society [BTS], 2003).

Despite the rapid proliferation in the number of transplant programmes and the number of transplant candidates worldwide, the number of organ donors has remained relatively stable. Most organs come from cadaver donors, with head trauma and cerebral vascular accidents being the cause of death in 85% of cadaver donors (UNOS, 2001). The option of living donation is a viable alternative only for a small segment of organ transplant patients (e.g. kidney, liver). Living organ donation rates vary across countries. For example, in the UK kidneys from living donors account for only 21% of transplants compared with 40% in Norway (BTS, 2003) (see 'Renal failure, dialysis and transplantation').

The major limiting factor in transplantation medicine is the shortage of donor organs. More and more patients are waiting for organs; many of them are dying while waiting. Expansion of the pool of

potential donors can potentially be made possible by increasing public awareness, widening organ donor criteria, the use of non-heart-beating donors or policies/schemes regarding presumed consent or even financial rewards for potential organ donor families. Xenotransplantation, organ engineering and cloning are also promising techniques and can potentially provide organs for transplantation in the future.

In general, the relative success of transplantation has led to a shift in research agendas beyond the success of the procedure and graft survival to include an examination of recipients' psychological response to organ transplantation and their functioning and quality of life' (QoL) (see 'Quality of life'). QoL has been extensively studied in transplant patients. Convergent evidence from a variety of transplant types and demographically diverse study cohorts indicates that quality of life is significantly improved with transplantation (Bravata *et al.*, 1999; Dew *et al.*, 1997). Gains are most consistently noted for the physical QoL domains and global QoL perceptions. Improvements in mental and emotional QoL dimensions are less clear.

Symptoms of anxiety and distress have been documented particularly at discharge from the hospital and during the early postoperative period that mark major adjustments in individual and family roles (Dew *et al.*, 2000; Engle, 2001). Unrealistic expectations of improvements in QoL on the part of transplant patients have been found to be associated with post-transplant depression (Levenson & Olbrisch, 1993).

There is also overwhelming evidence that transplant recipients show QoL advantages over similarly ill patients who have not received transplants, but the observed QoL levels do not always equal that of general population. Transplant recipients experience limitations in specific areas of functioning relative to healthy samples. Impairments are evident mainly in physical dimensions of QoL such as physical functioning, ambulation, mobility (Hathaway *et al.*, 2003; Pinson *et al.*, 2000). As such, return to work rates are lower than expected for transplant patients (Botsford, 1995). It is noteworthy though that fear of loss of health insurance and

disability benefits rather than physical limitations is one of the main reasons cited by transplant recipients in the USA for not returning to work (Engle, 2001).

There are also large variations in QoL outcomes across types of transplants. For example, kidney transplantation produces significant improvements in both physical and psychological aspects of QoL (Cameron *et al.*, 2000; Dew *et al.*, 1997). In contrast, liver, lung and heart transplant recipients report largest gains in those aspects of QoL most affected by their condition and smaller or no improvements in areas affected by psychological functioning (Bravata & Keefe, 2001; Limbos *et al.*, 2000).

In contrast to these variable patterns of change within specific areas of functioning, studies which examined global quality of life responses have uniformly indicated that recipients of transplanted organs overwhelmingly subscribe to the view that the overall quality of their lives improves post-transplantation. The discrepancy between detailed, specific and global QoL evaluations indicates that transplant patients view specific QoL areas very differently from how they view the overall quality of their lives. In assessing QoL these differences between global and specific QoL dimensions should be borne in mind.

There is a set of psychological issues around transplantation that most generic QoL instruments fail to capture. These range from the pre-transplantation period during which patients face the decision to pursue transplant, the evaluation process and the inevitable waiting period to the post-transplantation period during which time patients come against a whole new set of stressors, challenges and adaptive demands (Grady *et al.*, 1996; McQuellon *et al.*, 1997). Recipients of different transplant organs have similar types of concerns, although these may vary in the degree of importance. These include the cost and side effects of immunosuppressive medication, worries about the viability of the transplanted organ, fear of rejection and the need to adhere to a rigorous post-transplant care regime (Fallon *et al.*, 1997; Gubby, 1998; Jalowiec *et al.*, 1994; Kong & Molassiotis, 1999).

It has been argued that a viable organ transplantation, albeit a life-saving procedure for several end-stage medical conditions, does not cure disease but rather extends life by trading one chronic disease for another (Johnson, 1990). Transplantation is an ongoing treatment. Transplant patients are required to follow a lifelong, strict immunosuppressive medication regimen, attend frequent clinic and laboratory appointments and remain vigilant about physical changes that may signal organ rejection or infection.

Maintenance immunosuppression traditionally involves the use of a Calcineurin Inhibitor, either cyclosporin or tacrolimus. There is no consensus about whether the regimen with cyclosporin or tacrolimus is more effective; both are considered effective in preventing acute rejection (Keown, 2001). Major side effects are associated with each of the traditional immunosuppressive drugs used in transplantation, particularly cyclosporin (and related tacrolimus) and corticosteroids. Complications include the acceleration of vascular disease so that myocardial infarction and strokes are commoner in transplant patients than in age-matched controls. Transplant recipients also suffer from multiple other complications including bone loss (Julian *et al.*, 1992), increased incidence of fractures (Ramsey-Goldman *et al.*, 1999) and increased risk for the development of malignancy and infection as compared with age-matched population.

Immunosuppressive medications are challenging for patients owing their numerous side effects, including mood swings, sleep disorders, gastrointestinal problems, sexual dysfunction and tremors to name a few (Franke *et al.*, 1999; Jalowiec *et al.*, 1997; Moons *et al.*, 1998) (see 'Sleep disorders' and 'Sexual dysfunction'). Patients' subjective appraisal of immunosuppressive side effects and associated distress is a key to evaluating the balance between the benefits and burden of immunosuppressive regimens after transplantation. Symptom experience can affect QoL perceptions, may impede ability to return to work and may trigger non-adherence to immunosuppressive regimen (De Geest & Moons, 2000).

Accumulating evidence suggests that a considerable number of transplant recipients fail to adhere to post-transplant regimen (Laederach-Hofmann & Bunzel, 2000). Adherence difficulties appear to be even more prominent among adolescents (Rianthavorn *et al.*, 2004). This is of particular concern in the light of evidence indicating that poor adherence is a major determinant of rejection episodes, graft loss and death (Bunzel & Laederach-Hofman, 2000; Nevins & Matas, 2004). One study for instance, indicated that 78% of cases of renal graft failure in the second year after transplant were believed to be due to non-adherence (Kiley *et al.*, 1993) (see also 'Adherence to treatment').

There may be additional psychological issues that pertain primarily to the living donor transplantation. Feelings of guilt, for instance, have been found to be more prominent in living-donor than cadaveric kidney transplant recipients (Griva *et al.*, 2002). There is also a whole range of issues related to donation decision and the effects of donation on donors physical and psychological wellbeing (Olsbridge *et al.*, 2002). Many of the sentiments expressed by donors are happiness and satisfaction gained through being able to donate, as well as worry about the recipient's medical outcomes (Goldman, 1993; Simmons *et al.*, 1987). Adverse psychological responses, although not common, appear to be related to pre-donation ambivalence (Switzer *et al.*, 1996).

The recognition of these transplantation specific issues led to the refinement and evolution of the measurement of QoL and wellbeing in transplant populations. Transplantation-specific instruments such as the Transplant Effects Questionnaire have been designed to complement existing generic QoL measures by assessing transplantation-specific emotional and behavioural responses (Ziegelmann *et al.*, 2002).

Neuropsychological functioning in transplantation is an important outcome as cognitive capacity is intimately connected to activities of daily living (Putzke *et al.*, 2000), social and vocational adjustment (Bremer *et al.*, 1997) and mortality (Liu *et al.*, 1990). Most transplant populations have significant potential for cognitive impairments related to the nature of the specific disease processes (e.g. hepatic encephalopathy, uraemia) (Farmer, 1994). Neuropsychological dysfunction including decreased attention and concentration, memory deficits and diminished perceptual-motor co-ordination has been reported in patients with organ failure (Tarter & Switala, 2000). Neuropsychological functioning has been found to improve with transplantation and transplant patients have less impairments compared to non transplanted patients (Griva *et al.*, 2004). Patients undergoing heart (Bornstein *et al.*, 1995), kidney (Teschan *et al.*, 1979; Krammer *et al.*, 1996) and liver transplantation (Tarter *et al.*, 1990) experience substantial

albeit not full recovery of cognitive functioning. It is important, however, that there are individual differences and cognitive functioning does not return to normal in all transplant recipients (see also 'Neuropsychological assessment' and 'Neuropsychological rehabilitation').

Persisting cognitive dysfunction has been documented in bone marrow transplant (BMT) recipients (Harder *et al.*, 2002; Meyers *et al.*, 1994). This may at least in part be attributed to BMT conditioning regimen that involves high-dose chemotherapy, often combined with total body irradiation known to have adverse neurological effects (Padovan *et al.*, 1998). Kidney transplant patients on the other hand are less likely to experience cognitive

deficits relative to norms (Griva *et al.*, 2004; Teschan *et al.*, 1979). This variability in cognitive improvement may be determined by multiple factors such as the type of organ disease, the severity and chronicity of illness and co-morbidities as well as sociodemographic variables such as age and education level.

Cognitive and developmental delay appears to be common in paediatric transplant population although again there is substantial heterogeneity between and within transplant groups (Fine *et al.*, 2004). Further research is needed to explain the large individual differences in neuropsychological functioning and elucidate biological factors which influence cognitive problems in transplantation in both adults and children.

Urinary tract symptoms

Martin Cartwright and Mark Emberton

University College London

This chapter focuses on lower urinary tract dysfunction in middle-aged and older men.

Definition

The International Continence Society uses the term 'lower urinary tract symptoms' (LUTS) as an umbrella heading covering a range of urinary dysfunction as reported by the individual patient or their caregiver (Abrams *et al.*, 2002). Under this general heading individual urinary symptoms are sub-divided into three symptom groups according to their functional characteristics: storage symptoms, voiding symptoms and post-micturition (i.e. post-urination) symptoms. Definitions of the principal symptoms in each of these sub-groups are presented in Table 1.

Table 1. Definition of individual LUTS

Symptom Group	Definition
<i>Storage Symptoms</i>	
Frequency	Urinating too often during the daytime.
Nocturia	Waking from sleep to urinate once or more per night.
Urgency	Sudden compelling desire to urinate, which is difficult to defer.
Incontinence ^a	Any involuntary leakage of urine.
<i>Voiding Symptoms</i>	
Hesitancy	Difficulty initiating urination even when feeling ready to pass urine.
Straining to void	Requires muscular effort to initiate, maintain or improve the urinary stream.
Intermittency	A urinary stream which stops and starts on one or more occasions during the course of a single voiding episode.
Slow stream	Reduced urinary flow compared to previous or others' performance.
Terminal dribble	Prolonged end-stage of urination during which the flow is reduced to a trickle or dribble.
<i>Post-micturition Symptoms</i>	
Incomplete emptying	Feeling that the bladder has not fully emptied once urination has stopped.
Post-micturition dribble	Involuntary loss of a small amount of urine shortly after urination is thought to have finished (usually when rising from the toilet in women or after re-dressing in men).

^aIncontinence is further sub-classified into several types including stress incontinence, urge incontinence, mixed incontinence, continuous incontinence and nocturnal enuresis (Abrams *et al.*, 2002).

Prevalence

LUTS has become increasingly common with age. Evidence from community surveys shows that 20–30% of men over the age of 50 experience moderate to severe LUTS when assessed aggregately (e.g. in Germany, Berges *et al.*, 2001). The prevalence of individual urinary symptoms ranges from 6% for straining to 49% for terminal dribbling, with 93% of men (≥55 years) reporting some degree of current urinary dysfunction (Wolfs *et al.*, 1994). Extrapolated to the UK population these figures suggest there are between 1.8 and 2.7 million men (≥50 yrs) with a *moderate* to *severe* degree of (aggregated) urinary dysfunction and up to 8.3 million men (≥50 yrs) who currently experience at least one urinary symptom; albeit the majority of these symptoms will be mild.

Aetiology

The classification of LUTS into storage and voiding symptoms is a well established heuristic and has received both psychometric and, to a lesser extent, clinical support (Donovan *et al.*, 2000). Nevertheless, definitions of individual symptoms are purely descriptive and do not imply a particular causal mechanism or pathophysiology. In fact LUTS can occur secondary to renal, cardiac or neurological disorders. Urinary dysfunction resulting from these extra-LUT disorders, along with certain intra-LUT abnormalities such as prostate cancer, are collectively referred to as 'complicated LUTS'. This distinguishes them in terms of aetiology, treatment and prognosis from 'uncomplicated LUTS' which are assumed to have localized causes and are typically non-life-threatening. Around 90% of male LUTS cases presenting to secondary care are uncomplicated, this proportion is likely to be higher in primary care and higher still in the general community.

Traditionally urologists have assumed that uncomplicated LUTS in males are caused by bladder outlet obstruction (BOO) in the prostatic urethra due to benign prostatic enlargement (BPE). However, clinical evidence now shows that the association between LUTS, BOO and BPE is weak or non-existent (Lepor, 1998), although the samples studied cluster over a relatively narrow range of urinary dysfunction which would reduce the magnitude of the observed correlations. LUTS, it seems, are not usually attributable to an enlarged prostate gland or a physical blockage of the urethra. Notwithstanding this, both surgical and pharmacological treatments which either remove or reduce BPE and BOO are extremely effective in improving urinary symptoms. The explanation for this apparent contradiction appears to be that the treatment effect of both surgery and pharmacology is mediated by changes in the sensory

innervation of the prostate gland rather than changes in the size of the prostate gland per se (Lepor, 1998). It is now also recognized that age-related changes in bladder structure and functioning such as bladder neck hypertrophy, detrusor instability and impaired detrusor contractility can result in LUTS in men.

Fear of prostate cancer

Misinformation about the causes of LUTS in men has fostered a widespread belief that urinary symptoms are indicative of prostate cancer. The explanation for this putative link between LUTS and prostate cancer is simple and biologically plausible: as a tumour grows inside the prostate gland it will eventually press against the urethra, which runs directly through the gland carrying urine from the bladder, thus resulting in BOO and urinary symptoms. Despite the intuitive appeal of this explanation it is, at best, misleading. Prostate cancer develops in the peripheral zone of the gland well away from the prostatic urethra and therefore tumours tend to metastasize long before they have the opportunity to interfere with the urethra and urinary functioning. Consequently, curable (i.e. pre-metastatic) prostate cancer is almost always asymptomatic and there is no evidence of a clinically significant association between LUTS and prostate cancer at the population level (Young *et al.*, 2000) (see 'Cancer; prostate').

While there is evidence that fear of prostate cancer can increase the likelihood of medical help-seeking (Sladden *et al.*, 2000), coping theories such as Leventhal *et al.*'s (1984) common sense model of illness danger (see 'Lay beliefs about health and illness') would predict the existence of another group of men (who make different appraisals regarding the cause and curability of LUTS) for whom fear of prostate would act as a barrier to help-seeking (see also 'Delay in seeking help').

Quality of life

LUTS can have a significant negative effect on the quality of life (QoL) of the sufferer (see 'Quality of life'). Symptom severity is positively associated with interference with activities of daily living (getting enough sleep, going to places without toilets, going to the cinema, playing outdoor sports etc.) and negatively associated with sexual satisfaction. These relationships have been found to hold cross-culturally in samples drawn from Scotland, France, Japan and the USA (Girman *et al.*, 1998).

LUTS can affect partner's QoL through similar mechanisms (Sells *et al.*, 2000). In wives of patients seeing a urologist for LUTS, 47% reported that their social life was limited by their husband's urinary symptoms, 66% were worried about the possibility of their husband needing an operation and 71% were worried that the symptoms may be caused by cancer.

Help-seeking

Symptoms and manifest disease known to general practitioners represent only the tip of the illness iceberg. LUTS are no different in this respect and community surveys suggest that 60–70% of men who experience moderate to severe LUTS have never discussed their

symptoms with a doctor (Hunter & Berra-Unamuno, 1997). Taken together with the prevalence figures reported earlier, this suggests that there could be up to 1.9 million men in the UK (≥ 50 yrs) with moderate to severe LUTS who have never spoken to their primary care physician (GP) about their symptoms. Given the potential of LUTS to negatively impact on QoL, untreated urinary dysfunction in middle-aged and older men clearly represents a significant public health concern.

There is a general consensus among published studies that symptom severity and perceived bother are positively associated with help-seeking behaviour (i.e. having spoken to a doctor about the symptoms). Some studies have also shown that age increases the likelihood of having sought medical help (e.g. Hunter & Berra-Unamuno, 1997) and (e.g. Sladden *et al.*, 2000). Beyond this, there is little agreement about which other factors might drive men to seek help for LUTS. Most studies have tended to focus on symptom variables (e.g. severity, perceived bother, interference with activities of daily living) and demographic variables (e.g. age, education, marital status). However, one study which looked at the influence of components of the Health Belief Model found that cues to action ('I have received information from the mass media on voiding problems') and perceived benefits ('A GP can treat my voiding problems well') were more strongly associated with help-seeking than either symptom or demographic variables (Wolters *et al.*, 2002). The strongest cross-sectional predictor of help-seeking in this study was for the 'cue to action' item 'Others have advised me to visit the GP' leading the authors to conclude that social influence has a stronger impact on the decision to seek help than symptom severity or perceived bother (see 'Health belief model').

Treatment & self-management

Although there appear to be some cases of spontaneous remission, overall men with mild uncomplicated LUTS have a cumulative chance of clinically significant progression of 13, 24 and 31% over 1, 2 and 4 years respectively (Djavan *et al.*, 2004). For men who do seek medical help a cascade of treatment options is available including watchful waiting, pharmacology and surgery. Surgery (i.e. transurethral resection of the prostate) is indicated in patients with progressive or bothersome symptoms that are medically refractory but the procedure carries significant risks of long-term complications (e.g. incontinence, urethral strictures, bladder neck contractures, ejaculation problems and impotence). Pharmacological treatments are now the first-line treatment of choice for men with bothersome LUTS. Numerous randomized controlled trials support the efficacy of these drugs. However, follow-up studies of α -blockers have revealed long-term re-treatment rates of up to 49% over 3 years suggesting patient non-compliance with the medication due to intolerance (De La Rosette *et al.*, 2002).

Thus, there are many reasons why male LUTS patients may not currently be receiving treatment: not all men experience clinical progression; pharmacology will sometimes be ineffective; surgery may not be indicated or may be contraindicated; and some men who are prescribed pharmacological treatments will be non-compliant. For these patients self-management may help to minimize the impact of LUTS and concomitant bother.

Self-management for men with LUTS is not clearly defined but could comprise education, reassurance, general lifestyle modification and specific behavioural interventions (Brown & Emberton, 2004) (see, for example, 'Reassurance' and 'Behaviour therapy'). These self-management techniques are inexpensive, acceptable to

patients and allow male LUTS sufferers to gain some control over their symptoms. Their use should be encouraged as a primary intervention and as adjunct to pharmacological treatment, although further research is needed to formally evaluate their efficacy.

Vertigo and dizziness

Lucy Yardley

University of Southampton

When perception of orientation in space becomes disturbed, the resulting sensation may be described by sufferers as 'dizziness'. However, the technical term used by medical practitioners for an illusory perception of orientation and movement is 'vertigo' (not to be confused with the lay usage of the term to refer to a fear of heights). The sensations that characterize vertigo range from vague giddiness or unsteadiness to a feeling that oneself or the environment is tilting or spinning, accompanied by partial loss of postural control and a range of autonomic symptoms such as pallor, cold sweating, nausea and vomiting (see also 'Nausea and vomiting').

Dizziness is extremely common: around one in four people have experienced recent dizziness, one in ten people of working age report some degree of handicap due to current dizziness, and 2% of the working age population experience chronic, frequent, substantially handicapping episodes (Kroenke *et al.*, 2000; Yardley *et al.*, 1998a). The most common cause of dizziness and vertigo is disorder of the vestibular organ in the inner ear, which senses head position and motion, but dizziness can result from dysfunction of any part of the complex balance system, which integrates information from the vestibular, visual and proprioceptive senses (see also 'Tinnitus').

Vertigo is very often accompanied by emotional disturbance. Anxiety, panic disorder and agoraphobia are more common among patients with balance disorders than in the general population (Clark *et al.*, 1994; Monzani *et al.*, 2001; Sloane *et al.*, 1994), and signs of balance system dysfunction have been found in people with panic disorder and agoraphobia (Asmundson *et al.*, 1998; Jacob *et al.*, 1989, 1996; Yardley *et al.*, 1995). Reports of dizziness are also correlated with reports of anxiety in the community (Yardley *et al.*, 1998a). In older people, dizziness is associated with anxiety, falls, fear of falling and loss of independence (Burker *et al.*, 1995; Sloane *et al.*, 1989).

Early medical theories proposed a possible causal (psychosomatic) link between either personality or stress and the onset of some types of vertigo, but there is no good evidence as yet to support this hypothesis (for a review of this early work see Crary & Wexler, 1975). Furman and Jacob (2001) suggest a larger set of possible mechanisms that might explain the association between dizziness and anxiety, including: primary psychiatric disorder; chance co-occurrence; problematic coping with balance disorder; and overlap in the neural structures involved in dizziness and anxiety. Theory and research suggest that a complex combination of affective, cognitive and behavioural mechanisms, underpinned by psychophysiological and neurological processes, may contribute to the association between dizziness and emotional disturbance, as outlined below.

Perceptual-motor and behavioural causes of dizziness

Recovery from balance system dysfunction takes place naturally by means of a process of central adaptation known as 'compensation'. Any unusual combination of input from the vestibular organs, vision and proprioception at first provokes disorientation and postural instability. However, with continued experience of the new pattern of input which results from each position or movement, central recalibration of the balance system occurs, and dizziness is no longer provoked. It is therefore possible to become free of symptoms even if disease results in a permanently altered pattern of sensory input (for example, with loss of input from one balance organ). This process is very similar to adapting to environments which provoke motion sickness, and, just as it is necessary to remain at sea in order to acquire one's 'sea-legs', it is equally essential to engage in the activities which provoke dizziness in order to achieve compensation. Consequently, if movements or environments that provoke dizziness are avoided, then compensation does not occur and the dizziness will continue to be provoked.

Many people with balance disorders find that they become dizzy in environments which provide the visual, vestibular and somatosensory systems with unusual or conflicting information about orientation. People who have unconsciously come to rely more on visual than vestibular input for balance, sometimes because of vestibular disorder, may experience disorientation and instability when exposed to large-scale movement of the visual scene (e.g. passing traffic, moving crowds) or when the visual environment is too distant (e.g. in open spaces or high places) to provide useful input for control of balance (Beidel &

Horak, 2001; Redfern *et al.*, 2001). Similarly, people with imperfect compensation for vestibular imbalance often find that dizziness can be provoked by the relatively unusual and vigorous vestibular stimulation associated with abruptly starting and stopping in elevators and motor vehicles, or the motion of planes or boats.

Influence of affect, cognitions and arousal

Dizziness is a common symptom of anxiety and panic disorder, and so in some cases dizziness has a purely psychological origin. However, evidence of balance system dysfunction is found in a high proportion of patients complaining of dizziness (e.g. Clark *et al.*, 1994; Sloane *et al.*, 1994). Anxiety is frequently a response to dizziness caused by balance system dysfunction. Disorientation and vertigo appear to have an intrinsically frightening quality, perhaps because of the fundamental disruption of the relationship between the self and environment, the sense of losing control over one's body and movements, the unpredictability of attacks of dizziness, and the intensely unpleasant somatic sensations (Monzani *et al.*, 2001). Individuals who are prone to anxiety, especially regarding somatic sensations, are likely to develop more severe anxiety reactions to dizziness and vertigo (Hagnebo *et al.*, 1999; Sloane *et al.*, 1994) (see also 'Symptom perception').

Additional sources of anxiety about chronic dizziness include fear that it might be a sign of serious undetected disease, since it is often difficult to obtain a firm diagnosis, and fear of the social embarrassment that may be felt if an unexpected attack occurring in public leads to a sudden, apparently inexplicable loss of control (Yardley *et al.*, 1992). It has been shown that higher levels of disability (due to self-imposed restriction of physical and social activity) are predicted by negative beliefs, for example, that the dizziness would result in loss of control, serious illness, physical harm and being unable to behave normally (Yardley *et al.*, 2001). Moreover, if fear of dizziness or its consequences leads to avoidance of activities which provoke dizziness, this will retard or prevent compensation and also result in increased handicap. A vicious cycle can then ensue in which the dizziness and avoidance of activity can be maintained indefinitely. Since environments that provoke dizziness may also be feared and avoided, a form of agoraphobia may develop (Jacob *et al.*, 1989, 1996; Yardley *et al.*, 1995).

Anxiety about dizziness may in turn fuel further dizziness and dizziness-related handicap in several ways. Since anxiety arousal is itself characterized by physical symptoms (including dizziness) it may increase the intensity and symptoms of dizziness. Autonomic symptoms of anxiety are a predictor of handicap levels in dizzy patients (Yardley *et al.*, 1999). Since vestibular input feeds into ascending autonomic pathways it is possible that it could directly contribute to heightened arousal, and also that arousal levels might influence perception of vestibular input (Balaban & Thayer, 2001). In addition, anxiety arousal can lead to hyperventilation (over-breathing), which is associated with increased symptoms of dizziness and has been shown to interfere with postural control and central processing of vestibular input (Sakellari *et al.*, 1997; Yardley *et al.*, 1998b) (see 'Hyperventilation').

Therapy for dizziness with anxiety

The key to aiding recovery from balance system dysfunction is to prevent or reverse the cycle of activity restriction and continued dizziness. This can be achieved by 'vestibular rehabilitation', a programme of graded eye, head and body movements designed to stimulate the vestibular system and promote central compensation. Because these exercises at first provoke mild dizziness in a predictable manner, they also provide a means of restoring a sense of control over the dizziness, overcoming fear and avoidance of

activities that elicit disorientation, and regaining skill and confidence in balance (Beidel & Horak, 2001). Vestibular rehabilitation can be explicitly supplemented by elements of cognitive-behavioural therapy (Gurr & Moffat, 2001; Jacob *et al.*, 2001; Johansson *et al.*, 2001), but a simple therapy programme of graded exposure to movements and environments which provoke dizziness, accompanied by explanation of the causes of dizziness, has been shown to reduce negative beliefs about dizziness and result in reduced symptoms and handicap (Yardley *et al.*, 2001, 2004).

Vision disorders

Beth Grunfeld

King's College London

Currently, there does not exist a model for the psychological response to loss of vision. Any disorder that impairs sensory functioning is likely to have profound psychological effects. Acquired blindness requires a radical revision of one's basic assumptions about the world. One would expect the psychological response to loss of vision to be different under circumstances of sudden rather than of gradual loss of vision. Symptoms that have a gradual onset may be accompanied by coping strategies employed to compensate for diminishing sight ability and to reduce the negative consequences associated with that loss (Green *et al.*, 2002). This means that those who experience a gradual onset have more time to prepare themselves for the changes that are occurring but at the same time these changes may be easier to ignore thereby hindering the initiation of appropriate coping resources.

Low vision

Low vision has been defined as a permanent visual impairment that is not correctable with spectacles, contact lenses or surgical intervention and that interferes with normal daily living (Mehr, 1975). Vision loss has been ranked third, behind arthritis and heart disease, among conditions that cause persons over 70 to need assistance with daily living activities (LaPlante, 1988). It is estimated that over one million people in the UK could be registered as blind or partially sighted (Bruce *et al.*, 1991).

Patients with low vision tend to score lower in physical functioning and higher in role limitations caused by physical and emotional health problems (Scott *et al.*, 1999). There may also be problems due to an unrealistic hope of recovery or a refusal to adopt the new skills necessary for adjusting to life as a blind person, which can impact on the individual's independence (Fitzgerald *et al.*, 1987). It is suggested that patients should be given clear details about their prognosis and advice on how the loss could impact on their future (Fitzgerald & Parkes, 1998). Patients may also need recognition that both they and their families may need to follow a grieving process as they accept their loss of vision and experience the impact that this has on their lives.

It has been estimated that 90% of individuals affected by low vision maintain sufficient vision to benefit from training in the use of optical and non-optical devices and adaptive skills. However, data concerning the outcomes of low-vision services is sparse. There is a need to measure the outcome of low-vision rehabilitation to be able to argue the case for low-vision assessment with managed care plans, to improve services offered and to enhance funding for these services. The types of outcome measures that have been employed with this group include objective task-specific measures of functional ability (i.e. reading speed, reading duration and the

ability to read certain print size), patient satisfaction reports and frequency and type of low-vision aid used (Scott *et al.*, 1999). Improvement in reading has been noted among nine out of 10 patients attending a low-vision clinic in the UK (Margrain, 2000). Health-related quality of life has also been used as an outcome measure (in particular the SF-36, Visual Function Questionnaire (Steinberg *et al.*, 1994) and the National Eye Institute Visual Function Questionnaire (Mangione *et al.*, 1998)) and it has been shown that low-vision services are associated with improvement in the subjective functional status of patients (Scott *et al.*, 1999). In this instance the low-vision services comprised a visual examination and provision of magnification necessary for performing specific activities (reading newsprint, watching television, writing) along with training in the use of the aids provided. This same study recommended the use of vision-targeted questionnaires rather than general health-related quality of life questionnaires.

Eye movement disorders

In order to achieve clear vision one must be able to hold an image fairly still on a particular part of the retina, known as the fovea. Visual acuity declines greatly as the image moves away from the centre of the fovea. Each time you move your head or walk, the movement causes not only your head to move but also your eyes. If we had no eye movements then the visual world would appear to 'slip' on the retina with every head movement. This would have several consequences: our vision would be blurred and we would have great difficulty localizing objects as we move through the environment. A further consequence of poor eye movements would be that we would be unable to locate/move to objects of interest that appear in the periphery of our visual field. In fact eye movements allow us to hold images steady for clear vision, to bring objects of interest on to the fovea and also to track objects of interest as they move across the visual environment. We have six muscles that control the movement of the eye (known as the extra-ocular muscles) and these work together to move the eyes up/down, left/right and torsionally. Eye movement disorders fall into two main categories, i.e. problems coordinating the movement of the two eyes simultaneously and problems with particular directions of gaze.

Squint

Perhaps the most well known eye movement disorder is strabismus, otherwise known as a squint. A squint is a condition that arises

because of an incorrect balance of the muscles that move the eye, faulty nerve signals to the muscles and some refractive error (focusing faults). As a result the eye may turn in (converge), turn out (diverge) or sometimes turn up. Approximately 5 to 8% of children are affected by a squint or a squint-related condition. Many children with squints have poor vision in the affected eye. There is concern that there may be negative social bias against children with squints. A recent study asked school teachers to rate their perceptions of the children's personal characteristics (using a 10-item list of personal characteristics) based on their responses to whole-face photographs. Children with squint were rated more negatively on all 10 characteristics (Uretmen *et al.*, 2003). The authors argued that correction of strabismus through patching the good eye to encourage the weaker eye to be used, use of special eye drops, or surgery may provide cosmetic and psychosocial benefits, even when there is no hope of improving visual function. In addition, adult patients have reported difficulties with self-image and interpersonal relationships, having faced ridicule at school and work and having avoided activities which drew attention to their squint (Menon *et al.*, 2002).

Nystagmus

Nystagmus is the involuntary rhythmic movement of the eyes. Nystagmus occurs in numerous normal/nonpathological situations, for example it occurs when we make large or continuous head movements and serves to keep a stable image on the retina by compensating for the head movement. However, nystagmus can also be pathological and can result in continuous eye movements even with the head still, the result of which is a blurring of vision.

Patients may report oscillopsia, which is an illusionary movement of the visual environment. It occurs because the eyes are moving inappropriately and therefore each eye movement is perceived as a movement of the environment. In such cases nystagmus may be caused by a lesion in the vestibular system, the brainstem, the cerebellum or due to intoxication. Congenital nystagmus is thought to be present at birth, but is usually not apparent until the baby is a few months old. The number of people with congenital nystagmus that suffer from oscillopsia is much less than those with acquired nystagmus although this is dependent on the type stimulus and the quality of the viewing conditions (Gresty *et al.*, 1984). The lower incidence of oscillopsia in congenital nystagmus is thought to be because an infant, knowing no different, can adapt to the perception of motion better than an adult who previously had normal vision. However, around 15% of congenital nystagmus patients have strabismus (squint). In addition, long distance vision is limited, but most patients have sufficient vision to lead independent lives. Most sufferers can read small print providing that it is held close enough. Some patients can obtain a 'null point' which means that certain head positions can lead to a reduction in the amplitude of the nystagmus or eye movements, which improves their ability to see. In addition, level of vision varies during the day according to stress, tiredness or nervousness. Crossing roads, or getting about in busy places, such as supermarkets, can be difficult for a nystagmus sufferer. Some patients report concerns about their physical appearance due to the continuous movement of their eyes and the fact that holding their head in a particular position to obtain a 'null point' can look odd to the layperson.

Voice disorders

Ruth Epstein

Royal National Throat, Nose and Ear Hospital

Voice disorders represent an area of communication dysfunctions, which affects a large population of people. Individuals with voice disorders range from a simple case of laryngitis that usually resolves spontaneously to more physical or organic conditions such as laryngeal malignancy.

Symptoms

The main symptom in people with voice disorders is hoarseness or dysphonia, which describes an alteration in voice quality. It is difficult to define a normal or an abnormal voice quality in the absence of a fixed, uniform standard of abnormal voice but according to Aronson (1990) 'a voice disorder exists when quality, pitch, loudness or flexibility differs from the voices of others of similar age, sex and cultural group'. A voice disorder may also exist when the structure of the laryngeal mechanism, the function, or both no longer meet the voicing requirements of the speaker (Stemple *et al.*, 2000). In medical practice, hoarseness is described as a symptom of laryngeal disorder, which is often the first and only signal of disease, local or systemic, involving this area. The differential diagnosis is important as many different medical and surgical conditions may result in hoarseness.

Aetiology

Voice disorders can be aetiologically classified into organic and non-organic types; the latter are often referred to as functional or psychogenic types. In organic voice disorders, the faulty voice is caused by structural or physical disease of the larynx itself, or by systemic illness that alters laryngeal structure (Boone & McFarlane, 1988). Organic disorders of vocal mechanisms that may result in voice problems include keratosis, granulomas, leukoplakia, papillomas, carcinoma and other malignancies. Voice problems associated with nervous system involvement include spasmodic dysphonia, myasthenia gravis and vocal fold paralysis.

Functional or non-organic voice disorders are non-physical in origin or result from faulty habits of voice use. The voice sounds abnormal despite normal laryngeal anatomy and physiology. Non-organic disorders can be divided into habitual vocal problems, secondary to vocal misuse/abuse and psychogenic vocal problems. Vocal misuse includes behaviours of vocal abuse and the use of inappropriate vocal components, such as pitch, loudness, breathing strategies, phonation habits and speech rate. Habitual dysphonias include nodules, polyps, cysts, oedema, ventricular dysphonia, laryngitis and contact ulcer. Psychogenic voice disorders include musculoskeletal tension disorders and conversion voice disorders:

muteness, aphonia and dysphonia which can be traced to the anxiety or depression produced by life stress, psychoneuroses or personality disorders (see also 'Stress').

Incidence

The incidence of voice disorders is difficult to establish because figures vary dependent upon age, gender and occupation. Verdolini (1998) reported a prevalence of 3–10% in the general population. Herrington-Hall *et al.* found, in their review of patients who sought evaluation for voice disorders, that the ten most common patient occupations were retired, homemaker, factory worker, unemployed, executive, teacher, student, secretary, singer and nurse (Herrington-Hall *et al.*, 1988). In general, pathologies occurred more frequently in older populations, with the largest group of patients ranging in age from 45 to 64 years (Herrington-Hall *et al.*, 1988). Estimates of voice disorders for children are also variable but tend to exceed those for adult speakers. Typical prevalence rates range from as low as 6% to as high as 23% (Stemple *et al.*, 2000), mostly caused by vocal abuse.

Diagnosis

The primary objectives of the diagnostic voice evaluation are to discover the aetiological factors associated with the voice disorder, and to describe the deviant vocal symptoms. Mirror laryngoscopy is the most commonly used method of viewing the larynx. For more specialized studies, video stroboscopy, direct laryngoscopy, laryngography and radiology are used. The voice evaluation is performed in order to assist the laryngologist and the voice team in making a differential diagnosis and recommending appropriate treatment.

The differential diagnosis begins with categorizing the abnormal voice on the basis of laryngological, physiological and neurological evidence. Assessment of the voice-disordered patient is enhanced by input from various disciplines (otolaryngologist, speech and language therapist, voice scientist, neurologist, physical therapist, vocal coach or singing instructor) through a team approach.

Management and treatment

There are three general approaches to the management of voice problems: surgical, medical and behavioural (Colton & Casper, 1990). It is often the case, however, that optimal treatment requires the use of combined treatment modalities. Surgical management is considered the more radical form of intervention and is referred to as phonosurgery, i.e. surgical techniques aimed at improving

voice quality. The medical approach to the treatment of voice disorders refers to non-invasive techniques which do not involve surgical removal of tissue, reconstruction or alteration. The behavioural approach consists of voice therapy which aims at restoring the best voice possible within the patient's anatomical, physiological and psychological capacity.

The diagnosis of the voice disorder will determine the treatment. Some organic voice disorders will be improved by phonosurgery. In laryngeal carcinoma, surgery will be used to eradicate cancer.

Acute laryngeal problems in which the vocal folds demonstrate redness, swelling or irritation (e.g. resulting from gastroesophageal reflux) will be medically treated. When vocal abuse appears to be the cause of the laryngeal problem, voice therapy will be carried out, using principles of vocal re-education, and reduction of stress factors that drive the patient into patterns of vocal misuse. The treatment of conversion voice disorders, where the patient has a need to be partially or completely without voice, is based on re-establishing the patient's conscious awareness of greater phonatory capability, and discussing the emotional conflicts that have generated the voice disorder, while monitoring the possibility of referral for psychotherapy (see also 'Behaviour therapy', 'Cognitive behaviour therapy', 'Counselling' and 'Psychodynamic psychotherapy').

Progression from abnormal to normal voice occurs as a product of the patient's conscious, voluntary response to the clinician's

instruction and encouragement. In organic disorders, the main principle of therapy is either muscle strengthening or adaptation to the mechanical problems through compensatory phonatory and respiratory manoeuvres.

In non-organic voice disorders, involving excess musculoskeletal tension, treatment is based on the principle that when muscle tension is reduced, the larynx will return to its normal phonatory ability. This is achieved by mechanical relaxation of musculature and psychological release of the anxiety causing the tension.

Psychology and voice disorders

Knowledge of the principles and skills of psychological interviewing and counselling are essential in the diagnosis and treatment of voice disorders. Virtually all patients with voice disorders, organic or psychogenic, have some degree of emotional imbalance, either as a cause or effect of the problem. Many functional voice disorders disappear or improve during discussion of life stresses responsible for those disorders.

In voice therapy in particular, the association between stress, emotional states and voice has led to a very strong emphasis on psychodynamic theory in the explanation of the causes of some types of voice disorders. Awareness of more serious emotional problems in patients with voice problems can facilitate referrals to professional mental health specialists.

Volatile substance abuse

Michael Gossop

Institute of Psychiatry

Volatile substance abuse (VSA) is often, though inaccurately, referred to as 'glue sniffing'. It differs from other types of drug abuse in that it is primarily a problem of children and adolescents, and the substances used are legally available. Reliable prevalence estimates are difficult to obtain. Ashton (1990) found that between 3.5 and 10% of adolescents may have at least experimented with

volatile substances, and that between 0.5 and 1% of the secondary school population may be current users. Ramsey *et al.* (2001) found that 7% of a sample of young people reported lifetime use of volatile substances but only 1% had used within the last year and less than this within the last month, suggesting that this behaviour was not habitual or regular use. Solvent abuse is often very localized and in

these circumstances the percentage of young people using these substances may be considerably higher. The majority of volatile substance abusers are aged between 12 and 19. In a survey of over 2000 14–15-year-olds in London schools, Best *et al.* (2004) found the mean age of first use was 12.6 years, with those who used volatile substances tending to start use very soon after the first offer (see 'Adolescent lifestyle').

Volatile substances act like CNS (central nervous system) sedatives with a similar picture of acute intoxication. These substances are generally highly fat-soluble and diffusely toxic to the nervous system. The toxicology of each of the volatile substances may carry different risks for the user, and persistent VSA may create medical problems that require attention (Sharp & Rosenberg, 1992). Chronic abuse may lead to weight loss, muscle weakness, disorientation and lack of coordination. Chronic exposure to some organic solvents may cause polyneuropathy. Volatile substances affect brain function in many ways though most of these effects appear to be reversible. Exceptions can generally be attributed to cerebral hypoxia or a metabolic acidosis. There is also concern about the toxic effects of volatile substance abuse upon other organ systems, including kidney, liver, heart and blood. Deaths associated with VSA are rare, given the probable prevalence of the behaviour. Deaths may be due to asphyxia, aspiration of vomit, trauma, or direct toxicity (see 'Vomiting and nausea', 'Vertigo and dizziness' and 'Renal failure, dialysis and transplantation').

The possibility of making VSA an offence in Britain was considered in 1983, in consultation with a wide range of statutory and voluntary agencies. The majority view was opposed to it on the grounds that young people would be deterred from seeking help from adults or from helping agencies, that it would increase the likelihood of such behaviour becoming more deeply hidden, thereby increasing the risk of accidents in circumstances in which help would be unavailable, and that it would lead to an unnecessary criminalization of juveniles.

One factor underlying VSA is the ready availability of these substances. The average home is likely to contain dozens of substances which are capable of being abused, including aerosols (paints, lubricant sprays and deodorants), as well as lighter fuel, petrochemicals, glues, thinners and other solvents.¹ The almost universal availability of volatile substances creates a special problem since it is impractical to prevent the abuse of these substances through restricting access to them. In England and Wales, the Intoxicating Substances (Supply) Act of 1985 makes it an offence to supply or offer to supply any volatile substance to a person under the age of 18 if the substance is likely to be misused for the purpose of causing intoxication.

There are differences in the degree of risk associated with different types of volatile substances. Two of the more risky forms of VSA appear to be the inhalation of cigarette lighter fuel and inhaling the contents of fire extinguishers (Gossop, 1993). Both have been linked to fatalities. The level of risk to the user may also differ with the precise method of administration. Methods that involve putting

plastic bags over the head of the user are risky and may lead to asphyxiation (see 'Risk perception').

Because volatile substance abusers tend to be so young, concern can sometimes take the form of excessive reactions. The strength of these reactions, often coupled with demands for instant response, may complicate the ability of those concerned to identify and provide the most appropriate interventions. Only a minority of those who experiment with these substances go on to become regular users, and only a minority of regular users are likely to experience serious problems or harm as a result of their use.

Volatile substance abuse may reflect underlying psychiatric problems but this is not always the case. Some cases involve 'experimental' behaviour by otherwise well-adjusted individuals. Some cases reflect 'subcultural' patterns of abuse in which the individual has been socialized in the abuse of volatile substances by their peers. This raises questions about how most effectively to intervene in such cases. Although VSA clearly is a type of drug problem, it should not automatically be assumed that referral to a specialist drug dependence treatment service is the most appropriate response. Such services are often geared to the needs of adult (and young adult) users of drugs such as heroin, cocaine or amphetamine. Many of these drug takers will be severely dependent (addicted), and many will be drug injectors. In contrast, comparatively few volatile substance abusers will be addicted in the sense of being either physically or psychologically dependent upon their drugs. There is an obvious risk of exposing 15-year-old solvent abusers to an environment where they could be expected to be influenced by adult heroin injectors (see 'Drug dependency: opiates and stimulants').

Family doctors, social workers and other carers sometimes deal with their lack of expertise in this area by referring the user to another agency which is assumed to have greater knowledge or skills. This may be a psychiatry or a drug treatment service. Such referral may be neither necessary nor desirable. Many useful interventions can be delivered at the primary health care level or by non-specialists working with young people such as teachers, counsellors or social workers.

It can be useful to interpret the behaviour and problems of volatile substance abusers in terms of other more familiar adjustment problems that affect young people. The factors that lead to VSA may be similar to those that lead to other social adjustment problems, and although volatile substance abuse may be the presenting problem it may be only one of a number of problems, and not necessarily the most important. Best *et al.* (2004) found that schoolchildren who used volatile substances were also more frequent users of alcohol, cigarettes and cannabis: they reported more psychological health problems, greater involvement in criminal activities and lower levels of educational commitment. When viewed in a broader perspective, the types of interventions that are used with other adolescent problems may appear more applicable with volatile substance abusers. There is no simple or established treatment that can be applied specifically to those involved in VSA.

The risk of accidental injury is always a problem for the volatile substance abuser. Acute effects, like drunkenness, may

¹ A different form of drug misuse involves inhalants such as amyl and butyl nitrite ('poppers'). Unlike other volatile substances which are more often used by adolescents, these substances are typically used by young adults in clubs as part of the dance scene to intensify the euphoric experience, or during sex for the enhancement of sexual pleasure.

be accompanied by confusional or hallucinatory states. A worrying feature of VSA is that the risk is not proportionate to the degree or the duration of involvement. First-time users may be at high risk. The number of young people who die as a consequence of volatile substance abuse is relatively small in comparison

to the number of users but, tragically, many deaths have involved children (deaths have been recorded for 10- and 11-year-olds, and 60% of deaths are among people aged 17 or less) (Pottier *et al.*, 1992) (see 'Adolescent lifestyle' and 'Communicating risk').

Vomiting and nausea

David J. de L. Horne and Elizabeth A. Coombes

University of Birmingham and Cancer Centre

Phenomenology of vomiting and nausea

Feelings of nausea (N) and actual vomiting (V) are universal experiences of human beings and probably also of many animals. Most of the time both N and V are acute experiences that pass quickly and are of little medical or health significance. However, severe and/or prolonged N and/or V can be very distressing and even life threatening; for example in children when V is associated with diarrhoea and dehydration, or people who die through choking on their vomit.

As Stern (2002) has recently highlighted, N, like pain, fatigue and itchiness, is a private, subjective experience but one which is highly dependent upon the interplay of profound physiological and psychological factors. Both V and N share much in common as far as causal factors are concerned but V, unlike N, is an observable and objectively verifiable event. This has implications for medical assessment and treatment so that N may be under-recognized and under-treated compared with V. This is particularly pertinent in chemotherapy for cancer (e.g. Sun *et al.*, 2002) (see 'Chemotherapy').

N and V are associated with many aspects of illness and healthcare and frequently are of clinical significance (e.g. bulimia with induced vomiting; viral infections; side effects of treatments, such as chemotherapy (Osoba *et al.*, 1997) and in pregnancy (Chou *et al.*, 2003), where clear relationships have been found between depression and N and V.

Both N and V occur when a specialized part of the brain, called the vomiting centre, is stimulated by signals which can arise from

various points in both the brain and body; e.g. the digestive system, the parts of the brain responsible for consciousness, the inner ear, etc. Signals may also arise from an area of the brain called the chemoreceptor trigger zone, which stimulates the vomiting centre if it detects any harmful substances present in the blood. Anti-emetic drugs may act at any one or more of these locations. In addition, a person's cognitive appraisal of their situation is a key factor influencing the severity of their response, particularly in the case of N (Stern, 2002; Montgomery & Bovberg, 2003; Roscoe *et al.*, 2000). Both N and V, if prolonged, can have profound effects on quality of life (e.g. Osoba *et al.*, 1997; Kim & Morrow, 2003) (see also 'Quality of life').

Thus, while it is quite clear there are strong biological and physical factors affecting N and V, it is also apparent that psychological factors affecting emotions, cognitions and behaviours also have a key role. Experiencing N and V is distressing and so obviously produces a range of responses. These include trying to reduce the symptoms, often by medication, but also by learning to avoid situations that have been associated, at least temporarily if not directly causally, with N and V.

Measurement of nausea and vomiting

As mentioned earlier, V is directly observable and measurable but N is experiential. However, contemporary methodological approaches to measurement of subjective experiences do allow ready

quantification of N, in much the same way as measures of pain have been developed (see 'Pain assessment'). Analogue measures of intensity of an experience like N, or itchiness or pain are easily developed: Visual Analogue Scales are particularly useful and reliable and can be used on repeated occasions with the same patient (McCormack *et al.*, 1988). Thus, a patient could be asked to rate their degree of N by placing a mark on a ten-centimetre line with 'no nausea at all' at one end, and 'the worst nausea imaginable' at the other. This provides immediate feedback about where and when N occurs and also quantifies the effectiveness of any treatments for N. For V intensity can frequency and readily be measured. Such approaches have been very helpful, particularly for patients suffering the side effects of chemotherapy (e.g. Morrow & Dobkin, 1988).

Cancer treatments

Any search of the contemporary literature on N and V quickly reveals that N and V associated with chemotherapy treatments for cancer dominate the picture, especially when psychological aspects are considered. N and V from chemotherapy can be so severe as to lead to 50% of patients refusing or delaying chemotherapy even when it could be highly beneficial (e.g. Horne *et al.*, 1986; Lindley *et al.*, 1989). It should be noted that N and V are also quite common side effects of radiotherapy (Maranzano, 2001) but, as far as can be determined, there is no research, to date, upon whether this affects patients' acceptance of treatment (see 'Radiotherapy').

In spite of powerful, modern anti-emetic medication, such as ondansetron, N and V remain major problems associated with cancer treatments. In addition to post-chemotherapy or radiotherapy N and V there also exists the distressing phenomenon of anticipatory N and V (ANV), which is generally less well controlled by anti-emetic medication than post-chemotherapy N and V with ANV occurring in up to 35% of patients and AV in 16% and with refusal to continue therapy in up to 10% (Bakowski, 1984).

Psychological factors

This failure to effectively control chemotherapy-associated N and V but particularly the former, by anti-emetic medication alone has spurred on research into psychological factors contributing to high levels of N and V and to find psychological treatments that might help ameliorate these effects, either alone or in combination with anti-emetic medication. Even when vomiting is eliminated, many patients may still experience unpleasant, prolonged nausea, anxiety and general discomfort, not to mention the well documented distressing physical side effects of chemotherapy such as electrolyte imbalance, oesophageal tears, hair loss and skeletal fractures (Sagar, 1991).

Recent research has revealed post-chemotherapy N and V, to be associated with a number of major psychological factors, such as depression (Chou *et al.*, 2003); family conflict (Kim & Morrow, 2003); and a patient's expectations (or appraisals) of developing nausea, but not of vomiting (Roscoe *et al.*, 2000). However, psychological interventions (these have been primarily cognitive-behavioural), have had mixed effectiveness in reducing these symptoms,

but much greater efficacy when it comes to ANV (see Mundy *et al.*, 2003, for a major contemporary review).

Various factors are believed to increase the likelihood of patients exhibiting ANV. Some of these include: greater post-chemotherapy N and/or V, higher dosages and more emetogenic chemotherapy drugs, lengthier infusions, greater state and/or trait anxiety, tastes and smells associated with chemotherapy, being younger, a history of motion sickness, gastrointestinal susceptibility and being treated in a large group room rather than a small private room (e.g. Morrow & Dobkin, 1988; Cameron *et al.*, 2000).

Much of the phenomenology of ANV is readily accounted for by a classical conditioning paradigm (see 'Behaviour therapy'). For example, various incidental features of the chemotherapy process itself, such as the sight of the clinic entrance, the odour of the clinic, nurses' or doctors' uniforms, or even the mere thought of chemotherapy, are enough on their own to produce nausea and vomiting in some patients after two or three chemotherapy treatments (e.g. Horne *et al.*, 1986).

However, a classical conditioning explanation alone may be an oversimplification as it is now clear patient perceptions/appraisals/or interpretations of what is happening to them are very influential, and such appraisals will affect the coping strategies they use and their general perception of what their illness means to them (e.g. Meechan *et al.*, 2003) (see also 'Lay beliefs about health and illness').

From the evidence briefly reviewed here, it is possible to come to some conclusions about how psychological assessment and intervention can be used in combating the extremely unpleasant effects of nausea and vomiting.

Psychological assessment and interventions

For straightforward post-chemotherapy nausea and vomiting, the most effective treatment is by contemporary antiemetic medication. However, well designed studies of the effects of such drugs on ANV have not been carried out. In any case, patients who have particularly strong negative appraisals about chemotherapy could all probably benefit from appropriate psychological general preparation prior to chemotherapy commencing. In addition, the preparation of patients for chemotherapy rarely systematically utilizes the findings from psychology about preparation of patients for invasive medical and surgical procedures (Horne *et al.*, 1994a,b) (see 'Coping with stressful medical procedures').

It may be useful, and further research is certainly warranted, to assess all patients about to undergo chemotherapy for their levels of anxiety (including past history of phobic anxieties, especially blood and needle phobias), depression, 'conditionability', personal appraisals of their illness and its treatments, and to identify any environmental cues that could serve as conditioned trigger stimuli and reminders of chemotherapy, and so elicit ANV. The more comfortable, less institutional and more personal the setting for chemotherapy, the less likely is the occurrence of adverse psychological reactions to treatment, including ANV.

It would be helpful to detect those at risk prior to the first chemotherapy infusion because the ANV symptoms usually do not emerge until the third or subsequent chemotherapy treatment,

by which time much associative learning (conditioning) may have occurred.

References do occur in the literature to the effectiveness of such interventions as hypnosis, aromatherapy and acupuncture but space limitations here preclude further discussion of these except to indicate that they do raise questions about what constitute evidence-based psychological and 'alternative' therapies in cancer care; whereas, regarding psychological interventions for ANV, there is now good research evidence, that cognitive-behavioural therapies (CBT) are effective (Morrow & Dobkin, 1988; Mundy *et al.*, 2003) (see 'Cognitive behaviour therapy').

A CBT programme which the senior author (DH) has found helpful in treating medical phobic anxiety in association with ANV, involves a combination of training in relaxation using guided imagery (Horne *et al.*, 1999) systematic desensitisation to a medical phobic hierarchy combined with exposure to video-modelling of having a needle or catheter inserted (Horne *et al.*, 1986). The use of video-modelling is particularly useful because it allows patients to play the modelling videotape as often as they like whilst retaining control over exposure by using the pause and on/off switches. This is consistent with general evidence that modelling is an

effective means of preparation for invasive procedures (Horne *et al.*, 1994a,b).

Conclusions

Thus, to conclude, it is clear that N and V side effects of drugs occur with a variety of drugs but most worrying is their presence in cancer chemotherapy. New anti-emetic drugs are appearing which are more effective than previous anti-emetics. However, for some patients N and V remain a problem, particularly when, through conditioning and personal appraisals of their illness and its treatments, they develop ANV. Measuring psychological factors such as anxiety, depression, physiological arousal, conditionability and personal appraisals could be useful in detecting those patients at risk of developing ANV and cognitive behaviour therapies are clearly effective in ameliorating these distressing and dangerous side effects. In any case, given existing knowledge, proper psychological preparation of all cancer chemotherapy and radiotherapy patients is likely to significantly reduce unpleasant side effects, enhance coping with chemotherapy and improve quality of life.
